Table 4 reports share of preferences for R and SAS software estimates. Results show that 12.17%, 9.02%, and 8.97% of respondents viewed strategic mobility, mutual assistance, and settlement as the most desirable climate change adaptation policies, respectively. Based on SAS estimates, 11.63%, 9.51%, and 9.30% of respondents viewed settlement, emergency destocking, and prolific animal selection as the most desirable climate change adaptation policies, respectively. This indicates that share of preference for settlement estimated with SAS is higher than estimate from R. Conversely, share of preference for strategic mobility estimated with R is higher than estimate from SAS. Share of preference for mutual assistance under R is higher than that of SAS. This shows that mixed results prevail while estimating share of preferences under R and SAS. Results also indicate that SAS's algorithm converges faster than that of R.

Table 5 reports the intention to vote for or against each climate change adaptation policy. Results based on R estimation show that more than 70% of respondents would vote for the implementation of policies such as prolific animal selection (100%), vaccination (100%), settlement (84%), strategic mobility (77%), strategic destocking, and sheep and cattle fattening (74%). Forage cultivation (50%) and income generating activities (52%) had the lowest vote share among respondents.

Table 4 Share of preferences based on R and SAS estimates

	R		SAS
Strategic mobility	12.17%	Settlement	11.63%
Mutual assistance	9.02%	Emergency destocking	9.51%
Settlement	8.97%	Prolific animal selection	9.30%
Strategic destocking	8.50%	Water and soil conservation activities	8.86%
Prolific animal selection	8.44%	Strategic mobility	8.56%
Sheep and cattle fattening	8.39%	Transhumance	8.14%
Vaccination	8.13%	Mutual assistance	7.81%
Transhumance	7.53%	Sheep and cattle fattening	7.12%
Emergency destocking	6.54%	Income generating income	6.92%
Water and soil conservation activities	6.02%	Vaccination	6.20%
Changing herd composition	6.01%	Strategic destocking	5.70%
Income generating activities	5.26%	Changing herd composition	3.67%
Base: Forage cultivation	5.01%	Baseline: Forage cultivation	6.57%

Results based on SAS estimates indicate that more than 70% of respondents would vote the implementation of policies such as income generating activities (88%), water and soil conservation activities (82%), and settlement and strategic mobility (70%). Strategic destocking (26%) and changing herd composition (27%) had the lowest vote share among respondents. Results from Tables 3 and 4 further suggest that concordance between preferences for climate change adaptation polices and voting behavior does exist. Voting implementation results reveal that R and SAS estimates greatly vary.

Conclusion

A mosaic of climate change adaptation policies have been proposed to build rural household resilience capacity and diversify income and food strategies and improve their livelihood.

This chapter uses BWS approach to elicit Niger agropastoralists preferences for climate change adaptation policies. Using data collected from 271 agropastoralists, results indicate that agropastoralists have a clear preference for settlement, emergency destocking, prolific animal selection, water and soil conservation activities, strategic mobility, transhumance, and mutual assistance. While results also suggest that mean, standard error and standard deviation estimates of these preferences vary across R and SAS package, R package yielded more accurate results than SAS.

Results further suggest that share of preferences and vote for climate change adaptation policy implementation are software package dependent. Future research is to study the stability of climate change adaptation policies overtime. Lusk (2012) stated that public policy is highly interventionist and that policy preferences are more

Table 5 Agropastoral's vote for climate change adaptation policy implementation

R software			SAS software		
Climate change policy	Vote for implementation (%)	Vote against implementation (%)	Climate change policy	Vote for implementation (%)	Vote against implementation (%)
Strategic mobility	77	23	Settlement	70	30
Mutual assistance	64	36	Emergency destocking	63	37
Settlement	83	17	Prolific animal selection	60	40
Strategic destocking	74	26	Water and soil conservation activities	82	18
Prolific animal selection	100	0	Strategic mobility	70	30
Sheep and cattle fattening	74	26	Transhumance	65	35
Vaccination	100	0	Mutual assistance	57	43
Transhumance	67	33	Sheep and cattle fattening	53	47
Emergency destocking	62	38	Income generating income	88	12
Water and soil conservation activities	58	42	Vaccination	43	57
Changing herd composition	58	42	Strategic destocking	26	74
Income generating income	52	48	Changing herd composition	27	73
Forage cultivation	50	50	Forage cultivation	50	50

likely to change external shocks when climate change hit, food safety crisis occurred, and negative externalities happened.

Barriers to the Adoption of Improved Cooking Stoves for Rural Resilience and Climate Change Adaptation and Mitigation in Kenya

80

Contents

Abstract

Majority of Kenya's citizens reside in the rural areas where wood fuel is still the primary source of energy for cooking. Continuing reliance on wood fuel against the backdrop of burgeoning population poses huge threats to the country's forest cover, undermining capacity for climate change mitigation and adaptation. This study

conducted in Machakos and Laikipia counties explored; (i) women's perceptions of the health risks associated with dependence of firewood for cooking, (ii) women's attitudes and perceptions towards improved cooking charcoal stoves (ICS) as cleaner alternatives to traditional firewood stoves for cooking, and (iii) women's perceptions of barriers to adoption of improved cooking stoves. Study findings revealed that women were aware of the health risks associated with the use of firewood for cooking. However, despite these perceptions, upward trends in demands for firewood as a source of energy for cooking in the rural areas may persist in the next coming decades. Barriers to adoption of improved cooking stoves vary by sociocultural contexts. The study concludes that innovations that involve stakeholders especially participatory designs, monitoring, and evaluation of ICS might improve adoption levels. Moreover, innovations to increase adoption need to leverage on the opportunities provided by Sustainable development goal number 7 to accelerate adoption of ICS among other forms of cleaner, affordable, and sustainable sources of energy for cooking.

Keywords

Improved cooking stoves · Barriers to adoption · Rural resilience · Climate change mitigation · Women · Kenya

Introduction and Background

Sustainable development goal number seven, target 7.1 challenges the international development community and various governments to work towards achieving universal access to affordable, reliable, and modern energy services by 2030. It is estimated that about three billion people globally rely on biomass and coal burning for domestic use (WHO 2016). Majority of these population resides in developing nations (Clark et al. 2009). The solid biomass fuels available locally are such as wood, charcoal, dung, and agricultural residues for cooking, heating, and other domestic basic needs (Boampong and Phillips 2016). The emissions emanating from these energy sources pose health risks to humanity, among many other negative social and environmental impacts (Dickinson et al. 2015).

Ndegwa and others (2011) posit that 94% of the African rural population and 73% of urban population relay heavily on biomass energy especially for cooking and heating. They further state that wood fuel energy not only used as household energy but also used in schools, hospitals, colleges, small industries, and hotels. Women from rural areas and children below 5 years suffer most from health risks posed by biomass burning during long hours of cooking. The identified drivers of rising demands for wood fuel for cooking include, rapid population growth, inaccessibility to cheaper and affordable alternative energy substitutes, and the rising pervasive poverty and inequality.

Kenya has one of the largest rural populations that still rely on wood fuel as a primary source of energy for cooking. This preliminary study conducted Machakos and Laikipia counties explored; (i) women's perceptions of health risks and the socioenvironmental consequences associated with dependence of firewood for cooking, (ii) women's attitudes and perceptions towards improved cooking charcoal stoves as cleaner alternatives to traditional firewood stoves for cooking, and (iii) women's perceptions of barriers to adoption of improved cooking stoves by rural households.

Literature Review

Wood fuel is widely used in Kenya's rural areas and urban slums. It accounts for 68% of energy sources in the country with petroleum accounting for 22%, electricity at 9%, and coal at less than 1% (Ndegwa et al. 2011). It is estimated that biomass energy, firewood, charcoal, and agricultural wastes contributes approximately up to 70% of Kenya's energy demand and provides for almost 90% of rural household energy need. Dependence on wood fuel is among the contributors of deforestation exacerbating the country's greenhouse emissions. A study by Marigi (2017) has estimated that typical rural Kenyan family consumes about 11 kg of firewood daily, generating approximately 20.57 kg of carbon dioxide.

There is extensive research showing that traditional cooking stoves that utilize biomass contribute to a wide range of negative impacts on human health, air quality, and climate change. Although many agencies including World Health Organizations (WHO) recommend adoption of ICS in rural settings where cleaner sources of cooking are not available, to reduce indoor pollution, many communities are still challenged with appropriate stove selection, and sustained stove adoption and use. The efforts to better understand and provide solutions to this have faced several challenges. The challenges include matching new technologies with local socioeconomic conditions and cooking culture and designing comprehensive measurement strategies to effectively diagnose success or failure of these improved stoves.

Kenya is one of the countries where a great deal of research has continued to promote the adoption of improved cooking stoves in Kenya. Improved cookstoves have been recommended by many researchers as efficient and effective biomass-fuel stoves that reduce chronic obstructive pulmonary diseases, lung cancer, low birth weight, and premature mortality (Clark et al. 2009). In western Kenya, improved stoves were projected as human health survival especially to the children. The researchers promoted improved cookstove adoptions in the area with a goal to increase human survival through improving air, reducing disease, saving time and money, and reducing environmental degradation. Exposure to indoor air pollution has been blamed to poor human health especially women and both infants and small children who are present near the cooking site. Ezeh and others (2014) noted a 0.8% of neonatal deaths, 42.3% of post-neonatal deaths, and 36.3% of child deaths occurred in household using solid fuels for cooking; 70% of the deaths occurred in rural areas. Some of the promotional strategies in attempt to increase adoption of improved cooking stoves have included linking the prevalence of respiratory-related illness among household members to the indoor pollution associated with the use of firewood. These strategies have advocated for the use of improved cooking stoves as cleaner alternatives to mitigate indoor pollution, and research designs have revolved around generating empirical evidence to link adoption with improved health outcomes. Pilishvili et al. (2016) work showed that ICS were effective in reducing household air pollution leading to considerable acceptability in rural western Kenya. Also, the work by Silk and others (2012) work sought to increase adoption of locally produced ceramic cookstove in rural Kenyan household. Also, the work by Clark and others (2009) showed positive health impacts among women related to reduced indoor pollution following adoption of ICS.

Other researchers have attempted to leverage on ICS potential benefits of reducing indoor pollution to increase acceptability and adoption. Recent years have embraced much broader advocacy on the wider socioenvironmental benefits of ICS to entice communities' adoption. Jeuland and Pattanayak (2012) have investigated the benefits versus the costs of improved cook stoves in relation to wider implications of variability in health, forest, and climate impacts. The authors argued that adoption of ICS had broader benefits that included health improvement, time saving for households, preservation of forests, and reduction in emissions that contribute to global climate change. The authors concluded that households often find the improved cook stove technology to be inconvenient or culturally inappropriate resulting in disappointing uptake.

Liyama and others contend that ICS reduce deforestation and greenhouse gases that increase global warming leading to climate change. Other researchers who have explored related environmental benefits of ICS adoption include, Kiefer and Bussmann (2008) and Jeuland and Pattanayak (2012). These researchers have evaluated the benefits and costs of ICS on health, forests, and climate impacts, concluding that improved stoves provide improved health and time saving in household, preserve forests and related ecosystem and reduce emissions contributing to global climate change. On the contrary, biomass burning in inefficient cookstoves negatively impact on household level, community and national level, and regional and global level.

Both collecting and combustion of solid fuels used in household levels affects women and girls. Njenga et al. (2017) emphasize that scarcity of firewood forces women and girls to travel long distances looking for the commodity. The authors' claim has become part of the advocacy for improved cookstoves to ensure women could invest time in economically productive activities. Additionally, collecting and carrying is life threatening as women can suffer body injuries, rape, or attacked by wild animals (Njenga et al. 2017). Unsustainable firewood harvesting contributes to forest degradation, further contributing to loss in a nation's carbon sink. According to Loo et al. (2016), demand of biomass fuels is threatening forest cover given the rising demand for the commodity by schools, hotels, industries, among others, hence high emissions leading climate change.

The progress of achieving large-scale adoption and use of ICS has been slow and literature has little information of the slow uptake. Some researchers have contended that cost is not a barrier to adoption pointing that adoption and use of improved stoves is low even when households have given ICS without a charge. A study done in Peru, in 26 villages, only 46% of households used improved stoves given free of charge (Adrianzén 2010). The findings left the authors puzzled by the difficulties communities faced adopting ICS technologies given the benefits such as reducing household health burden related to indoor air pollution (Ezeh et al. 2014).

Materials and Methods

A questionnaire with open- and closed-ended questions was used to collect data from a sample of 54 women from the rural parts of Laikipia and Machakos County in 2018. In most rural areas in Kenya, cooking is one of the main chores for women. Data collected included energy sources for cooking for households, perceptions of health and environmental problems associated with the use traditional cooking stoves, extent of use of ICS, perceptions of socioenvironmental benefits, perceived importance to a household portfolio of the different sources energy for cooking, individual perceptions related to future trends of the usage of the different sources of energy for cooking, and perceived barriers to the adoption of ICS. Additional questions included sociodemographic information. Descriptive statistics were used to summarize data. Inferential statistics (independent t-test) were used to examine relationships between variables by region.

Results and Discussion

Sociodemographic Characteristics of the Sample

Table 1 below summarizes sociodemographic characteristics of the sample. Majority of the respondents in both counties were aged between 18–29 and 30–59 years. These are the productive age groups in a country and reliance on firewood collection and cooking takes away time that could be invested in productive economic engagements. The average household size for Machakos was 5.77, while that of Laikipia was 4.77. The differences in household size, number of primary school going children, and number of children under 5 years old between Machakos and Laikipia were statistically significant, $t(52) = 2.45$, $p < 0.05$, $t(52) = -4.74$, $p < 0.05$, and $t(52) = -6.06$, $p < 0.05$, respectively.

Source of Energy for Cooking and Perceived Importance of Various Sources by Study Sites

Majority of the respondents from the two study areas mentioned relying on both firewood and charcoal for cooking. The researchers further probed sources of energy for cooking. Majority cited that firewood was collected from nearby woodland resources (see Fig. 1). However, majority also mentioned buying both firewood and charcoal. During 1960s, majority of Kenya's rural population probably never imagined of a time when obtaining firewood would cost money, hence purchasing

Table 1 Sociodemographic characteristics of the sample

Variable	Category	Machakos % (Mean ± SD)	Laikipia % (Mean ± SD)
Age	18–29	15	25
	30–59	77	75
	60 or above	8	0
	18–29	15	25
Marital status	Married	77	57
	Single	12	21
	Separated	4	0
	Windowed	8	21
	Married	77	57
Average household size		5.77 ± 0.54	4.64 ± 1.72
Average number of school-going children		1.65 ± 1.9	3 ± 1.22
Average number of children under 5 years old		0.81 ± 0.83	2.46 ± 0.88

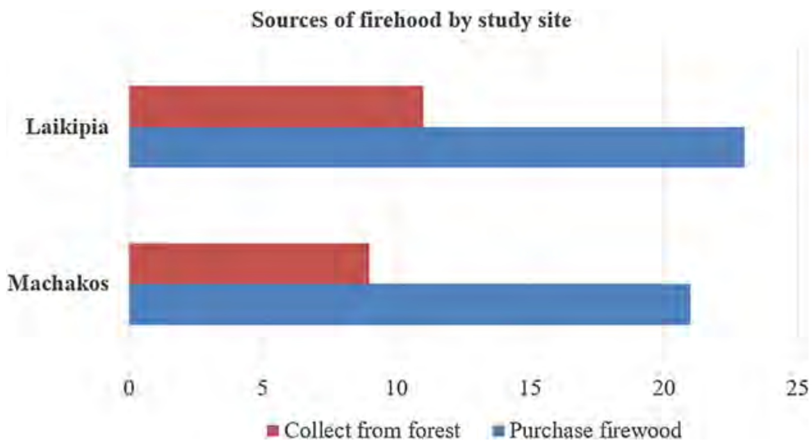

Fig. 1 Households' sources of firewood. (Source: Survey data)

firewood once regarded an abundant and free resource highlights that over the years sources of firewood have declined to the point that households must purchase the commodity. On average, respondents from Machakos spend 88.5 ($SD = 20.72$) per bundle of firewood, while those from Laikipia spend 237 ($SD = 50.00$) on firewood. On average, respondents from Machakos spend 48.40 ($SD = 4.95$) on charcoal, while those from Laikipia spend 57 ($SD = 5.39$). The differences in households' expenditures on both firewood and charcoal between the two counties were statistically significant, t (df) = 9.97, $p < 0.05$ (firewood), t (df) = 8.90, $p < 0.05$ (charcoal). Respondents were asked how much money they spend on a month to meet expenses related to energy for cooking. Results revealed that showed that on average, households in Machakos spend 2475 ($SD = 35.54$) compared to 875 ($SD = 144$) in Laikipia. The differences in monthly expenditures between the two counties were statistically significant, t (df) = 6.67, $p < 0.05$.

Continued reliance on firewood for cooking can be attributed to affordability and availability. In Laikipia, communities have access to adjacent forests for firewood. Moreover, the increase in vendors using motorcycles to ferry firewood further plays role in providing the commodity to households. Mobile vendors make it more convenient for households to save time that would otherwise be spent collecting firewood. It appears from the results obtained that firewood is a little more costly in Laikipia than in Machakos. This is probably because besides cooking, households in Laikipia also use firewood and charcoal for warming the house especially in the evening and during the cold season. It is also probable that most charcoal used in Laikipia is transported from distant sources, unlike in Machakos where residents rely on adjacent counties, Makueni and Kitui for the commodity.

Researchers asked respondents "who in the household was responsible for collecting firewood." Results obtained showed that women and children were involved in collecting firewood for cooking; however, men were largely involved in the collection and sale of firewood (see Fig. 2). Respondents were asked who in the household was responsible for paying for charcoal and firewood. Machakos, women households were responsible for meeting monthly energy expenses, while in Laikipia, men played that role. Few respondents mentioned children; these are probably elderly women who rely on their children or grandchildren for financial support.

Fig. 2 Persons in the household responsible for paying household expenses related to energy used

In Laikipia, much of the responsibility of fetching firewood belongs to the wife; according to the findings of this study, it was observed that 78% of household expenses on firewood were done by men. Men in the region are involved more in forest destruction activities that include logging and charcoal burning. Sourcing of firewood and charcoal is expensive and all household budget for it. In Laikipia, majority of husbands play a significant role in meeting household needs mainly because they participate in preparing them (firewood and charcoal), transportation, and in some instances marketing. Another observation is that they buy firewood in larger quantities in form of sacks and large firewood bundles attracting higher value covered by majority of husbands. To some husbands, it is a full-time business.

In Machakos, it appears that the responsibility paying for fuel is perceived as feminine responsibility; majority of respondents at 53.8% admitted that it is the responsibility of the wife, 38.5% said it is husband's responsibility, while only 7.7% said it is the children who pays for fuel expenses.

Several researchers have noted the gendered division of labor when it comes to firewood collection and provisioning at the rural settings. Edelstein et al. (2008) have pointed on the gendered politics of firewood, contending that women have to transverse long distances to gather firewood. The implication is that women spend more time looking for energy sources instead of engaging in productive economic activities. Respondents were asked what other challenges beside increasing scarcity, women encountered when looking for firewood. One challenge that was frequently mentioned were increasing number of conflicts. All respondents from Laikipia reported experiencing conflicts associated with firewood collection. Conflicts over firewood may take a variety of forms, for instance, some sources are as a result of youth in the collection and sale of firewood for income. Other conflicts may be related to emerging rising demand from hotels, schools, small industries, and hospitals.

Table 2 summarizes respondents' perceptions in relation to the importance of various sources of energy for cooking in both Counties. The study observed that the main sources of energy for cooking is firewood and charcoal. This indicates rural population rely on trees for source of energy for cooking and warming, and therefore, there is need for energy saving technologies in both counties.

Results revealed that cow dung is not an important source of energy for cooking in Laikipia (90%) but an important a source of energy for cooking in Machakos (28%). Crop waste is not a source of energy in Laikipia (100%), but somehow a source in Machakos (42%). Due to high rate of population, Machakos may have faced acute deforestation situation, where in some places only cow dung and crop waste are the only source of energy for cooking and warming. Silk et al. (2012) pointed out that where fuel becomes expensive, the disadvantaged population turns to the available cheap ones including plastics.

Findings showed that also saw dust was somehow a source of energy in both counties: Machakos 38%, while Laikipia 17.8%. Kerosene is used for cooking in both counties: Machakos 80.7%, while Laikipia 100%. Kerosene is a common fuel even in rural small towns and can be purchased using <50 shillings. Handling kerosene stoves is easy despites its high production of particulate matter and carbon

Table 2 Perceived importance various energy sources for cooking by study site

Cooking energy source	Region	Not important (%)	Somewhat important (%)	Very important (%)
Cow dug	Machakos	72	12	16
	Laikipia	90	0	0
Crop waste	Machakos	58	31	12
	Laikipia	100	0	0
Saw dust	Machakos	58	39	4
	Laikipia	36	18	4
Firewood	Machakos	4	**35**	**66**
	Laikipia	0	**32**	**68**
Charcoal	Machakos	0	**39**	**62**
	Laikipia	0	**38**	**61**
Kerosene	Machakos	19	58	23
	Laikipia	0	46	54
LPG	Machakos	31	27	42
	Laikipia	0	89	11
Biogas	Machakos	50	46	4
	Laikipia	18	82	0

monoxide which endangers human health. A study by Pilishvili et al. (2016) observed that additional hour of kerosene use was associated with 5% increase in mean kitchen particulate matter. LPG is also a common source of energy in Machakos (69.2) and Laikipia (100%) as well as biogas recording 82.1% in Laikipia and 46.1% in Machakos.

Cow Dung and Crop Waste

In both regions, cow dung and crop waste according to the research indicate that majority saw it as not important. However, Machakos 16% indicated that it is a very important energy source. Machakos study indicates that some household of study have cleared most of the trees for other development activities. Therefore, the only available cheap fuel source is cow dung and crop waste which contributes high rate of indoor air pollution. This implies that higher health problems on both women and children in Machakos than in Laikipia. In Machakos, over 80% of the households has a cow and they live within the homestead; therefore, the energy source is always available but only preferred in time of extreme need. Promotion of improved cook stove in Machakos started many years back led by Nongovernmental organizations and the government. It therefore implies that majority of homes have an improved stove that easily used dried cow dung to cook. The climate in Machakos favors quick drying of the dung hence less time is needed to prepare it. The fact that 16% noted it as very important implies that the population entirely depends on cow dung for cooking. Use of crop waste is seasonal and fuel energy sources like maize, sorghum, and grass stalks are mainly available after harvest, therefore is an important energy source in Machakos. The pattern shows that those who regard it as very important are less than those who perceive it as somewhat important. It therefore implies that there is a certain population that entirely depends on crop waste for cooking and this indicates the possibilities of having serious biomass smoke-related health cases in Machakos than in Laikipia (Silk et al. 2012). In Laikipia, cow dung and crop residue are not important at all, since there are other better easily available energy choices. Also, the proximity to the forest enhances accessibility to the energy sources.

Kerosene, LPG, and Biogas

Kerosene as an energy source was noted as more important in Laikipia than in Machakos. This could be attributed to cost and availability since interviewed Laikipia residents seem more sound economically and price determines energy source to use (Silk et al. 2012). Again, one must have a stove designed to use kerosene. This therefore implies increased kerosene related indoor particulate matter pollution according to Pilishvili et al. (2016). In Laikipia, distribution networks for kerosene are more improved than Machakos, hence underlining the product mix concept that states that there is a correlation between products availability and consumption. Few Machakos women (23%) may be relying totally to Kerosene as a source of cooking, while for the rest, kerosene is mostly for light and biomass fuel for cooking. The study is from rural Machakos where few able household use electricity for light. Kerosene for cooking, compared to biomass fuel, is expensive for rural poor households. This could be the reason for low use of kerosene in Machakos.

LPG was noted as very important in Machakos than in Laikipia. However, those who stated as somehow important were at 89% meaning that they consider it necessary but it is not the only solution to energy needs. The price of a product like LPG determines the offering which the customers are willing to give to buy the targeted product. The importance attached to it in Machakos may imply that it is used for major cooking and different affordable packaging sizes in the market attracts many customers. In Laikipia, it seems the energy source LPG is used for light cooking mainly in the morning and late in the evening.

Biogas was noted as very important in Machakos as compared to Laikipia. However, on average, biogas was noted to be used more in Laikipia. This could be attributed by the fact that it requires relative huge investment to establishing a zero-grazing unit.

Women's Perceptions of Health Risks Associated with Reliance on Firewood

Participants were asked to list what they perceived as the health risks associated with the use of traditional firewood stoves for cooking. The lists of mentioned problems were entered in an Excel spreadsheet, and a tally was done to generate a graph summarizing frequently mentioned health risks/illnesses. Results obtained showed that the frequently mentioned health risks, in order of the most to least frequently mentioned health risks included: chest pain, sneezing, irritating eyes, breathing problems, and congestion of throat. Figure 3 summarizes the frequency of mention

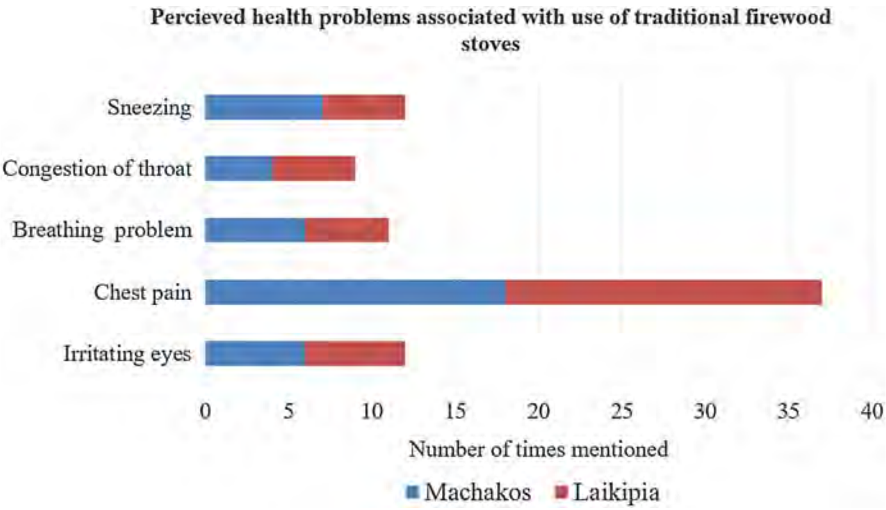

Fig. 3 Perceived health risks associated with the use of firewood traditional stoves for cooking

of the different health risks by respondent study site. Majority of women described chest pain to be a serious health risk. This was consistent across the two study sites. The secondly mostly mentioned health risk was sneezing, again patterns of the number of women describing sneezing problems were consistent across the two study sites. The third most mentioned health risk was eye irritation, and again, patterns of the number of women describing eye irritation problems were consistent across the two study sites. The least frequently mentioned health risk was congestion of throat, and again patterns of the number of women describing congestion of chest problems were consistent across the two study sites. Health risks mentioned can be summarized as respiratory and eye irritation illnesses. All these illnesses are associated with indoor pollution due to smoke and soot emanating from the burning of firewood. ICS are reported reduce indoor pollution related to smoke, and consequently, reduce the illnesses mentioned by the respondents in this study. Where adoption of ICS is challenge, some development agencies have innovated smoke hoods as options for reducing smoke, hence reduced levels of indoor pollution.

Perceived Future Trends on Use of Various Forms of Energy Sources

Respondents were asked what they perceived to be future trends on use of various forms of energy sources. Table 3 summarizes participants' responses by county. Results showed that almost all the respondents from Laikipia (100%) perceive the use of firewood to remain in the upwards trends (96.4%) compared to 46% from Machakos county. It is unclear what might inform this sort of perceptions. Respondents' perceptions correspond to the expected trends of firewood use in the coming decades, one would anticipate potential decline in negative impacts on forest cover further undermining climate mitigation measures and rural resilience (Njenga et al. 2017).

Table 3 Perceived future trends on use of various forms of energy sources by study site

Energy source	Region	Falling significantly (%)	Falling slightly (%)	Don't know (%)	Will remain about the same (%)	Rising slightly (%)	Rising significantly (%)
Cow dung	Machakos	54	9	15	4	19	–
	Laikipia	57	14	0	21	7	–
Crop waste	Machakos	46	12	8	19	8	8
	Laikipia	82	0	0	18	0	0
Firewood	Machakos	19	27	4	4	12	35
	Laikipia	0	0	0	0	**43**	**58**
Charcoal	Machakos	19	23	–	12	19	27
	Laikipia	0	0	–	4	**14**	**82**
Kerosene	Machakos	4	12	–	23	31	31
	Laikipia	0	64	–	32	4	0
LPG	Machakos	–	15	8	–	**15**	**62**
	Laikipia	–	0	0	–	**61**	**39**
Biogas	Machakos	12	19	2	4	19	23
	Laikipia	0	0	0	18	**14**	**68**

Participants from Laikipia, however, anticipate an upward trends in the use of LPG (100%). In addition, majority of respondents from Laikipia (82%) anticipate an upward trend in the adoption of biogas, compared to only 42.3% in Machakos county. LPG provides a capability to prepare meals in a shorter time, especially children's foods (Khadilkar 2015). Market for LPG have continued to provide attractive cylinder sizes affordable to low-income clientele. Also, majority of the women have an appeal for LPG as a clean energy for cooking, especially where mothers are accompanied by their children during cooking. Abundant crop waste, largely wheat and maize to support zero grazing is probably the reason for the perceived rise in biogas adoption in Laikipia.

Respondents from Machakos anticipate an upward trend in the use of kerosene. Besides cooking, kerosene also used for lighting in most rural homes in Machakos. Women overwhelmed with domestic chores prefer lighting a kerosene stove especially for lighter meals. Machakos has limited availability of crop residue and farm-based biomass. In Laikipia, respondents perceive a decline on the future use of kerosene for cooking. It is unclear what might inform this anticipation.

LPG use in Machakos is likely to rise significantly due to the ongoing government subsidy and use of flexible packaging containers. In Machakos, the current generation of population is constructing modern houses which have no kitchens to light firewood or charcoal giving preference to clean energies like LPG and biogas. In both counties, family sizes are becoming smaller with an average of two children, hence demand for heavy cooking will cease with time and demand for clean affordable energy like LPG and biogas will rise.

Perceived Barriers to Adoption of Improved Cooking Stoves

Respondents were asked on perceived barrier to adopt ICS. Table 4 summarizes responses by county. Results reveal that improved cook stoves are perceived to be costly compared to traditional stove. In both counties, Machakos (57.7%) and Laikipia (57.2) studies, cost was perceived to be a barrier to owning ICS. Some of these cook stoves are unaffordable by rural women especial those with no/little income. Jeuland and Pattanayak (2012) concur with this point when their study argued that women find it expensive to pay for the stove and self-learning of length of time to understand how properly to use the new technology.

Availability of charcoal affects adoption of ICS more in Laikipia (77.6%) than in Machakos (42.3%). The study shows that cost of charcoal affects ICS adoption in Laikipia (96.4%) more than Machakos (42.3%).

Stove design is probably not perceived as barrier in Machakos (34.4%); however, majority of the women from Laikipia (60.7%) seems to suggest design as problem. Stove designs acceptance depends on the provision benefits of cooking styles and needs of a given locality (Khadilkar 2015). Masera et al. (2007) cited the difficult of using some stove design to prepare traditional foods in Mexico. Also accepting a design means being able to use and repair. Therefore, improved cook stove may not be meeting the traditional needs of cooking in Laikipia. Also, low rate of literacy in

Table 4 Perceived barriers to adoption of improved cooking stoves by study site

Perceived hinderance	Region	Not a hinderance (%)	A little hinderance (%)	Don't have experience with this (%)	Somewhat a hinderance (%)	A very huge hinderance (%)
High cost	Machakos	12	19	12	15	42
	Laikipia	0	43	0	43	14
Availability of charcoal	Machakos	1	27	15	19	23
	Laikipia	18	4	0	**68**	**11**
Cost of charcoal	Machakos	15	27	15	15	27
	Laikipia	0	4	0	**39**	**57**

	Laikipia	40	0	0	**61**	**0**
Availability of stove	Machakos	39	23	0	27	12
	Laikipia	0	0	0	**32**	**68**
Takes long to light	Machakos	27	31	8	15	19
	Laikipia	0	61	0	39	0
Takes too long to cook	Machakos	35	19	20	20	8
	Laikipia	0	43	57	0	0

the society may not be receptive of new technology ideas. Improved cook stoves availability is a barrier to own one in Laikipia county (100%), while in Machakos County (38.5%) is not an hinderance. Lighting ICS is not termed as a big issue in ICS ownership in both counties Machakos (30.8%) and Laikipia (60.1%). Cooking food using ICS in Machakos (34.6%) is not a barrier of owning one, but in Laikipia majority (57.1%) reported that they lacked experience of time taken in cooking. Sometimes new technologies are not accepted immediately because of the way users fear to change their behavior of cooking, other stove increase fuel consumption or increase time spend in cooking (Jeuland and Pattanayak 2012).

High Cost

In Machakos, high cost of stoves was noted as a major hindrance at 42% in stoves adoption. Today, due to challenges in livelihood income, every cent spent in a family counts and expenditure is based on priorities like paying school fees and buying food for the family. Possible reason could be that the stoves are never budgeted for and in some cases, it is perceived as luxurious and not a solution to indoor pollution. Most promoters of the stoves ask for prompt payment at once making them unaffordable. As mentioned earlier, domestic costs in Machakos are met by women with little or no support from men. Therefore, even if the stoves are sold at a discounted rate, they will always seem expensive. Also, the rural women may lack adequate information/awareness of benefits of improved cook stoves. ICS promoters in most cases mention short-term benefits such as saving firewood/charcoal but forget long-term benefits such health benefits. With this, concerned population end up missing crucial information especially health problems of children and mothers. The implication is that the adoption rate will be low, and firewood and biomass use continue creating negative impact to the environment.

Availability of Charcoal

This is also a major hindrance when it comes to stoves adoption in Machakos. Even though improved cook stove uses less charcoal, it must be of high quality and size to avoid smoking, and this is a challenge. In Machakos, charcoal is produced illegally, outside Charcoal Producer Association (CPA), hence inadequate in the market. For the last two decades, illegal charcoal production and land for agriculture degraded trees in rural Machakos and affected the availability of charcoal. The concept of demand and supply applies, if charcoal is not adequately available, it becomes expensive.

Cost of Charcoal

The reason for low adoption in Laikipia is noted as the cost of the charcoal at 57%. Possible reasons are due to the existence of other sources of energy which are cleaner and cheaper. Marketing of charcoal in Laikipia is mainly in bags and this to many is a huge cost.

Design of the Stove

In Machakos, the design of the stove was noted as a hindrance. Possible reasons could be the fact that stove design determines efficiency of cooking, size of cooking pot too, and the type of food to cook. Most of ICS are imported to Machakos rural areas and may be the designs do not meet the cooking needs of Machakos rural women. Again, some improved designs need specialist for repair which require funds when compared with three stone. Further, energy saving stoves are designed to save charcoal use, therefore their efficiency is lower and cannot be compared to the three stone firewood stoves. Stove design also influences the time taken to light the stove. According to the pattern from the research, stove design is a bigger hindrance in Laikipia. Availability of firewood and the need to warm houses during cold season are possible reasons. Improved cook stoves are made of vermiculite stone to reduce heat loss hence they do not warm the houses. The implication is that even if the stoves are acquired, they are never adequately used.

Availability of the Stove

This seems to be a huge hindrance in Laikipia, and the all the interviewees fell in the category of somewhat a hindrance (32%) and some stated it is a very huge hindrance (68%). Marketing of improved stoves is a huge business in the energy sector. Private companies have invested a lot and they need return on investment. Distribution of improved cook stoves is low in regions with adequate energy sources like charcoal and firewood, since few people buy them. This translates to low adoption rate and increased forest destruction to sustain the preferred energy sources.

Takes Too Long to Light

Respondents from Machakos (205%) seem to find the time it takes to light ICS to be problematic. Women engaged in household activities value time management. Due to heavy responsibilities within domestic arena, women are assisted to light stoves by their children. But children may face challenges lighting new designs. The comparison is based on traditional stoves. Lighting an improved stove requires a bit of skills that may be a challenge to the elderly. The problem is exacerbated by a lack of special gel for lighting cook stoves. To hasten lighting ICS, majority of the households use kerosene or old newspapers which adds to the cost/expenses of ICS for a household. The implication is that regular use of the stove does not happen.

Takes Too Long to Cook

Observed responses by study sample from Machakos county might be due to mostly preferred traditional diet in this region. Generally, improved cook stove is meant for light cooking. Quality of charcoal in Machakos is a factor since the best charcoal is from indigenous trees classified as hard wood which is rare in the region. Traditional foods are potentially most preferred due to economic challenges; however, cooking traditional dishes takes relatively longer compared to modern dishes. This has implications since ICS are relatively less used particularly among the elderly women.

Lessons Learned, Study Limitations, and Recommendations for Future Research

Even though access to cheaper sources of firewood continue to diminish, use of firewood for cooking still remains the most accessible form of energy for cooking in Kenya's rural areas. This trend is likely to persist in the next coming decade. Women are aware of the health risks associated with reliance on this source of energy. Given that low adoption of ICS as alternative methods of cooking may persist, there is need for interventions that reduce indoor pollution problems associated with continued reliance on firewood. This study was based on participants sampled from two counties; future research may need to include a representative mix of regional ethnic groups in Kenya. The variability on barriers to adoption highlight the need for a highly contextualized design and production of ICS to enhance adoption in culturally diverse contexts. Future research may need to explore the possibility of participatory design in which members of rural communities participate in designing ICS that appeal to their cultural preferences. This potential can be explored via the technical vocational institutions now almost distributed in every county in Kenya.

Conclusion

Citizens in Kenya's rural areas are aware of the health and negative socio-environmental consequences of relying on traditional unimproved firewood cooking stoves. However, there is still an inertia for continued dependence on firewood in the coming decades. Drivers of the perceived upward trends are a result of interaction of many factors. Barriers for adoption of ICS vary according to cultural taste and perceptions of ICS. Diminishing cheaper sources of firewood due to rapid population growth resulting to subsequent smaller land parcels imply future vulnerabilities by rural households as the cost of purchasing firewood is likely to keep rising, posing additional economic burden to households in terms of money spent purchasing firewood, but also on treatment of illnesses associated with indoor pollution from burning firewood. There is need to promote agroforestry as a potential option for meeting anticipated upward trends in demands for firewood to ensure resilience of rural livelihoods and sustainability of current efforts to improve the forest cover in Kenya.

Abstract

Climate change is a global issue threatening food security, environmental safety, and human health in tropical and developing countries where people depend mainly on agriculture for their livelihood. Nigeria ranks among the top in the global yam production. It has the largest population in Africa and has been able to secure food for its growing population through food crops especially yam. Unfortunately, the recent increase in termites' colonies due to climate change threatens yam yield. Besides harming man and environment, pesticides are expensive and not easily accessible to control the pests. This prompted a study which aimed at applying a biotrado-cultural approach in controlling the termites, as well as improving soil chemical properties and yam production. The study hypothesized that *Chromolaena odorata* and *Elaeis guineensis* sludge improved soil nutrient and yam yield and consequently decreased termites' outbreak. In a randomized design experiment of five blocks and five replicates, five different treatments including unmanaged (UM), *Vernonia amygdalina* (VA), *Chromolaena odorata* (CO), *Elaeis guineensis* (EG) liquid sludge, and fipronil (FP) were applied in termites-infested agricultural soil. Data were collected and measured on the responses of soil chemical properties, termites, and yam yield to treatments using one-way ANOVA, regression, and multivariate analyses. The result showed that *Chromolaena odorata* (CO) and EG treatments were the best treatments for controlling termites and increase yam production. Termites were successfully controlled in VA and FP treatments, but the control was not commensurate with yam production. The experiment needs to be extended to other locations in the study region. It also requires an intensive and long-term investigation in order to thoroughly understand (i) the influence of climate change on the termites' outbreak, (ii) the extent of termite damage to the crops, (iii) the impacts of climate change and variability on yam yields, (iii) the agricultural and economic benefits of the applied treatments, and (iv) the ecological and human health safety of the treatments.

Introduction

Climate change has globally become a serious threat to environment and man especially in the areas of food security and rapid growing population. Though the impacts of climate change have no geographical boundary, yet the countries in sub-Saharan Africa tend to suffer more because of several reasons including socio-economic, political, and ecological factors (Slingo et al. 2005; Kurukulasuriya et al.

2006). The Assessment Reports of the Intergovernmental Panel on Climate Change (IPCC) urged that, even with the predicted climate change scenarios, extreme events may still occur with devastating effects in more vulnerable areas, causing severe long-term food insecurity (Boko et al. 2007; Christensen et al. 2007).

Yam (*Dioscorea* spp.) is a tuber crop which serves as a major staple food for about 34% of the world's population. In comparison to other tuber crops, yam is a vital source of essential minerals including carbohydrates, vitamins, proteins, and dietary fibers (Olajumoke et al. 2012). In 2004, the world's yam production was estimated at about 46.8 million metric tons, and West Africa accounted for more than two-third of this global production (Sartie et al. 2012). Nigeria ranks highest in yam production among the sub-Saharan African countries (CGIAR 2004). Yam is a highly preferred food crop in Nigeria because:

(i) It is one of the easiest and fastest food to be prepared in different flavor.
(ii) Yam tubers can be preserved for longer time (4–6 months) at ambient temperature unlike sweet potato (*Ipomoea batatas* L.) and cassava (*Manihot esculenta*). The sustainability of yam as a source of food for every household is high, even during the onset of the rainy season when food tends to be scarce, yam tubers will be available (Loko et al. 2015). Hence, yam is locally referred as "enyi nwa-ogbuenye na'uwu" meaning "the orphan's salvager in time of famine."
(iii) Economically, yam tubers are high sources of income for the indigenous farmers, and this helps to alleviate poverty (Olorede and Alabi 2013).
(iv) Socio-culturally, yam promotes the social life of the people: several festivals (such as New Yam Festival, Yam title coronation, and marriage) are celebrated by communities, groups, and individuals using yam (Osunde and Orhevba 2009).

During cultivation, yam has its tubers buried in the soil which is the habitat of most ant species especially termite. Termite (*Isoptera*) has been described as one of the yam tubers' main destructive fauna (Atu 1993; Loko et al. 2015). Common among the termite species that damage the yams are the *Microtermes*, *Ancistrotermes*, and *Macrotermes* (Loko et al. 2015). The damage consists of feeding and destruction of planted setts of yam (including tubers, leaves, stems), and yam staking materials, as well as release of methane (Zimmerman and Greenberg 1983). Yam tubers to be harvested are sometimes heavily tunneled in termite-infested soil because the *Microtermes* spp. seldom build colonies within tubers and create apparent hollows. In Nigeria, it has been reported that in soils with high termite infestation, farmers lose more than 5 t ha^{-1} of yam due to damage by termites (Atu 1993). However, in the tropics and subtropics, termite has been reported as litter decomposer, and a key player in soil formation (Richard et al. 2006; Belyaeva and Tiunov 2010), yet it degrades the soil quality (Devendra et al. 1998).

Globally, the net impact of climate change has been predicted to include increase in pest damage to agricultural resources (Lovett et al. 2005). In tropical Africa precisely, climate change has crucial role in the striving, reproduction, and crop-destructive ability of the pests by making the environment favorable for them. Due to variations in weather especially rainfall and temperature, termites' outbreak and infestation become acute. Studies have shown that an average annual rainfall and temperature below 100 cm and 27°C, respectively, promote the survival and catastrophic impacts of the pest (Atu 1993; Richard et al. 2006; Belyaeva and Tiunov 2010). Though termites have been reported to be present throughout the year in most tropical countries of Africa (Wood 1995), their agricultural and economic damage tend to be exacerbated during periods of low rainfall (Ahmed et al. 2011). In the study conducted on the potential impact of climate change on termite distribution in Southern Zambia, Ahmed et al. (2011) found that after a drought, the number of pestiferous termite species increased drastically. Similarly, another study, performed in Uganda by Pomeroy (1976), demonstrated that the distribution of termites' mounds was significantly correlated with temperature and that large termite mounds were absent in areas of lower temperature and high rainfall. Kemp (1955) observed that climate was the principal factor determining the distribution of termites in Northeastern Tanganyika (Tanzania). Farmers in Nigeria, Uganda, and Zambia have reiterated that termite problems are more serious now than in the past (Atu 1993; Sekamatte and Okwakol 2007; Sileshi et al. 2009). Damage by the pests is higher during dry periods than in periods of regular rainfall (Logan et al. 1990). The rapid increase in termite damage might also be attributed to climate change-induced drought. For example, in the last two to three decades, drought associated with El Niño episodes has become more intense and widespread in Africa (Harrington and Stork 1995). Many studies have previously established strong nexus among climate change, termites invasion, and damage to agricultural resources (Jones 1990; Kemp 1955; Logan et al. 1990; Nkunika 1998; Bignell and Eggleton 2000; Eggleton et al. 2002; Ahmed and French 2008; Ahmed et al. 2011; Beaudrot et al. 2011; Rouland-Lefèvre 2011; Buczkowski and Bertelsmeier 2017).

Ikpo-Obibi is one of the important yam-producing communities in Nigeria with more than 80% of the population engaging in agriculture. It is pathetic to report the farmers' ordeal with the climate change-induced termites in the process of yam production. Despite the nutritional and socioeconomic benefits of yam, the termites' attack poses great challenge.

In terms of the control measures, most farmers in Africa have attempted the application of different pesticides, yet sustainable solution was never achieved. For example, in Nigeria, some farmers have applied pesticides such as fipronil, aldrin, imidacloprid, chlorpyrifos, sulfluramid, and heptachlor to control the pests by dressing the yam setts and farmlands. The problems of inaccessibility, high costs, human health safety, and ecological effects of these pesticides limit their usage (UNEP 2000; Boonyatumanond et al. 2006; Sánchez-Bayo 2014). The need for a sustainable method of ameliorating this yam pest and to have increased yield became crucial due to higher food demand from the growing population. In other West African country such as Ghana, it was reported that traditional methods (wood ash, cow dung, and aqueous extract of plant residues "dawadawa") have been successfully used to control the yam pests (Asante et al. 2008). The records about such traditional applications are yet to be found in Nigeria. Therefore, the present study aimed at appraising a new biotrado-cultural approach of coping with the climate change by controlling the termites, improving the soil properties, and increasing yam production using aqueous extract of *E. guineensis*, *V. amygdalina*, and *C. odorata*. The study also compared the impacts of these plant materials on the soil, yam yield, and termites in relation to the result from the fipronil treatment. It is hypothesized that (i) *C. odorata* enriched the soil minerals and increased yam yield by reducing the effects from climate change and the termites; (ii) the attraction of *E. guineensis* sludge to termites makes it an intervening material that reduced the pests' attack on the yam tubers and consequently enhanced the soil organic carbon (Corg); and (iii) *V. amygdalina* and fipronil treatments can successfully control termites but they have high concentrations of trace elements which aggravate the impacts of climate change and exert negative effects on the soil and yam production. Within this context, the following questions were addressed: (a) What are the variations in the concentrations of soil chemical properties, under the different treatments applied, and how significant are these concentrations? (b) Which of the applied treatments and season increased soil essential minerals? (c) Does increase in Corg and rainfall increase yam production? (d) How sustainable is the fipronil application in relation to termites' control, soil fertility, and yam yield? (e) To what extent does the variability in climate influence the termites and their impacts on yam production?

Materials and Methods

Study Area

Ikpo is one of the oldest villages among the eight villages in Obibi community in Etche Local Government Area (ELGA) of Rivers State, Nigeria. The farmland is located within latitude 5°06′52.7″N and longitude 7°11′59.4″E (Fig. 1) with an area of about 52.2 km^2 and a gentle sloping altitude ranging from 50 m to 100 m above sea level. The mean annual rainfall ranges from 100.4 cm to 241.7 cm and mean annual temperature ranging from 26.5 °C to 28.3 °C (SPDC 1998) (Fig. 2). The study was conducted from 2013 to 2016 under rainfed conditions. The mean monthly rainfall (cm) and temperature (°C) of the study site varied (Fig. 2) with 2013 and 2014 indicating normal rainfall years, 2015 revealing a dry year, and 2016 wet year. Though the study area has variations in rainfall that shows a bimodal rainfall distributional trend, yet no month without rainfall. Early-season rain begins in either late January or February and ends in July, and this is categorized as the early growing season. On the other hand, the late-season rain starts in August and ends in December (Nwaogu et al. 2017).

Geologically, the study site lies within Niger Delta Basin, and it is characterized by the Benin or coastal plain sand formation. The age of these formations ranges from Miocene to Eocene.

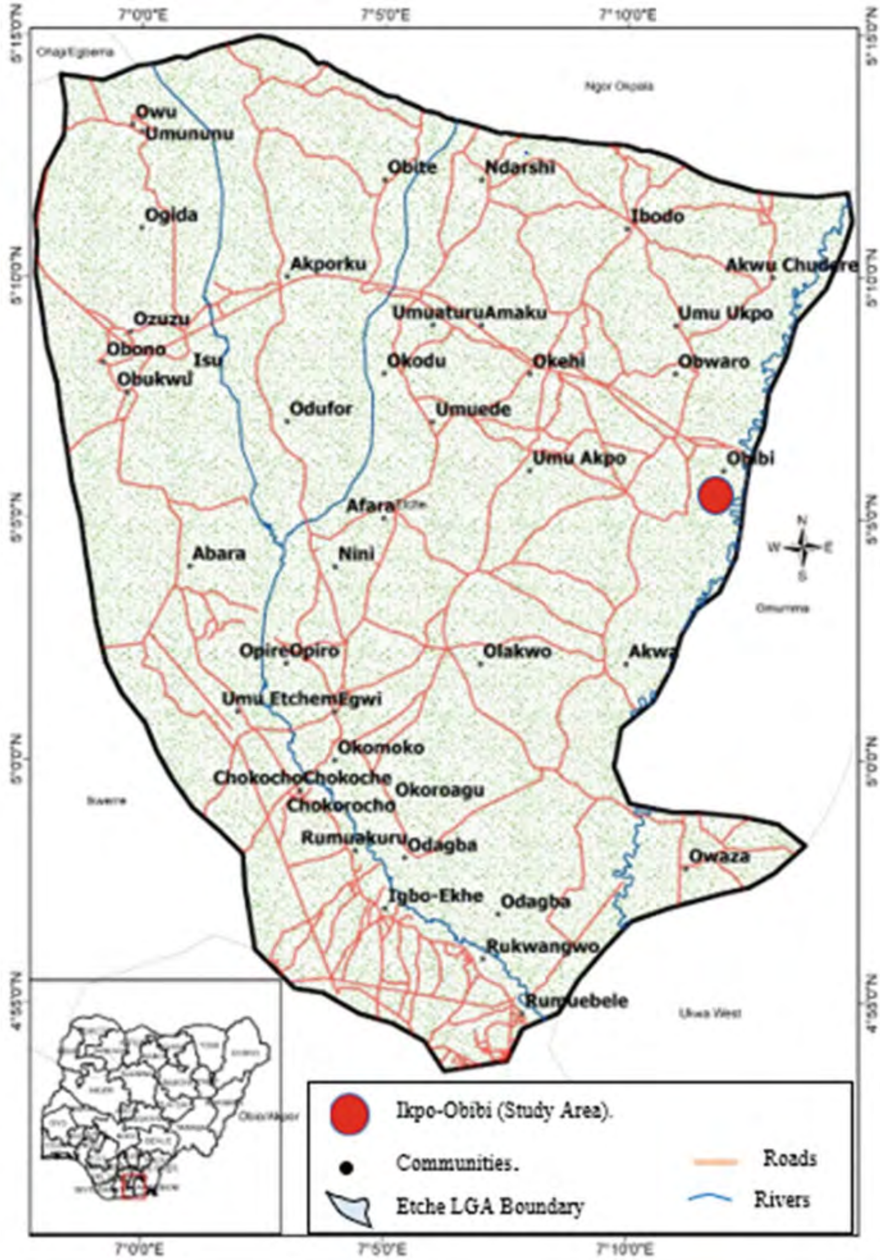

Fig. 1 The study area: Ikpo village in Obibi community, Etche LGA of Rivers State, Nigeria

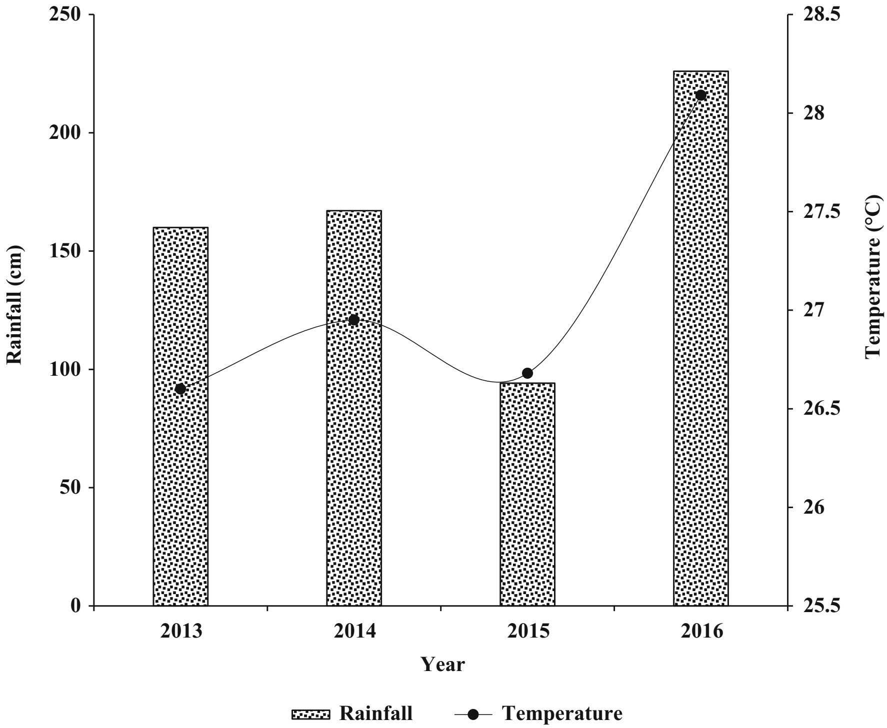

Fig. 2 Mean annual rainfall and temperature of the study area

The shallow parts of the formations are composed mainly of non-marine sand deposited in alluvial or upper coastal plain (Doust and Omatsola 1990). The soil composition of the study area consisted of fine alluvial content which is an extension of the rich sediments from the River Niger Delta alluvial soil. Presently, the heavy anthropogenic activities (e.g., mining, farming, grazing), pests, and environmental factors have influenced the soil properties (Table 1).

The study area is a typical rainforest region with traces of mangrove and freshwater swamp forests toward the south (Nwankwoala and Nwaogu 2009). There are bushes with trees and shrubs, as well as patches of grasslands dominated by elephant grasses where most farming activities are performed.

There are several termites' mounds which are between 2–7 m high and 2–5 m in diameter that cover the land space forming high termite mound density per hectare. Though the study site has for some years been dominated by termites, the activities of these pests to a large extent depend on climatic conditions. From the growing period to the maturity stage, the termites destroy the development of the crops planted at the site. This at most times leaves the rural farmers with little or nothing to be harvested. At planting and harvesting, five different species of termites were identified as the most common yam-destroying termites: *Amitermes evuncifer*, *Macrotermes bellicosus*, *Microtermes obesi*, *Trinervitermes oeconomus*, and *Trinervitermes geminatus* (Atu 1993; Loko et al. 2015).

Table 1 Soil (0–15 cm depth) chemical and physical properties in the study site prior to the experiment

Soil property	Mean ± standard error
Corg (mg kg^{-1})	5481 ± 311

Clay (g kg^{-1})	161 ± 4.3
Textural class	Sandy-loam
Bulk density (Mg m^{-3})	1.3 ± 0.1

Experimental Design, Yam Cultivation, and Treatments

The study was conducted in a randomized block design (Fig. 3). The area covered 5,400 m^2 with about 80% of the entire field being used for the yam cultivation and treatments, while the remaining percentage consisted of the borders around the entire treatment plots. Each plot consisted of 144 m^2 (12 m × 12 m) and was separated by 4 m (column) and 2 m (row) buffer zones. Land preparation for the experiment took place in 2012, and the first phase of the experiment was performed in 4 years (2013–2016) characterized with differences in annual rainfall and temperature. For instance, 2013 and 2014 had a normal rainfall, 2015 was a dry year, and 2016 recorded excess rainfall.

The experimental design includes five blocks, five replicates, five different treatments (UM, unmanaged; VA, *Vernonia amygdalina*; CO, *Chromolaena odorata*; EG, *Elaeis guineensis* liquid sludge; FP, fipronil) (Fig. 3), and their chemical compositions (Table 2).

The land was cleared and the plants' litter removed. Yam planting heaps of 80–100 cm high and 100–120 cm in diameter were prepared every year before the first rainfall of the year. After the first 2–3 rains of the year, yam setts were planted on the prepared heaps/mounds which were at the intervals of 15–20 cm with the cut face placed up (Fig. 4).

Based on the local tradition, the mounds were preferable to the ridges because they promoted easy staking and enhance the production of larger yam tubers when compared with ridges. The VA, CO, and EG treatments were traditionally processed by crushing, soaking in water, and squeezing out the sludge which were stored in 0.7 liter plastics (Appendix Figs. 8, 9, 10, 11, and 12). These were preserved in a cool

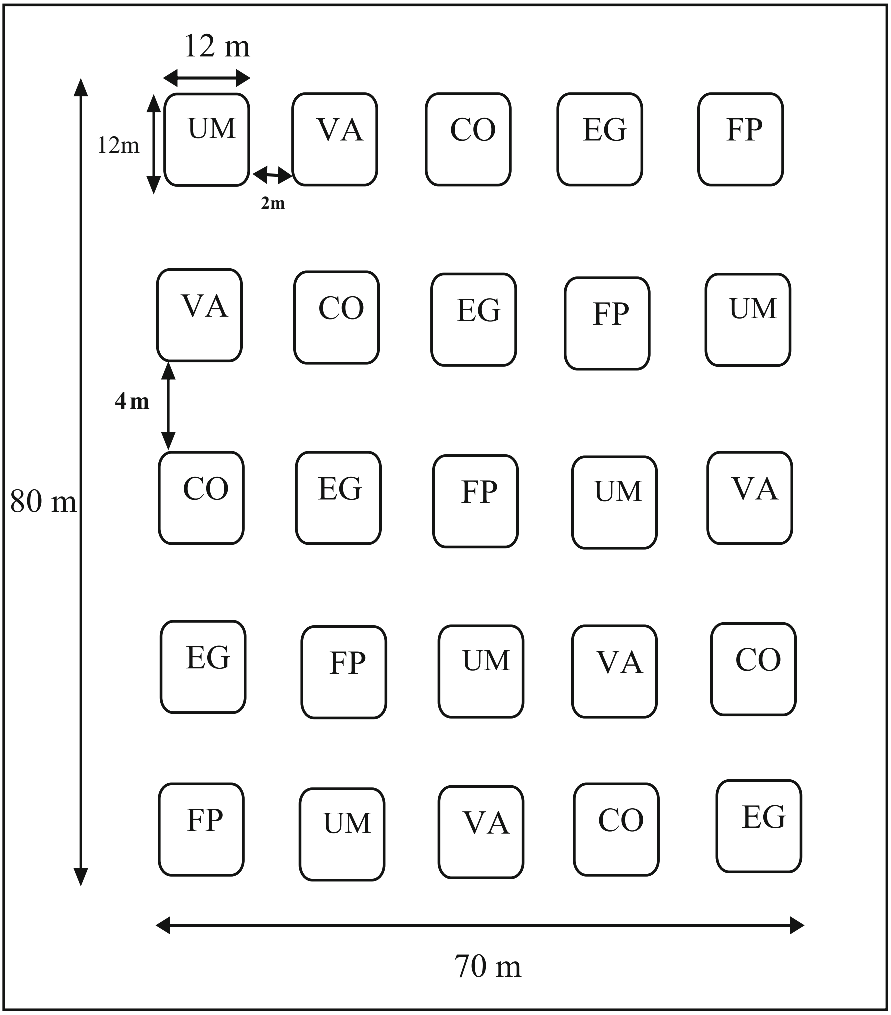

Fig. 3 Experimental design block for the study. Treatments were UM (unmanaged), VA (*Vernonia amygdalina*), CO (*Chromolaena odorata*), EG (*Elaeis guineensis* liquid sludge), FP (fipronil)

temperature to prevent fermentation before being applied to the yam heaps. On the other hand, the aqueous dilution of fipronil (Fipronil (120068-37-3); Alina Zhao, Ningbo Samreal Chemical Co., Ltd., China) was prepared as prescribed on the product label for termites' control. The prepared treatments were applied by dressing the yam setts. Between 0.2 and 0.3 litters of sludge (or aqueous) were dropped in and around every heap where the yam was planted. This was performed three times (in February/March, August, and November) for each growing season. By using hoes, manual weeding was performed three times (in late May, August, and November) for each growing season. Two stakes, each of 200–300 cm in height,

were used for staking the yam plants to vine over them – one stake for two plants and the other stake used for bracing the adjacent. Yam tuber harvesting was done in December each year following the local tradition.

Soil Sampling and Chemical Properties Analyses

In February/March and December, five soil sub-samples (0–15 cm soil depth) from individual treatment plot were randomly collected using a graduated auger. The soil samples were mixed and air-dried; visible pebbles, biomass residues, roots, and other organic debris were removed. Before taken to the laboratory for analysis, the samples were ground in a mortar to pass a 2 mm sieve. All measurements and analyses were performed within 30 days of sampling. The soil pH (H_2O) was determined by the method of McLean (1982). Organic carbon (Corg) was measured using the Walkley and Black wet oxidation method (Nelson and Sommers 1996). Total nitrogen (Ntot) was analyzed using micro-Kjeldahl method (Bremner and Mulvaney 1982). Available P, K, Ca, and Mg were extracted using Mehlich III solution (Mehlich 1984) with reagent and concentrations determined by introducing the inductively coupled plasma-optical emission spectrometry (ICP-OES: 720 Series, Agilent Technologies, USA). On the other hand, the concentrations of the trace elements (Cu, Mn, Cr, Fe, Zn) were determined following the Clayton and Tiller (1979) method. The concentrations were further analyzed using ICP-OES analyzer. The mean of five sub-samples from each monitored treatment was used for the statistical analyses.

Termites Sampling

The number of termites per heap was collected three times per year: in February/March (during planting), August (during the short break, that is, the August rainfall break), and December (during harvesting). These periods coincided with the low rainfall months which formed the peak season for the termites' activities (Loko et al. 2015). The termites were observed and counted using the Zoom Handheld Lighted Magnifier Glass (MagniPros 5.5″, USA) by randomly selecting the yam heaps and excavating through to the soil profile where the yam tubers could be found. One-third of the heaps were sampled per plot.

Yam Yields

At physiological maturity, after 9–10 months (that is, in December), the yam tubers were harvested by randomly selecting the yam heaps and excavating through to the soil layers where the yam tubers could be found. One-third of the heaps were sampled per plot. The harvested tubers were washed using water. They were thereafter weighed, and result was recorded in yield per hectares.

Statistical Analyses

To test the effects of treatments on the soil chemical properties, yam yield, and number of termites, a one-way ANOVA was used. In addition, a repeated-measures ANOVA was applied to deduce the effect of year, treatment, and year x treatment interaction for number of termites, yam yields, soil minerals, and trace elements. The ANOVA was applied after the assumptions of normality were met. Regression analysis was used to test the relationship between yam tuber yield (t ha^{-1}) and number of termites per yam soil heap. All analyses were conducted using the IBM SPSS Statistics Version 20 (IBM Corporation 2011) (www.ibm-spss-statistics.soft32.com) and the STATISTICA 13.0 software (StatSoft, Tulsa, OK, USA), while all data were expressed as means of five replicates.

Furthermore, a multivariate analysis such as redundancy analysis (RDA) followed by a Monte Carlo permutation test with 999 permutations in the Canoco 5.0 software (Šmilauer and Lepš 2014) was used to measure the effect of the different treatments on soil chemical properties during the 4 years. Ordination diagram was produced by using the CanoDraw program software which prompted the presentation and visualization of the RDA results of the experiment.

Results

Soil Chemical Properties

The concentrations of all the monitored soil chemical properties were significant under the different treatments except for Mn and Cu (Table 3). Most of the measured minerals showed higher concentrations under the CO treatment when compared with VA, EG, UM, and FP treatments. On the other hand, VA and FP treatments had higher trace element concentrations and higher pH when compared with the other treatments. All the essential soil minerals were significantly affected by time and treatment, but not all were affected by the combination of both (i.e., time × treatment interaction) (Table 4).

No significant effect of treatment on soil chemical properties calculated by RDA was recorded in 2015 (Table 5). The variability of soil chemical properties explained by treatments subsequently increased from the initially 24% in 2013 to more than 25% in 2014 and more than 50% in 2016. Variability explained by treatments was constantly above 20% between 2013 and 2016.

The treatments were categorized into three different groups in relation to the concentrations of soil chemical properties as were revealed by the ordination diagram (Fig. 5). Based on the RDA analysis of the data collected during the 4 years, CO and EG treatments formed the first group, VA and FP treatments as the second group, and UM treatment as the third group. The relationships between individual soil element and treatment are visible from the ordination diagram (Fig. 5).

Yam Tuber Yield and Termites

The mean annual yam tuber yields under CO and EG treatments were significant, while UM, VA, and FP treatments never showed any significant differences during the study years (Fig. 6). Year 2015 had the lowest yam tuber yields under the different treatments, while 2013 had the highest.

The results from the total number of termites per yam heap showed that UM and EG treatments were significant at $P < 0.05$, while records for VA, CO, and FP treatments revealed no statistical differences in the years (Fig. 7). Year 2015 had the highest number of termites per heap, whereas 2016 had the lowest. The relationships between yam tuber yield and number of termites per heap were negatively significant under the CO and EG, while UM treatment ($R^2 = 0.50$; $P = 0.045$) showed a marginal weak relationship (Table 6).

Table 3 Mean concentrations (mg kg^{-1}) of soil chemical properties (minerals and trace elements) under the different treatments in 2013–2016. *P*-value represents corresponding probability value. Numbers represent the average of five replicates; ± represents standard error of the mean (SEM); significance differences ($P < 0.05$) between treatments in accordance with the Tukey's post hoc test are shown by different letters in the row (a < b < c < d < e). Treatment abbreviations (UM, VA, CO, EG, and FP) are described in Fig. 3

Discussion

Soil Chemical Properties

The chemical elements contained in the treatment materials and the prevailing climate substantially influenced the soil chemical properties and consequently exerted significant effects on the different treatments. For example, the

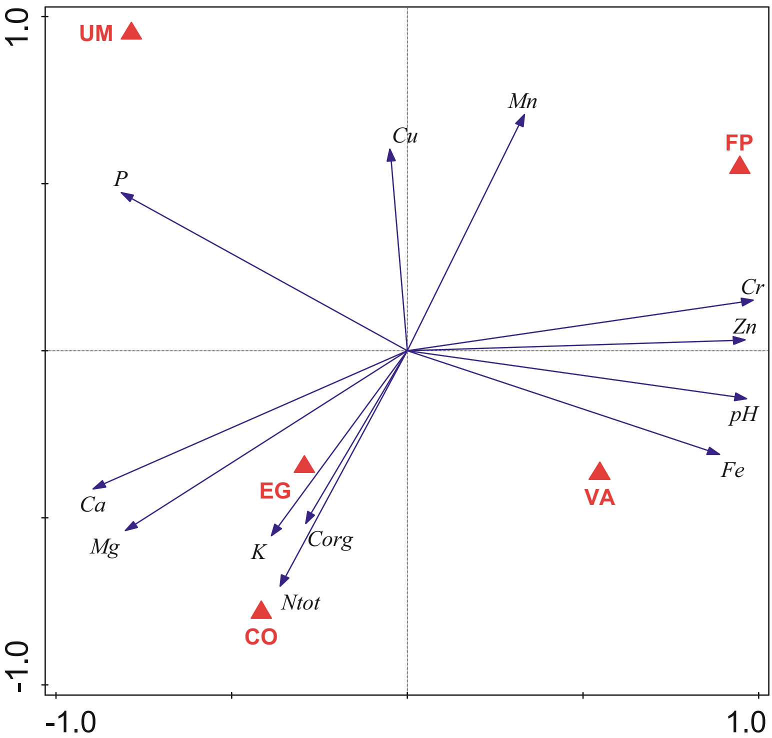

Fig. 5 Ordination diagram showing result of the RDA analysis of soil chemical properties data collected in 4 years (from 2013 to 2016) in different treatments. Treatment abbreviations are explained in Fig. 3

application of *Vernonia amygdalina* and fipronil (FP) elevated the concentrations of most trace elements in the soil, while *Chromolaena odorata* increased the contents of soil organic carbon and other minerals especially in the favorable climate years. Several studies have reported the effects of the exotic plants and organic residues of *V. amygdalina*, *C. odorata*, and *Elaeis guineensis* on the soil chemical properties and microbes (Kushwaha et al. 1981; Obatolu and Agboola 1993; Quansah et al. 2001; Peveling et al. 2003; Koutika et al. 2004; Callaway et al. 2004; Gbaruko and Friday 2007; Banful and Hauser 2011; Tondoh et al. 2013; Agbede et al. 2014; Gandahi and Hanafi 2014; Nurulita et al. 2014; Ngo-Mbogba et al. 2015; Ajayi et al. 2016; Dawson and Schrama 2016; Veldhuis et al. 2017).

It was discovered in the study that VA and FP treatments recorded relatively high soil pH, and this might be attributed to the high concentrations of the trace elements. This finding was consistent with other studies which have revealed that the elevation of heavy metals in most agricultural soils often leads to soil alkalinity (Nederlof et al. 1993; Lenart and Wolny-Koładka 2013; Almaroai et al. 2014) and V. *amygdalina* like *Baphia nitida* accumulates high heavy metals in the region (Ogbonna et al. 2013). On

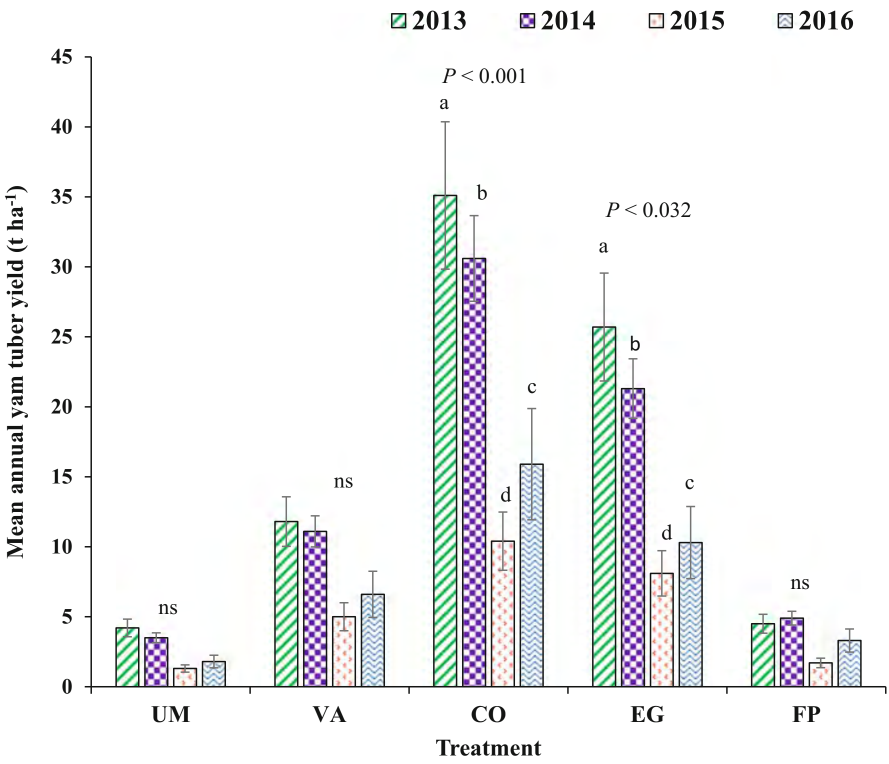

Fig. 6 Mean annual yam tuber yield (t ha^{-1}). Error bars represent standard error of the mean (SEM). P-value represents corresponding probability value. *ns* indicates that the results of ANOVA analyses were not significant. the contrary, other authors have reported high concentrations of exchangeable Cd and Zn in agricultural soils because of decrease in pH (Sumi et al. 2014).

Although *C. odorata* has been established to be a threat to the soil minerals by some authors (Muniappan et al. 2005), in contrast, several studies in West Africa have positive records about *C. odorata* (Obatolu and Agboola 1993; Goyal et al. 1999; Quansah et al. 2001; Tondoh et al. 2013; Agbede et al. 2014). In agreement with our study, CO treatment revealed increased concentrations of Corg, Ntot, K, and Ca especially in the optimal precipitation years. This might be explained by the deep rooting system of *C. odorata* that mobilizes soil mineral nutrients which are turned into organic and plant-available nutrients in conducive climate (Kushwaha et al. 1981; Tondoh et al. 2013). Other possible reasons for high contents of minerals in the *C. odorata* soil could be due to high contents of leaf biomass and earthworms (Tian et al. 2000; Kone et al. 2012), fast decomposing rate of *C. odorata* (Roder et al. 1995), and the elevated activities of the soil microbes (Mboukou-Kimbasta et al. 2007; Banful and Hauser 2011; Ngo-Mbogba et al. 2015; Dawson and Schrama 2016).

Significance differences ($P < 0.05$) between treatments in accordance with the Tukey's post hoc test are shown by lowercase letters (a > b > c > d). Treatment abbreviations were explained in Fig. 3

Table 6 Relationships between yam tuber yield (kg heap^{-1}) and number of termites per yam heap for the years under the different treatments

Treatment	Equation	R^2	P-value
UM	Y = – 0.0059X + 17.593	0.50	0.045
VA	Y = – 0.014X + 18.824	0.21	0.079
CO	Y = – 0.2456X + 35.04	−0.87	<0.001
EG	Y = – 0.064X + 29.618	−0.75	0.012
FP	Y = – 0.0128X + 15.53	0.24	0.063

On the other hand, *E. guineensis* (EG) treatment had elevated soil organic carbon and total nitrogen in our study. This result was consistent with many studies which reported that the oil palm residues promote the scavenging activities of ants which enrich the soil minerals (Frouz et al. 1997; Gandahi and Hanafi 2014; Nurulita et al. 2014; Gray et al. 2015).

No significant effect of treatment on the soil chemical properties was recorded in 2015 as shown by the RDA analysis. The low amount of rainfall recorded in 2015 contributed to the insignificant role of treatments on the soil because the elements from the treatments required enough soil moisture to show reasonable influence on the soil chemistry (Fernelius et al. 2017).

Yam Tuber Yield and Termites

The highest yam tuber yields were found in the CO treatment. This might probably be explained by high Corg, Ntot, P, K, Ca, and Mg in the soil under the CO treatment which consequently increased the crop yield (Obatolu and Agboola 1993; Quansah et al. 2001; Tondoh et al. 2013; Agbede et al. 2014). Similarly, 2013 and 2014 had the highest yam tuber yields across the different treatments. This was attributed to the optimum rainfall in 2013 and 2014 which did not only favor the activities of the microbial organisms but also helped to decrease the number of the termites' attack on the yam tubers. Though the oil palm (EG) liquid sludge attracted more termites in the soil yet, the EG treatment had higher yam tuber yields than UM and VA treatments. This could be because the termites fed more on the oil palm sludge instead of the yam tubers. Besides, the termites' activities improved the soil minerals (Oviasogie and Aghimien 2003; Muhrizal et al. 2006; Guo et al. 2007; Wu et al. 2009).

The total number of termites per yam heap were significant under UM and EG treatments. This was because of the suitability of the unmanaged and *E. guineensis* (EG) treatments which promoted the termites' activities when compared with the VA, CO, and FP treatments that either constrained or killed the ants (Peveling et al. 2003). Though without high yam yields, fipronil application was the easiest method to eradicate the termites from either destroying the yam tubers or carrying out any activities in the yam farmland. But the risk of fipronil on the soil, environment, and human health has been reported by many authors (Keefer and Gold 2014; Sánchez-Bayo 2014; Lopez-Antia et al. 2016).

Limitations of the Study

Some of the limitations for the study are:

(i) Poor access roads and footpaths to the farm sites where the studies are conducted
(ii) Destruction of some established experiments by mammals such as rabbits (*Oryctolagus cuniculus*), rats (*Rattus*), grasscutters (*Thryonomys swinderianus*), antelopes (*Bovidae*), and others
(iii) Ability to convince the rural farmers to give their farmlands for such research because some of the farmers are afraid that their land might be taken by the government or the research institutes
(iv) Inadequate fund to perform intensive studies: labor, field, laboratory and statistical analyses, and publications
(v) Dearth of literature on the topic in Nigeria and lack of robust data on the climate and other variables

Conclusion

Climate change with its variability was found as a factor which has important influence on yam tuber production because (i) the termite colonies increased when there is low rainfall, (ii) the damage caused by the pests exacerbates during dry season than in wet season, and (iii) optimal rainfall enhances soil moisture and promotes the soil microbial activities and decomposition of organic matter which in turn elevates the soil fertility. *Chromolaena odorata* (CO) treatment has been found to be the best single option in managing the termites' infested farmland to increase yam yield. On the other hand, integrating CO and EG treatment is recommended as this might produce higher yield. Though the termites (pests) were successfully reduced under the VA and FP treatments, this reduction was not commensurate with the yam tuber yield. The high content of the trace elements in the VA and FP treatments was attributed to the reason for declined yields because the fipronil is a good soil-binding substance which limits organic decomposition and nutrient cycling. It is also important to state here that a 4-year study is a short term to conclude that *C. odorata* and *E. guineensis* sludge are sustainable for reducing the yam pests (termites) and their harmful activities.

Since climate change is expected to continue locally and globally, this will have further influence on the distribution and intensification of termites which in turn affects agricultural resources. There is crucial need for the effectiveness of termite management strategies which include integrated pest control methods. Furthermore, as most of the termites are soil inhabitants, soil degradation and low rainfall are the main factors promoting their distribution and forage behavior in both tropical and subtropical ecosystems. Thus, there are high chances for aggravated economic devastation of termites' outbreaks in the region due to climate change. Therefore, the experiment needs to be extended to other locations in the study region. It also requires an intensive and long-term investigation in order to thoroughly understand (i) the influence of climate change on the termites' outbreak, (ii) the extent of termite damage to the crops, (iii) the impacts of climate change and variability on yam yields, (iii) the agricultural and economic benefits of the applied treatments, and (iv) the ecological and human health safety of the treatments.

Abstract

Despite the dissemination of climate information from national meteorological systems, arable farmers still have challenges of dealing with climate-related risks. This study investigated the effect of using indigenous knowledge-based forecasts (IFs) and scientific knowledge-based forecasts (SFs) on the climate change perceptions of arable farmers in the Rwenzori region, Western Uganda. Data on socio-economic characteristics, use of forecasts, and climate change perceptions was collected from 580 arable farmers and the probit model was used in the analysis. The findings indicated that use of IFs only increased the likelihood of perceiving increase in the frequency in occurrences of droughts and floods. Using both SFs and IFs had a significant positive effect on perception of unpredictable rains and the increase in drought incidence among arable farmers. Although forecasts are important drivers of perceptions, other factors, such as gender, social capital, and dissemination of climate change information by radio, enhance climate change perceptions. Active participation of arable farmers in the dissemination of forecasts by national meteorological services could improve perceptions of climate related risks.

Scientific forecasts · Indigenous knowledge · Indigenous forecasts · Climate change perceptions · Arable farmers · Uganda

Introduction

Despite the dissemination of scientific knowledge-based climate forecasts (SFs) by national meteorological systems, arable farmers still face challenges of dealing with climate-related risks. The impact of 1.5 degrees centigrade of global warming will significantly decrease agricultural production and access to water, and increase drought frequency and dry spells in Africa (IPCC 2018a). SFs influence disaster risk perceptions in general and climate change perceptions in particular for arable farmers and pastoralists. The climate change perceptions of arable farmers can influence farmers' adaptation to extreme weather events. Failure to use SFs may have negative effects on the adoption of disaster risk-reduction strategies. Failure to use early-warning information has resulted in loss of property, livestock, crops, and human lives as a result of disasters such as floods and droughts. For example, the floods in Mozambique in 2000 had a huge humanitarian effect on the local communities (Moore et al. 2003). Indigenous and scientific forecasts enhance climate change adaptation strategies of pastoralists (Nkuba et al. 2019b) and arable farmers (Nkuba et al. 2020a). Climate information use can improve the climate change perceptions of arable farmers, leading to better adaptation to extreme weather events and improved resilience to climate-related disasters. There are initiatives that are promoting a co-production of climate information which involves indigenous and scientific forecasts (IPCC 2018b). In this chapter, drought increase refers to increase in frequency and severity of droughts and flood increase refers to increase in frequency and severity of floods.

The most common climate change perceptions among farmers in Uganda include flood increase (Mubiru et al. 2015), drought increase (Cooper and Wheeler 2017; Mubiru et al. 2015; Napa 2007; Okonya et al. 2013), rainfall seasonality change (Cooper and Wheeler 2017; Napa 2007; Okonya et al. 2013; Tiyo et al. 2015), and temperature increase (Mubiru et al. 2015; Napa 2007; Okonya et al. 2013; Tiyo et al. 2015). The perceptions commonly cited in the Rwenzori region include flood increase, drought increase, and rainfall seasonality change (Oxfam 2008; RTT 2011). The use of indigenous knowledge-based climate forecasts (IFs) and SFs influences climate change perceptions in Uganda (Napa 2007; Waisswa and Otim 2012). In spite of high or widespread access to SFs due to the proliferation of radio stations in Uganda's rural areas (NAPA 2007), the use of IF is still high (Napa 2007; Okonya and Kroschel 2013). The spatial location of the Rwenzori, region combined with relief features such as Mount Rwenzori, forested areas, and flood plains in lowlands, makes it vulnerable to extreme weather events (Oxfam 2008; RTT 2011). Research in Uganda has shown that agro-ecological zones have an influence on climate change perceptions (Mubiru et al. 2015; Okonya et al. 2013; Tiyo et al. 2015). Climate-related disasters that occur in Uganda include droughts, floods (Oxfam 2008), landslides, temperature increase, and rainfall seasonality change (Napa 2007). Therefore, this chapter has taken into account agro-ecological zones.

Farmers' use of IFs as a source of climate information influences their climate change perceptions. The literature shows that IFs have influenced the livelihoods of farmers globally. Such influence has, for instance, been reported in Australia (Green et al. 2010), West Africa (Nyong et al. 2007; Roncoli et al. 2002), East Africa (Speranza et al. 2010), Southern Africa (Kalanda-Joshua et al. 2011; Kolawole et al. 2014; Motsumi et al. 2012), Samoa (Lefale 2010), New Zealand (King et al. 2008), the Artic (Pennesi et al. 2012), Mongolia (Andrei 2010), British Colombia in Canada (Gearheard et al. 2010), and Asia (Galacgac and Balisacan 2009). IFs have influenced the choice of crop enterprises among arable farmers.

Climate change perception studies using econometric models to analyze the effect of climate information have produced mixed results. A study done in Kenya revealed that climate information positively and significantly influenced farmers' climate change perceptions (Ndambiri et al. 2013). However, while several other studies (Gbetibouo 2009; Silvestri et al. 2012; Tesfahunegn et al. 2016) have reported that climate information positively influenced climate change perceptions, the influence was not statistically significant. In fact there are also studies (Bryan et al. 2013; Gbetibouo 2009) that have reported that climate information negatively influenced farmers' perceptions. Thus, there seems to be a lack of unanimity about the direction of influence that climate information has on farmers' perceptions of climate change risks. Most of the literature does not specify whether farmers used IFs or both IFs

Table 1 Explanatory variables for climate change perceptions

Source: Authors specification

and SFs. In fact, there is little literature on the influence of IF only or of both SF and IF on climate change perceptions of arable farmers and pastoralists.

Studies have also shown that there are a number of other factors that influence climate change perception (Table 1). These include household background factors such as farm experience, age, gender, education level, livelihood choices, farm income, and institutional factors such as agricultural extension, market access, access to credit, access to farm organizations and location-specific factors (Chingala et al. 2017; Deressa et al. 2008; Gbetibouo 2009; Habtemariam et al. 2016; Maddison 2006; Silvestri et al. 2012; Tesfahunegn et al. 2016). Climate change perception studies that included climate information in their analysis (Gbetibouo 2009; Ndambiri et al. 2013; Silvestri et al. 2012; Tesfahunegn et al. 2016) did not take into account the difference between the use of IFs and SFs, which this study has done. Studies on climate change perception have revealed that arable farmers' perceptions include drought increase, flood increase, rainfall season change, temperature increase, unpredictable rainfall increase, and rainfall decrease (Chingala et al. 2017; Deressa et al. 2008; Gbetibouo 2009; Maddison 2006; Nhemachena and Hassan 2007; Silvestri et al. 2012).

The above review of related previous studies demonstrates several realities that (a) climate information influences farmers' climate change risk perceptions but with mixed results as to the direction of influence; (b) there are other factors that may have a bearing on farmers' perceptions of climate-related risks; and (c) there is a paucity of literature on the relative influence of IFs only and/or of IFs and SFs on farmers' perceptions of climate-related risks. This study thus contributes to ongoing efforts and debate regarding the influence IFs as well as IFs and SFs on arable farmers' perceptions of climate-related risks in the Rwenzori region of Western Uganda by addressing the question "Do IFs and/or SFs influence climate change perceptions of arable farmers?" Overall, this study contributes to the climate change perception literature that relates to the influence of the use of indigenous knowledge forecasts and scientific climate forecasts on the behavior of arable farmers in Africa, in the Rwenzori region of Uganda. It also suggests what the implications are of access and use of climate information on climate change perceptions of farmers. The scope of this chapter addresses the effect of climate information on climate change perceptions of arable farmers in Western Uganda and does not cover pastoralists.

Materials and Methods

The Study Area

In the Rwenzori region of Western Uganda where the study was done (Fig. 1), farmers have reported perceiving evidence of climate change such as rains becoming more unpredictable, drought increasing in frequency and intensity and floods becoming more frequent and disastrous (Oxfam 2008). Agro-ecological zones include mountainous, lowland, mountainous and forested, wetland, and forest (Fig. 1). This agro-ecological diversity makes the Rwenzori region a good case study area for investigating how local agro-ecology influences climate change perceptions. The various agro-ecological zones are spread over the districts of Kabarole, Kyegewa, Kyenjojo, Ntoroko, Kamwenge, and Bundibugyo within the Rwenzori region and Kibale in the adjoining Bunyolo region (Fig. 1). Because this region is endowed with fauna and flora of wildlife-protected areas such as Queen Elizabeth, Kibale, Semiliki, and forested protected areas, the use of IFs is highly prevalent (Nganzi et al. 2015). Although access to SFs is high due to the proliferation of FM radio stations in Uganda (Jost et al. 2015), the use of SFs is not very high (Okonya and Kroschel 2013). Arable farming is a major source of livelihood. Rwenzori region is a multiethnic society, with many tribes whose rural livelihoods are influenced by indigenous knowledge systems. There is high variability in the onset of rains in Rwenzori region (Nkuba et al. 2019a). Indigenous forecast indicators are commonly used as sources of climate information (Nkuba et al. 2020b).

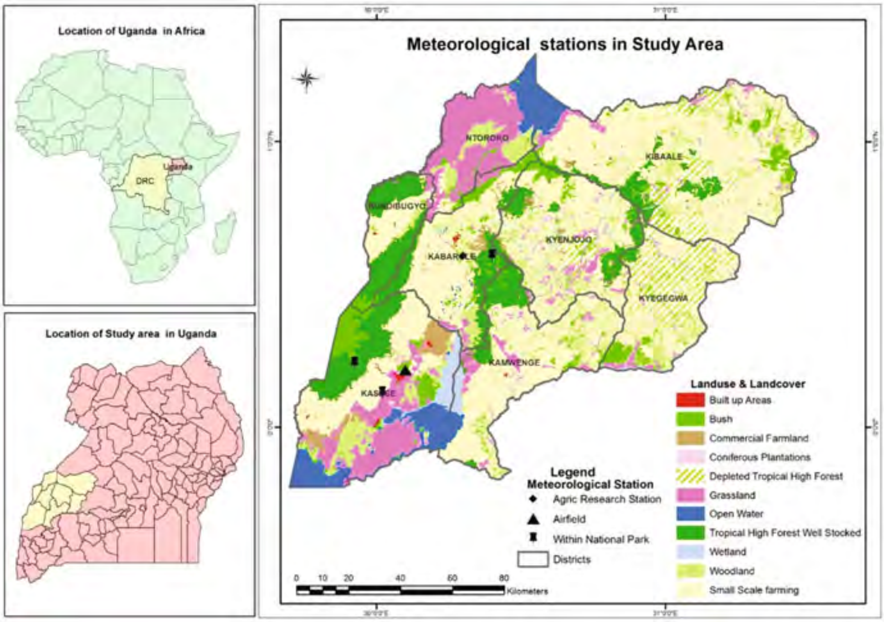

Fig. 1 Location map of study area

Sample Size, Data Collection, and Analysis

A two-stage stratified sampling approach (Cochran 1963) was employed to select the respondents. Farming systems and agro-ecosystems including mountainous, lowland, forested, wetland, and mountainous and forested formed the basis for the strata. The first stage units were the local agro-ecological systems, and the second-stage units were households. The statistically selected sample size of farmers was allocated to the selected districts using proportional allocation to size, where the size represents the number of households in a particular subcounty in the selected district. Based on a population of the study area of 102,496 households according to the 2014 Uganda population census report, a sample size of 778 was randomly selected with 95% confidence level and a margin of error of 3.5%. To allow for replacement in the sample of those who might back out of the study, a 19% of the statistically selected sample was included giving a total study sample of approximately 924. This was also to ensure good sized subsamples (for those who use IF and SF, and IF only). After data cleaning, 17 incomplete questionnaires were eliminated from the final analysis. The total sample size was therefore 907, and of these 580 were arable farmers, 269 were pastoralists, and 57 were agro-pastoralists. This chapter limits itself to the 580 arable farmers.

A household survey conducted from August to October 2015 was used to gather data through a face to face administered questionnaire on climate change perceptions, household characteristics, and climate information use. Pilot testing of the questionnaire translated into the local language was done before the household survey to ensure both content and measurement validity, and the local languages were used by trained research assistants. Data was analyzed using Stata 12 statistical software. The probit model was used in the analysis.

Empirical Model

Various econometric models have been used in climate change perception studies such as the probit model (Gbetibouo 2009; Maddison 2006), the logistic model (Silvestri et al. 2012; Tesfahunegn et al. 2016), the multinomial logit model (Bryan et al. 2013), and the Heckman probit selection model (Deressa et al. 2008; Ndambiri et al. 2013). For this study, the probit model was used in the analysis.

The empirical model is specified as follows:

$$Y_{ij} = f\ (H, I, A, W, S, G, U,) + \varepsilon \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

where $Y_{ij}(j = 1{,}2{,}3{,}4{,}5{,})$ representing the climate change perceptions of farmers [$Y_{1i} = 1$, if drought increase (0 otherwise). $Y_{2i} = 1$, if floods increase (0 otherwise) $Y_{3i} = 1$, if unpredictable rains (0 otherwise)$Y_{4i} = 1$, if rainfall seasonality change (0 otherwise) $Y_{5i} = 1$, if temperature increase (0 otherwise)].

Household characteristics (H): the level of education, age, gender, and farming experience; use of climate information (U): use of IF only, use of both IF and SF; institutional characteristics (I): access to agricultural extension, access to improved crop, credit, and nonfarm resources; agro-ecological area (A): forested, lowland, mountainous, wetland, mountainous, and forested; wealth (W): farm size; sources of climate change information (S): radio, fellow farmer, old IK farmer, newspaper; access to government program climate change interventions (G). The expected signs for the variables are indicated in Table 1.

Results

Socio-Economic Characteristics of Arable Farmers

The descriptive characteristics show that respondents were mostly male (Table 3), of average age 46 years. The average farm size was 7.95 acres. Arable farmers mainly used the forecasts for predicting onset and cessation of rains (Tables 2). Majority of the arable farmers attained primary level of education (Table 3). The most common climate change perceptions were rainfall seasonality change and unpredictable rains (Table 4). Radio was a very important source of climate change information (Table 5).

The Effect of Forecast Use on Climate Change Perceptions of Arable Farmers and Pastoralists

The results show that the use of both IFs and SFs or IFs only has a positive effect on the climate change perceptions of arable farmers (Tables 6 and 7). Arable farmers using IFs only were more likely to perceive drought increase by 22% and flood increase by 8%. Arable farmers using both (IFs and SFs) were more likely to perceive unpredictable rains by 18% and drought increase by 18%. There are peculiarities in the effect of forecast use on climate change perceptions. Five-day forecasts had a negative influence on the climate change perceptions of arable farmers (Tables 6 and 7). This suggests that arable farmers do not have much confidence in short range forecasts with regard to their perceptions of risks associated with extreme weather events. The use of both IF and SF for onset of rains had a negative influence on arable farmers' perceptions of climate-related risk (Table 7). This could be due to variability in rainfall onset prediction.

The Effect of Other Factors on the Climate Change Perceptions of Arable Farmers

Agro-ecology zones increased the likelihood of arable farmers perceiving climate change risks (Tables 6 and 7). Being resident in mountainous areas increased the likelihood of perceiving rainfall seasonality change by 22%. Rainfall seasonality change was more likely to be perceived by famers using both (SF and IF) in forested areas by 13%, wetland areas by 21%, and lowland areas by 18% (Table 7). Rainfall seasonality change was more likely to be perceived by famers using IF only in forested areas by 14%, wetland areas by 23%, and lowland areas by 19% (Table 6). Drought increase was more likely to be perceived by famers using both (SF and IF) in forested areas by 17%, mountainous areas by 15%, wetland areas by 29%, and lowland areas by 20% (Table 7). Agro-climatic risks, such as pest and disease

***, **, and * denote that significance at the 1%, 5% and 10% levels respectively perception studies. Failure to consider agro-ecological zones in climate change adaptation programs and policies can lead to poor adaptation. The findings also reveal that gender increased the likelihood of arable farmers perceiving climate change (Tables 6 and 7). Being male increased the likelihood of arable farmers' perceptions of drought increase by 7%. Men influence the choice of crop enterprises in farming households based on their climate change perceptions. A participant in a focus group discussion (FDG) reported that "now there is when you want to sow groundnuts but because of the early onset of the rains before you have planted then you plant maize instead." There are mixed results regarding the effect of agricultural extension on climate change risk perception. Agricultural extension access decreased the likelihood of pastoralists' perceptions of drought increase but increased the likelihood of perception of temperature increase. It is plausible that agricultural extension is the source of information on temperature increase received in the 10-day forecasts from the Uganda National Meteorological authority. Agricultural extension access decreased the likelihood of arable farmers' perceptions of flood increase by 8%. This suggests that agricultural extension is not effective in reducing risk attitudes associated with floods.

The results further indicate that access to credit and farmers' organizations increased the likelihood of arable farmers perceiving rainfall seasonality change by 18% and 23%, respectively. This suggests that access to credit contributes to rainfall seasonality change risk perception. The results further indicate that access to farmers' organizations increased the likelihood of arable farmers perceiving drought increase by over 11% and unpredictable rains by 16%. This suggests that social capital contributes to risk perception.

The study shows that access to nonfarm enterprises had a significant positive influence on climate change perception. Access to nonfarm enterprises increased the likelihood of arable farmers' perceptions of unpredictable rains by 18%. This could be attributed to arable farmers reinvesting their nonfarm incomes in agricultural technologies which are climate sensitive (Farmers tend to invest in agricultural inputs, hiring labor (Reardon et al. 1994)). The study also shows that there are mixed results regarding the effect of climate change information (depending on the source) on climate change risk perceptions. For instance, on the one hand, access to radio had positive effect on climate change risk perceptions. Climate change information from listening to radio also increased the likelihood of perceiving drought increase by arable farmers by 13% for those who use IF only and 7% for those who use both. This implies that radio is an effective dissemination mechanism for climate change information.

On the other hand, climate change information gained from fellow farmers negatively influenced climate change risk perceptions by more than 17% (Tables 6 and 7). This could be due to inadequate information about climate change. A participant in an FGD reported not having information on climate change. This calls for capacity building in farmer-to-farmer networks, with climate change messages inserted in agricultural extension interactions. Climate change information given by elderly farmers had a positive effect on perceptions of change in rainfall seasonality by more than 15%. Elderly farmers accumulate knowledge and improve their risk attitudes towards climate-related risk over time. Estimation of temperature increase involves consideration of maximum and minimum temperatures over long periods of time, which meteorologists calculate using models created by statistical software.

This study has established that the source of climate change information matters in arable farmers' perceptions of climate-related risks. The study produced mixed results regarding the effect of education on climate change risk perceptions (Tables 6 and 7). On one hand, education was inversely related to the perception of increase in rainfall seasonality change among farmers, and on the other, education seemed to have a positive influence on arable farmers' perceptions of an increase in the unpredictability of rainfall. This suggests that irrespective of level of education, changes in the onset and cessation of rains are not easily perceived by farmers. This could be due to the effect of climate variability on onset of rains. A key informant reported that onsets of rains were highly variable.

Discussion

The study findings reveal that being male, climate information, access to agricultural extension positively influenced perceptions of drought increase among arable farmers, which is consistent with study of Vietnamese farmers undertaken by (Thi Lan Huong et al. 2017). However, the study also shows that there are mixed results regarding the effect of agricultural extension on climate change risk perception, which is in agreement with earlier studies that showed a positive effect (Bryan et al. 2013; Deressa et al. 2008; Gbetibouo 2009; Opiyo et al. 2016) and others that showed negative effect (Silvestri et al. 2012). Research shows that agricultural extension is a dissemination mechanism for climate information and climate change information (Deressa et al. 2008; Gbetibouo 2009; Opiyo et al. 2016). Bryan et al. (2013) indicated that agricultural extension positively influenced perceptions of temperature increase among arable farmers in Kenya, but Nkonya et al. (2015) reported that agricultural extension in Uganda and Nigeria was weak in disseminating climate change information, making it less relevant in improving the resilience of farmers to climate-related risks. This is consistent with the study's findings that show that access to agricultural extension negatively influenced perceptions of flood increase among arable farmers.

The results show that using IF only positively influenced perceptions of flood increase among arable farmers which is consistent with Thi Lan Huong et al. (2017) who reported that climate information had a positive effect on Vietnamese farmers' perceptions of flood increase.

The results show that the use of both IF and SF has a positive effect on arable farmers who perceive unpredictable rains, which is consistent with Bryan et al. (2013), indicated that SF positively influenced farmers' perceptions of rainfall variability. The findings reveal that credit access increased the likelihood of arable farmers' perceptions of climate change, which in agreement with an earlier study by Silvestri et al. (2012). The study revealed that climate change information from radio increased the likelihood of perceiving drought increase by arable farmers which is consistent with Deressa et al. (2008); Habtemariam et al. (2016), who indicated that climate change information had a positive effect on perception. The study shows that there are mixed results about the effect of education on climate change perceptions which is in agreement with earlier studies that showed a positive effect (Bryan et al. 2013; Deressa et al. 2008; Habtemariam et al. 2016; Ndambiri et al. 2013; Opiyo et al. 2016; Silvestri et al. 2012; Tesfahunegn et al. 2016; Thi Lan Huong et al. 2017) and others that showed negative effect (Gbetibouo 2009; Piya et al. 2012). Research has shown that education increases access to information that improves farmers' resilience to climate-related risks (Opiyo et al. 2016). The study established that irrespective of the level of education, changes in onset and cessations of rains are not easily perceived by arable farmers. Research has shown that there is high variability in onset of rains in Kenya (Recha et al. 2012), Botswana (Byakatonda et al. 2018), and South Africa (Moeletsi and Walker 2012) making an accurate prediction of start of rains a hard undertaking for national meteorological services.

The study reveals that access to farmers' organizations increased the likelihood of arable farmers perceiving climate change which is in agreement with earlier studies (Piya et al. 2012; Tesfahunegn et al. 2016). The study shows that there are mixed results regarding the effect of nonfarm access on climate change perception, which is consistent with earlier studies (Silvestri et al. 2012) that showed a positive effect and others that showed a negative effective effect (Deressa et al. 2008; Ndambiri et al. 2013; Opiyo et al. 2016; Piya et al. 2012; Tesfahunegn et al. 2016). Nonweather dependent ventures such as small and medium enterprises may have a negative effect on arable farmers' perceptions of climate-related risks, while climate sensitive ventures such as livestock and crop sales have a positive effect on perceptions (Opiyo et al. 2016). Deressa et al. (2008) have indicated that nonfarm incomes may contribute to making high-income farmers less risk averse.

The study shows that agro-ecological zones increased the likelihood of arable farmers perceiving climate change which is consistent with Deressa et al. (2008), who reported that being resident in highlands had a positive effect on farmers' perceptions of climate change. Other scholars (Fadina and Barjolle 2018; Gedefaw et al. 2018) have also reported the influence of agro-ecology on perceptions of climate-related risks.

Conclusion

The study has established that the use of scientific and/or indigenous knowledge-based forecasts had varying influence on the perception of climate-related risks among arable farmers in the study area. Specifically, the study has revealed that use of IF only increased the likelihood of perceiving climate change as drought increase and flood increase. The use of both SF and IF positively influenced the perceptions of unpredictable rains and drought increase by arable farmers. The study has proven that SF complements IF in arable farmers' perceptions of climate change. The study has established that the source of climate change information matters in farmers' perception of climate-related risks. The study highlights the importance of forecast information sourced from indigenous knowledge systems and meteorologists regarding farmers' perceptions of climate-related risks under rain-fed agriculture. This therefore underscores the need for the integration of indigenous knowledge forecasts with the national meteorological services. Although forecasts are an important aspect of equipping farmers with information that will help them perceive climate change, the results of this study show that the direct impact of forecasts in enhancing farmer perceptions is limited to specific risks. Therefore, climate information, although necessary, is not sufficient; other factors are also important. Gender, social capital, and radio dissemination of climate change information require special attention when developing and implementing strategies for improving resilience to climate-related risks in rural livelihoods. The active participation of arable farmers and pastoralists in forecast dissemination by National meteorological services would improve farmers' perceptions of climate-related risks.

Lessons Learnt

Indigenous forecasts and scientific forecasts enhance arable farmers' perceptions of climate change. Indigenous knowledge systems play an important role in climate-related risk perception. Factors such as gender, social capital, and dissemination of climate change information by radio improve climate change perceptions.

Future Prospects

An increase in infrastructural investment in meteorology would improve farmers' perception of climate-related risks. This would investment would increase the precision of meteorological forecasts by having a higher meteorological density at district level, consequently improving the early-warning system of climate-related disaster risks.

Abstract

Critical or extreme atmospheric conditions which could result in flood disasters are important output for numerical weather forecast. This research applied thermodynamic variables to investigate the environment of two flood scenarios in West Africa as captured by the Tropical Rainfall Measurement Mission (TRMM) satellite. Results from the two case studies of flood events, in (i) Burkina Faso and (ii) Nigeria savannah, investigated in this research work, indicated that the September 1st 2009 flood, which was as a result of a single volumetric rainfall event of 408,070.60 ((mm/h)*km^2) with 65% convective region in Burkina Faso, was initiated by interactions between extremely large lower tropospheric wind shear and cold pool dynamics. The case of the Nigeria savannah floods between July and September, 2012, was triggered by both continuous rainfall and release

of water from the lagdo dam in Cameroon, which affected most of the communities in the river Benue axis. The continuous rainfalls were found to be as a result of extremely high convergence of moisture in the river Benue axis at different locations and periods. One of such rainfall events, as captured by TRMM satellite during September 29, 2012 in the Nigeria rainforest zone, indicated that the volumetric rainfall is 351,310.9 ((mm/h)*km^2) with only 34% convective portion. From these results, it can be deduced that a combination of thermodynamic environmental variables, volume rainfall, and other satellite-derived convective parameters could provide important information for flood forecasting.

Introduction

Annually, between March and early October, severe precipitation event which are often associated with flash floods events frequently cause severe damage and loss of property and lives in most countries of West Africa (Balogun et al. 2018). This climate change hazard has been linked to pressures from socioeconomic and physical factors (Merem et al. 2019). The magnitude and frequency of climate hazards have generated serious concerns in recent years in Nigeria, since the 2012 flood disaster in the country and most other West African countries in particular. Flood disasters have been a major occurrence that keeps recurring annually, in some parts of Nigeria (Magami et al. 2014). A Post-Disaster Needs Assessment (PDNA), of the 2012 Nigeria flood, was conducted by the Federal Republic of Nigeria (FRN) with technical support from United Nations, European Union, and World Bank. The major aim of the assessment was to reduce the impact of future disasters, since the floods are due to climate change (Nigeria-PDNA 2013).

Burkina Faso, which is surrounded by other West African countries particularly in the south, shared both Savannah and Sahel climates of West Africa. The economy is specifically based on cotton production and gold mining (WB 2017). Most parts of the country, and Ouagadougou which is the capital in particular, were ravaged by a devastating flood event on the 1st of September 2009 (GBF et al. 2010). This was a result of an extreme single-day rainfall amount of 261.3 mm (Karambiri 2009; GBF et al. 2010; Galvin 2010). GBF et al. 2010 stated that the September 1st 2009 flood event affected 11 out of the 13 regions in Burkina Faso with the majority of the impacts observed to be concentrated in Ouagadougou. According to GBF et al. (2010), the flood event caused at least 46 deaths and about 120,000 victims were affected. The economic impact was estimated at $201 Million USD in damages, $33 Million USD in losses, and $266 Million USD in reconstruction needs (GBF et al. 2010). (Galvin 2010) concluded that the flood event was "*heavy*," "*extreme*," "*enormous*," and "*exceptional*"; while GBF et al. (2010) concluded that the single-day rainfall represented almost one-third of the total rainfall received annually during the monsoon season. The flood event has a return period of more than 10,000 years according to a preliminary statistical analysis by Karambiri (2009).

The 2012 flood disaster in Nigeria was caused by continuous heavy rainfall and the release of water from Lagdo Dam and Lake Nyos in the Cameroon. The water released affected border towns in Nigeria (Ojobor 2014). NIMET (2012) had earlier predicted, in early March during the 2012 rainfall prediction, and cautioned the Nigerian government about the possibility of continuous rainfall, which could result in destructive flooding in most states in Nigeria, with emphasis on the river basin or catchment and coastal communities of Nigeria. NIMET (2012) advised the government of Nigeria to organize public enlightment programs so as to minimize the damages, devastation, and casualties, in terms of lives and properties, most importantly in locations and communities close to rivers, dams, among others. According to Ojobor (2014) and Agada (2015), a huge number of the populations were largely displaced in these communities, due to the 2012 flood event, as predicted by NIMET (2012). The intention was to help Government agencies and the populace to put necessary measures in place to mitigate the effects of flood waters (Ojobor 2014). The second warning came in August 2012 from Cameroun. Akaeze (2012) stated that the Nigerian Government was officially written by the Cameroon government that the Lagdo Dam located in Cameroun has already filled to capacity as a result of continuous rainfall in the location of the dam and if such rainfall amount should continue in the following week, the dam will overflow and will result in recurrent overflow of water (Akaeze 2012). According to Njoku (2013), the Cameroon authority referenced paragraph 3 of article 111, in the 2010 Nigeria–Cameroon Joint Commission regarding the interchange of relevant information as regard the situations around the Lake Nyos and Lagdo Dam, so that the Nigerian Government will take precautionary measures around the flood areas so as to avoid severe loss.

This chapter was contributed in 2019 to investigate the atmospheric environment of the two case studies discussed above. The major limitation was lack of ground observations to validate the satellite data used for this chapter.

The TRMM and ERA: Interim Data Description

This chapter investigates high resolution (0.1 × 0.1) TRMM 2A25 radar-derived rainfall product, alongside derived products of the European Centre for Medium-range Weather Forecasts (ECMWF) interim reanalysis (ERA-Interim: Simmons et al. 2007; Dee et al. 2011) dataset to investigate the two (2) case studies.

The TRMM orbital data provided date, time, location, and orbit number analyzed in the case studies. The parameters analyzed from the TRMM orbital data are: Infrared (10.8 micron) brightness temperature, near-surface reflectivity, 85 GHz PCT (Polarization Corrected Temperature), and near-surface rain rate. The parameters analyzed from the environment, of ERA-Interim reanalysis dataset are Sounding (skew – T) to further provide information on convective development, convective available potential energy (CAPE), moisture fluxes, lifted index, and vertical wind shear. The environmental parameters were analyzed at 6-hour intervals a day before, during, and a day after the case study event(s).

The 2009 Flood in Burkina Faso

The severity of the September 1st 2009 flood made it a focal point of this chapter. The TRMM snapshot of a Mesoscale Convective System (MCS) on September 1, 2009, covering southern and western Burkina Faso, is shown in Fig. 1a–d. The Visible Infrared Scanner (VIRS), in the TRMM satellite, estimated the brightness temperature as low as 178 K in Fig. 1a. The pattern of the MCS, as shown by the near surface reflectivity (Fig. 1b), 85 GHz Polarization Corrected Temperature (PCT, Fig. 1c), and the near surface rainfall (Fig. 1d), clearly indicated that the system is a line squall which spans several kilometers. The rain rate from the single system is over 130 mm/h and the MCS is only 65% convective (Table 1), meaning that the trailing stratiform portion (region) within the system is 35%. The volume of rainfall (volumetric rainfall) from the single system is 408,070.60 ((mm/h)*km^2) (Table 1). The total number of flashcount from the single system is 191 as estimated by the Lightning

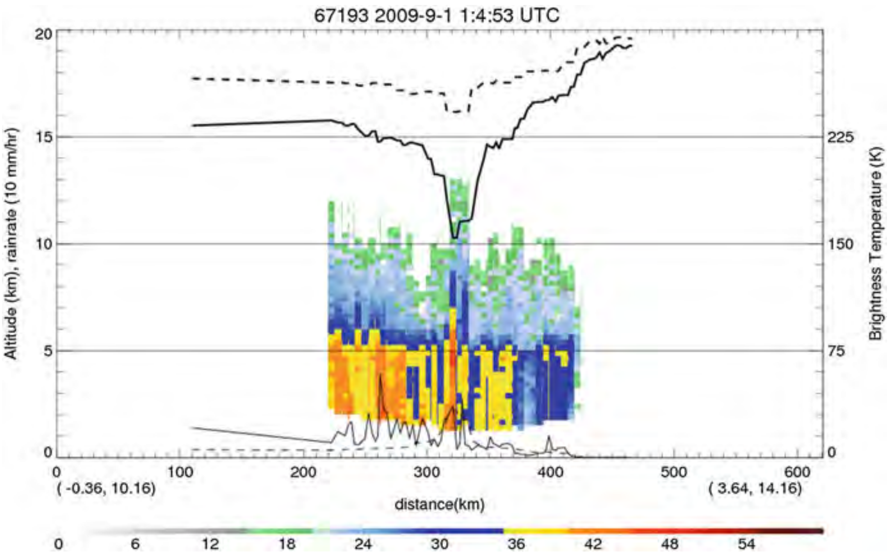

Fig. 2 Vertical cross section of the MCS which occurred on September 1, 2009

Imaging Sensor (LIS) of the TRMM satellite. The system was captured at exactly 1:04:53 am on the 1st of September 2009 by the TRMM satellite. The vertical cross section, in Fig. 2, shows that the system is about 200 km horizontally and reaches about 13–14 km altitude, which is close to the tropopause.

The thermodynamic parameters considered in this chapter to discuss the environment of this system are moisture flux convergence at the 1000 mb (hpa) level, lifted index, wind shear between 1 and 3 km, and the skewt diagram (which will provide information on the Lifting Condensation Level (LCL), Level of Free Convection (LFC), Cloud Base (CB), Cloud Top (CT), among others). The environment of the system was investigated a day before the system was captured, the day the system was captured, and the day after the system was captured.

On the August 31, 2009, a day before the flood, the location where this system occurred clearly indicated weak moisture divergence (tendency of a clear sky), in the range of 0–10 kg m^{-2} s^{-1} occurring in the zone, but south of this zone is the presence of strong moisture convergence (mechanism by which air is lifted for cloud formation) in the range of 55–80 kg m^{-2} s^{-1}. A close observation of the time periods indicates that the moisture convergence seem to be migrating northward toward the location of the system. At 18Z, part of the location of the system is already experiencing weak moisture convergence. During the night time of September 1, 2009, there was a stronger moisture convergence south of the flood event zone, but the moisture convergence was still weak in the flood event zone. Other periods (6Z, 12Z, and 18Z) did not show strong moisture convergence on the 1st of September 2009, which was the day of the flood. On 2nd of September 2009, the entire environment in which the flood occurred encountered moisture divergence, which indicated that the environment is already dry or in clear sky condition. From the analysis of the moisture flux convergence in the location of the flood, there is tendency that the system developed south of the location, and migrated northward into the zone.

The lifted index (LI), similar to the Convective Available Potential Energy (CAPE), is used to assess low level parcel (in)stability of the troposphere. A negative lifted index (LI) indicates that the boundary layer is unstable with respect to the middle troposphere. Such is an environment in which convection can occur. The more negative the LI, the more unstable the troposphere and the more buoyant the acceleration will be for rising parcels of air from the Planetary Boundary Layer (PBL). On the 31st of August 2009, the environment experienced weak instability during the night, morning, and day time, whereas during the evening time, the environment became more unstable. On the 1st of September 2009, the night time, which was preceded by the evening period of 31st August 2009, showed that the environment of the flood event location was more stable (lesser instability) than the preceding evening. A day after the flood scenario, the stability of the environment was similar to the previous day. From these discussions so far on (in)stability in the environment of the flood scenario using lifted index, it was obvious that the environment was not strongly unstable during the flood scenario event of 1st September 2009. The only case where large instability was observed, in the range of −4 to −5 K, was during the evening period which preceded the night time when the flood scenario occurred. In all the other periods, only marginal instabilities were observed, which may not be strong enough for buoyant acceleration of air parcels in the Planetary Boundary Layer (PBL).

The question from the foregoing is can deep convective clouds develop under this kind of environment in which the moisture convergence and instabilities were relatively weak? The zone where the flood event occurred was in the Sudano and it occurred during the JJAS season, which is the season for strong convective storms in the zone.

Vertical wind shear is an important factor for determining the development of Mesoscale Convective Systems (MCSs, Chen et al. 2015). Many studies have examined the effects of vertical wind shear on intensity and organization of convective systems, especially for squall lines (Rotunno et al. 1988; Weisman and Rotunno 2004; Coniglio et al. 2006; Takemi 2006), similar to the event being examined in this section. The effects of strong wind shear on cloud system organization depend on the altitudes where the strong wind shear occurs. Lower level shear is also favorable for organizing systems into lines or quasi-lines (Wu and Yanai 1994; Robe and Emanuel 2001; Richardson et al. 2007; DeLonge et al. 2010), as a reminder that the TRMM snapshot earlier presented showed this particular system to be an organized MCS (squall line). The vertical low level (1–3 km) wind shear seemed to gradually developed into a severe (>8 s^{-1}) scale wind shear, from the night (0Z) of August 31, 2009 through to the evening period (18Z) of 31st August 2009, in the location of the flood event. This strong (severe) low level vertical wind shear, which is most severe in the eastern axis of the flood location, extends into the flood location during the evening period of 31st August 2009 and night time (0Z) of 1st September 2009 (which was the exact time the MCS was captured). This severe low level vertical wind shear could have initiated the development and evolution of convective cloud, and hence MCS similar to the finding that lower level shear directly influences the initiation and evolution of convective clouds due to interactions between lower tropospheric shear and cold pool dynamics (Rotunno et al. 1988; Moncrieff 1992; Xu et al. 1992), which could have originated from the 1000 mb moisture convergence located southward and migrated northward into the location of the flood event. Historical studies (Simpson 1969; Charba 1974) have shown that a region/zone dominated by evaporatively cooled air which was transported to lower levels via convective downdrafts and thereafter, upon reaching the surface, spread out in the form of a density current is referred to as a convective cold pool region. Goff (1976) stated that cold pools often displaced warmer environmental air as they spread out to adjacent zones. This displaced ambient air is often buoyant and are then uplifted, and thus results in the development or initiation of new convective clouds (Goff 1976; Warner et al. 1980). Droegemeier and Wilhelmson (1985) had noted that two or more collisions of cold pools are effective trigger mechanism for initiation of convection. In addition, Tompkins (2001) and Langhans and Romps (2015) stated in their works that cold pools often bring surface gusty winds that intensify sensible and latent heat fluxes, and thus modifying the thermodynamic characteristics and moisture structure of the boundary layer. The vertical wind shear subsides slightly, although still in the severe category, but maintained the severe category up till the night time (0Z) of the next day (September 2, 2009). Thereafter, the low level wind shear dropped to moderate category on the morning (6Z) of September 2, 2009 and other periods (12Z and 18Z) of the same day.

By the interaction between low level wind shear and cool pools in convective cloud initiation and development (or evolution), especially in the roles these parameters play in the Burkina Faso flood event of 1st September 2009, the next assessment of the case study is to investigate the cloud structure through the use of skew-t diagram.

Results showed that the Convective Available Potential Energy (CAPE) environment was positive (+) for all the periods (0Z, 6Z, 12Z, and 18Z) on the 31st August 2009, with the peak mean CAPE value (1392.42 J/kg) indicated by the evening period (18Z), which was the period that preceded the night time (0Z) of 1st September 2009 when the MCS system was captured. During the night time (0Z) when the MCS system was captured, the top of the cloud is around 13–14 km similar to the height estimated by the TRMM satellite in the cross section plot discussed earlier. The mean CAPE value dropped significantly during the morning (6Z), day (12Z), and evening (18Z) periods of the same day and through all the periods (0Z, 6Z, 12Z, and 18Z) of the second day, which was September 2, 2009.

Records from the flood, which lasted in the memory of the inhabitant, has it that 180, 386 victims were affected, 62 victims were wound, 41 died, and 33,172 homes were destroyed (Schlef 2018).

The 2009 flood created a lasting and strongly negative impression on the victims; they described the flood as "*catastrophic*" and "*big*" and one public official called floods "*bitter experiences*" while a flood victim said "*what we lived through, we have no desire to experience again*" (Schlef 2018). The flood victims and some public officials also shared their personal stories, revealing the unquantifiable and sometimes long-lasting effects of experiencing a devastating flood: "*We left the house . . . it overflowed . . . I didn't know how to swim, so they dragged me along . . . even now when it rains at night I can't sleep – I'm afraid! And I'm not the only one*" (Schlef 2018).

The 2012 Flood in Nigeria

Between July and October 2012, floods which resulted from the predicted heavy rains and the released water from Lagdo dam in Cameroon pushed rivers over their banks and submerged hundreds of thousands of acres of farmland. By mid-October, these floods had forced 1.3 million people from their homes and claimed 431 lives (Agada 2015). The severity of the 2012 Nigeria flood made it a focal point of this chapter. The TRMM snapshot of a Mesoscale Convective System (MCS), with an extreme volume rainfall (Table 2) of 351,310.9 ((mm/h)*km^2) on 29th September 2012 (one of the days of the flood), in Ofutop II (a community close to Ikom Cross River state) is shown in Fig. 3. The Visible Infrared Scanner (VIRS), in the TRMM satellite, estimated the brightness temperature as low as 186 K in Fig. 3a. The rain rate from the single system is over 140 mm/h and the MCS is only 34.1% convective (Table 2), meaning that the trailing stratiform portion (region) within the system is 65.9%. The total number of flash count from the single system is 5 (Table 2) as estimated by the Lightning Imaging Sensor (LIS) of the TRMM satellite. The system was captured at exactly 7:38:20 am on the 29th of September 2012 by the TRMM satellite. By the last three (3) sentences (stratiform region was 65.9%, only 5 flashcount was estimated, and the system occurred in the morning diurnal), clearly this system is more of stratiform than convective, which would have lasted for a long time before it completely decayed. The vertical cross section in Fig. 4 shows that the system extends over 200 km horizontally and reached only about 8 km altitude in the atmosphere, and no depressed brightness temperature was observed in the cross section of the system.

As was analyzed for the Burkina Faso flood scenario, the thermodynamic parameters to investigate the environment of this system are: moisture flux convergence at the 1000 mb (hpa) level, lifted index, wind shear between 1 and 3 km, and the skewt diagram (which will provide information on the Lifting Condensation Level (LCL),

Table 2 Summary of some parameters from the observed system during 29th September 2012

Latitude	Longitude	% convective	Size (km^2)	Volrain ((mm/h)*km^2)	Flashcount (#)
6.78	7.13	34.1	83190.8	351310.9	5

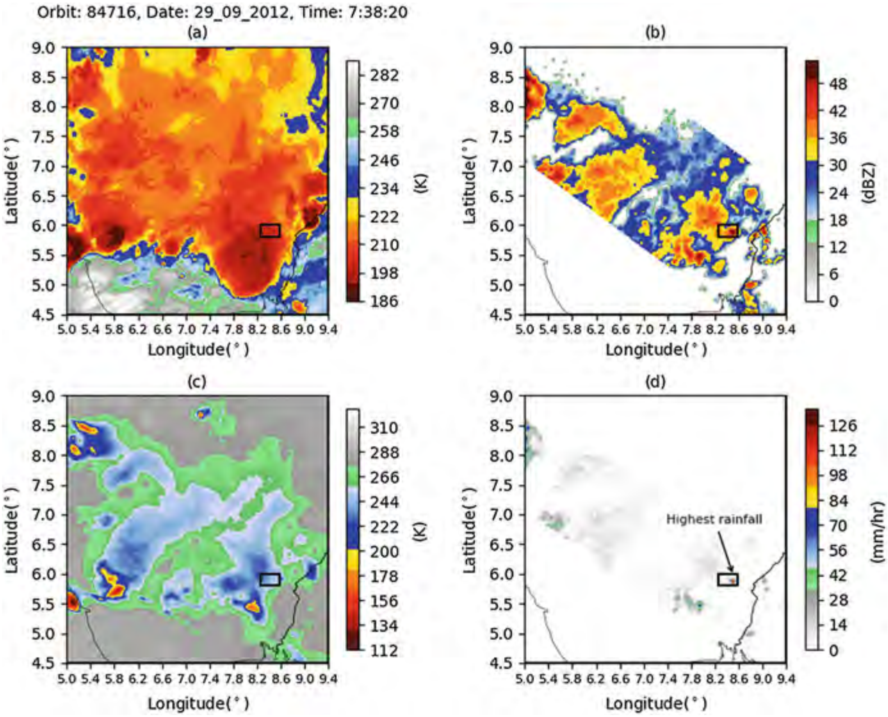

Fig. 3 Case study of TRMM-observed MCS which occurred on September 29, 2012 in Nigeria, where (**a**) Infrared (10.8 micron) brightness temperature (Tb), (**b**) PR near surface reflectivity, (**c**) 85GHz PCT of MCS, and (**d**) 2A25 near surface rain rate

Level of Free Convection (LFC), Cloud Base (CB), Cloud Top (CT), among others). For this case study, the environment of the system was investigated a day before the system was captured, the day the system was captured, and five (5) additional days after the system was captured because the flood affected many parts of Nigeria, and was reported to last many days beginning from around July to around mid-October.

On 28th of September 2012, a day before the system was captured by the TRMM satellite, extreme low level moisture flux convergence was observed during all the periods (0Z, 6Z, 12Z and 18Z), especially along the axis of the river Benue bank, which were the most affected areas (the Nigeria savannah zone). The communities in Nigeria affected by this extreme low level moisture flux convergence are Aguleri in Anambra state, Katsina Ala in Benue state, Makurdi in Benue state, Ikom in Cross River state, Lokoja in Kogi state, among others. It has been noted by Ismail and Siadari (2017) that if the atmosphere is unstable with abundant low-level moisture and a mechanism exists to lift the air (thereby releasing the potential instability), convective weather and rainfall (showers) can develop. On September 29, 2012, the affected areas were still under the influenced of extreme low-level moisture flux convergence, including Ofutop II in Cross River state where the peak rainfall rate was observed. On September 30, 2012, Aguleri community in Anambra state was

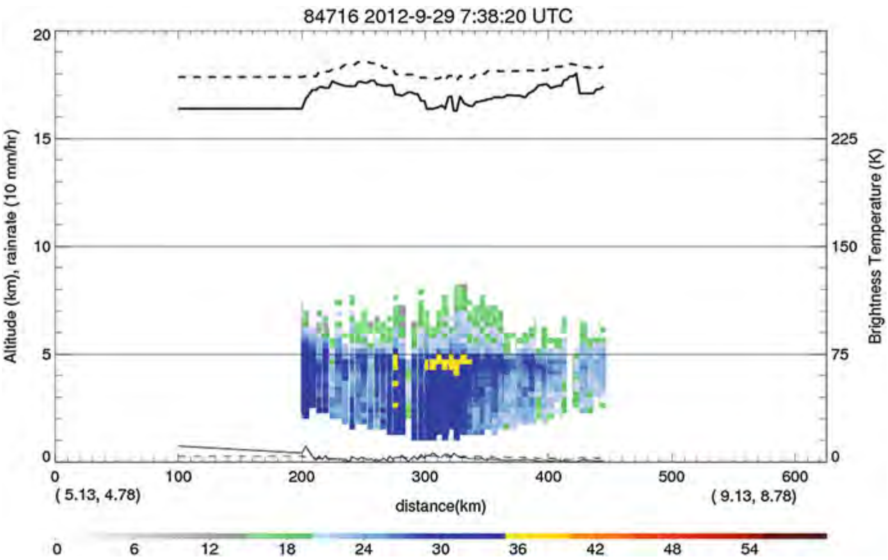

Fig. 4 Vertical cross section of the MCS which occurred on September 29, 2012

under the influence of extreme low level moisture flux convergence during the night time. According to Vanguard newspaper of 7th October 2012, the then governor of Anambra state, Governor Peter Obi, had to suspend the Independence Day celebration of Nigeria, slated for 1st of October 2012, so as to pass through the flooded Onitsha-Osomala road in Nmiata and Ogbaru road in Anambra West in other to supervise the removal of victims trapped in their communities by the devastating flood event. Vanguard newspaper of 7th October 2012 further stated that the entire Nzam, Aguleri Otu (a community where the then President of Nigeria, Goodluck Jonathan, commissioned the Orient Petroleum facility), Nmiata, Odekpe, Osomala, Osuche, Atani, Amii, Umuzu, and other communities in Anambra state were under water. Properties that worth billions of naira in the four local government areas of Anambra state, where these communities were situated, were destroyed by the flood. According to the Vanguard of 7th October 2012, the governor was able to persuade the people to leave their properties and secure their lives. He, the then Governor Peter Obi, thereafter used canoe to visit other communities trapped across the River Niger basin of Anambra state. By the time the then governor Peter Obi returned to his entourage to continue his inspection of other affected communities, flood had already filled the whole road through which he would leave. The governor and his entourage had to walk through the flood (Fig. 5a), which leveled-up to their waists, in other to reach the convoy of vehicles. On 1st through to 4th October 2012, all the communities along the River Benue axis were still under the influence of extreme low level moisture flux convergence. This implied that the communities would have experienced continuous heavy precipitation during these periods, apart from the water that was released from the lagdo dam (see Fig. 6) in Cameroon.

Fig. 5 Situations during the 2012 flood in Anambra state (**a** and **b**). (Source: Emmanuel et al. 2015)

Fig. 6 Map showing Nigeria, Cameroon, Benue River, and Lake Lagdo in Cameroon (http://en.wikipedia.org/wiki/). (Source: Agada (2015))

It was also reported (Vanguard, October 7, 2012), that about 79, 000 people were displaced in Cross River State. Out of the number, more than half – 49, 918 – were displaced by flood as a result of the release of water from Lagdo Dam in Cameroon. In Ikom Local Government Area, close to the community where the peak rainfall was observed on 29th September 2012, the flood also displaced 26 communities and destroyed one school and two markets.

The stability of the environment, on 28th September 2012 indicated that the entire zone under investigation was extremely unstable, particularly during the evening time (18Z) of the day that preceded the MCS event that was captured by TRMM satellite. It clearly showed that the Ofutop II community in Cross River was extremely unstable during the evening period of 28th September 2012 and during the night (0Z) of September 29, 2012 (the day the MCS was captured by TRMM satellite). During the morning time (6Z), the instability of the environment in Ofutop II of Cross River state had subsided to moderate category, but increased again to severe category during the day (12Z) and evening (18Z) periods. On September 30, 2012, the day that preceded the governor's visit to communities, Aguleri in Anambra state was under extreme instability during the evening period (18Z). Places like Makurdi and Katsina Ala in Benue state were also under extreme instability during the same evening diurnal. On 1st through to 4th October 2012, most communities in the affected zone were under moderate to extreme instability as indicated by the lifted index, particularly during the night (0Z), day (12Z) and evening (18Z) periods. The morning diurnals showed weaker instabilities in most cases during these periods (1st – 4th October, 2012).

On the 28th of September 2012, there was severe – extreme – wind shear in the environment of the event, which cut across the seven communities under investigation in this work. The most extreme wind shear was observed in Lokoja of Kogi state during the evening period (18Z) of 28th September 2012, which was earlier observed during the night period (6Z) of the same day. Lokoja was under the influence of extreme low level vertical wind the second day, 29th September 2012 during the night (0Z) and evening (18Z) periods. Because the entire Nigeria savannah environment was under the influence of strong moisture convergence during this period, hence the presence of cool pool dynamics in combination with the extreme low level vertical wind shear, among other factors would definitely had initiated deep convective systems, particularly in Lokoja and surrounding Benue state. Ofutop II and surrounding Ikom, in Cross River state, were particularly under the influence of severe low level vertical wind shear on the 28th September 2012 in all the periods. On 29th and 30th September 2012, the low level vertical wind shear in Ofutop II was already suppressed. It was noted that Lokoja in Kogi state and Makurdi in Benue state were still under the influence of extreme low level vertical wind shear on 30th September 2012. On 1st of October 2012, all the Nigeria savannah communities under investigation were influenced by extreme low level vertical wind shear. This convective environment remained under the influence of extreme low level vertical wind shear during 2nd, 3rd, and 4th of October 2012. Agada (2015) stated that the two most affected areas were Kogi and Benue States.

Results for the Ofutop II community where the peak rainfall rate was captured by the TRMM satellite showed that the Convective Available Potential Energy (CAPE) environment was positive (+) for the night time (0Z) on the 28th September 2012, with the peak mean CAPE value (4672.80 J/kg) and highest cloud top (slightly above 15 km) indicated by the evening time (18Z). During the night time (0Z) of 29th September 2012, which was the diurnal that preceded the morning time (0Z) of 29th September 2012 when the MCS system was captured, the top of the cloud as

Fig. 7 Areal view of Lokoja, Kogi State, under the siege of flood. (Source: Vanguard 2012)

shown by the skew-t diagram was around 14–15 km, quite different from the height estimated by the TRMM satellite in the cross section plot, because the location (Ofutop II in Cross River state) under investigation is different from the nadir latitude–longitude of observation by the TRMM satellite. The mean CAPE value dropped significantly during the morning (6Z), day (12Z), and evening (18Z) periods of the same day but increased during the day (12Z) and evening (18Z) periods (12Z and 18Z) of the second day, which was 30th September 2012.

According to Vanguard (2012), horror came in the shape of suicide in one of the resettlement camps in Kogi State where two victims of the ravaging floods decided to take their own lives. They could not bear the loss of properties (Vanguard 2012). In relief camps in Kogi, 20 people have already died. The conditions were worst, two bags of rice for 2000 victims per day: How would it go round? The flood ravaged Lokoja (Vanguard 2012) as shown in Fig. 7 above.

Conclusions

A combination of TRMM observed convective properties and reanalysis dataset have provided valuable information for analyzing flood scenarios in West Africa and have proved reliable based on the results generated from this research work.

At the time of written this chapter, flood disasters has become a yearly occurrence in all the locations affected by the 2012 Nigerian flood. There is no specific climate change adaptation strategies adopted in any of these locations. The inhabitants watched their properties and farmlands destroyed every year. There cry had always been to the government, but in all, relief materials are what they get in return.

Because this climate change hazard has become an annual occurrence in some parts of Nigeria and West Africa in general, this work therefore suggest that governments in affected countries put in place mitigation strategies to reduce the impact of future occurrence.

Abstract

The maintenance of soil productivity is important for sustained crop yield in low-input systems in the tropics. This study investigated the impact of four different land use types, namely, maize and cassava cropping, woodlot/plantations, and natural forests on soil productivity components, especially soil carbon accretion, at six sites within two agro-ecological zones of southern Ghana. Soil properties were significantly different between sites and ecological zones. The coastal savanna zones, which is a low rainfall zone had relatively lower soil carbon storage than the high rainfall forest-savanna transition zone. Soil productivity conditions in the later zone were much more favorable for cropping than the former. Land use types significantly affected the soil carbon (*SOC*) storage within the two ecological zones. In the low rainfall zone, soil carbon accretion by maize cropping, cassava cropping, and plantations were 48%, 54%, and 60%, respectively, of the forest carbon stock (47,617 kg/ha). In the transition zone, the soil carbon accretion was over 90% of the forest value (48,216 kg/ha) for all land use types. In effect use of land use types in maintaining soil productivity must consider the conditions in a given ecological zone.

Introduction

Soil organic carbon (*SOC*) is a major component of productivity in low-input cropping systems of the tropics. Soil carbon influences the physical, chemical, and biological properties of the soil. Many studies have indicated that the reduction in the *SOC* can result in significant decrease in the available water capacity (Hudson 1994), structural deterioration, and an increased bulk density (Shu et al. 2015). Also, the contribution of the *SOC* to soil fertility maintenance is also well established. Crop yield reduction is often associated with *SOC* losses, largely because the *SOC* is a major reservoir of nutrients, especially in the tropics where external inputs continue to remain low (Sanchez et al. 2009). Estimates by Lal (2006) indicated that maize yield could decline by 30–300 kg ha^{-1} for every ton ha^{-1} of *SOC* in the root zone. Regarding soil biology, the *SOC* is a major source of nutrition and energy for microbial life. Some authors describe the *SOC* as the "... life blood" of tropical soils (Acquaye 1989). Though the *SOC* plays a dominant role in tropical agriculture, other soil properties may also enhance the overall productivity. Nutrients elements such as nitrogen, which is largely derived from organic matter mineralization, phosphorus from rock minerals, and the overall cation retention capacity are important factors that also determine soil and crop productivity.

Soil carbon and hence productivity is not permanent but may change rapidly depending on land use type and management (Zerihun 2017; Waddington et al.

2010; Reynolds et al. 2015). Much of the literature (Burras et al. 2001; Sa et al. 2001; Batlle-Aguilar et al. 2011) indicates that the conversion of forest to agriculture and other forms of land use such as plantations and woodlots is the major cause of soil productivity decline in the tropics. Brams (1971) showed a 50% reduction in the *SOC*, only 5 years after forest clearing in Sierra Leone.

Residue management methods employed in agriculture also lead to changes in *SOC*. Adiku et al. (2009) showed in Ghana that where crop residues were removed (e.g., by burning, or cutting to feed animals with no return of manure), the *SOC* declined rapidly from the long-term fallow land value of 18 g kg^{-1} to 7 g kg^{-1} with 4 years of maize cropping. However, where the residues were maintained as mulch, the rate of *SOC* decline was much slower, from 18 g kg^{-1} to 15 g kg^{-1} over years. A greater buildup of SOC in forests than other land use types would be expected because of long-term continuous litter addition (Brinson et al. 1980), for example, by avoidance of cultivation losses and reduced decomposition due to lower temperatures under a tree canopy. For croplands, the constant disturbance of the soil enhances *SOC* decomposition (Lal 1997; Hulugalle et al. 1984; Kang 1993; Dalal et al. 1991), and the constant harvest or removal of plant organic material (Feller 1993) would increase the *SOC* loss due to the partial exposure of the soil to high temperatures during off-seasons.

Despite these findings, the manner in which land use types affect soil carbon storage in different ecological zones is not well understood. The question of interest here is whether a given land use type will equally impact soil properties in different rainfall and vegetation zones. In other words, can we generalize that cropping will adversely affect soil productivity irrespective of the carbon input capacity of different ecological zones? This aspect of research is still lacking in Ghana, even though it has relevance for the design and management of soil productivity. The focus of this chapter is to examine how four land use types (forest, woodlot/plantation, cassava cropping, and maize cropping) affect soil carbon content and other properties at six farming sites of Ghana (across two ecological zones).

Materials and Methods

Sites

Six (6) farming sites from two agro-ecological zones, all in southern Ghana, were selected for this study (Fig. 1). Three of the farming sites (Accra Metropolis, Ga East District, Ga West District) fall in the coastal savanna zone of Ghana and receives 650–1000 mm rainfall. Though the vegetation is largely grassland, some derived savanna locations still host original pockets of forestland. The dominant soil type of the Greater Accra Region based on FAO/UNESCO classification is Ferric Acrisol and Umbic Leptosol (Soil Research Institute 1999). The remaining three sites (Yilo Krobo District, Shai Osudoku District, and Upper Manya District) fall within the forest-savanna transition zone (hereinafter transition zone) receiving 1500–2000 mm rainfall. Vegetation is largely forest at some portions and mixed with grassland in other portions. The soils of the transition comprise Cambic Arenosol and Calcic

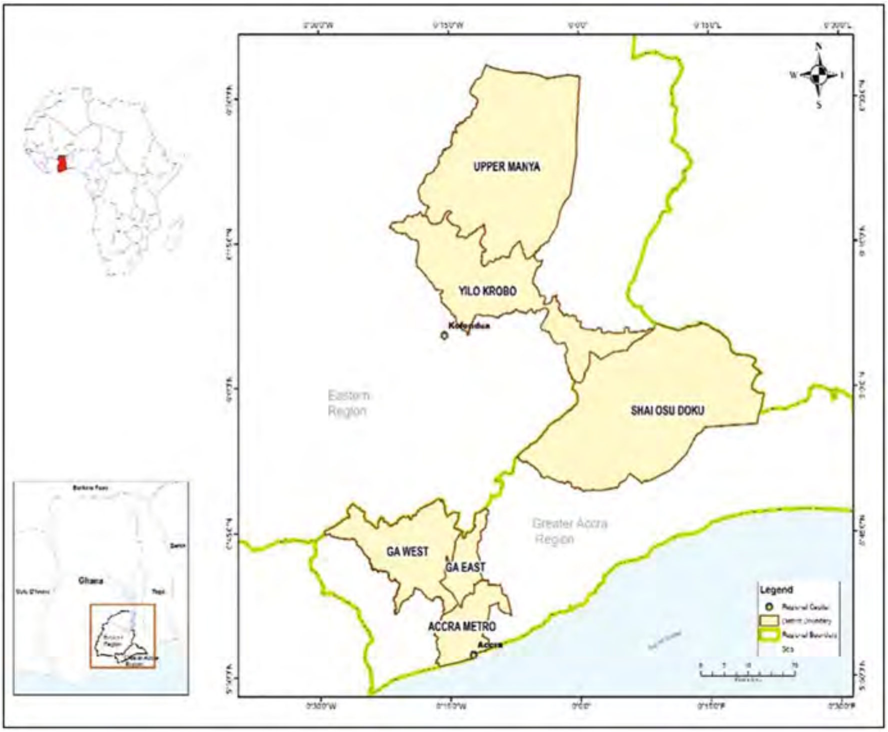

Fig. 1 Map shows position of Ghana in West Africa (top left), the location of the study sites in southern Ghana (bottom left), and the details of the districts (Ga West, Ga East, Accra Metropolis, Yilo Krobo, Shai Osudoku, and Upper Manya) used in Ghana

vertisol. Rainfall in both ecological zones is bimodally distributed, with a major wet season from March to July and a minor wet season from September to November. Agriculture is the main source of livelihood at all the sites.

The first site (Accra Metropolis) in the coastal savanna zone was located at the University of Ghana Farm and hosts a forest of more than 150 years old. Nearby the forest is cleared area which has been cropped to maize (*Zea mays*) and cassava (*Manihot esculenta*) for more than 20 years by University Farm workers. The maize fields receive periodically modest fertilizer application of not more than 30 kg N ha^{-1}. Also, located at the University Farm is an 18-year-old woodlot of *Leucaena species* established on a previously cropped land. Experimental plots at the University Farm were not included in this study. The soils under the forests and woodlots have little mechanical disturbance for many years, but the croplands are plowed and cultivated annually. The second site in this zone (Abokobi) also carried a 70-year-old forest with adjacent lands cropped to maize and cassava for not more than 10 years. A plantation of plantain (*Musa* spp.) was established near the forest. The third site (Pokuase) carried a forest of more than 70 years, an oil palm (*Elaeis guineensis*) plantation as well as cassava and maize farms.

The fourth site (Yilo Krobo), which is located in the transition zone carried a forest of more than 50 years, an oil palm plantation and relatively young crop farms of maize and cassava. The fifth site (Shai Osudoku) holds a protected forest with mature trees of more than 100 years old. For this reason, soil sampling was restricted to the fringes of the forest. Other land use systems at this site include an 18-year mango (*Mangifera indica*) plantation, maize, and cassava farms. The sixth site (Upper Manya) has a forest of more than 50 years old, along with oil palm plantations, and recent arable farms.

Table 1 Land use types at the two agroecological zones

Site	Ecology	Rainfall (mm)	Dominant soil	Land use	Age (years)
Accra-Metropolis	Coastal savannah	700	Ferric Acrisol	Maize	10
				Cassava	10
				Woodlot	20
				Forest	>150
Ga-East	Coastal savannah	800	Ferric Acrisol	Maize	5
				Cassava	8
				Plantation	6
				Forest	>70
Ga-West	Coastal savannah	800	Umbic Leptosol	Maize	4

				Forest	>50

Farmers' best estimates

Sampling and Analysis

For this study, four land use types, namely, maize cropping, cassava cropping, plantations (teak, mango, plantain, oil palm, woodlot), and natural forests were selected (Table 1). Fifty-four (54) farms across the six sites were selected and visited from April to May 2017, and soils were sampled from each land use type from the depth of 0–20. The cropping history of the 54 farms were documented during a prior survey by Owoade et al. (2017). At each site, at least three maize and three cassava farms were sampled in triplicates and bulked to obtain a composite sample for each farm. In addition, soils were sampled from the plantations and the natural forests.

The disturbed top soil (0–20 cm) and separately sampled undisturbed soil cores were brought to the laboratory for analysis. The bulk density was determined on the soil cores. Disturbed soils were air-dried, crushed, and sieved through 2-mm sieve for the determination of texture, total soil carbon, pH, total nitrogen, available phosphorus, and exchangeable cations (K, Mg, Ca, Na). Exchangeable bases were determined by extraction with 250 ml of buffered 1.0 M ammonium acetate followed by flame photometric determination and the effective cation exchange capacity (ECEC) was determined as the sum of exchangeable cations. Soil texture determination followed the procedure of Bouyoucous (1951) as modified by Day (1965) using sodium hexametaphosphate as the dispersant. Soil pH was determined in 1:1 soil to water ratio using a MV88 Praitronic pH meter and electrode. Available phosphorus (AvP) was determined colorimetrically after extraction with Bray 1 solution (Bray and Kurtz 1945) and the concentration measured using a UV-Spectrophotometer. Total soil carbon and nitrogen were determined using TruMac Carbon, Nitrogen, and Sulfur analyzer (Model N1914).

The soil carbon content was converted to stocks (C_{st}) using:

$$C_{st} = A \times \rho_b \times z \times SOC \tag{1}$$

where A is the land area (1 ha $= 10^4$ m^2), ρ_b is the soil bulk density (kg/m^3), and z is the soil depth (0.20 m).

Statistical Analysis

Analysis of variance was conducted using MINITAB software to determine the influence of land use types and site location on soil properties.

Table 2 Variation of soil properties with sites

Site	Ecology	Bulk density (g/cm^3)	SOC (g/kg)	pH	Avail P (mg/kg)	N (mg/kg)	ECEC (cmol/kg)
Accra Metropolis	Coastal savanna	1.27 ± 0.16	12.4 ± 6.0	4.4 ± 0.4	18.7 ± 12	4.3 ± 0.4	3.11 ± 0.86
Ga East		1.38 ± 0.10	11.49 ± 5.0	5.05 ± 0.5	10.9 ± 6.0	4.1 ± 0.3	3.06 ± 0.91

Results and Discussions

Effect of Site Locations on Soil Properties

There were significant differences among some soil properties at the various sites (Table 2). For example, soil texture, expressed as clay ratio (sand + silt)/clay), differed significantly with site, with high values (>11) at sites 1, 2, 5, and 6, and low values (4–5) at locations 3 and 4 (not shown). The bulk density differed significantly with site ($p = 0.007$) with higher values observed for the coastal savanna zone (1.3–1.4 g/cm^3) than in the transition zone (1.2–1.3 g/cm^3). The *SOC* also differed significantly with site ($p = 0.000$), with higher values in the transition zone (1.3–2.4 g/kg) than the coastal savanna zone (1.2–1.6 g/kg). Apparently, the higher *SOC* of the transition zone could be attributed to a greater carbon input by the high rainfall and more forest vegetation than the savanna ecological zone. The higher SOC of the transition zone may explain, the lower bulk density values, as these two properties are inversely related.

The pH differed significantly ($p = 0.000$) between ecological zones with the transition zone having higher values (6.0–6.2) than the coastal savanna (4.4–5.6). Soil pH differences may have consequences to crop performance because most nutrient elements are usually available in the pH range of 5.5–6.5 (Motsara and Roy 2008). The available P was significantly different ($p = 0.008$) among the sites. Though site 1 (Accra Metropolis) in the coastal savanna zone had the highest value (18.7 mg/kg), and the variability was also very high (SD = 12 mg/kg). Except for the site 6 (Upper Manya) which had the lowest available P (7.9 mg/kg), the average P values were quite similar for the two ecological zones; 11–18 mg/kg for the coastal savanna and 8–16 mg/kg for the transition zone. In general, the available P levels were somewhat adequate for plant growth, given a threshold of 11 mg/kg (Adeoye and Agboola 1985). Total nitrogen values varied significantly with site ($p = 0.000$) with higher values for the coastal savanna (1.1–4.3 mg/kg) than the transition zone (1.2–3.6 mg/kg). Though the ECEC can be considered as generally low but differed significantly ($p = 0.000$) between ecological zones, with the transition zone having 4.3–6.8 cmol/kg and the coastal savanna having 3.1–4.1 cmol/kg. Based on the soil property values, it may be concluded that the transition zone provided a much better soil condition for cropping than the coastal savanna zone.

Not all the soil properties were significantly affected by land use type. Across all sites, land use type had significant ($p = 0.003$) effect on the *SOC*, with a clear-cut difference between the *SOC* of the forest (21 g/kg) and the rest of the land use types where the *SOC* ranged from 13.0 (maize) to 14.0 (woodlot/plantation) g/kg (Table 3). Land use type also had significant effect ($p = 0.000$) on the bulk density, with the forests having the lowest value (1.2 g/cm^3) and maize farms having the highest (1.34 g/cm^3). There were no significant effects of land use types on available P, N, ECEC, or pH.

The interactive effects between sites and land use type were only significant for the *SOC* and bulk density. Incidentally, these two properties are the major determinants of the total carbon stock (Eq. 1). Land use type significantly ($p = 0.013$) affected the total carbon stocks at the various sites in the order: forest > plantation > cassava > maize. Across the sites, the forest soils had the highest average storage of 48,216 ± 12,811 kg/

Table 3 Variation of soil properties with land use types

Land use	Bulk density (g/cm^3)	SOC (g/kg)	pH	Avail P (mg/kg)	N (mg/kg)	ECEC (cmol/kg)
Maize	1.34 ± 0.15	13.0 ± 7.40	5.6 ± 0.79	14.8 ± 7.7	2.50 ± 1.3	4.60 ± 0.1.6
Cassava	1.29 ± 0.08	15.00 ± 6.4	5.70 ± 0.82	11.61 ± 7.0	2.90 ± 1.4	4.60 ± 2.4
Plantation	1.32 ± 0.14	14.0 ± 5.90	5.60 ± 0.82	11.80 ± 6.3	3.00 ± 1.3	4.40 ± 1.7
Forest	1.20 ± 0.10	20.9 ± 6.9	5.30 ± 0.71	13.10 ± 10	2.70 ± 2.3	5.10 ± 2.5
p-value	0.005	0.003	NS	NS	NS	NS

Table 4 Land use effects on soil carbon stocks

Region	Land use	Carbon stock (kg/ha)	% Forest carbon
Coastal savanna			
	Maize	24,316 ± 12,155	48
	Cassava	27,671 ± 10,839	54
	Woodlot	30,325 ± 4450	60
	Forest	50,491 ± 12,755	–
Forest-savanna transition			
	Maize	41,897 ± 12,263	88
	Cassava	43,001 ± 10,007	91
	Plantation	45,019 ± 14,786	95
	Forest	47,382 ± 20,252	–

ha "..(not shown) 4" followed by plantations (36,774 ± 14,482 kg/ha), cassava (35,007 ± 14,014 kg/ha), and maize (33,905 ± 12,811 kg/ha). Other studies (Djagbletey et al. 2018) have also reported higher soil carbon stocks for denser forests in the Guinean savanna zone of Ghana. In other works, carbon stocks as high as 59,450 kg/ha determined for forest soils in the semi-deciduous forest zone of Ghana by Dawoe (2009).

With regard to ecological zones, the results showed that the differences in land use impact on soil carbon in the transition zone was smaller than in the coastal savanna zone (Table 4). In the coastal savanna zone, maize accrued 48% of the forest carbon stock, while the cassava and plantation accrued 54% and 60%, respectively, suggesting that the plantations were most effective in soil carbon restoration. With regard to the transition zone, however, the soil carbon restoration effectiveness was generally high 90–95% for all the land use types. Though the plantations impact was again the highest, values above 90% accretion generally suggests that all the land use types were equally effective.

Options for *SOC* accretion must consider the differential effects of land use types as well as ecological zones. Our observations indicated that cropping of the land depleted the *SOC* the most. The reduction of *SOC* stocks on cropped lands can be attributed to factors such as the harvest removal of plant organic matter (Feller 1993), constant disturbance of the soil that enhances decomposition (Lal 1999; Hulugalle et al. 1984; Kang 1993; Dalal et al. 1991), and the partial exposure of soil to high temperatures during off-seasons when vegetation cover is reduced. These researchers (Yilfru and Taye 2011; Caravaca et al. 2002; Malo et al. 2005) also recorded greater SOC in forest compared to cultivated land. Though our sampling did not include intercropping systems, the observation that cassava cropping accrued high carbon stock than maize suggests that a maize-cassava intercropping could, perhaps, maintain a higher carbon addition, because of the longer life cycle of cassava and higher SOC accretion than maize.

The plantation land use type showed a higher SOC accretion but would require relatively long periods of time to achieve, thus preventing cropping of the lands for some time. Presumably, a combination of plantation and cropping is desired to ensure both crop productivity as well as *SOC* maintenance. This can be accomplished by agroforestry, which has been promoted in many parts of the tropics to enhance crop yields (Kang 1993), but the adoption rates have continued to be very low. Apparently, the competition between live trees and crops for resources in agroforestry systems can reduce crop productivity (Ong et al. 1991), thereby handicapping the adoption of the system by farmers. Tree-crop rotations, as practiced under the traditional shifting cultivation, could also be an effective alternative to agroforestry. The tree phase of the rotation would permit the rebuild of the *SOC* which is depleted during the cropping phase. This traditional shifting cultivation needs to be further researched for its role in soil carbon management and crop production.

Conclusion

Soil productivity in Ghana is influenced by both land use type and agro-ecological zone. Findings from this study indicated that soil productivity conditions for agriculture were less favorable for agriculture in the coaster savanna than the forest-savanna transition zone. Furthermore, land use types had significant impact on the carbon storage, with maize-based cropping systems having the lowest carbon stocks. Woodlot/plantation types of land use restored the SOC and productivity more effectively than croplands. In effect, the effectiveness of land use systems for soil productivity maintenance differs with agro-ecological zones. This must be factored into the design of land management measures.

Contents

Abstract

Kenya is a developing country with a population of 47,213,282 people this comprises of 56% low-income earners. Small businesses and crop production represent 23% of the income within the country, which is at risk as soils become less productive. Various factors have led to this, climate change and land overuse being leading causes. Without adaptation, the rural to urban migration will continue to increase.

Through Internet of Things (IoT) and specifically wireless sensor networks, we can change how we obtain and consume information. Small-scale farmers can collect data and in exchange receive useful information about their soils, temperature, humidity, and moisture content hence make better choices during crop production. Connected end devices bring in data, which is currently sparse in relation to small-scale farming. IoT will enable analysis and informed decision-making including crop selection, support equipment, fertilizers, irrigation, and harvesting. The cloud-based analysis will provide information useful for policy making and improvement.

This chapter presents a wireless sensor network (WSN) in mesh topography using XBee communication module, communication, and raspberry pi, combined with a cloud-based data storage and analysis. We successfully set up a proof of concept to test a sensor node that sends information to a RPi and onto an online visualization platform.

Introduction: Background on Kitui County, Kenya

Kitui County is one of Kenya's 47 counties located in the lower eastern region of the country. The county has eight subcounties, namely, Kitui Central, Kitui South, Kitui East, Kitui Rural, Kitui West, Mwingi North, Mwingi West, and Mwingi Central. There are three livelihood zones in the county, marginal mixed farming, mixed farming livelihood zone, and formal employment, contributing 44%, 52%, and 4% of the population, respectively. The county has a population of 1,136,187 (Kenya National Bureau of Statistics (KNBS) 2019) people and covers an area of 30,570 square kilometers, of which 6,370 square kilometers is covered by Tsavo National Park (Magee et al. 2017). A large part of this County constitutes arid and semiarid land, and therefore over 50% of the population practice mixed farming and hence cultivate small pieces of land, and therefore the farming is heavily dependent on rainfall.

Climate Change and its Impact in the Region

Africa is considered to be one continent with the highest growth in population at 3% annually (IMF 2019). It is projected that by the year 2050, it will constitute about 25% of the world population (World Bank 2019). In addition, the mortality rate has reduced thereby straining available resources. Sustaining this growth has led to increase in social problems like rural to urban migration and lower yield in the food basket among others. As a result the majority of the active working force has moved to cities and towns to look for alternative sources of income.

The smallholder farmers have not been influenced by the "Green Revolution" as they have continued with the practice of nonuse of chemical fertilizers, pesticides, and genetically modified organisms. These inherent practices are referred to as "traditional farming." (Onwonga and Freyer 2006). In more recent years, farmers have become more reliant on extension officers. With the devolution of government services, extension officers have become few in some areas and highly concentrated in others (Franzel et al. 2014). These officers are expected to visit farmers to provide advisory services. It is usually tedious and time-consuming for both the farmer and the officer. There is thus need to investigate and keep record of weather conditions for better decision-making for small-scale famers who are the backbone of the economy in Kitui County (Magee et al. 2017). In addition assessment of cumulative health risk is a challenge in real-world situations because of limited data available for place and population-related pollution exposure (Solomon et al. 2016). With continued primary data collection, it is possible to create models that are more accurate in relation to this region.

The current weather stations within the country are a lot more concentrated in one half of the country and not so much on the other half. See map below (Fig. 1).

This study proposes to use a raspberry pi (RPi), a microcomputer quite popular now with IoT devices; it is of low-cost and easily adaptable to various conditions. The XBee is able to transmit information within short-range communication with very good accuracy and also low-power utilization and low-costs. The other parts of the paper will discuss methodology for the data collection, data transmission, storage, and visualization.

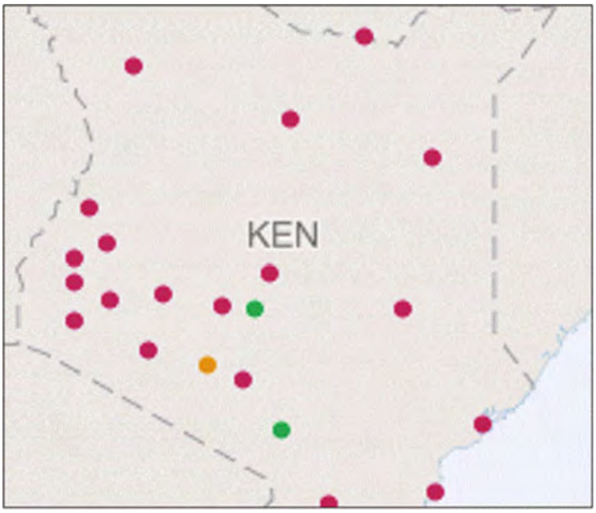

Fig. 1 Weather stations in Kenya (Solomon et al. 2016)

Other Studies

Studies have been done in agriculture and in pollution; however there is dearth in a studies combining pollution monitoring and agricultural parameters data collection. A review of previous studies has shown a gap in combination of these parameters which are of use to small-scale farming (Rehman et al. 2011) developed a WSAN with sensor and actuator nodes to provide controlled water supply; this is very geared toward precision agriculture. In 2016 (Raja et al. 2016) used various types of sensors to monitor temperature and moisture values of the soil. The data was shared to a central station periodically and concentrated on soil data. A similar study was undertaken in 2015 by (C and S 2015). This study builds on work done by (Rehman et al. 2011) where remote monitoring was done for data collection and information shared with research facilities (Vatsal and Bhavin 2017). Worked on a system showing real-time temperature and relative humidity and once again only concentrated in agricultural information for display locally.

There are several systems designed for precision agriculture. They, however, mostly solve the problem of irrigation or temperature control. Those in environment solve data collection challenges, while those in agriculture solve a single or at most two challenges.

Methodology

The Internet of Things (IoT) is described as connecting everyday objects via sensors and actuators to the Internet where the devices are intelligently linked together enabling new forms of communication between things and people and between things themselves. This technology has advanced rapidly in the last few years and has become quite popular in environment monitoring. The basic concept is illustrated in the figure below (Fig. 2).

IoT offers new and innovative ways to monitor and manage remote operations. "It allows having eyes and ears in remote places, constantly feeding applications and data stores with information. The low-cost of 'things' allows observing and

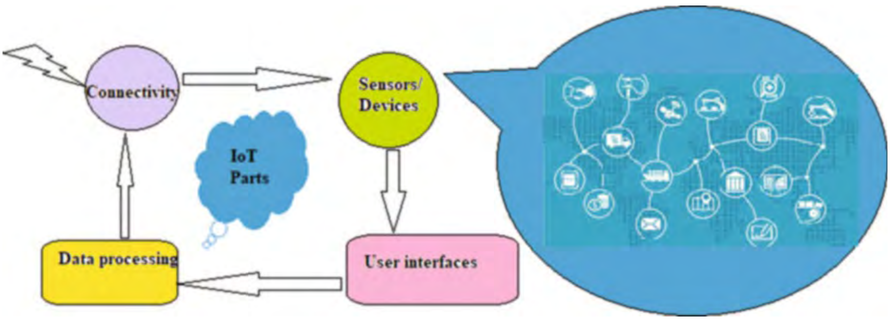

Fig. 2 Basic parts of an IoT system

managing activities that were previously out of reach. With the Internet of Things, it is also possible to collect information about events that were once invisible, such as correlating weather patterns with industrial production" ("IoT in action – Towards Data Science" 2020). The advancement in wireless sensor networks is used in monitoring and controlling of various aspect in an agricultural field. In the same light, weather aspects for a station field. A wireless sensor network is composed of hardware and software. These are low-cost and low-power smart sensor nodes which monitor physical conditions. In our initial prototype test case, we monitored temperature, moisture, and pollution. These nodes can be spread across a large geographic area (Fig. 3).

A node: The main components of a sensor node are a microcontroller, transceiver, external memory, power source, and one or more sensors. The controller performs tasks, processes data, and controls the functionality of other components in the sensor node. The sensor node or mote can be deployed infield to form wireless sensor network for crop management and environment monitoring system (Fig. 4).

This study uses ZigBee, an IEEE 802.15.4 for the wireless sensor network of nodes. It is common in networking standard for personal area networks. The physical layer of ZigBee operates in the unlicensed industrial, scientific, and medical radio bands of 868 MHz, 915 MHz, and 2.4 GHz depending on the region. In this study, we adopt 2.4 GHz band because it is unlicensed in Kenya. The ZigBee protocol

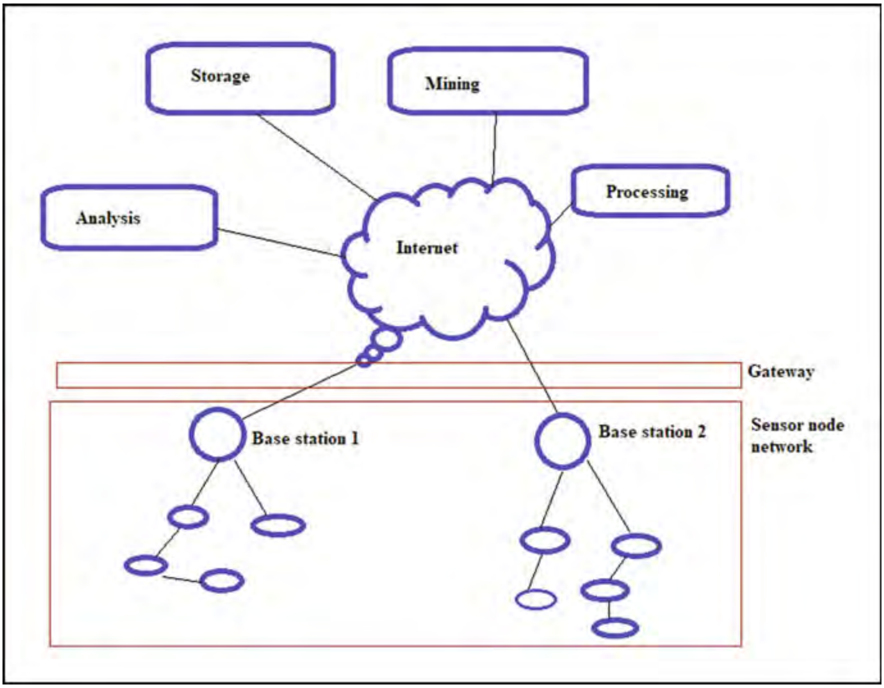

Fig. 3 Node based IoT system with offsite processing

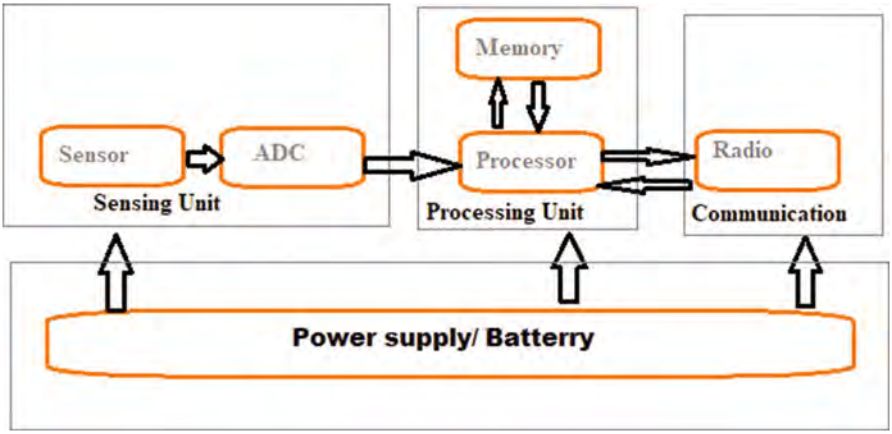

Fig. 4 Block diagram of a node

mainly focuses on low-cost and low-power consumption. The low-power consumption characteristic is necessary since sensors are usually placed at a remote location where battery power supply is virtually the only option. In order to attain a low-power consumption characteristic, the ZigBee protocol operates at low data rates (250 kbps at 2.4 GHz); this imposes its limitation where high data transmission applications are required. From node to the servers, it is thus more realistic to use other applications, for instance, Wi-Fi (802.11) which offer high data rates. This is only done from the coordinator node. Depending on the situation and environment, the networks can take three forms of topologies: star, cluster tree, and mesh. Our study uses the mesh topology. A mesh network is accomplished by allowing devices in the cluster tree to topology communicate with each other using multiple routes. Consequently, the devices are able to send and receive messages reliably even when their preferred path is down or congested. This is the major advantage of a mesh network over star and cluster-tree networks. However, a mesh network has no guarantee of bandwidth since no synchronization is used which requires disabling of beacon mode (Fig. 5).

Mesh topology, also referred to as a peer-to-peer network, consists of one coordinator, several routers, and end devices. The following are the characteristics of a mesh topology: A mesh topology is a multi-hop network; packets pass through multiple hops to reach their destination. The range of a network can be increased by adding more devices to the network. It can eliminate dead zones. A mesh topology is self-healing, meaning during transmission, if a path fails, the node will find an alternate path to the destination. Devices can be close to each other so that they use less power. Adding or removing a device is easy. Any source device can communicate with any destination device in the network. Compared with star topology, mesh topology requires greater overhead. Mesh routing uses a more complex routing protocol than a star topology" ("2.3 ZigBee Topologies | Introduction to the ZigBee Wireless Sensor and Control Network | InformIT" n.d.).

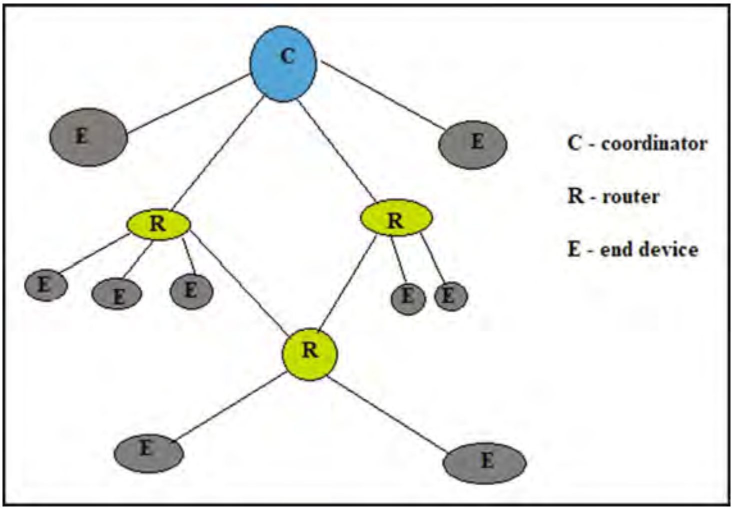

Fig. 5 Mesh-based network system

System Design

This study proposes the combination of solving challenges in environment and in agriculture with a single system at the same time contributing to data enhancement for policy issues in both precision agriculture and pollution primary data.

The building of pollution stations within the country present a problem of security and management. Having these stations placed at small farms and distributed keeps them safe. On the other hand, implementation of monitoring stations for local farmers is expensive and the communities lack the knowhow of management of the information collected. The cloud-based data management platform will provide this, while interested stakeholders (policy makers) will support the management of data. Kitui County is vast and most small farms lack connectivity to the main power grid. For the system to be self-sustaining in terms of power, the study uses solar photovoltaic and rechargeable batteries to power all electrical devices. The system incorporates a remote monitoring mechanism through a General Packet Radio Service modem to report soil temperature, soil moisture, WSN link performance, and photovoltaic power levels.

Having a system that encompasses data collection and data dissemination provides end to end solution for both small-scale farmers and policy makers.

The general workflow of the monitoring system consists of the following:

1. Taking temperature, humidity, and pollution data (PM 2.5 and PM 10) samples at predefined time intervals (Sensors)
2. Reading this data at a local level (Arduino Uno)
3. Sending data via a coordinator node (Raspberry Pi)
4. Visualizing data online

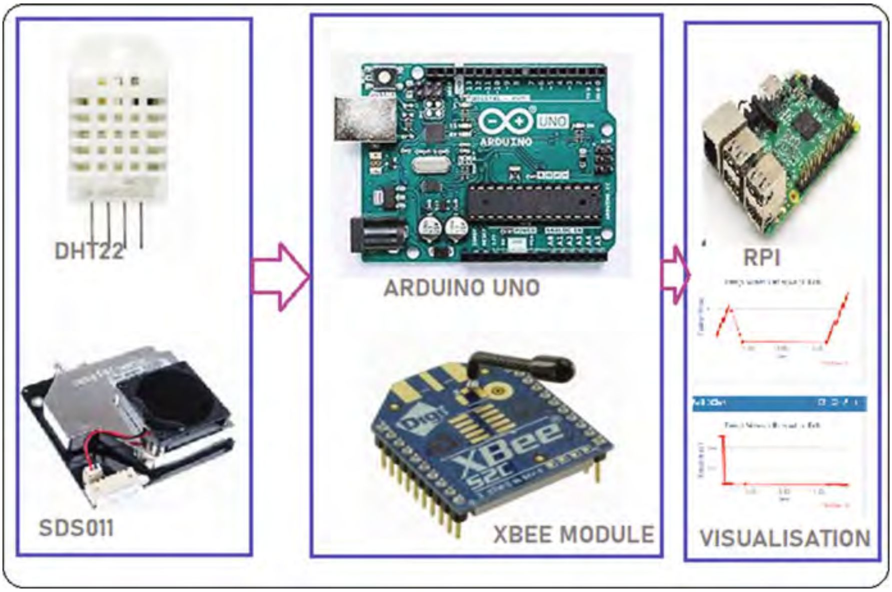

Fig. 6 Detailed block diagram of our system

5. Going to sleep
6. Waking up and repeating the previous steps (Fig. 6)

Hardware needed for the end point of the system:
For the sensor node:

1. Raspberry pi 3B – this is a low-cost, credit-card sized computer that plugs into a computer monitor or TV and uses a standard keyboard and mouse. It is a capable little device that enables people of all ages to explore computing and to learn how to program in languages like Scratch and Python (Raspberrypi.org n.d.)
2. Arduino UNO – Arduino is an open-source electronics platform based on easy-to-use hardware and software (Arduino.cc n.d.)
3. Humidity and temperature sensor – DHT22 Sensor
4. Pollution sensor SDS011
5. Connectors – female-female, male-female, and male-male
6. Resistors

Software used in this project:

1. XTCU – This was used in this system to setup the XBee radios so that they can transmit data between each other.
2. NOOBS – This is the operating system needed to setup a RPi.
3. Python.
4. JSON.

5. Arduino IDE.
6. ThingSpeak is a free online platform that was used for data visualization

System Implementation and Experiments

To set up and test this system, the XBee devices were first activated and set up using XCTU (a tool available online for free). They were all coded under the same network for ease of communication. The RPi was loaded with the necessary operating system (NOOBS) which comes with python – a coding language. In the project we also set up the Internet access for the raspberry pi as it acts as the gateway in this system.

On a laptop, we installed Arduino IDE (which is a development platform for Arduino boards) and also the sketches to run the two sensors for our prototype. JSON here is used as the shell to transfer data in a compact mode from the Arduino to the RPi.

On the RPi we run a program to call the data from the Arduino to the RPi and tested the same locally. Finally on ThingSpeak, we added the required APIs and run the visual data from our system.

The diagrams below further define our various steps (Figs. 7 and 8):

Once the codes were tested and found to be producing steady outputs, we put the sensors in a monitored environment – domestic fridge with proper calibration to test the humidity and temperature parameters and the results were displayed on the local Arduino software as 169% humidity and 12° Celsius continuously and repeatedly (Fig. 9).

```
#include<SoftwareSerial.h>
#include <SDS011.h>
#define Tx, Rx;
float p10,p25;
int error;

SDS011 my_sds;

void setup() {
  my_sds.begin(Tx,Rx);
  Serial.begin(9600);
}

void loop() {
  error = my_sds.read(&p25,&p10);
  if (! error) {
    Serial.println("P2.5: "+String(p25));
    Serial.println("P10:  "+String(p10));
```

Fig. 7 Figure 15 – clips of Initial codes for SDS sensor

```
#include <dht.h>

#define dht_apin A2 // Analog Pin sensor is connected to

dht DHT;
void setup(){

  Serial.begin(9600);
  delay(500);//Delay to let system boot
  Serial.println("DHT11 Humidity & temperature Sensor\n\n");
  delay(1000);//Wait before accessing Sensor

}//end "setup()"

void loop(){
  //Start of Program
     DHT.read11(dht_apin);
```

Fig. 8 Clips of Initial codes for DHT sensor

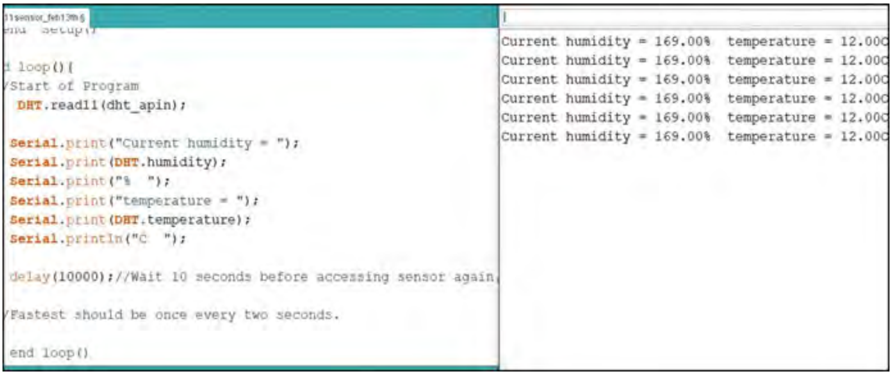

Fig. 9 Testing the DHT11 for both humidity and temperature in a controlled environment

We then transferred the tests to the natural environment and connected the router XBee connected to the raspberry pi. We were able to read the results from the temperature and humidity sensor as well.

We also run similar tests on the SDS011 – pollution sensor and obtained a consistent flow of results as below.

Once this was done, we then connected the end nodes to the router node for data aggregation. This was done using the python on the raspberry pi and wrapping the file using Json. We could then see our data collected using the IDs EN1, EN2, and EN3 from the three Arduino/XBee connected end nodes (Figs. 10, 11, 12, and 13).

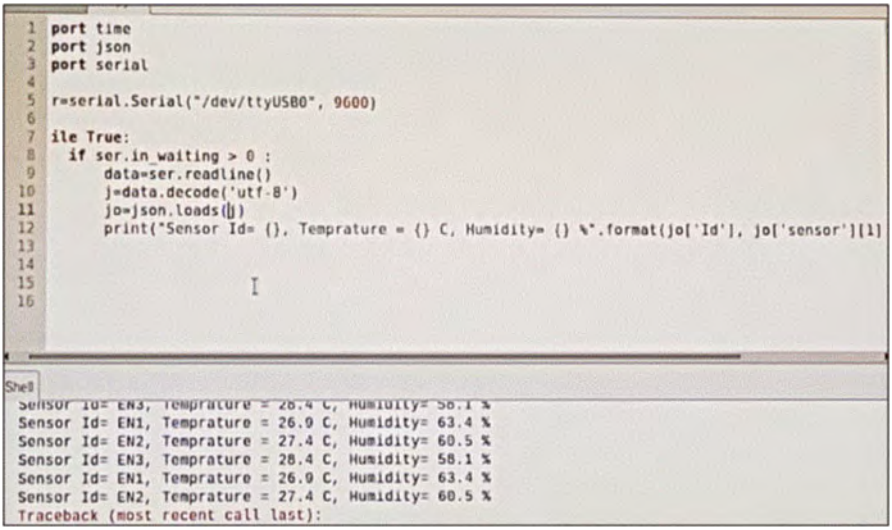

Fig. 10 Data accessed locally on RPi from three Arduino stations with DHT sensor only

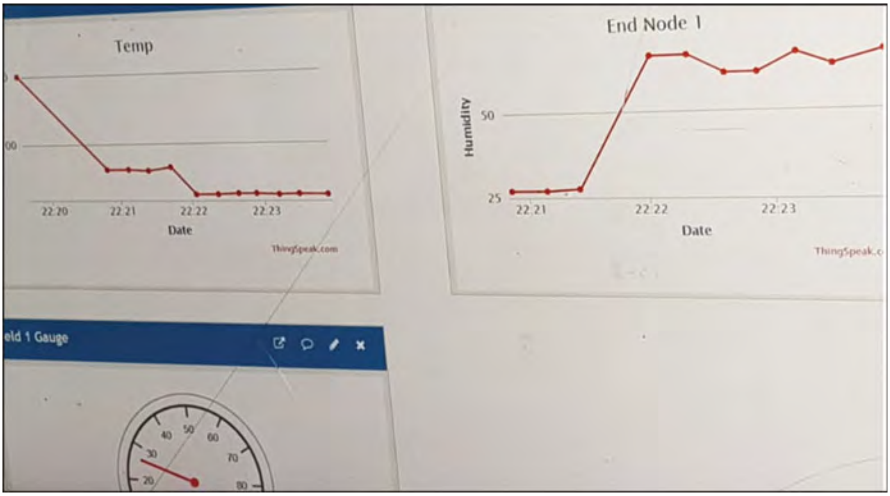

Fig. 11 Display on ThingSpeak of test data – screen shot taken during the testing of the prototype

Conclusion

The phase of the entire project included:

1. Coming up with a design to collect data from sensors via a sensor node.
2. Sending the data to an online visualization platform via a control node and this step has been successful.

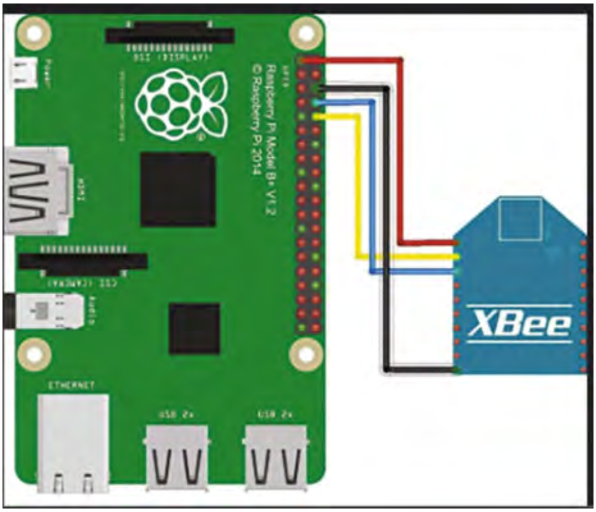

Fig. 12 XBee connection to RPi (drawn using Fritzing software)

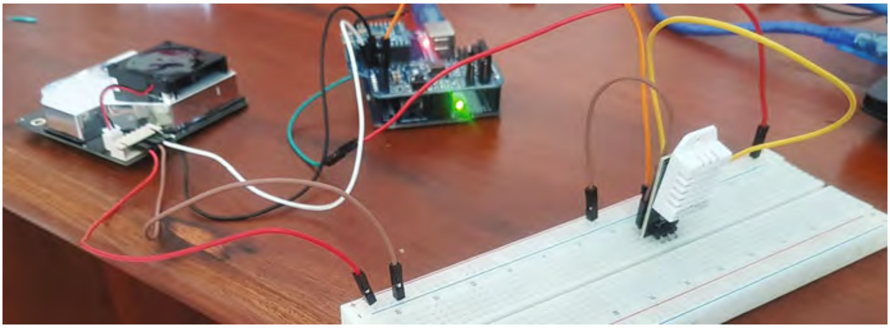

Fig. 13 Sensor node using Arduino, XBee, DHT22, SDS011

Continuing work in this project involves adding a local database for localized data storage and adding a GSM module that allows ease of access of the online data remotely. The online platform and visualization will also be improved to be more robust with a private platform that can be more scalable in the future.

Abstract

The aims of this chapter are to seek answer, through a document review, case studies, and thematic content analysis, to which direction Southern Africa should take in the face of climate change and to suggest a framework for adaptations by communities experiencing climatic events. Acknowledging that the fundamental set of ideas provided by indigenous knowledge (IK) works best at a small scale, the chapter argues for the need to seriously value IK-based response practices in the knowledge hybridization agenda. The worsening vulnerability potentiated by the increasing magnitude and severity of climate change impacts is a reminder that local-based indigenous response practices in Africa need to be complemented. Adaptation to climate change calls for real and surreal measures all being applied in combination. Across Africa, these measures have, at times, included the preservation of forest resources which increased carbon sinking and enhanced community resilience against climate change. Universalistic and orthodox sciences have punctuated and amplified these efforts by speaking of such initiatives as mitigation and adaptation through programs, e.g., Reducing Emissions from Deforestation and Forest Degradation (REDD+) and ecosystem-based adaptation (EbA). The merits of the two approaches have resulted in increasing call among scholars for the merging of these programs with IK. However, it remains to be fully understood how such a hybrid approach could be operationalized without treating the latter as an inferior element in climate science discourses.

Introduction

The complexity of climate change has attracted global attention and the various institutions worldwide to come up with adaptation and resilience methodologies and strategies (UNDP 2018). Throughout history, people and societies have successfully adjusted to and coped with climate change and extreme events. While climate change is a global issue, it is felt on a local scale (Silber 2013). This is because climate change affects many dimensions of development, including society, politics, science, economics, and moral and ethical questions (Henderson et al. 2017; Ogolla 2016). Local institutions are therefore at the frontline of adaptation as they attempt to factor in the local effects and how to mitigate these negative effects of climate change. This has resulted in the development of initiatives where climate change is factored into a variety of development plans on how to manage the increasingly extreme disasters and their associated risks, how to protect coastlines and deal with sea-level rise, how to best manage lands and forests, how to deal with and plan for reduced water availability, how to develop resilient crop varieties, and how to protect energy and public infrastructures (UNFCCC 2007; Carter et al. 2015; de Witt 2018).

Carbon dioxide, the heat-trapping greenhouse gas (GHG) that is the main contributor to global warming, has high longevity as it can remain in the atmosphere for hundreds of years (Dabasso et al. 2014). Even if the global community manages to establish strategies that can successfully reduce GHG emissions into the atmosphere, climate change and global warming will still be experienced and affect future generations. Thus, climate change continues to be a persistent global issue (Bauer and Scholz 2010). In Southern Africa, the effects of climate change have been experienced at a large scale as the region lacks adequate technology and proper management of its resources (Thinda et al. 2020). In addition, the combination of other various aspects of the region, such as its geographical exposure that has low levels of human development, weak institutions, high levels of inequality, and high dependence on agriculture, makes the African people vulnerable to the effects of climate change, especially those in the Southern African region as it is warming up at a faster rate than the global average (Kupika et al. 2019).

Climate change adaptation is a complex process that requires efforts from different stakeholders. The various problems that currently overwhelm Africa, for example, poor governance, lack of technology, and prevalence of poverty, make it difficult to establish the best approaches to achieve climate change adaptation. Basically, there are two available options that can be employed by the governments, namely, indigenous knowledge systems (IKS) and universalistic science. The former refers to the tested and proven knowledge that is used by local communities from their many years of observing and experiencing environmental phenomena, whereas the latter includes sophisticated techniques and approaches that are often associated with Western technologies and advanced way of mainstreaming climate change (Chirisa et al. 2018). These two approaches have their individual merits.

While some proponents view IKS as primitive and less reliable (e.g., Briggs 2005; Widdowson and Howard 2008), others assert that universalistic science is often too complicated and costly for African communities, which will result in their failure to maintain such a sophisticated technology (Wallner 2005; Simpson 2010; Walsh 2011). This causes ambiguity with regard to choosing the best approach to be employed to achieve climate change adaptation. In the same vein, this chapter proposes a hybrid method that considers the integration of both IKS and universalistic science. Thus, how Southern Africa can best adapt to climate change is investigated by weighing the strengths and limitations of the two knowledge systems in the context of climate change responses in the region. Through a document review, case studies, and thematic content analysis, the study determines the direction that Southern Africa should take in the face of climate change. The area of interest is shown in Fig. 1, which consists of Angola, Botswana, Eswatini, Lesotho, Malawi, Mozambique, Namibia, South Africa, Zambia, and Zimbabwe. It isolates specific themes to show how climate change responses have been pursued in the region. The chapter begins with a conceptual treatment of climate change adaptation in the frame of the distinctive knowledge forms (IKS and conventional knowledge systems) in the theory and practice of climate change responses. It then draws from existing scholars how these knowledge forms have characterized climate change mitigation and adaptation in Southern Africa. The discussion highlights the strengths

Fig. 1 The case study, Southern African Region. (Source: Extracted from google.com/maps © Map data AfriGIS (Pty) Ltd)

and limitations of these knowledge systems and concludes that a hybrid system could be the best approach for driving an effective adaptation agenda in the region.

Climate Change Response in Southern Africa

Although climate change will place additional stress on Southern Africa's resources, some authors argue that there is considerable adaptive potential (Karsenty et al. 2012; Wang and Corson 2015; Kupika et al. 2019). In order to promote a meaningful and sustainable development in the region, the probable impacts of global climate change need to be considered, as well as the best alternative that fits the regional context. In the science of climate change, the two approaches that guide climate change responses are mitigation and adaptation. Mitigation is concerned with stabilizing the levels of heat-trapping GHG and reducing its emissions into the atmosphere, whereas the focus of adaptation is on taking measures to respond to the observed or anticipated climate change impacts (Klein et al. 2005; IPCC 2014). Climate change has been the greatest threat to provision of infrastructure and facilities for human improvement in countries in the Global South. Thus, it calls for the need to develop mitigation and adaptation strategies that enhance the resilience of the region (Mugambiwa 2018; Kupika et al. 2019). The major goal in mitigation is to avoid human interference in the climatic system and balances, whereas adaptation is a practice where human and natural systems devise appropriate measures in response to climate change impacts. In Southern Africa, most of the mechanisms developed by rural communities are complex and mainly based on culture and IK in the production of subsistence crops (Green 2008; Mugambiwa 2018). Mugambiwa (2018) stresses that Southern Africa's priority is to adapt to the climate change already being experienced anticipated in the region.

In the employment of the mitigation and adaptation approaches, it is critical to identify specific strategies, where IKS has been used, mainly in conjugation with universalistic science to strengthen the response system. The United Nations-based programs, Reducing Emissions from Deforestation and Forest Degradation (REDD +) and the ecosystem-based adaptation (EbA), are worth mentioning. These have been largely introduced through universal science that advocates for the reduction of GHG emissions into the atmosphere. Arguably, the knowledge of local and indigenous people has been found to be effective in the reduction of GHG emissions into the atmosphere (Kupika et al. 2019). Indigenous knowledge is already viewed as pivotal in several fields, such as sustainable development, agro-forestry, traditional medicine, biodiversity conservation, soil science, ethno-veterinary science, applied anthropology, and natural resource management (Mafongoya and Ajayi 2017). Many scholars highlight the significant role that IK plays in climate science and in facilitating climate change adaptation (Nyong et al. 2007; Green and Raygorodetsky 2010; Speranza et al. 2010; Crona et al. 2013; Ford et al. 2016; Chanza and Mafongoya 2017; Reyes-Garcia et al. 2019).

Knowledge Driving Climate Change Responses in Southern Africa

The different forms of knowledge, used either individually or jointly, characterize the climate change responses in Southern Africa to achieve climate change adaptation. The definition of IK is very complex and distinguishes sciences from other knowledge traditions (Mugambiwa 2018). There is no universal knowledge to which science is privy and to which all other knowledge traditions must defer. Knowledge is produced with relevance to specific contexts and questions, including Newtonian physics and Palikur astronomy (Perez et al. 2007). Indigenous knowledge is known as local or traditional knowledge and is defined as the beliefs and intellectual behaviors of indigenous societies, or local information about the relationship between humans and their environment (Mafongoya and Ajayi 2017). This knowledge is accumulated, developed, and transmitted through local community experiences and know-how across generations. Therefore, one can argue that IK is based on the cultural beliefs of a community and that it is orally transferred from one generation to another (Casper 2007; Bryan et al. 2011; Baudron 2011). Thus, there exists a binary divide between universalistic science and IK (Appignanesi 2018). Western science is seen to be systematic, objective, open, and dependent on a detached center of rationality and intelligence. From a radical perspective, universalistic science is understood to represent modernity, whereas IK is perceived as a traditional and backward way of life (Briggs 2005; Bauer and Scholz 2010). Clearly, these knowledge forms seem to be divergent and have been differently criticized. The cleavage between Western science and indigenous science is explored by Briggs (2005). Briggs (2005) argues that the use of IK is riddled with problems and challenges as it focuses on the (arte)factual, stating that this knowledge form has been romanticized. Wallner (2005) contends that Western science can become "very immoral" and "very dangerous" as it lacks subjectivity. From an African perspective, however, several scholars argue that IKS has been a sustainable factor in development of physical artefacts in space like infrastructure provisioning as it has minimized damage to the environment by allowing people to live in harmony with nature for generations (Kupika et al. 2019). Table 1 compares IK and universalistic science.

Local knowledge about ecosystems has been used in different parts of the world in an effort to respond to climate change. Universalism is defined as the epistemological and philosophical orientations taken by scientists of claims about the world or a particular issue in question (Green 2008). Western science is centralized and associated with the machinery of state, and its bearers believe in its superiority. The differences between IK and Western scientific knowledge are best described in the following grounds:

- Substantive grounds: there are differences in the subject matter between IK and Western knowledge.
- Methodological and epistemological grounds: the forms of knowledge employ different methods to investigate reality.
- Contextual grounds: IK is more deeply rooted in its environment (Mugambiwa 2018).

Therefore, it is undeniable that both Western science and IKS play significant roles in promoting sustainable development through mitigation and adaptation

Table 1 Major differences between IK and universalistic science

Major differences	Western/formal science	IK
Mode of transmission	Written, formally documented	Oral, repetitive
Substantive differences	To construct general explanations; is removed from people`s daily lives	Concerned with immediate and concrete necessities of people`s daily livelihoods
Methodological and epistemological differences	It is open, systematic, objective, and analytical. It advances by building rigorously on prior achievements	It is closed, non-systematic, and holistic rather than analytical. It advances on the basis of new experiences, not on the basis of deductive logic
Contextual differences	It is divorced from epistemic framework in search for universal validity	It exists in a local context anchored to a particular social group, in a particular setting, at a particular time

Adopted from: Mafongoya and Ajayi (2017) measures. The full conceptualization of IK can greatly contribute to the strengthening of the resilience of poor societies or marginal areas in Southern Africa. One of the best approaches to employ for climate change adaptation in poor regions is the ecosystem-based approach (Chanza and de Wit 2016; SSSI 2018; USAID 2018). In Zimbabwe, this is crucial especially to small-scale farmers as they are more prone to the effects of climate change. It is predicted that billions of people, particularly those in developing countries, face water and food shortage as well as greater risks to health and life as a result of climate change (Shava et al. 2009; Shames et al. 2012; Wang and Corson 2015). Thus, fully assessing the benefits of both science and IK in the face of climate change in Southern Africa is crucial. In an effort to adapt to climate change, there are conceptual issues that need to be considered. This chapter considers four factors that may possibly provide insights into the adaptation approach that may be employed in Southern Africa. The conceptual issues of vulnerability, EbA, REDD+, and resilience are discussed in the following sections.

Vulnerability Concept

In relation to climate change, vulnerability is the degree to which a system is susceptible to, and unable to cope with, the adverse effects of climate change, including climate variability and extremes (UNFCCC 2007; IPCC 2014; Mavhura 2019). Climatic stress is already causing much pressure on the African region, making it highly vulnerable to the impacts of climate change (UNFCCC 2007; Bauer and Scholz 2010; Mugambiwa 2018). In Southern Africa, the poor predominantly depends on natural resource-based livelihoods, which are climate-sensitive. This makes them mostly vulnerable to poverty as they have minimum capacity to economically manage and cope with the damage caused by natural disasters or incremental degradation (Swinkels et al. 2019). Africa is well known to have diverse climates that are considered to be the most variable in the world on seasonal and decadal time scales. This makes the region's societies and ecosystems most prone to climatic events largely in the form of frequent floods and droughts (UNDP 2018). Africa's vulnerability to climate change also opens up room for its exposure to famine and widespread disruption of socioeconomic well-being as well as climate-sensitive diseases, such as diarrhea, malaria, and tuberculosis.

Ecosystem-Based Adaptation Concept

Adaptation to climate change is associated with adjusting to expected or actual climate. The goal of adaptation is to reduce the vulnerability of the environment, regions, or societies to the harmful and dire effects of climate change (Green 2008). It also involves making the most of any potential beneficial opportunities associated with climate change. Ecosystem-based adaptation therefore refers to the management of ecosystems to enhance ecological structures and functions essential for ecosystems and the people to adapt to multiple changes, including climate change

(Kupika et al. 2019). This approach has the potential to contribute multiple benefits through the reduction of vulnerability to climate change as well as contribute to socioeconomic development and conservation (Mafongoya and Ajayi 2017) Ecosystem-based approaches include the maintenance of safety nets as a mechanism that best serves as a coping strategy during scarcity periods to enhance livelihood security. Some approaches implored under EbA include the following:

- Restoration of ecosystems that can reduce the exposure of human settlements to extreme weather events or climate change, e.g., combining the "building with nature" techniques with hard-engineering infrastructure to restore mangrove coastlines that reduce the risks of flood, erosion, and saline intrusion and support adaptation to sea-level rise (Bauer and Scholz 2010).
- Integration of sustainable ecosystem management practices into broad landscape-level planning processes. For example, integrated watershed management in peri-urban areas, which has proven to enhance water regulation to support the supply of water for drinking and hydroelectricity generation in cities.
- Payment for ecosystem services to diversify income generation and build adaptive capacity, for example, conserving a shoreline mangrove and coral reef system to maintain economies based on ecotourism, recreational activities, and fisheries.
- Climate mitigation by maintaining or enhancing carbon stocks with safeguards in place to support adaptation, for example, collective management of forested landscapes that promotes social learning to conserve forest function and structure, biodiversity and habitat connectivity, and climate-smart agriculture with agroforestry systems.

At the center of this approach lies the recognition of nonlinear feedbacks between social and ecological processes. Ecosystem-based approaches can be applied to all types of ecosystems and at different scales from local to global (NASA's Global Climate Change n.d.). Chanza and de Wit (2016) suggest that EbA should be best articulated at the local level where it can promote adaptation governance through IK. They also argue that the concept provides multiple benefits to society and the environment as it contributes to reducing vulnerability and increasing resilience to both climate and non-climate risks. Many cases in Africa have also shown that EbA approaches involving local people using their IKS can promote climate proofing and emission reduction (Hachileka 2010; Lo 2016; van Niekerk et al. 2017).

REDD+ Concept

The UN-based REDD+ program is an incentive-based tool that bases its work on public and private agents' self-interest in conservation strategies and the fact that they are well capable of calculating the opportunities as well as the costs associated with the reduction of GHG emissions into the atmosphere (Karsenty et al. 2012). The main concept of REDD+ is to make performance-based payments, which means that forest users and owners are paid to reduce GHGs emitted into the atmosphere

(Angelsen 2009). Payments for environmental services gives the forest owners the opportunity to receive incentives to motivate them to manage forests better and also minimize the rate at which deforestation occurs (Baudron 2011). Therefore, the concept of REDD+ is a rewarding mechanism to actors involved in keeping and restoring forests as well as a mechanism with the main objective of reducing carbon emissions (Karsenty et al. 2012; Skutsch and Ba 2010).

The concept of REDD+ has been implemented at a global level through the United Nations Development Program (UNDP) as a strategy to reduce GHG emissions into the atmosphere while promoting economic development, especially in developing regions, such as Africa (UNDP 2018). Developing countries have a competitive advantage in the carbon market if they choose to conserve their forests rather than convert them for agricultural use (Gantsho and Karani 2007). The REDD + mechanism thus invests in providing incentives to projects that promote forest conservation and conversion, afforestation, and reforestation (Wang and Corson 2015; Leach and Scoones 2013; Shames et al. 2012). This has led to the introduction of carbon markets that have successfully paved way for developing countries to earn funds through forest conservation. The plus sign on REDD+ indicates how the concept is also dedicated to the enhancement of forest carbon stock which can also be referred to as forest rehabilitation and regeneration, carbon removal, negative emissions, negative degradation, or carbon uptake (Angelsen 2009). Chanza and de Wit (2016) reveal opportunities for the success of this initiative if local communities can use their IKS in forest conservation. In Kenya and Tanzania, for example, the success of REDD+ projects has been attributed to participatory planning where the knowledge of local citizens in technical analysis has helped in addressing the drivers of deforestation and forest degradation (Richards and Swan 2014).

Resilience Concept

There is no universally accepted definition of resilience. The vast and growing literature available on urban resilience demonstrates the complexity of the concept as a target, as well as the challenges of mainstreaming recommendations into the urban development practice (UN-HABITAT 2017). The concept of resilience originated from ecological studies, exploring the varied ability of ecosystems to absorb and adapt to external pressures (Dau Kuir-Ayius 2016). The Intergovernmental Panel on Climate Change (IPCC) (2014, p. 1772) defines it as “the capacity of social, economic, and environmental systems to cope with a hazardous event or trend or disturbance, responding or reorganising in ways that maintain their essential function, identity, and structure, while also maintaining the capacity for adaptation, learning, and transformation.” Understanding that human systems function as complex, interdependent, and integrated social-ecological systems is crucial to understanding how resilience-based planning, development, and management can protect life and assets as well as maintain the continuity of functions through any plausible shock or stress (Sekar et al. 2019; UN-HABITAT 2017; Dau Kuir-Ayius 2016). Thus, the Southern African region needs to develop resilient strategies that will assist them in coping with climate change (Doyon 2016; Dau Kuir-Ayius 2016; UN-HABITAT 2017; Kupika et al. 2019). Scholarship treating IK and climate change resilience is still developing (Bohensky and Maru 2011; DeAngelis 2013; Makate 2020). Despite the phenomenal growth in resilience literature, Bohensky and Maru (2011) express the lack of clarity and empirical evidence for the relationship between IK and resilience. Citing the utility of IK in agricultural projects, Makate (2020) argues that in establishing resilience to climate change, local communities should be seen as equal partners in the development process. The next section discusses the strengths and limitations of the existing climate change response practices in Southern African countries.

Experiences with Climate Change Responses in Southern Africa

The study found out that in its trajectory to curb the effects of climate change, Southern Africa is largely driven by modernity. However, due to the slower development of this region compared with the Western and European regions, it is difficult to implement technologically advanced measures owing to its limited manpower, poor resource management, and inadequate finances to make use of the science. Therefore, traditional knowledge and IK play a significant role in climate change adaptation in many rural communities (Green 2008; Mafongoya and Ajayi 2017; Kupika et al. 2019). However, due to modernity, it is now rare to find pure IKS practices that are not contaminated with the conventional construct of adaptation practices. Thus, it is important to fully understand indigenous-based practices that continue to shape the adaptation landscape in the African context and to assess the strengths and limitations of such strategies. This chapter argues that one way to complement the strengths of adaptation practices in the region is to complement the two forms of knowledge. Conscious of the blending gaps that have been highlighted in adaptation literature, the next sections also propose how the two knowledge systems can jointly work best.

In Southern Africa, there exists a diverse and unique group of cultures, including the Shona, Ndebele, Zulu, Tswana, Xhosa, Pedi, Tshangni, Venda, and Suthu, among many others (Mabogunje n.d.; Hanyani-Mlambo 2002). The main common aspect of all these African cultures is that they all started as hunters, gatherers, nomads, and pastoralists. Their traditions and way of living are still being practiced today, especially in marginal areas, for instance, in the Mbire District in Zimbabwe and the Khoisan in the Kalahari Desert of Botswana (Dube et al. 2014). In this regard, it can be safe to agree that traditional knowledge is also an ecological knowledge. It involves adaptation processes that have been handed down from generation to generation, and thus, they are useful in climate change adaptation (Dabasso et al. 2014).

The renewal of IK throughout generations has ensured the well-being of many Southern African people through ensuring food security, early warning systems, environmental conservation, and disaster risk management (Mawere 2010). Therefore, it can be deduced that the people rely on this traditional knowledge for social capital and food production as a way to ensure survival. The advent of universalistic science that has enabled the invention of technologies, machines, and concepts that are mostly unsustainable has led to IK being disregarded as it is considered as backward and old (Carmody 1998; Mugambiwa 2018).

Towards a Hybrid Knowledge Approach in Climate Change Adaptation

Climate change adaptation calls for more than just local experiences or scientific knowledge. Effective adaptation to climate change in Southern Africa requires the best knowledge regardless of where it is coming from (Shava et al. 2009). Hybrid knowledge from both sources is only possible through collaborative process, community participation, and involvement and interactions between the locals and scientists. It is also important to acknowledge that IK can provide solutions to food insecurity and poverty (Hussein and Suttie 2016). Appropriate and effective use of IK can promote a number of advantages that can match those of conventional science. These include environmental conservation and management of disasters in terms of prevention, mitigation, recovery, prediction or early warning, preparedness, and healing through traditional medicinal practices by producing traditional foods. In Kenya, the Maasai traders have relied on the benefits provided by the earth's resource, which has ensured a stable livelihood for centuries (Wang and Corson 2015).

As the world warms, traditional weather indicators may become less and less valuable. Individual species will adapt to the impacts of local climate change in idiosyncratic and unpredictable ways. Animals may change their behaviors or their ranges, whereas plants may begin flowering at different times. It is feared that these changes might render traditional knowledge less reliable. One way to strengthen the hybridization of IK and universalistic science in terms of climate change response is to revitalize or strengthen local institutions (Mararike 2011; Makate 2020). According to Makate (2020), the integration approach can work best only where climate adaptation practitioners build from existing local-based knowledge forms, rather than moving to replace them. When strengthened, local institutions can enhance the employment and scaling success of climate adaptation projects and innovations. Such efforts will improve information sharing, resource mobilization, stakeholder coordination, network establishment, and capacity building with local citizens as well as provide leadership and control of climate adaptation programs. The technological orientation of adaptation practice as seen through irrigation infrastructure in the agricultural sector, for instance, can be enhanced if local farmers are given sovereign rights over the traditional crop or animal varieties of their choice. Accordingly, it is reasonable to suggest that using the two knowledge forms individually will not provide solutions to the increasing threats of climate change in Southern Africa.

Conclusions and Recommendations

Given the sensitivity of the entire socioeconomic sectors and natural systems to the increasing climatic events, the Southern African region is expected to devise appropriate mitigation and adaptation practices. The region faces a quandary in terms of the trajectory that it should take in its development plan in the context of the existing and anticipated climate change threats. Climate change is starting to be factored into a variety of development plans on how to manage the increasingly extreme disasters faced by humanity and their associated risks, how to protect coastlines and deal with sea level rise, how to best manage land and forests, how to deal with and plan for reduced water availability, how to develop resilient crop varieties, and how to protect energy and public infrastructure. In other parts of the world, countries are working on building flood defenses, plan for heat waves and high temperatures, install water-permeable pavements to better deal with floods and stormwater, and improve water storage and use. However, in the absence of national or international climate policy direction, cities and local communities worldwide have focused on solving their own problems on climate change. The importance that communities in Southern Africa place on IKS in the face of climate change deserves recognition. However, due to changing seasons, IKS needs to be integrated with scientific methods as it cannot address the magnitude of the challenge alone. In the face of global climate change and its emerging challenges, unknowns, and uncertainties, it is important to base the decision-making for policies and actions on the best available knowledge. The multisectoral and cross-scale nature of climate change responses, such as REDD+ and ecosystem-based adaptation approaches, requires the integration of a range of disciplines, actors, and institutions interacting at different levels and influencing diverse decision networks.

Equity and Justice in Climate Change Adaptation: Policy and Practical Implication in Nigeria

87

Contents

Abstract

Over the past decade, justice and equity have become a quasi-universal answer to problems of environmental governance. The principles of justice and equity emerged as a useful entry point in global governance to explore the responsibilities, distribution, and procedures required for just climate change adaptation. These principles are designed primarily through the establishment of funding mechanisms, top-down guides, and frameworks for adaptation, and other adaptation instruments from the UNFCCC process, to ensure effective adaptation

for vulnerable countries like Nigeria that have contributed least to the issue of climate change but lack adaptive capacity. Global adaptation instruments have been acknowledged for adaptation in Nigeria. Climate change has a detrimental impact on Nigeria as a nation, with the burden falling disproportionately on the local government areas. As Nigeria develop national plans and policies to adapt to the consequences of climate change, these plans will have significant consequences for local government areas where adaptation practices occur. Although the local government's adaptation burden raises the prospects for justice and equity, its policy and practical implication remains less explored. This chapter explores the principles of justice and equity in national adaptation policy and adaptation practices in eight local government areas in southeast Nigeria. The chapter argues that some factors make it challenging to achieve equity and justice in local adaptation practices. With the use of a qualitative approach (interview (n = 52), observation, and document analysis), this chapter identified some of the factors that constraints equity and justice in local government adaptation in southeast Nigeria.

Adaptation policy · adaptation practices · environmental justice · equity · Nigeria · local level

Introduction

The gap between the developed and developing nations as regards development is extending to the risks and security issue of climate change. While almost all countries are affected by the risk and security impacts of climate change, it is widely recognized that developing countries are more vulnerable, lacks adaptive capacity (Tabbo and Amadou 2017), and would suffer disproportionately (Stallworthy 2009; Rübbelke 2011). This is particularly the case for developing countries in Africa living in poverty (IPCC 2014). Wide recognition that industrialized countries are overwhelmingly responsible for climate change has slowly led to conceptualizing adaptation as a global issue with a formidable dilemma of equity and justice in developing countries such as Nigeria (McManus et al. 2014; Thomas and Twyman 2005). Scaling adaptation as a global issue recognizes an international responsibility to provide financial support and funding for undertaking adaptation at the national or local level in developing countries (Benzie and Persson 2019; Ciplet et al. 2013; Saraswat and Kumar 2016). Despite the funds obtained by some developing countries for climate change adaptation, implementing adaptation at the local level continues to be challenging.

Many of the impacts of climate change, such as floods and drought, are experienced at the local level (Rauken et al. 2015). As a result, the burden of climate change adaptation practices falls disproportionately on the local government area. Adaptation is a localized phenomenon that addresses local circumstances with the need for local solutions and actions (Corfee-Morlot et al. 2011; Measham et al. 2011; Moore 2012; Nalau et al. 2015). Conceptualizing climate change adaptation as a local phenomenon is based on the principle of subsidiarity, which is a belief that tasks should be trusted with the lowest level, where the local actors are always able and willing to govern their natural resources effectively (Lockwood et al. 2009). This approach to adaptation assumes that local actors have the required resources to practice adaptation in isolation.

However, local government in Nigeria is embedded in a broader multiscale governance context comprising a range of government actors from the state, the federal, and global levels. Thus, current thinking poses that adaptation plans should be understood and developed at national and subnational levels, practiced at the local level, and funded via international institutions (Benzie and Persson 2019). As a result, local adaptation is increasingly supporting and driving adaptation initiatives and policies within the framework provided by national and state-level legislation (Vogel and Henstra 2015). The extent to which these adaptation policies consider vulnerabilities and impacts of climate change at the local level as well as the extent to which local government participates in instituting national adaptation policies and frameworks are debatable. Against this backdrop, different scholarly voices have emerged over the years, arguing that adaptation decision-making at policy and practical levels has justice and equity implications (Few et al. 2007; Paavola and Adger 2006; Thomas and Twyman 2005).

Nigeria has instituted national adaptation plans and policies as well as established climate change institutions to aid adaptation. Despite the adaptation policies and institutions, some local government areas struggle to cope with and respond to climatic impacts. This is because there are no regulations and institutions designed to foster climate change adaptation in the local government area (Oulu 2015). Presently, the local government institutions carrying out adaptation, such as the ministry of environment and planning, department of works, and local emergency management agency (LEMA), are not designed for climate change challenges. This chapter discusses prospects for justice and equity principles in Nigeria's national adaptation policy and local adaptation practices. This chapter affirms that equity and justice are the important normative goal in both national and local climate change adaptation, but argue that the practice of equity and justice in climate change adaptation is often embedded in the illusion of inclusion. Without due consideration of equity and justice at all levels of governance, there would be a tension between the underlying principle of fair adaptation and participation by the local governments and vulnerable groups in Nigeria. Alternatively, a more instrumental approach to appropriate adaptation at the local level is more likely to succeed as long as local government inclusion is made explicit from the outset.

This chapter discusses the perceived role of equity and justice regarding national adaptation policy at the federal level and adaptation practices in eight local government areas in southeast Nigeria. With the use of a qualitative approach through interview and document analysis, this chapter explores the principles of equity and justice in policies and practices of climate change adaptation in Nigeria.

Conceptualizing Justice and Equity as It Relates to Climate Change Adaptation

Climate change issues give concern for different types of justice: distributive, procedural, recognition, compensatory, and restitutive justice (Ciplet and Roberts 2017; Khan et al. 2019; Klinsky and Dowlatabadi 2009; Rawls 1971). The basic structure in the subject of climate change justice here is that different communities experience differentiated impacts of climate variability in part by the political system as well as by economic and social circumstances. This differentiated physical and social vulnerability to climate change impacts create deep inequalities between developing and developed countries. Vulnerable developing countries lack the tools and adaptive capacity required to develop the appropriate response to climate risks. The development of tools and adaptive capacity both at the local and national level has been a significant focus on global adaptation, especially regarding equity and justice. However, equity and justice issues of adaptation are more readily discussed at the global, regional, and national levels than at the local level (Thomas and Twyman 2005), even though adaptation practices are undertaken at the local level.

At the global level, the differentiated vulnerability to the impact of climate issues was brought to the international community's attention in November 2006 at the United Nations Framework Convention on Climate Change (UNFCCC) held in Nairobi, intending to identify situations that increase or reduce the capacity to adapt (Vogel et al. 2007). It was then argued that adaptation would promote benefits that can lead to equitable and sustainable development (Adger et al. 2009). The 2015 Paris Agreement includes a global goal on adaptation through reducing vulnerability to climatic impacts, reinforcing adaptive capacity, and strengthening resilience (International Summit on Climate Change held in Paris 2015). One of the commitments of developed countries under the UNFCCC is to assist developing countries to meet their adaptation cost. If more impoverished country gains access to adaptation funds through equity and justice schemes, adaptation can be improved. Global governance is considered especially relevant for Nigeria and other developing countries, as these countries are already struggling to meet climate change's security challenges (Nightingale 2017; Nath and Behera 2011). The principle of environmental justice is focused on the existence of inequity in the distribution of environmental hazards, where the environment is understood to create a condition for social justice (Schlosberg 2013). As climate change increases, environmental justice is given more broad consideration with a growing focus on sustainability and transformative politics and practice to affirm the socio-ecological unity and the interdependence of all species.

There are essential points to why equity and justice have become two crucial concepts in climate change adaptation discourse at the global and national levels. First is the principle of justice, which emerges as a reaction to the claim that devastating climate extremes such as flood, drought, and desertification made worse by climate change pose additional negative implications for vulnerable developing countries and poverty-affected communities (Nay et al. 2014). The susceptibility to climate risk goes beyond biophysical vulnerability to include human well-being, social, economic, and political factors underlying social vulnerability (Kelly and Adger 2000; Otto et al. 2017), which put vulnerable countries in a constant state of crises. Therefore, adaptation should be evaluated based on justice criteria that would benefit all groups of society as well as the future generation by providing the information and resources needed for adaptation, especially for those most vulnerable to climate change impacts.

Second, equity is a concept referring to fairness in the distribution of outcomes or distributive equity (Miller 1992). As regards climate change, Nay et al. (2014) argue that developing economies depend more on climate-sensitive activities that are more impacted by climate variability. They argue further that these developing economies also lack the political and organizational capacity to adapt to climatic impacts. Thus, the outcome of the equity principle should ensure that:

- The vulnerable are treated fairly for unduly bearing the burdens of climate change impacts
- There is an inclusive decision-making process
- There is an inclusive framework for taking and facilitating adaptation action
- There is a relationship between climate change adaptation and other factors that affect livelihoods (McManus et al. 2014)

However, within these developing countries, the social, institutional, and political structures can play an essential role in climate change adaptation. The relationships that exist between the individuals, the communities, and the state are also essential. Thus, adaptation at the local government is often enabled or hindered by other issues such as social structures, power relations, political and institutional structures, as well as the broader higher level of governance arrangements (Lawrence et al. 2015; Simonsson et al. 2011). These relationships often reaffirm the status quo and are likely to influence the issues of equity and justice in local adaptation practices. According to Eriksen et al. 2015, injustice and unfairness exist when the politically powerful actors set up institutions that advance agendas that exclude local knowledge, needs, and voices of the marginalized in adaptation decision-making. These powerful actors with authority further influence adaptation by claiming the right to legitimize or undermine different types of knowledge (Eriksen et al. 2015). Adaptation policies are often designed at the national level and may disproportionately affect vulnerable communities if they are excluded during policy design (Urwin and Jordan 2008). Understanding the local context of vulnerability through local participation in adaptation policies is essential for equitable and justifiable adaptation. This implies a process of social interaction and joint decision-making by stakeholders across governance scale in adaptation. However, from a systems perspective, one of the challenges facing such provision is associated with the complexity of social interactions involved in multilevel adaptation decision-making.

Climate Change in Nigeria

Nigeria is one of the most vulnerable countries and is highly dependent on climate-sensitive sectors. The country is located in the tropics that give her a hot tropical climate, consisting of variable rainy and dry seasons depending on location. Given the country's climatological cycle and size, there is a considerable range in total annual rainfall across Nigeria, from south to north, and in some regions from east to west. Wet and dry season prevails in the east and west, while a steppe climate with little precipitation is found in the far north. Temperature and humidity remain relatively constant throughout the year in the south, while the season varies considerably in the north (Ajayi et al. 2019). The most significant total precipitation is in the southeast along the coast around Bonny (south of Port Harcourt) and east of Calabar with annual rainfall around 4,000 millimetres (mm). The regularity of drought periods has been among the most notable aspects of Nigeria's climate in recent years, particularly in the north's drier regions (Akande et al. 2017; Haider 2019). These droughts indicate the considerable variability of climate across tropical Africa and severely affect the drier margins of agricultural zones occupied primarily by pastoral groups.

The southeast is one of the most developed regions in Nigeria, with the second-highest population density. In 2015, the southeast had a total population of 40 million. Southeast Nigeria falls within the latitude of 6′ N and 8′ N and longitude of 4′30′E and 7′30′E, describing the country's inland region. Southeast Nigeria is of the wet tropical type climate with mean annual temperatures between 21 °C and 34 °C. The temperature is highest around March in the southeast (Iloeje 2009). The mean minimum temperature is relatively close to the coastal area, with annual rainfall exceeding 3500 mm (Njoku 2006; Nwagbara et al. 2013). In recent years, rainfall has become significantly more substantial in the southeast. In 2012, River Niger reached a record of 12.84 m above sea level. Water levels have also risen in upstream Cameroon, Mali, and Niger. These countries feed the River Niger and River Benue, which flow through Nigeria. River Niger flows through the southeast region leading to severe flooding. In 2012, flooding led to two million displacements and three hundred and sixty-three (363) deaths. In 2017, 12 states, including states in the southeast, were severely affected, leading to 200 deaths and over 600,000 displacements (Orji 2018). As climate change leads to more rainfall, floods disasters are becoming more devastating in Nigeria, especially in the southeast region. The southeastern region is also exposed to mild drought during the dry season.

Preparing for Climate Change Adaptation in Nigeria

Nigerian started showing a keen interest in climate change issues since 1994. The first national climate communication in 2003 was aimed at shedding more light on the consequences of climate change and its impact on developmental goals. With the support of development partners such as the United Nations Development Program (UNDP), the European Union (EU), United States Agency for International Development (USAID), as well as intergovernmental, regional organizations and nongovernmental agencies, several climate change adaptation strategies and policies have been designed and approved. Nigeria initiated a comprehensive planning process for adaptation by developing the National Adaptation Strategy and Plan of Action on Climate Change for Nigeria (NASPA-CCN). Prioritized adaptation measures in the NASPA-CCN report tend to focus on agriculture, forestry, water resources, human health, human settlement, energy, transportation and communication, industry, disaster and security, livelihoods, vulnerable groups, and education. In NASPA-CCN report, there is a recognition that climate change adaptation can best be achieved through multilevel effort requiring global, national, state, local government, nongovernmental, and civil society coordination (BNRCC 2011). In addition to this, Nigeria has instituted policies and established climate change institutions to aid adaptation. Policies such as National Policy on Erosion and Flood Control, National Water Policy, Nigeria Drought Preparedness Plan, National Forest Policy, National Health Policy, the National Policy on Environment supports (for prevention and management of disasters such as floods, drought, and desertification) and Nigeria's Agricultural Policy were developed to protect agricultural land resources from drought, desert encroachment, soil erosion, and floods (BNRCC 2011). Nigeria has established a climate change framework such as the National Framework for Application of Climate Services – NFACS (to reduce communities' vulnerability by implementing the National Agricultural Resilience Framework for the agricultural sector). Nigeria has also established a climate change department under the federal ministry of environment. The country relies on NIMET (Nigerian Meteorological Agency) and NEMA (National Emergency and Management Agency) for climate-related disaster warnings, prevention, and response. At the state level, departments of climate change are functional in some states and non-functional in others. There are no known climate change departments at the local government areas; hence, exiting ministries are carrying out adaptation actions.

Exploring the Equity and Justice Perspective of Climate Change Adaptation in Nigeria

This section of the chapter takes an equity and justice perspective of adaptation policy and practice in Nigeria, which provides a useful framework for understanding the factors that promote or hinder local government adaptation. The local government areas that are the focus of the chapter are situated in the southeast zone, where the population is (a) vulnerable to climate-related floods and mild droughts, (b) lack adaptive capacity, and (c) agitating for separation from Nigeria due to poor social and political representation. Interviews, observation, and document analyses were used as the primary data sources to explore the perceived impact of equity and justice on national adaptation policies and local adaptation practices in southeast Nigeria. This chapter analyzed the national adaptation plan and other important documents. The key documents analyzed include the National Adaptation Strategy and Plan of action on Climate Change for Nigeria (NASPA-CCN) and Nigeria Intended Nationally Determined Contribution (INDC 2016). Other documents include scientific articles, policy documents, newspapers, conference speeches, and media contents (Fig. 1).

Interviews and observations were carried out between September 2017 and January 2018. The interview was conducted ($n = 52$) with actors working at the federal, the state, and the local government parastatals. At the national level, ten

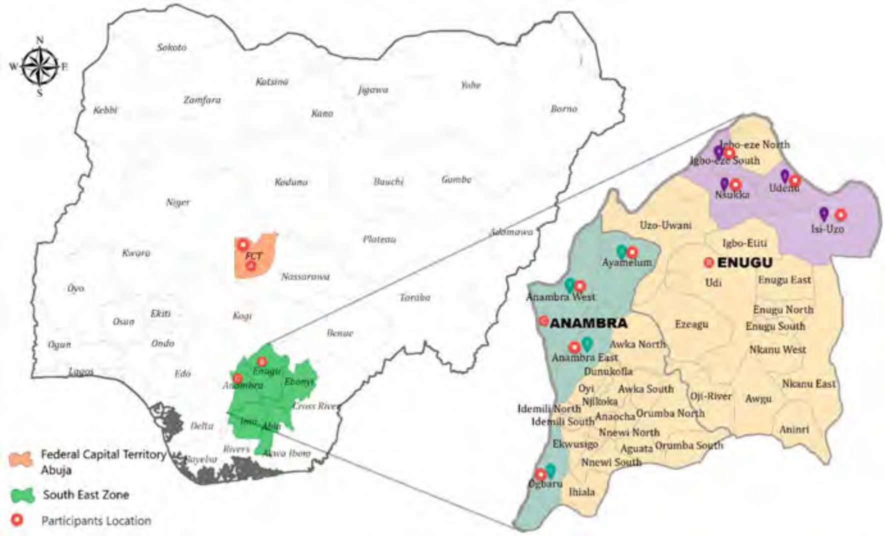

Fig. 1 Map of Nigeria showing the participant's locations

participants from the federal department of climate change were interviewed. These federal-level participants are labeled FGP (Federal government participant). At the regional level, ten participants from two states in the southeast (Anambra and Enugu state) were interviewed, where five participants were selected from each state. These participants are involved in adaptation across the state ministry of ecology, environment and climate change, the state ministry of works, and the state emergency management agency (SEMA). The state-level participants are labeled SGP (state government participants). At the local government level, 32 participants were interviewed from eight local government areas in southeast. Four experts were selected from each of the eight local government areas. These local government-level participants are labeled LGP (Local government participants). Among these participants are engineers involved in areal planning and infrastructural management, officials engaged in environmental protection, and local emergency management agencies (LEMA). Four of the local government areas, Anambra east, Anambra west, Ayamelum, and Ogbaru, are situated very close to water bodies. With the majority of the population living near the riverine area, flooding is the largest source of climate-related losses. The other four local government areas, Igbo-Eze south, Isiuzo, Nsukka, and Udenu, are situated in highlands where both floods and mild droughts are sources of climate-related losses affecting the population. Flood and drought in the southeast impact livelihood, health, crop production, livestock, groundwater dryness, and infrastructure damage. Interview questions focused primarily on how fair adaptation policies are for local government adaptation practices.

The observation was used to collect data on the adaptation practices and activities designed to cope with climate-related disasters. Data obtained through the observation method were noted and analyzed based on a follow-up question for confirmation. The interview, observation, and document analysis data were coded and categorized using Nvivo 11. The data was identified and categorized thematically using the inductive and data-oriented approach. The findings will be analyzed using the following questions as a structuring tool: what are the physiological and social vulnerability of climate change in the eight southeast local government areas in Nigeria? How is Nigeria adapting to climate change impacts? Who is responsible for adaptation policies and practices? What role do the principles of equity and justice play in adaptation in Nigeria's local government areas? These questions would be explored in three subsections. The first section will give an account of the vulnerability of local government areas to climate change. The second subsection will explain how global adaptation is affecting Nigeria's adaptation policy and practices. The last section will then explain the effect of global equity and justice on local adaptation practices.

Vulnerability and Impact of Climate Change in Nigeria

Climate change in Nigeria leads to changes in the frequency and intensity of weather and climate extremes. Nigeria's climate extremes hit people in multiple different ways. Warm temperatures cause more evaporation of water, while changes in precipitation lead to heavy rain but also swings into drought conditions. Nigeria is one of the most vulnerable countries to climate variability (IPCC 2014). The most frequently cited vulnerability is sea level rise, floods, droughts, sandstorms, landslides, erosion, intensified desertification, and general land degradation (Medugu et al. 2010). These extreme events have broad consequences for farmlands, livestock, and built infrastructures such as buildings, roads, and railways, as well as fundamental societal concerns, such as disputes over environmental resources, food security, water security, health implications, loss of livelihoods, internal and external migration, and loss of life (BNRCC 2011; IPCC 2014). The broad consequences of climate change make it imperative to assess the level of a country's vulnerability to climate change and capacity and readiness for adaptability. This chapter identified vulnerability to climate change at the national, regional, and local levels. Some vulnerability factors are frequently identified across all three scales: poverty, access to resources, livelihood opportunities, and health. Vulnerability to climate change is distributed disproportionally in Nigeria. The northeast and northwest zones are vulnerable to desertification, heat wave, loss of freshwater, intensive drought, bush burning, loss of arable lands, and livestock loss. The southeast and southwest are vulnerable to sea level rise and salinization, intensive rainfalls, floods, and damages to built infrastructures. It would be nearly impossible for preparation to be made towards adapting to these changes if the vulnerability is not adequately understood, especially from the angle of the most affected parties at the local level.

The IPCC conceptualizes vulnerability as a function of the state of a social system and the biophysical nature of climate change effects that the system face (IPCC 2007). Vulnerable to climatic impacts, Nigeria covers different frameworks.

These include risk hazards, political ecology, and socio-ecological system frameworks. Within the risk and hazard field, vulnerability is the susceptibility of people and things to losses attributable to a given level of danger, a given probability that a hazard would manifest itself in a particular way, and with a particular magnitude (Alexander 2002: 29). This field of vulnerability often neglects to address how human contribute to climatic hazards as well as the societal context in which climate hazards takes place. In political ecology, vulnerability is a characteristic of a person or group and their situation that influences their capacity to anticipate, cope with, resist, and recover from the impact of a natural hazard (Wisner et al. 2004). In the social-ecological system framework, vulnerability is a state of susceptibility to harm from exposure to stress associated with environmental and social change and the absence of capacity to adapt (Adger et al. 2006). Multiple factors such as environmental exposure, socioeconomic, political, and cultural factors operating at different levels drive vulnerability in Nigeria's local government areas. Climate hazards only lead to disaster if there is biophysical or/and social vulnerability. Biophysical vulnerability to climate change is understood as a function of environmental exposure, while the social vulnerability is a function of socioeconomic, political, and cultural characteristics of a society (Otto et al. 2017).

In Nigeria, vulnerability plays out locally. This chapter attempt an assessment of some local government areas' vulnerability to climate-related flood and drought around two dimensions, biophysical vulnerability and social vulnerability. Results show some similarities in the participant's perception of climatic impacts and adaptation measures.

Table 1 shows that flooding is the largest source of climate-related losses in four low land, local government areas in the southeast, as the participants explained. With an estimated 30% of the population living near the riverine area, in Anambra east, Anambra west, Ayamelum, and Ogbaru, loss of house settlement, loss of farmland, transportation, limited energy supply, and erosion are constant plight experienced by local communities. Out of 16 participants from low land, local government areas 14 have experienced vulnerability to flooding while 2 knows people that have experienced flood vulnerability. LG participants explained that during flooding, the only transportation system is local boats. However, they argue that using resilient structures such as iron and other metallic products to construct roads and bridges can make the situation better. Flooding causes desperate living conditions leading to the temporal fleeing of millions of people. The electric power supply in the southeast is limited at ordinary times. Flood hazards negatively influence the already limited power supply, forcing households and businesses to use generators that emit CO2 and other dangerous gasses to the detriment of human health and environmental safety.

Table 1 illustrates the frequently identified adaptation strategies used to adapt to the effect of climatic hazards. The various adaptation measures identified by LG participants are flood management, town planning, and waste management. Flood management takes place through the construction of an effective drainage system. LGP participants explained that the local communities' drainage system is weak as some drainage systems are poorly constructed. Rainwater leads to overflow and

Table 1 Local government physical and social vulnerabilities and adaptation strategies

	Local Government Area	Climate changehazards	Biophysical vulnerability to climatic hazards	Social vulnerability to climatic hazards	Effects of climatic hazards	Adaptation strategies
Lowland	1.1) Anambra east 2) Anambra west 3) Ayamelum 4) Ogbaru	Floods	Very vulnerable to exposure	1) Economic 2) Governance 3) Infrastructures	1) Loss of farmland, 2) Loss of housing 3) Erosion 4) Poor transportation 5) Energy 6) Migration	1) Flood management 2a) Avoid building on flood plains 2b) Use resilient infrastructure 3) Soil management 4) Resilient infrastructure and drainage system. 5) Energy and infrastructure management
		Mild droughts	Very low		1) Agriculture, 2) Water distribution	1) Irrigation 2) Use of deep water and boreholes
Highland	1.1) Igbo-Eze South 2) Isiuzo 3) Nsukka 4) Udenu	Floods	Moderately vulnerable to exposure	1) Lack of economic resources 2a) Dysfunctional government structure 2b) Lack of important institutions	1) Agriculture 2) Erosion 4) Transportation 4) Water security 5) Energy 6) Migration	1) Improve the agricultural system 2) Conservation agriculture and soil management 3) Use of resilient materials and functional drainage system 4) Water resource management 5) Energy and infrastructure
		Mild drought	Moderately vulnerable		1) Agriculture 2) Water distribution	1) Irrigation technology 2) Use of underground water

flood incidents because the drainage systems are often not appropriately channeled. Poor town planning leads to improper house settlements where people construct houses on floodplains. LGP participants agree that communities must adhere to town planning to avoid the loss of house settlements. Proper town planning discourages people from building on floodplains and using resilient structures that can withstand extreme weather variability. Poor waste management leads to people's disposal of waste when it is raining. These wastes block the drainage system and contribute to flooding.

Erosion is another hazard linked to climate variability in the low land, local government areas of southeast. LGP participants explain that people have lost their houses and farmlands to erosion. They also explain that erosion losses are not as severe as losses from the flood as erosion occurs slowly. LGP mentioned soil management and planting of trees as necessary measures used to reduce erosion. In Anambra east, Anambra west, and Ogbaru, the LGP participants explained that trees' planting is not sustainable due to firewood consumption.

Slow onset events such as drought are also having a substantial impact on crop production, livestock, and water distribution in low land, local government areas but at a deficient level. The use of irrigation and digging for clean water is common in these local government areas during drought. However, LGP explained that the use of irrigation is constrained by limited irrigation facilities based on available resources.

In the local government areas located in highlands, mainly: Igbo-Eze south, Isiuzo, Nsukka, and Udenu, the LGP participants explained that households are not often in danger of losing their homes due to moderate flooding instead, it is agriculture, gully erosion, road infrastructures, and energy distribution that are impacted. There is an uneven distribution of rainfall, and participants noted that the length of dry periods is on the increase. LGP participants in the local government located in highlands note that drought is a climatic hazard, leading to water shortage, with notable negative impacts on the farmers' crops, livestock, and income. These participants suggest that rainfall is often not sufficient for their agricultural production and household needs. Field observation revealed that different household sources water from streams and boreholes.

Table 1 illustrates that apart from massive flooding in the low land local government area, there are similarities in climate change challenges as well as similarities in adaptation measures in both the low and high land local government areas. The most remarkable difference between the low land local government areas and the high land local government areas is their preparedness. LGP explained that even though climate change is leading to unpredictable rainy seasons, those in riverine areas are often more prepared, which inspires more proactive adaptation strategies. In the Anam community, people come together to construct tall buildings to adapt to floods. Households are often not caught off guard as they proactively get temporal housing settlements and their boats ready for transportation as soon as flood starts.

In all the local government areas, it was indicated that the adoption of the adaptation measures frequently mentioned is moderate due to lack of resources. Though communities in the southeast are already implementing numerous strategies to cope with climate change, LG participants agree that the adaptation measures are carried out on individual, group, and community levels. The reasons given for low adaptive capacity vary from access to funds, lack of climate change awareness, and lack of human resources in the face of climate change. Nigeria context throws light into how physical vulnerability interacts with social vulnerability in climate change adaptation issues. Looking at climate change as both biophysical and social problems allows political and socioeconomic measures to evaluate the effects on the poor and vulnerable.

Adaptation Policies and Practices in Nigeria

Policy Implications of Adaptation Governance in Nigeria

Since UNFCCC first conference in 1995, nations have convened to institute and implement binding climate agreements, either as regards to mitigation or adaptation. These binding agreements have lasting impacts on how global climate treaties and national climate policies evolve. These agreements also help determine how financial resources to adapt are distributed (Gurwitt et al. 2017). Nigeria has been engaging in international climate policy negotiations since 1994 when the country becomes a party to the United Nations Framework Convention to Climate Change (UNFCCC). Nigeria ratified Kyoto Protocol in 2004 and submitted the first national climate communication in 2003 and the second national communication in 2014. United Nations Framework Convention on Climate Change provides funding to developing countries with National Adaptation Plans of Action (NAPAs). Under such treaties, countries are required to develop NAPA to adapt to climate change. Nigeria prepared its National Climate Change Action Plan in 2011, which led to the Nigeria Climate Change Policy's approval in 2012.

NAPA provides Nigeria and other least developed countries (LDCs) with an opportunity to meet their urgent and immediate needs for adapting to climate change. In 2015, Nigeria prepared its Intended Nationally Determined Contribution (INDC) and signed the Paris Agreement in 2017. These policy documents' common objective is to demonstrate political commitment to adaptation and communicate the overall government approach to adaptation. Nigeria's policy plan helps identify climate change impacts and vulnerabilities and identify areas where the country's adaptive capacity can be improved (INDC 2016). Adaptation policy targets different sectors of Nigeria's society such as agriculture, freshwater, coastal resources, forest, biodiversity, health and sanitation, human settlement, energy, transportation and communication, industry and commerce, disaster, migration and security, livelihood, education, and vulnerable groups. Nigeria Climate Change Action Plan and INDC report recognize that achieving an adaptation goal would require international support due to its low adaptive capacity. As explained in (BNRCC 2011), Nigeria National Adaptation Strategy and Plan of Action on Climate Change, Nigeria seeks to:

- Detail financial needs assessment to accurately determine the economic costs of climate change adaptation
- Revise the National Fiscal Policy to incorporate the cost of climate change adaptation
- Create a national financing mechanism to support real adaptation needs
- Access necessary international adaptation funding and technologies and manage those funds well

The above are top-down measures that would trickle down to the local level. Within the Nigerian climate policy document, the role of the federal government, the state government, the local government, the private sector, and civil society are made explicit. The federal government is responsible for instituting policies while the local government is responsible for implementing adaptation policies. The issues emphasized in Nigeria's Plan of Action are issues of collaboration, transparency, and finance. BNRCC (2011) report indicates that the federal and state governments would collaborate with the local government to strengthen communities' adaptive capacity by providing:

- Information and technological know-how, facilitating financial and other measures
- Put in place adaptation communication to allow all stakeholders to participate actively in climate change adaptation (NASPA-CCN, 2011)

However, FG participant notes that Nigeria's adaptation policy is increasingly influenced by intergovernmental organizations, as the submission of these documents and reports is relevant to obtain proper support. FG and SG participants explained that adaptation policies encompass climate change issues affecting all Nigerians and strategies to solve those issues. On the other hand, LG participants indicate that the adaptation policy is a one-fit document that lacks knowledge of local problems and solutions. Proposals for an international climate change adaptation policy recognize local representation, even though there are hardly any inquiries to ensure local representation inclusion.

Actors Perspective on Adaptation Governance in Nigeria

FG, SG, and LG participants were asked about their role in climate change adaptation practices. All the FG participants claim that they have engaged in different adaptation practices. Twenty percent of SG participants admitted that they had taken no action but are aware of several adaptation projects. The LG participants claim to have engaged in different adaptation activities such as road construction, house construction, helping community members during rescue operations, and helping to deliver aids.

When asked about who is responsible for climate change adaptation practices, FG and SG participants were quick to point fingers to developed nations. They claim that

Nigeria has benefited from international climate change adaptation funds; however, LG participants explain that individuals and groups carry out adaptation practices on a low scale, as the funds have not translated into effective adaptation practices in the local government areas in the southeast. All participants perceived the role of local government in different ways. The FG participants thought that the local government is getting the necessary resources to help communities address climate change issues. The SG participants are aware of the local government plight as it relates financial and technological resources but insists that the local government is in the position to help local communities adapt.

Interestingly, LG participants think that local government programs to address climate change are indigent. The main reason for this perception appeared to be communication and governance issues. Communication issues bother on perceived lack of consultation and transparency on the part of the state and federal government. The reason for the governance issue included the perception of autonomy and mistrust of the state and federal government. LG participants expressed that federal and state government interferes in local government matters.

When asked about the collaboration in climate change adaptation, the FG participants rate collaboration between the three government levels as excellent. The SG participants rate the relationship between the federal and state government levels as good and state with local government as fair. The LG participants thought there is almost zero collaboration between the local government and other government levels. Eighty percent of LG participants describe the collaboration between the local and the other government levels as servant–master collaboration.

Equity and Justice in Adaptation Policies and Practices in Nigeria

Global equity and justice are essential to plan and mobilize the resources needed to implement adaptation actions. However, it could not be straightforward for international policy to lay claim in sovereign affairs taking place within a sovereign territory. The dilemma of equity and justice in climate change adaptation takes different dimensions in Nigeria. In Nigeria, like many developing countries, contributing minimally to climate change issues, climate variability has become a significant threat to survival and sustainable development, especially for vulnerable individuals and communities (Ilevbare 2019). Nigeria is vulnerable to climate security issues with low adaptive capacity.

On the one hand, there is a top-down international rule system to promote adaptation ambition and accountability. On the other hand, climate change implicates domestic sensitivities in Nigeria. There is a diverging perception of how global equity and justice scheme is impacting Nigeria adaptation policies and practices. The result indicates that there is a fundamental difference between interpretations of equity and justice by FG, SG, and LG participants.

In this section, a perceived overview of adaptation policy and adaptation practices will be presented. A shared perspective on equity and justice is essential not only for transparency but also for ensuring that fair and just adaptation reaches the most vulnerable people. Those at the federal and state level view adaptation as the responsibility of the developed country that has contributed most to climate change issues, while those at the local level think adaptation is the responsibility of the national and state government. This view is reflected in the policy report, which indicates that Nigeria needs assistance from international, regional, and non-governmental organizations to reach its intended adaptation goals (INDC 2016). LG participants indicate that the vulnerable local government is struggling to meet adaptation requirements despite the fund Nigeria government acquires for adaptation projects. Results show that there are several reasons why justice eludes the vulnerable communities. FG participants claim that Nigeria, as a country, still lacks the technological and financial resources despite funding from international and regional agencies. SG and LG participants agree that resources for adaptation are lacking in all government levels but argue that other factors play a significant role in poor adaptation practices. The common factors mentioned are the institutional context, social structure, power relations, and fiscal capacity for the effective management of natural resources and adaptation funds.

In Nigeria, social structure can be viewed through institutionalized relationships organized around family, religion, education, politics, media, and economy. These institutions organize the social relationship of the southeast to other regions of Nigeria. The southeast and southwest are predominantly Christians, while the northeast and northwest are predominantly Muslims. The different zones with various ethno cultural groups merged into one country in 1914. The different zones have different tribal groups, languages, and cultures. The differences in culture, politics, and tribal identification affect people's relationships with one another. Culture and ethnoreligious politics influence the distribution of resources in Nigeria (Brown 2013).

It was previously found that political corruption and bad leadership affect the southeast zone (Ogundiya 2010). Southeast is a zone where an estimated 50% of the population feel that they are not part of Nigeria. This resentment can be attributed to the Biafra Civil War that killed millions of southeasterners from July 1967 to January 1970. The southeast feels marginalized, leading to some citizens advocating for fresh separation (Olajide et al. 2018). LG participants explained that due to Nigeria's political structure, the southeast lacks resources and infrastructures, which makes adaptation more difficult. Unequal policies and patterns of government structure driven by national and regional political and economic priorities benefit a particular segment of society while making others more vulnerable. Another issue in the southeast is that the service and industry sector are paid more attention at the expense of small-scale agriculture and fisheries (Nzeadibe et al. 2011), even though LG participants note that the farming communities are the most vulnerable in the southeast.

Nigeria operates federalism with an overconcentration of power at the national level (Akinsanya 1999). In this aspect, the politicians at the national level hold a more considerable amount of power to determine what happens to the vulnerable local population as regards climate change impact. Local government lacks autonomy and depends on the state and national government. This dependency leads to weak institutionalization and local government underutilization, allowing constant intervention from the state and federal government (Acheoah 2018). Adaptation policies are formulated at the state and national levels while adaptation practices take place at the local level. LG participants explained that local knowledge is often not sought during policy formulation, making it challenging to implement such policies in practice. When the state and federal government neglect the most vulnerable participation at the local government, vital communication that encourages collaboration is lost.

Interview and field observation indicate that Nigeria's institutional capacity for climate change adaptation at the federal, state, and local government level is undeveloped and weak. Oulu (2015) argues that establishing effective institutional frameworks is crucial for climate change adaptation. Even with the presence of adaptation policy and climate change department at the federal level, adaptation practices are carried out by the existing National or State Emergency Management Agency (NEMA and SEMA). These two agencies were not designed for climate change adaptation. Only two of the local government areas in the southeast have a Local Emergency Management Agency. NEMA is an existing risk management agency that takes the issue of climate change adaptation as one of its many functions. Climate change adaptation and mitigation goals are now assigned to the ministry and department of the environment. However, LG, SG, and FG participants explain that proven competencies and technological resources in the existing institutions are low.

The budgetary constraint is one of the factors inhibiting adaptation in local communities in Nigeria. However, participants from the federal, the state, and the local government areas have different explanations on how budget constraints hinder adaptation. FG and SG participants claim that budgetary constraints are because of Nigeria's poor economic condition. The LG participants attribute budget constraints to the local government's lack of financial independence. LG participants suggest that the local government also lacked autonomy that contributes to its lack of financial independence required to tackle the issue of climate change adaptation. Fieldwork observation indicates that local government relies on SEMA for relief and settlements for internally displaced people. LG participants explain that the local actors that know the communities well are often not consulted during these visits.

Conclusion

This chapter recognizes that adaptation practices in local governments in southeast Nigeria have equity and justice implications. Environmental equity and justice focus on ensuring that the most vulnerable communities and countries are not left to bear the burden alone. It was argued that climate justice should include mechanisms to ensure that most impacted at the local level have their interests considered (Thomas and Twyman 2005). However, this chapter found that vulnerability to climate change is mostly experienced at the local level, with the burden of adaptation falling disproportionately on the local government areas. Though Nigeria has developed adaptation policies that detail strategies to reduce and avoid climatic impacts, the local government is excluded from decision-making in adaptation policies, and thereby their vulnerability is often not reflected in the policy documents. This is because climate change adaptation policies and practices at the national level of governance are not open for representative dialogue, especially with the local government's participation. This chapter argues that by excluding the local government in the southeast in adaptation decision-making, the national adaptation plan and policies ignore local adaptation needs and knowledge and do not reflect local vulnerability. Beyond local participation, the interaction between the national authority and local knowledge needs to rely on fairness and accountability. Unless the most vulnerable adapt, risks associated with climate change could increase vulnerabilities, and more inequality.

Financial and technological resources remain crucial in helping the poor and vulnerable communities adapt to climate change risk and climate security issues. Access to these resources is vital for adaptation practices. The United Nations Framework Convention on Climate Change (UNFCCC) provides funding to ensure that the most vulnerable countries are not left to deal with climate change alone. The inclusion of local government in adaptation decision-making will ensure that global funding is easily translated into local practice and that adaptation resources are correctly channeled. This chapter also indicates that it is essential to understand issues such as social structure, power relations, institutional context, and budgetary constraints and how they affect local government adaptation. Thus, local government adaptation practices are not independent of preexisting sociopolitical and governance structures in developing countries like Nigeria. This chapter recommends the local government's inclusion in decision-making and formal adaptation governance to encourage partnership and transparency.

Climate-Induced Food Crisis in Africa: Integrating Policy and Adaptation

88

David O. Chiawo and Verrah A. Otiende

Contents

Abstract

Climate change threatens development and economic growth in Africa. It increases risks for individuals and governments with unprecedented negative impacts on agriculture. Specifically, climate change presents a major threat to food security in Africa for the long term due to the low adaptive capacity to deal with successive climate shocks. There is a need for greater awareness of the trends of food crisis patterns and adaptive initiatives. The objective of this chapter was to analyze the trends of the food crisis in Africa within the past 10 years and adaptive initiatives. Quantitative data analyzed for food security indicators were

obtained from the United Nations Food and Agriculture Organization (FAO) and World Development Indicators (WDI) available at the Environment and Climate Change data portal. Policy and adaptation measures related to climate change were reviewed in 26 countries in Africa, with the view to highlight their integrative nature in enhancing food security. High prevalence of undernourishment was observed in six countries, all in sub-Saharan Africa (SSA) including Chad, Liberia, Central African Republic, The Democratic Republic of the Congo, Zambia, and Zimbabwe. Countries with a high land acreage under cereal production recorded reduced undernourishment. Niger demonstrated effective adaptation for food security by registering the highest crop production index in extreme climate variability. However, Kenya appears to be the most predisposed by registering both high climate variability and below average crop production index. It is observed that diversification and technology adoption are key strategies applied across the countries for adaptation. However, the uptake of technology by smallholder farmers is still low across many countries in SSA.

Introduction

Climate change threatens development and economic growth in Africa. It will increase risks for individuals and governments with unprecedented negative impacts across all sectors of the economy. Specifically, climate change presents a major threat to food security in Africa for the coming decade due to low adaptive capacity to deal with successive climate shocks, despite the trend of the rapid pace of population growth. Population growth in sub-Saharan Africa is likely to experience by far the most rapid relative expansion more than doubling to 2.0 billion by 2050 (Bongaarts 2009). The positive population growth is attributed to technology transitions in health care; however, it is expected to generate increased demand for agricultural land and forest products (Brandt et al. 2017), calling for a matching assemblage of technology and policies to enhance food security to limit the possible impact to the environment.

An overwhelming majority of hungry people are found in developing countries, particularly in Africa (Abegunde et al. 2019). With increasing recognition of present and future impacts of climate change, the United Nations Framework Convention on Climate Change (UNFCC 2006) has identified the poorest people living in developing countries as the most vulnerable due to their dependence on natural resources and rain-fed agriculture for survival. However, agriculture remains the dominant employer of rural residents in Africa (e.g., Kalungu and Leal Filho 2018; Belay et al. 2017; Mutunga et al. 2017; Cobbinah and Anane 2016). Smallholder farming creates opportunities for an estimated 175 million people in Africa, of which about 70% are women (AGRA 2014). Across the world, smallholder farmers are considered to be disproportionately vulnerable to climate change because changes in temperature, rainfall, and the frequency or intensity of extreme weather events directly affect their crop and animal productivity (Vignola et al. 2015).

The vulnerability of smallholder farmers is a concern because they represent 85% of the world's farmers and provide more than 80% of the food consumed in the developing world; therefore, what happens to smallholder farmers will have significant social, economic, and environmental consequences globally (Vignola et al. 2015). By their sheer numbers and with optimal productivity, they would have a huge impact in addressing food insecurity (Abegunde et al. 2019), but because of low resource capacity, inadequate skills, and lack of enabling policies, they remain susceptible particularly to climate variability in Africa. Climate change adaptation has become necessary to alleviate the impacts of extreme weather events, especially on rural farmers whose primary livelihood is climate dependent (Cobbinah and Anane 2016).

There is a looming food security crisis in Africa for the next decade due to limited adaptive approaches to extreme climatic conditions of drought, floods, and high temperatures due to climate change (Abegunde et al. 2019). IPCC special report suggested that an increase by 2 °C could exacerbate food crises with crops under rain-fed agriculture dropping by 50% in some African countries by 2020 (IPCC 2018). The current and future impacts of climate change have attracted increasing scholarly work on climate change adaptation (Cobbinah and Anane 2016; Burnham and Ma 2016; Lasco et al. 2014) and its widespread incorporation into national policy and international dialogue (IPCC 2007, 2013). Responding to the effects of climate change requires the continuous development of new adaptive initiatives and improvement of the existing ones and enhancing their widespread adoption by smallholder farmers (Kalungu and Leal Filho 2018). Pursuing appropriate adaptation initiatives in line with realities in Africa is thus vital. A recent study highlighted a positive link between public response and the capacity of farmers to adapt to climate change in sub-Saharan Africa (Abegunde et al. 2019). However, a gap exists in critical review of the role of existing climate change adaptation policies in enhancing the adoption of the initiatives. The objective of this chapter is to analyze the spatiotemporal trends of the food crisis in Africa and adaptive approaches with the view to model a framework for climate change adaptation pathway for Africa.

Definition of Key Concepts

This chapter uses the definition of food security by the United Nations Food and Agriculture Organization (FAO) as food is available at all times; that all persons have means of access to it; that is nutritionally adequate in terms of quantity, quality, and variety; and that it is acceptable within the given culture (Silvestri et al. 2015; Conceição et al. 2016; Luximon and Nowbuth 2010). The chapter defines climate change as a change of climate that is attributed directly or indirectly to human activity that alters the composition of the global atmosphere that is in addition to natural climate variability observed over comparable periods (UNFCC 2006). The chapter adopts the meaning of climate change adaptation (Mutunga et al. 2017) in that adaptation to climate change is the adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploit beneficial opportunities.

Methods and Research Design

The analysis was based on four World Bank food security indicators including average prevalence of undernourishment, land under cereal production, extreme climate change variability, and crop production index. Dataset was obtained from World Development Indicators (WDI) (WDI available at Environment and Climate Change data portal http://africaclimate.opendataforafrica.org/kaoatif/world-development-indicators-wdi). R was for spatial analysis (R Core Team 2020) using shapefile for 52 African countries from Map Library (Map Library is available at http://www.maplibrary.org/library/stacks/Africa/index.htm). Both dataset and shapefile used are licensed under CC BY 4 and are open for public access (Publicly available for any use according to open data standards and licenses under the Creative Commons Attribution 4.0 International license (CC-BY 4.0)). Adaptive and policy strategies applied across Africa were reviewed at local, national, and regional scales. Countries were selected based on the undernourished index and vulnerability to climate change. Spatial patterns were analyzed for undernourishment, land under cereal production, crop production index, and climate change variability in all the 52 African countries according to the shapefile. The spatial patterns were used to identify the countries for review of adaptation and policy strategies. High undernourishment prevalence countries above 40% and low prevalence countries below 10% were selected for review of adaptation and policy strategies for comparison and criticism. Additional counties for review of adaptation and policy were selected based on vulnerability to climate change, low or high crop production index, and landmass under cereal production (Figs. 1 and 2). A total of 26 countries were reviewed across Africa with a larger proportion in SSA. The approach presents a conceptual model integrating climate change adaptation and policy initiatives to illustrate the effective pathway to climate change adaptation in Africa for food security.

Patterns of Climate-Induced Food Crisis and Adaptation in Africa

This section is structured in three parts: the first part presents the results of spatial analysis of food security in Africa for the last 10 years, adaptation initiatives in the second part, and policy initiatives in the third part.

Spatial Trends of Food Crisis in Africa

The prevalence of undernourishment (PoU) is defined by FAO as an estimate of the proportion of the population whose habitual food consumption is insufficient to

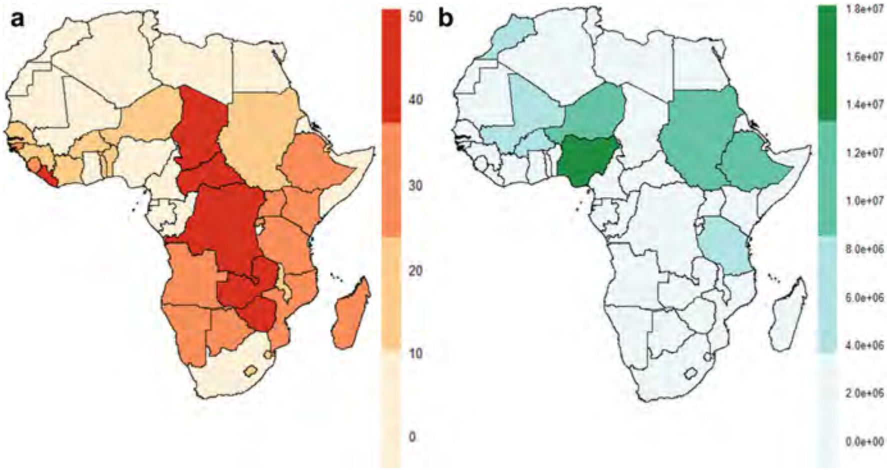

Fig. 1 Spatial patterns of climate-induced-food crisis in Africa. (**a**) Average prevalence of undernourishment (% of the population) in Africa for the period 2009–2017. (**b**) Land under cereal production (hectares) for the period 2009–2017 (Authors own)

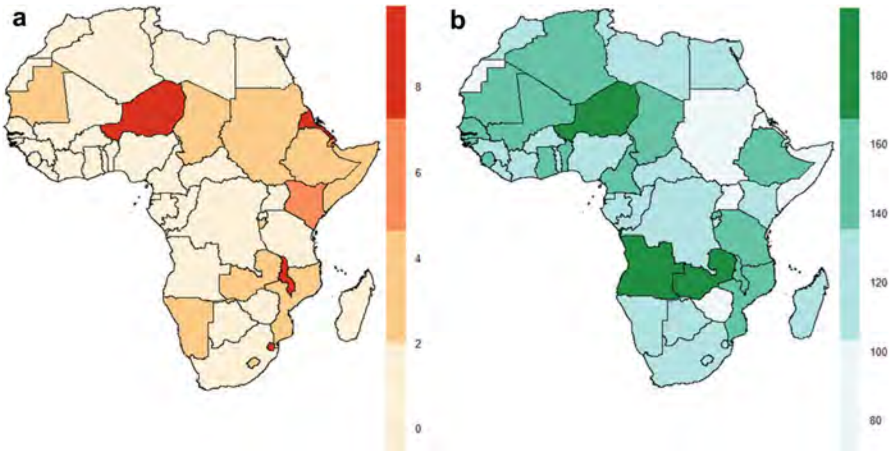

Fig. 2 Spatial patterns of extreme climate change variability and crop production index in Africa. (**a**): Droughts, floods, extreme temperatures (% of the population). (**b**): Crop production index for the period 2009–2016 (Authors own)

provide the dietary energy levels that are required to maintain a normal active and healthy life. The spatial trends of undernourishment in the last 10 years reveal a high prevalence of 40–50% in six countries (6), all in sub-Sahara Africa (SSA) including Chad in the Sahel and Central Africa, Liberia in West Africa, Central African Republic and the Democratic Republic of the Congo in Central Africa, and Zambia and Zimbabwe in Sothern Africa. Low prevalence is observed in North Africa with all countries registering below 10% of undernourishment (Fig. 1a).

Countries with a high land acreage under cereal production recorded reduced undernourishment (Fig. 1a). Nigeria had the largest landmass under cereal production in the last 10 years with a peak of 18 million hectares (Fig. 1b). Other countries above the average of landmass under cereal include Sudan, Ethiopia, Tanzania, and Niger. It is predicted that a possible cross-border trade policy or intercountry relationship between neighboring countries could be influencing the production of cereals, e.g., Sudan and Ethiopia and Niger, Nigeria, Burkina Faso, and Mali. Most countries in Southern Africa have lower than average landmass under cereal production. Although South Africa has below average landmass under cereals, the undernourishment prevalence was still low for the period of analysis, a pointer toward effective diversification or technology adoption in climate change adaptation (Fig.1b).

High incidences of extreme conditions due to climate change including droughts, floods, and extreme temperatures are high in four countries that experienced the highest extreme climate change variability in the last 10 years including Niger, Eritrea, Malawi, and Swaziland. However, these countries registered average to high crop production index an indication of effective climate change adaptation. Kenya appears to be more predisposed to extreme climate change variability in East Africa (Fig. 2a). The leading countries in Africa in crop production are Niger, Angola, and Zambia. A good example of how effective climate change adaptation can lead to food security is Niger, which experiences the highest in extreme climate variability, but registers the highest crop production index. It is important to note that Nigeria had a higher landmass under cereal production (Figs. 1b and 2b), but Niger registered a higher crop production index in the same period pointing toward possibilities of application of multiple adaptive initiatives beyond increasing acreage. Sudan, South Sudan, Eritrea, Somalia, Zimbabwe, and Western Sahara are African countries with the lowest crop production index despite experiencing average and below of extreme climate change variability (Fig. 2).

Climate Change Adaptation Initiatives in Africa

Scientific evidence indicates that the earth's climate is rapidly changing, owing to increases in greenhouse gas emissions leading to raised average temperature and altered the amount and distribution of rainfall globally (Dasgupta et al. 2014). There is growing evidence that the effects of climate change are expected to be greater than the global average in sub-Saharan Africa due to projections of a warming trend characterized by the frequent occurrence of extreme heat events with a 4 °C warming scenario (Serdeczny et al. 2016), increasing aridity, and a decline in rainfall (Belay et al. 2017). Sub-Saharan Africa is particularly vulnerable to these climatic changes because of overdependence on rainfed agriculture on which the livelihoods of a large proportion of the region's population currently depend (Serdeczny et al. 2016).

There are reports of higher drought risks; extreme weather events such as floods, pests, and high temperatures; and diseases faced by farmers in recent years, exacerbating the food crisis in Africa (Mutunga et al. 2017; IPCC 2018). There is evidence from the literature that the current impacts are more severe in rural and smallholder farming communities (Cobbinah and Anane 2016) especially in Africa. This presents the logic that an adaptation initiative is promising only if it fulfills the objective of increasing food security, increases resilience, and is adaptive for smallholder farmers (Descheemaeker et al. 2016). Therefore, adaptation is deemed more important in Africa than mitigation (Descheemaeker et al. 2016). There is a need to strengthen adaptive strategies to ensure food security in Africa. Our review categorizes climate change adaptation in Africa under nine (9) key thematic areas including *diversification, ecosystem-based adaptation*, *climate advisories and information, collective action, technological interventions and innovation, credit facilities, change of patterns, insurance, and capacity building.*

Diversification

Different types of diversification initiatives are applied in Africa including sector diversification, agriculture product diversification and crop diversification, tree-based diversification, and livelihood diversification to adapt to climate change. Diversification provides smallholder farmers with a diversity of diet and improves their income and nutrition security, particularly in sub-Saharan Africa where rainfed agriculture is rampant. For example, Mauritius diversified agriculture with the rapid expansion of industrialization for exports in textile and the development of tourism to promote sector diversification and crop diversification. Also, the Government of Mauritius widened access to lands to be leased out to small planters specifically for agriculture product diversification (Luximon and Nowbuth 2010). While in Mauritius the initiatives to diversify agricultural products seem to be incentivized by the Government, in Kenya, they are largely driven by smallholder farmers through off-farm employment, leasing of land (Kalungu and Leal Filho 2018), mixed cropping and livestock farming (Mutunga et al. 2017), and introducing new crops that are drought resistant or switch to a different variety of the same crop (Crick et al. 2018).

In Morocco, farmers practice crop diversification with intercropped vegetables and tree-based diversification using high-value crop trees (HVC), e.g., drought-tolerant species of fig, almond, and pomegranate and olive varieties (Kmoch et al. 2018). In Ethiopia, farmers practice crop diversification, agricultural product diversification by increasing the integration of crops with livestock, and tree planting. However, reducing the number of meals is common for livelihood diversification to adapt to limited food supply (Belay et al. 2017). In Tanzania, farmers diversify agricultural products by growing vegetables in the offseason and sell livestock during drought, while in South Africa, livelihood diversification and focus on livestock are common in case of crop failure. In Mozambique, farmers diversify to other food sources to meet the dietary needs and shift focus to other means of livelihood beyond agriculture. Farmers in Ghana diversify to enhance food production through multiple cropping, combine improved and local crop varieties, and shift from palm oil to maize and sweet potatoes (Burnham and Ma 2016). Focus on cultivating cash crop (cashew) and engaging in non-farm-based activities, e.g., business, are also common in Ghana. Cashew cultivation is viewed by small landholdings in Ghana as a better livelihood option compared to non-farm-based activities (Cobbinah and Anane 2016). To adapt livestock husbandry to the effects of the extreme of climate change, rural communities in sub-Saharan Africa have diversified to goats instead of cattle and sturdy African breeds instead of more productive crossbreeds (Descheemaeker et al. 2016). In northwest Tunisia, small ruminant farms are better able to adopt the organic farming system and to adapt to warming or precipitation increases by switching to heat-tolerant animals like goats or crops such as Sulla (Khaldi et al. 2012).

Crop diversification together with the diversification of income from multiple sources (cash and in-kind, farm, livestock, crops, and off-farm) is considered to be key "buffer strategies" smallholder farmers pursue to deal with risks of climate change to agrarian environments in Africa (Silvestri et al. 2015; Cobbinah and Anane 2016; Burnham and Ma 2016; Belay et al. 2017; Khacheba et al. 2018; Mutunga et al. 2017). The effectiveness of diversification initiative has been observed in food-secure female-headed households who allocate twice as much land to HVC, e.g., fruits, such as mango and oranges, and then their food-insecure counterparts (Silvestri et al. 2015). This concept in Malawi has demonstrated a gender perspective in climate change adaptation that could be a wake-up call to many African countries to enhance women's adaptive capacity and resilience to climate change (Nyasimi et al. 2014). Indigenous fruit tree production for improved nutrition and income is successful in Malawi, Zambia, and Zimbabwe. Fruit consumption has clear health and nutrition benefits such as providing essential micronutrients and protecting against chronic diseases. Even though fruit consumption in Africa is low, fruit trees fulfill a vital role in contributing to food security, because the fruit is consumed seasonally at a time when households run out of food (Kiptot et al. 2014). There is a need to extensively explore diversification through fruit trees across many African countries to enhance food security.

Ecosystem-Based Adaptation

Ecosystem-based adaptation is the use of biodiversity and ecosystem services as part of an overall adaptation strategy to help farmers adapt to the adverse effects of climate change (Vignola et al. 2015). There is a rapidly growing interest in ecosystem-based adaptation for its potential social, environmental, and economic benefits (e.g., Cerdán et al. 2012; Namirembe et al. 2014; Vignola et al. 2015). Agroforestry provides environmental and social benefits as part of farming livelihoods. In most documented cases of successful agroforestry establishment, tree-based systems are more productive, more sustainable, and more attuned to people's cultural or material needs than treeless alternatives (Mbow et al. 2014). Trees or shrubs on farms and forest-agriculture integration are gaining preference among farmers in Africa. Despite the productivity of agroforestry systems, it has not been fully adopted in many African countries, e.g., Kenya's intention to achieve a 10% target of tree cover on farmers' acreage is yet to be realized (Oloo 2013). There is a need for more insights into the productivity and environmental performance of agroforestry systems across Africa (Mbow et al. 2014). Agroforestry with leguminous fodder plants to support food requirements for livestock during extreme weather is gaining attention among farmers in sub-Saharan Africa (Cobbinah and Anane 2016). In

Tanzania, farmers focus on planting trees as hedgerows, while in Nigeria on-farm trees are used to shade crops and animals (Burnham and Ma 2016). Tree-based agroforestry is also popular in Morocco where farmers use bi- or triennial trees like olives to increase tree cover on-farm (Kmoch et al. 2018).

Improved tree fallows using leguminous trees are encouraged in maize fields in Malawi, Zambia, and Zimbabwe as low cash-input agroforestry practices to restore soil fertility (Keil et al. 2005). Studies in semi-arid areas in Tanzania showed that agroforestry tree species producing high-quality litter could enhance post-fallow soil nutrient availability and crop yields through mineralization of soil organic matter and green manure (Kimaro et al. 2008). In Mauritius, farmers promote the use of organic farming, using organic manure which is more resistant to drought and also reduces the risk of floods (Luximon and Nowbuth 2010), and in Kenya, farmers using locally available organic matter prepare organic manure (Oloo 2013). Farmers in Morocco adapt to the effects of climate change like floods by encouraging conservation agriculture through minimum tillage and increase of soil cover (Kmoch et al. 2018). Minimum tillage and crop rotation were observed to increase farm maize productivity by about 26–38% for minimum tillage and 21–24% for crop rotation in Zambia (Kuntashula et al. 2014). In sub-Saharan Africa rangeland, farmers practice grazing and rangeland management to enhance manure collection, storage, and application (Descheemaeker et al. 2016).

Planting cover crops and the use of manure for soil conservation to prevent soil erosion and to improve soil fertility respectively are common among smallholder farmers in Tanzania, Kenya, and Ethiopia (Mutunga et al. 2017; Belay et al. 2017; Burnham and Ma 2016). Farmers in Ethiopia are observed to practice both soil and water conservation (Belay et al. 2017). In Burkina Faso, farmers arrange stone lines on-farm and in the field to capture surface runoff for micro-water harvesting and to prevent soil erosion due to flash floods, and in South Africa, farmers build bunds along contour lines to slow down water runoff (Burnham and Ma 2016).

Technology and Innovation Adoption

The adoption of appropriate technologies in small-scale farming is an important response to the effects of climate change and variability, especially in Africa (Kalungu and Leal Filho 2018). Farmers largely apply integrated pest management as a means of pest control (Luximon and Nowbuth 2010). Literature indicates a wide use of technological intervention to enhance adapting dairy farming in Tunisia, e.g., farmers in Tunisia build up fodder reserves in favorable years, increase concentrate distribution, manage nutritional requirements, and promote drinking water ad libitum (Hajer et al. 2018). They are keen on the choice of breed and maximize the use of agri-byproducts as feeds. To improve productivity, farmers in Tunisia enhance irrigation potential at the farm level. Farmers also adjust calving periods by concentrating them within favorable feeding periods (Belay et al. 2017). Building fodder reserves for animals is also documented in Burkina Faso (Burnham and Ma 2016). Farmers in Burkina Faso also overcome the shock of drought by producing dry season vegetables using irrigation and the use of improved seeds.

In Kenya, farmers in semi-arid regions apply a combination of technological interventions under Framing Technologies, e.g., soil fertility management, irrigation soil conservation, and water management row planting and terracing. There is high-level awareness on the use of hybrid crop varieties, pesticides, and changing crop variety depending on climate variability (Mutunga et al. 2017; Kalungu and Leal Filho 2018). Planting short seasoned crops and resistant crop variety and feed preservation for farm animals have also been recognized as key adaptive interventions among Kenya farmers (Oloo 2013). Rotation cropping of cereals and legumes and irrigated fruit trees are common in commercially orientated farming systems in Morocco, with agro-silviculture (growing of trees and agriculture crops together in the same lands at the same time) dominating all irrigated farms (Kmoch et al. 2018). There is input intensification in Ethiopia to enhance farm-level productivity (Belay et al. 2017), and in Tanzania, farmers use well irrigation and plant quick maturing and drought-resistant varieties (Burnham and Ma 2016). Framers in South Africa increase distances between crop rows and practice irrigation. Farmers in South Africa also plant late-maturing fruit trees to enhance food availability during low harvests (Burnham and Ma 2016). In Ghana, farmers plant high yield varieties (Belay et al. 2017). In other countries relay cropping and mixed intercropping are practiced. By providing nutrients to crops, these technologies can potentially help farmers improve their soils and incomes, thereby improving food security in Malawi, Zambia, and Zimbabwe (Kiptot et al. 2014).

Farmers in many African countries aim at enhancing farm-level productivity by planting early maturing varieties and drought-tolerant crops and changing crop variety to match prevailing weather conditions, e.g., in Nigeria, Mozambique, Angola, and Kenya among other countries (Burnham and Ma 2016). The use of drought-tolerant maize has been documented in Angola, Benin, Kenya, and many other African countries (Nyasimi et al. 2014). Technological intervention in sub-Saharan Africa is observed to enhance sustainable intensification in post-harvest storage, choosing adapted crops and cultivars, intercropping and rotation with dual-purpose legumes, water harvesting, and irrigation to adapt local farmers to the adverse effects of climate change to agro-ecosystems. Similarly, technology is expected to enhance the choice for animal types and breeds that are better adapted to heat stress and dry conditions and to improve the storage of food and feed (Descheemaeker et al. 2016).

Moreover, technologies to reduce post-harvest losses are in consideration; e.g., the use of metal silo technology in household maize storage in Kenya has proved effective in protecting stored grains from attack by storage insect pests, sustaining maize supply while reducing the burden on the natural environment (Gitonga et al. 2013; Tefera et al. 2011). Other adaptation technologies promote water allocation efficiency for irrigation. For example, the water–energy–food (WEF) nexus is promoting the uptake of drip irrigation among smallholder farmers in Morrocco (He et al. 2006). WEF technology has been promoted as a demand-side management option for reducing water consumption while maintaining yields, particularly through minimizing nonproductive evaporative losses (Jobbins et al. 2015). In Ethiopia, other technologies that maximize precipitation utilization in dryland are promoted, e.g., increasing the length of the fallow period before planting to increase the amount of pre-plant stored water in the soil and retention of large amounts of crop residue on the soil surface to decrease runoff (Woyessa and Bennie 2007).

Climate Advisory and Extension

Climate advisories and information offer opportunities to inform farmers of climate-related risks, e.g., agrometeorological advisory program and weather and climate bulletins in Mali, and inform farmers on decisions such as variety selection, planting times, and the timing of inputs in Mali (Carr and Onzere 2018). Access to climate change information and extension services is encouraged in Kenya (Mutunga et al. 2017). However, 76% still have limited access to agricultural extension services (Kalungu and Leal Filho 2018). Extension services enhance access to information about new agricultural technologies and innovations. The use of weather information by farmers in Ghana is well documented (Belay et al. 2017). The use of early warning signs, weather forecasts, and agricultural extension services are indicated as important in enhancing the adaptation of farmers to climate variability in sub-Saharan Africa (Descheemaeker et al. 2016; Mbow et al. 2014). In East Africa, climate advisory and extension services remain low among smallholder farmers leading to limited capacity to use climate data (Atela et al. 2018; Singh et al. 2016) and climate illiteracy (Spires et al. 2014). However, the role of ICTs in scaling climate information services (CIS) is gaining attention (Atela et al. 2018). For example, short-term climate information through community worker initiative in Uganda provides 10-day, monthly, and seasonal weather forecasts to farmers on their mobile phones via SMS (Singh et al. 2016).

Access to weather information is observed to significantly influence the likelihood of adopting improved crop varieties, making adjustments in the timing of agricultural activities and investing in improved land management practices, and increasing fertilizer use among farmers in West Africa (Wood et al. 2014). Risk management practices that generate and disseminate agro-advisory services and weather information are important adaptive initiatives in Africa (Nyasimi et al. 2014).

Other Adaptive Initiatives

Increasing acreage as an initiative to enhance productivity is being practiced in some African countries, e.g., about 46.4% of the landmass in Mauritius is under agriculture, to enhance the production of crops and livestock (Luximon and Nowbuth 2010). The basis of increasing farm size is to increase food crop production to overcome low food crop productivity by maintaining normal productivity. However, this approach is facing sustainability concerns, e.g., continuous expansion of farmlands with a further clearing of the forest in Ghana has potential implications for deforestation, which will, in turn, exacerbate climate change in Ghana (Cobbinah and Anane 2016). Collective action involving collaboration among farmers is being practiced by local farmers and households. Community center approach to livestock management in Morocco (Kmoch et al. 2018), cooperatives and community-based development projects in South Africa (Belay et al. 2017), and social production and natural resource management-related groups in West Africa (Wood et al. 2014) have contributed both to limiting the risks and enhancing the capacity to adapt to climate change.

Change of pattern in planting times or moving animals is considered among some farmers in different areas: planting just before the onset of rains and moving animals, changing planting dates, and planting near a river in Kenya and Ghana (Belay et al. 2017; Mutunga et al. 2017; Descheemaeker et al. 2016); planting date adjustment in Ethiopia, Kenya, and Nigeria; planting early as possible after first rain (Belay et al. 2017; Oloo 2013), moving livestock to other areas, store fodder, and selling animals in South Africa (Belay et al. 2017); seasonal herd migration in sub-Saharan Africa (Descheemaeker et al. 2016); and temporary migration in Tanzania (Belay et al. 2017). *Capacity building* of climate change adaptation is recognized as a means of enhancing their ability to adopt desired initiatives related to technology adoption and diversification. Building capacity of farmers on climate change adaptation is documented in Mauritius (Luximon and Nowbuth 2010). In Mali, a farmer observer has been trained to enhance the capacity of most farmers in southern Mali (Carr and Onzere 2018). Capacity building of water user associations combined with local knowledge and scientific expertise is common in Morocco (Kmoch et al. 2018). In Zambia, the capacity of farmers is enhanced through conventional agricultural extension systems and participatory farmer interactions (Kuntashula et al. 2014). *Insurance* as a means of climate change adaptation is at trial in sub-Saharan Africa (SSA) to address climate-related risks faced by farmers (Descheemaeker et al. 2016). Weather-based index insurance is being tried in Mali (Carr and Onzere 2018). Adaptation planning in the form of insurance, with or without external support, is being tried in Kenya and Senegal (Crick et al. 2018). However, these products in general face low rates of adoption across SSA due to weakness of regulatory environment and financial facilities, basis risk, quality and availability of weather data, capacity building of stakeholders (farmer, insurer, and regulator), and lack of innovation for local adaptation and scalability (Ntukamazina et al. 2017).

The use of *credit facilitie*s has also been documented in Kenya (Mutunga et al. 2017) and Mauritius among other countries (Luximon and Nowbuth 2010). A study in Nigeria found a positive impact of commercial bank credits to food security by up to 8% (Osabohien et al. 2018). However, there is evidence that traditional credit use, among smallholder farmers, is extremely low in SSA (Adjognon et al. 2017), pointing to weak or no policy across many countries to enhance implementation.

Policy Initiatives for Climate Change Adaptation

Climate change is progressively hurting agricultural production in Africa (Kalungu and Leal Filho 2018; Crick et al. 2018; Mutunga et al. 2017; Belay et al. 2017; Burnham and Ma 2016). Adoption of suitable adaptation strategies is thus a prerequisite to supporting the majority of smallholder farmers in reducing the effects of climate change (Hajer et al. 2018; Cobbinah and Anane 2016; Belay et al. 2017; Kmoch et al. 2018). Many factors, among them, are policies and markets and have been identified to define responses of the farmers to climate change shocks (Peter et al. 2017; Hummel 2016; Magnan et al. 2011; Kalame et al. 2009).

Policy to Enhance Diversification and Risk Management

Climate change adaptation policy in Mauritius made available 200 acres of agricultural land widening access to land for lease to small planters for agriculture diversification enhancing food production in the country (Luximon and Nowbuth 2010). Mauritius government advanced some incentives to farmers to support diversification, e.g., agricultural credit from the bank and subsidy on the price of farm input, guaranteed price for some farm produce, and offered some facilities to livestock breeders. Mauritius has the policy to limit food products locally produced to local consumption, while the country exploits the opportunity of cross-border initiatives (CBI) set by FAO with Madagascar, Mozambique, and Tanzania to increase production for domestic consumption (Luximon and Nowbuth 2010). A similar policy on price control also succeeded in Tunisia by reducing the exposure of Tunisian farmers to the food price volatility in the world markets and cautioning local households from the risk of scarcity in food supply (Chemingui et al. 2001). Participating in trade relations with the European Union (EU) and enhanced political cooperation has promoted the diversification of income sources from the trade of agricultural products (Chemingui et al. 2001).

Multi-sectoral Policies on Climate Advisory and Extension

In Namibia, the national-level development policy context of Vision 2030 guides Namibia's national, long-term development related to climate change adaptation. Climate change is mainstreamed in agriculture, disaster response strategies, and marine resources. The policy strengthens Namibia's meteorological services by supporting the work of the National Climate Change Committee in mainstreaming climate change adaptation and strengthening capacities to respond to it (Crawford and Terton 2016). The National Climate Change Strategy and Action Plan (NCCSAP) in Namibia has a direct link to enhancing climate change adaptation initiatives by setting up adaptation action on diversification of crops to adapt to erratic rainfall. It focuses on the increased use of improved crop varieties, conservation of indigenous livestock breeds, and diversification of livelihoods through tourism and wildlife conservancies (Crawford and Terton 2016). The policy aims to enhance capacities and synergies at individual, local, institutional, national, regional, and systematic levels to ensure successful implementation of climate change response activities and adequate funding resources for effective adaptation (Crawford and Terton 2016).

National-Level Policies for Adoption of Ecosystem-Based Initiatives

Policies on restoration or management of biodiversity and ecosystem services could confer multiple adaptive benefits, e.g., the use of shade trees in coffee farms (i.e., producing coffee as an agroforestry system), and could ensure the continued provision of key ecosystem services like pollination, natural pest control, conservation of water and soils, etc. as well as buffering coffee from extreme temperatures and rainfall, leading to more stable production under climate-related stresses (Vignola et al. 2015). Despite the growing interest in ecosystem-based adaptation, there has been little discussion of how this initiative could be enhanced among smallholder farmers while ensuring the continued provision of ecosystem services on which farming depends (Vignola et al. 2015). Policies on land use planning, forest-agriculture integration, and landscape-based adaptation are in line with enhancing local adoption of an ecosystem-based approach to climate change adaptation (Mbow et al. 2014). In South Africa, municipal climate adaptation plans use a sectoral approach to encourage greater interaction among different sectors and provided a clearer understanding of the needs and roles in climate adaptation (Roberts 2010). A specific case where policy implementation has been seen to influence the adaptation of technology and diversification initiatives was seen in the implementation of Global-GAP policy in the production of French beans in Kenya. The policy expected farmers to comply with certain climate adaptation strategies. The implementation supported changing crop variety, water harvesting, finding off-farm jobs, and soil conservation (Peter et al. 2017). The National Adaptation Plan 2015–2030 was developed by the Kenyan government to enhance adaptation capacity at macro-level. From the thematic perspective, Kenya's National Climate Change Action Plan (NCCAP 2018–2022) has prioritized adaptation initiatives focused on food security (GOK 2018).

Regional-Level Policies and Treaties

Regional treaties and international policies affect people's mobility in the context of climate change, and environmental change is strongly influenced by different international, regional, and national policies in the fields of migration, development, and environment. The crucial importance of mobility and migration within the West African region means that subregional initiatives, treaties, and regulations are particularly significant (Hummel 2016). Economic Community of West African States (ECOWAS)s common approach on migration enabling citizens to enter freely, reside, and settle in member countries is particularly important to livestock farmers in Senegal and Mali as one possible response to changing ecosystems (Hummel 2016).

Some regional commitments to enhance food security including the *Comprehensive Africa Agriculture Development Programme (CAADP)* and the subsequent *Malabo Declaration on Accelerated Agricultural Growth and Transformation for Shared Prosperity and Improved Livelihoods* are in place. However, the commitment to achieve the targets of the agreements may need upscaling. For example, the implementation of the agreement to allocate at least 10% of public expenditure to agriculture in Malabo Declaration remains low, with only Botswana and three other African countries including South Africa, Malawi, and Senegal engaging in public spending on agriculture worth above 10% (Mink 2016). Similarly, the implementation of the Paris Agreement to combat climate change by accelerating and intensifying climate actions remains weak with most countries making only small and cosmetic changes in transforming Intentional Nationally Determined Contributions (INDCs) to Nationally Determined Contributions (NDCs) (AFDB 2015).

National-Level Policies for Technology Adoption

Policies aligned to climate change adaptation could influence the adoption of technology. For example, Senegal Agriculture Programme was established in 2006 in response to an increase in outmigration from rural areas. This policy aimed at enhancing the use of technology in agriculture to generate sustainable incomes to attract young people to stay in their villages, enhancing rural development (Hummel 2016). Institutionalization of climate change adaptation into policy has the potential to enhance agricultural productivity. In Durban in South Africa, the climate adaptation policy ensuring that 50% of the food consumed by the rural poor is locally produced has led to the adoption of technology and diversification initiatives enhancing agricultural productivity (Roberts 2010). Policy context on climate change and agriculture in Ghana demonstrates a strong focus on the application of technology and innovation in agriculture as an engine for growth and development. Ghana's Shared Growth Development Agenda (GSGDA 2010–2013) highlighted the importance of facing climate change technological solutions such as drought-tolerant crop varieties and a transformation from rain-fed to irrigated agriculture, as well as reducing deforestation through agricultural expansion to improve the robustness of the sector to adapt to climate change (Sarpong and Anyidoho 2012). The government of Ghana has embarked on the implementation of a policy on reforestation through large-scale plantation development and small-scale on-farm regeneration activities to promote adaptation to climate change through ecosystem-based approaches. A similar initiative in reforestation has also been tried by the government of Burkina Faso (Kalame et al. 2009) and Kenya (Oloo 2013). However, there is fear that without proper planning, coordination, funding, and incentives to farmers for adoption, failure of reforestation policy could lead to large-scale deforestation and degradation, like in the case of Burkina Faso (Kalame et al. 2009).

Regional Policies and Trade-offs

In Morocco, food security trade-off policies are applied at the national level. Sufficiently transparent pricing model, subsidy, import substitution (increasing domestic production and reducing imports), intensification, and subsidizing farmers to grow cereals, either through deficiency payments or targeted input subsidies, have made cereal farming more lucrative (Magnan et al. 2011). Nonetheless, countries should observe that the application of trade-off policies does not contravene World Trade Organization regulations. Mauritius is often referred to as one of the very few developing countries to have overcome poverty and hunger by participating successfully in the globalization of the world market. Application of policy that enhances sector diversification to export-oriented agricultural diversification and industrialization aimed at reducing the dependence on food imports and increasing national food self-sufficiency. The implementation of the policy led to the attainment of national self-sufficiency in potatoes (Koop 2005). Policy on the modernization of agriculture and insulation of local farmers from external competition has permitted Tunisia to substantially increase its outputs, yields, and self-sufficiency rates in products considered as being strategic, such as cereals, vegetables, oil, and livestock products (Chemingui et al. 2001). Food self-sufficiency policy has influenced the development of irrigated farming in Botswana as a possible complement to rain-fed agriculture to enhance the production of cereals, mainly maize and sorghum (Lado 2001). The model food security pathway for African countries is summarized in Fig. 3.

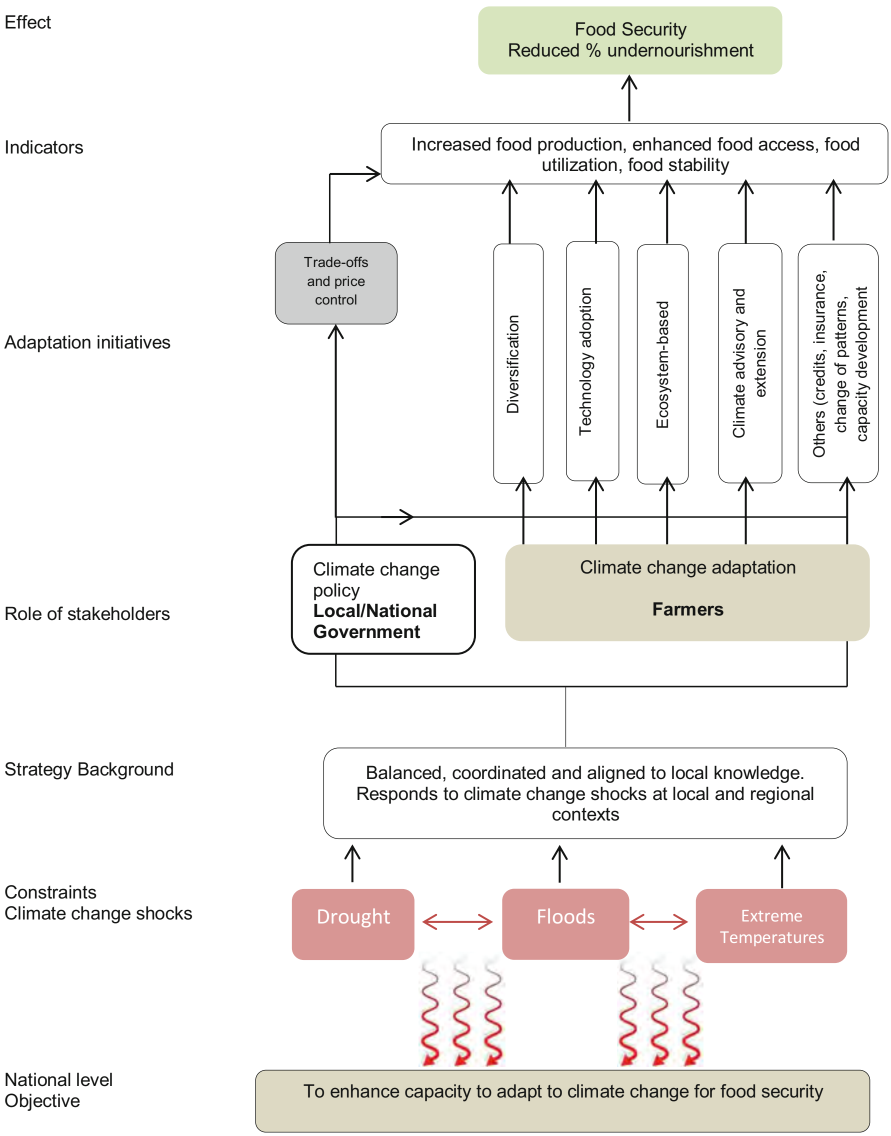

Fig. 3 A conceptual model of climate change adaptation pathway for food security in Africa. Balancing between climate change policy and adaptation (Authors own)

Conclusion

High prevalence of undernourishment was observed in six countries, all in SSA including Chad, Liberia, Central African Republic, the Democratic Republic of the Congo, Zambia, and Zimbabwe. Countries with a high land acreage under cereal production recorded reduced undernourishment as observed in Nigeria, Sudan, Ethiopia, Tanzania, and Niger. Five countries including Niger, Eritrea, Malawi, Swaziland, and Kenya experienced extreme climate variability in the last 10 years including droughts, floods, and extreme temperatures. Despite the extreme climate variability, Niger, Eritrea, Malawi, and Swaziland still registered average to high crop production index, an indication of effective climate change adaptation. Niger demonstrated effective adaptation for food security by registering the highest crop production index in extreme climate variability. However, Kenya appears to be the most predisposed by registering both high climate variability and below average crop production index.

Diversification and technology adoption were key strategies applied across countries. However, the uptake of technology by smallholder farmers is still low across many countries in SSA. There are efforts to mainstream climate change policy in agriculture at local, national, and regional levels to enhance technology adoption, capacity building, and funding. There is a need to strengthen policy to promote climate advisory and extension, climate literacy, and capacity to use ICTs to disseminate climate information services. A lack of commitment by governments to regional agreements to enhance food security and climate action has been observed. Only Botswana, South Africa, Malawi, and Senegal had spent on agriculture worth above 10% of national expenditure in line with the *Malabo Declaration*. Similarly, the implementation of the *Paris Agreement* to combat climate change by accelerating and intensifying climate actions remains to be weak in most countries.

The chapter maps the patterns of climate variability and undernourishment prevalence and establishes the linkages between policy initiatives and adaptation actions. Future academic explorations may focus on gaps in gender perspectives in climate change adaptation and effective ICTs for the dissemination of climate information services among smallholder farmers in SSA.

Acknowledgments Strathmore University provided information on the call for the research. Food and Agriculture Organization of the United Nation (FAO) through the online platform provided information on food security indicators and desktop data for analysis and World Development Indicator (WDI) for Environment and Climate Change data through the online data portal.

Abstract

Climate change contributes significantly to the looming food insecurity in the rain-fed agricultural countries of Africa, including Nigeria. There is a gender dimension in climate change impacts and adaptation strategies along Agriculture

Value Chain (AVC) in Nigeria. The chapter gender analyzed the aspects of climate change impacts; identified the indigenous and expert-based artificial adaptation strategies; assessed the gender differences in the adaptation strategies; and provided the gender implications of the indigenous adaptation strategies among actors along the AVC. The chapter adopted a value chain-based exploratory design with gender analysis as the narrative framework with Gender Response Theory as the theoretical background. There were gender differences in the production, economic, and social dimensions of the climate change impacts along the AVC. The indigenous climate change adaptation strategies were availability, low cost, and easily accessible; hence they were popularly adopted by male and female AVC actors. The adopted indigenous adaptation strategies challenged the social relations, influenced reordering of social and gender relations, participation, and power relation among the male and female actors along the AVC.

Keywords

Gender · Farmers · Indigenous · Climate change · Adaptation strategies · Gender Response Theory · Agriculture Value Chain

Introduction

Food security influences agricultural production security. However, the diversion of government attention and political will from agriculture to the oil economy marked the beginning of food insecurity in Nigeria. While the population continues to increase, food production is decreasing at an alarming rate. Agriculture is a significant sector that impacts the socioeconomic livelihoods of the majority of the people of Nigeria, because it is the primary source of livelihoods for the majority. Unlike the oil booms that give direct benefits to a few minorities, Nigeria possesses a pro-agriculture environment and climate. Until the discovery of the oil boom in Nigeria, which marks the sharp diversion of the economic and political attention of the government away from agriculture to the oil boom, Nigeria was food sufficient and a significant exporter of most significant crops in Nigeria. The gap between the rich and the poor is widening as the benefits from oil booms increases, and agricultural production decreases.

Downie (2017) identified uncompetitive environment for agribusiness, inadequate input supply, poor market access, poor access to credit, lukewarm political commitment, and neglected agricultural research system as the obstacles to agricultural development in Nigeria. However, global warming-induced climate change and variability are worsening the situation. Ground-based observations and satellite data from the United States National Aeronautics and Space Administration (NASA) revealed that the first 6 months of 2016 were the warmest 6-month period since 1880 when records of temperatures begin (NASA 2016). The two major ice sheets are melting much faster relative to the past decades (Intergovernmental Panel on Climate

Change-IPCC 2014). During 2003–2013, disasters cost nearly US$1.5 trillion in global economic damage (Food and Agriculture Organization-FAO 2015).

The impacts of climate change and variability on agriculture is higher in the rain-fed agricultural nations such as Nigeria. Climate change is a significant push factor in agriculture in Nigeria due to the resultant irregular rainfall pattern and temperature swings resulting from climate change impacting agricultural production negatively along the value chain (Christopher and Jonathan 2011; Apata 2013; Acosta et al. 2015).

The impacts of climate change along the Agriculture Value Chain (AVC) have gender differences. Gender roles and gendered access and control over resources influence the gender difference in the vulnerability to climate change impacts by the male and female actors. The female gender is the most disadvantaged in terms of access to and control over resources, participation and contribution to decision-making at all levels, which makes them deficient in asset base; hence they are highly vulnerable to disasters such as from climate change and variability (FAO 2013; Gutierrez-Montes et al. 2018). This chapter explains the theory underpinning responses (adaptation/mitigation) of male and female AVC actors to the stimuli from climate change and variability.

Literatures (FAO 2011; Okali 2012; IPCC 2014; UNDP 2014) revealed that factors enhancing females' high vulnerability to the effects of climate change and variability are: (i) low adaptive capacity; (ii) fewer endowment and entitlements than men; (iii) unequal survival opportunities (for instance, limitations in mobility/migration); (iv) low decision-making potentials; and (v) inadequate access to and control over critical resources.

Kolawole et al. (2014) and Williams et al. (2019) affirm that the majority of farmers in Africa are smallholders and depend on local instead of scientific meteorology information for their adaptation to climate change and variability. Weather forecasting and early warning information to reduce vulnerability to climate change and variability are not readily available to farmers, are mostly written in technical jargons not smoothly comprehensive to local farmers, and are usually expensive to access (Raymond et al. 2010; Kolawole et al. 2014; Myuri et al. 2017). Scientific meteorology information requires technical skills to understand and adopt. Indigenous meteorology information is acquired through experiences and socialization by the parents and elders. According to Kolawole et al. (2014), both local and scientific meteorology information are products of observation, experimentation, and validation. However, scientific meteorologist adopts systematic procedure, while the process for the local one is unregulated, unorganized, and limited; hence the later may be less accurate and valid but could serve as stepping stone to the former. The local meteorology information could be useful in establishing a local weather experimental station to enhance farmers' access to the information for improved adaptation to climate change impacts.

Projects centered around the climate-smart agriculture (CSA) approach usually promote the adoption of technologies, as well as practices and services aimed at increasing agricultural productivity while enhancing producers' climate adaptation and mitigation capacities (Louman et al. 2015; Williams et al. 2019).

According to Gutierrez-Montes et al. (2018), if women have equal access to such technologies and practices and take ownership over the resulting benefits, Climate Smart Agriculture (CSA) may have a more significant effect on family well-being. To better understand the relationship between CSA, gender, and rural livelihoods, there is a need for well-defined and efficient indicators (SMART indicators) that allow project managers and policy-makers to assess and evaluate CSA programs or interventions in terms of their impact on gender relations (Gutierrez-Montes et al. 2018)

Women are known to be more involved in agricultural activities than men in sub-Saharan African (SSA) countries, Nigeria inclusive with as much as 73% involved in cash and food crops, arable and vegetable gardening, 16% in postharvest activities, and 15% in agroforestry (FAO and ECOWAS 2018; FAO 2019). The percentage of work done by women farmers far outweighs that of men, especially in Nigeria; they are major stakeholders for sustainable development (Faniyi et al. 2018, 2019; FAO 2019; National Bureau of Statistics-NBS 2016). There is gender role differentiation of immense dimension within African agriculture. Women make a significant contribution to food production and processing, but men seem to take more of the farm decisions and control the productive resources (Anaglo et al. 2013; Eger et al. 2018).

Nigeria accounts for nearly 20% of continental GDP and about 75% of the West Africa economy; despite this dominance, its exports to rest of Africa was at 12.7%, and only 3.7% of total trade is within the Economic Community of West African States (FAO and ECOWAS 2018; Aduwo et al. 2019). Despite the prominence of oil in the country's economic wealth, agriculture still contributes significantly to the Nigerian economy. The country's agriculture sector provides direct employment for about 75% of the population (NBS 2016; Alao et al. 2014). In the 1970s and 1980s, agriculture contributed nearly two-thirds of Nigeria's GDP. Currently, it provides about 40.2%, employs approximately 70% (males and females) of the labor force, accounts for more than 70% of non-oil exports and, most importantly, provides over 80% of the country's food needs (FAO 2010; FAO and ECOWAS 2018). With a population of over 180 million and still growing, agricultural development is vital for the attainment of food security and sustainable development in Nigeria.

Women farmers in rural areas are the majority of the agricultural workforce and should be empowered and provided free access to resources and participation in decision-making and programs (Bayeh 2016).

Women constitute a significant part of the agricultural labor force, and their contribution is essential to the success of the Economic Recovery and Growth Plan (ERGP) in the Federal Republic of Nigeria (FAO 2019; Faniyi et al. 2018). Although Women's roles are evident along the Agriculture Value Chain, the economic reward is not commensurate; they are not adequately benefiting from agricultural policies, programs, and budgets.

United Nations Development Program (UNDP 2014) report revealed that in Nigeria, women play a dominant role in agricultural production where they make up some 60–80% of the farm labor force, depending on the region, and they produce two-thirds of the food crops. Yet, the female farmers are among the voiceless, especially concerning influencing agricultural policies, programs, and development.

In Nigeria, a wide gender gap exists, and women in agriculture are worse for it (Aduwo et al. 2019). Nigeria agriculture is a rural community based, and 70% of the poor in Nigeria are in the rural areas, 59% of the poor household heads have women as heads (FAO 2011, 2013). Women constitute 70% of agricultural labor force; 60–70% of food crop producers; approximately 100% of food processors; 80% of food storage and transportation from farm gate to village market; 90% of hoeing and weeding work in farms; and 60% of harvesting and marketing services (Christopher and Jonathan 2011; Apata 2013). Despite the significant position of women in agriculture, men make major farm decisions and have access to land. Most women do not have the right to landed property, are denied access to credit and relevant capacity building opportunities, information, and participation (Anaglo et al. 2013; Eger et al. 2018).

The Objectives

Specifically, the chapter:

(i) Gender analyzed the dimensions of climate change impacts
(ii) Identified the indigenous and expert-based artificial adaptation strategies
(iii) Assessed the gender differences in the adaptation strategies
(iv) Provided the gender implications of the indigenous adaptation strategies among actors along the Agriculture Value Chain (AVC)

The Theoretical Framework: Gender Response Theory (GRT)

Gender Response Theory – GRT propounded by Deji (2019) is the adopted theory in this chapter. Gender Response Theory states that males respond to stimuli (push or pull factor) by substitution while females respond by addition. And that male's response is usually more prompt than the female's, based on higher economic and social potentials.

Pull factors include positive and attractive forces such as new technology/innovation/idea/knowledge, to mention a few. Push factors include negative/repelling/adverse situations or circumstances such as climate change/variability, conflicts, poverty, ill-health, natural disaster, to mention a few.

GRT propound that usually male will respond to stimuli by substitution (replacing the old with the new). In contrast, females will often respond by addition (building on the existing local conventional or currently adopted knowledge/innovation/technology, to mention a few).

GRT was proven at four main levels of response, namely:

(i) Knowledge (indigenous and expert-based) – socialization, awareness, evaluation
(ii) Attitude (cognitive, affective) – interest, willingness

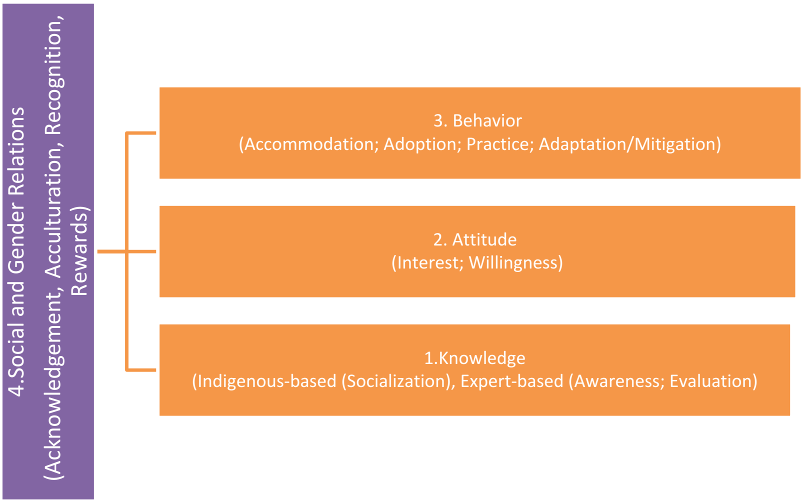

Fig. 1 Operational model of Gender Response Theory – GRT (Deji 2019)

(iii) Behavior (utilization of the knowledge as improvement or defensive/risk aversion strategy) – accommodation, adoption, practice, and adaptation/mitigation
(iv) Social and gender relations (responsibility, role, participation, engagement, decision-making, agency) – acknowledgment, acculturation, recognition, rewards (Fig. 1).

GRT confirms gender differences in the human response to stimuli (pull or push factor). The theory affirms that: the indigenous knowledge is a common asset to both male and female; males are likely to substitute their indigenous knowledge for new/modern/scientific/expert-based knowledge, while the females are likely to add the new knowledge to the indigenous knowledge; males are likely to respond to new knowledge/innovation/technology more promptly than the females; and that the economic and social relation potentials, especially the decision-making power, influence the promptness of the male's response to (adoption of) the new knowledge/innovation/technology, to mention a few.

Climate change is a push factor in agriculture, with significant impacts on rain-fed agriculture that characterizes most developing nations like Nigeria. Male and female are involved in activities along the AVC; climate change has implications along the AVC and may have gender dimensions as pounded by the Gender Response Theory. Logically, the male and female AVC actors will respond to climate change/variability impacts more or less differently. Hence, GRT is the adopted theoretical framework for this chapter.

The following narrative sections in this chapter are textual, qualitative, and secondary data, originated from field experience and literature through rigorously digested knowledge and established information from the author's field experience of over 20 years, covering all the ecological regions in Nigeria.

Agriculture Value Chain (AVC)

Agriculture Value Chain comprises interrelated activities and actors at different nodes from the point of decision and sourcing for inputs to the final stage when the agricultural product is processed, distributed, and consumed by the end users. The value chain in this chapter focused on crop cultivation (Fig. 2). Although the content of the activities may vary within different agricultural crop enterprises, they have many similarities.

1. Inputs: Includes finance, land, labor, tools and machines, seeds and seedlings and plant cuttings, chemicals, membership of agricultural associations and networks, extension and advisory services, training on required knowledge and skills, to mention a few. Required activities are sourcing, acquisition, transportation, storage, repair and maintenance, participation, to mention a few.
2. Land preparation: Includes activities such as land clearing, harrowing, landscaping, ridging, nursery bed construction, laying of irrigation pumps, to mention a few.
3. Planting: Planting/sowing, transplanting, grafting, budding, to mention a few.
4. Cultivation: Includes activities to enhance the germination and growth of the planted materials. It includes weeding, thinning, supplanting, staking, mulching, wetting and irrigation, fertilizer, and chemical applications, pest controls, transportation, to mention a few.

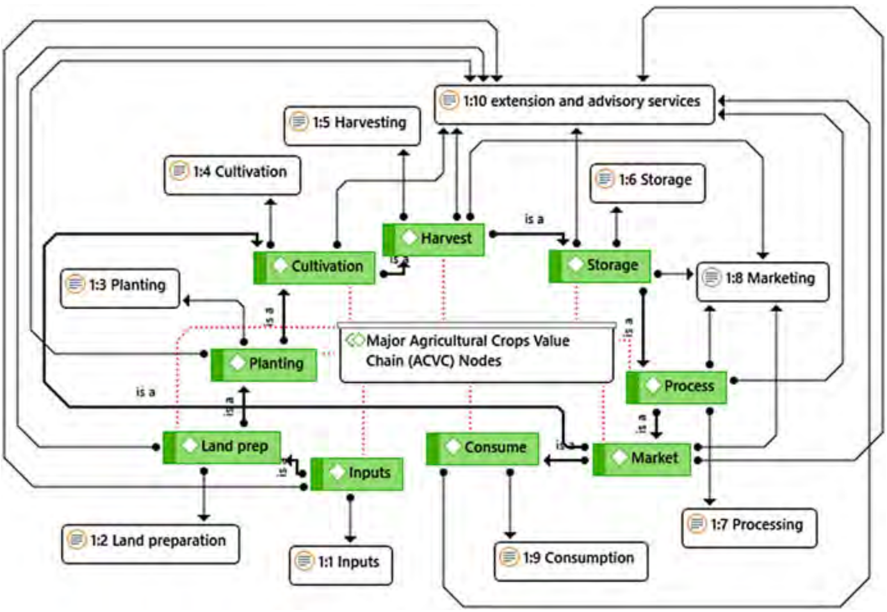

Fig. 2 Agriculture Value Chain (AVC) – Crops (Source: Deji 2019)

5. Harvesting: Harvesting, packing, transportation, marketing, consumption, to mention a few.
6. Storage: Packing, loading, transportation, application of preservatives, cleaning, and preservation, to mention a few.
7. Processing: Transportation, conventional processing, value-addition, packaging, labeling, to mention a few.
8. Marketing: Transportation, packaging, selling, buying, record keeping, savings, advertisement, to mention a few.
9. Consumption: Purchasing, transportation, preparation, cooking, value addition, packaging, distribution, storage, to mention a few.

Gendered Dimensions of Climate Change Impacts Along AVC

Figure 3 shows the significant indicators of climate change and variability as experienced in Nigeria, such as irregular rainfall pattern and quantity; fluctuation in temperature; and increase in wind and storm intensity. Furthermore, Fig. 1 indicates the primary and secondary impacts of climate change and variability. The significant consequences include decrease in rainfall/water shortage; irregular temperature fluctuation; dry weather; decline in soil moisture and fertility; an increase in drought incidence; and a rise in flood incidence.

The secondary impacts have two dimensions along the AVC, such as (1) production and economical and (2) social and gender relations. The dimension of production and economical includes inappropriate planting periods; low and poor yields; loss of species; decrease in agro-biodiversity; increase in epidemics; and increase in postharvest losses. The social and gender relation impacts dimension encompasses the reordering in social and gender roles and relations along the AVC.

Figure 4 shows the significant impacts of climate change indicators such as irregular rainfall pattern and quantity, flooding, rise in temperature, and wind storms at each of the seven nodes along the AVC.

1. Input node (access and utilization): Climate change impacts are: scarcity of some inputs such as fertilizer due to the high rate of damages done by heavy rainfall and high temperature. Poor quality of some inputs such as seedlings due to temperature and rainfall fluctuations; increase in the cost of production arising from spending more money and time; and high rate of damages/breakdown and difficulty in using farm machinery.
2. Land preparation: Major climate change impacts include unfavorable soil moisture and texture; loss of topsoil; increase in frequency of land preparation activities such as plowing and harrowing due to an increase in the rate of weed growths; and increase in cost.
3. Planting: Unpredictable planting time resulting to early and delay planting; repeated planting and thinning; utilization of more planting materials and resources like time, money, and labor; increase in wastages of resources like time, money, and labor; and higher pressure on the land leading to soil hardening and loss of fertility.

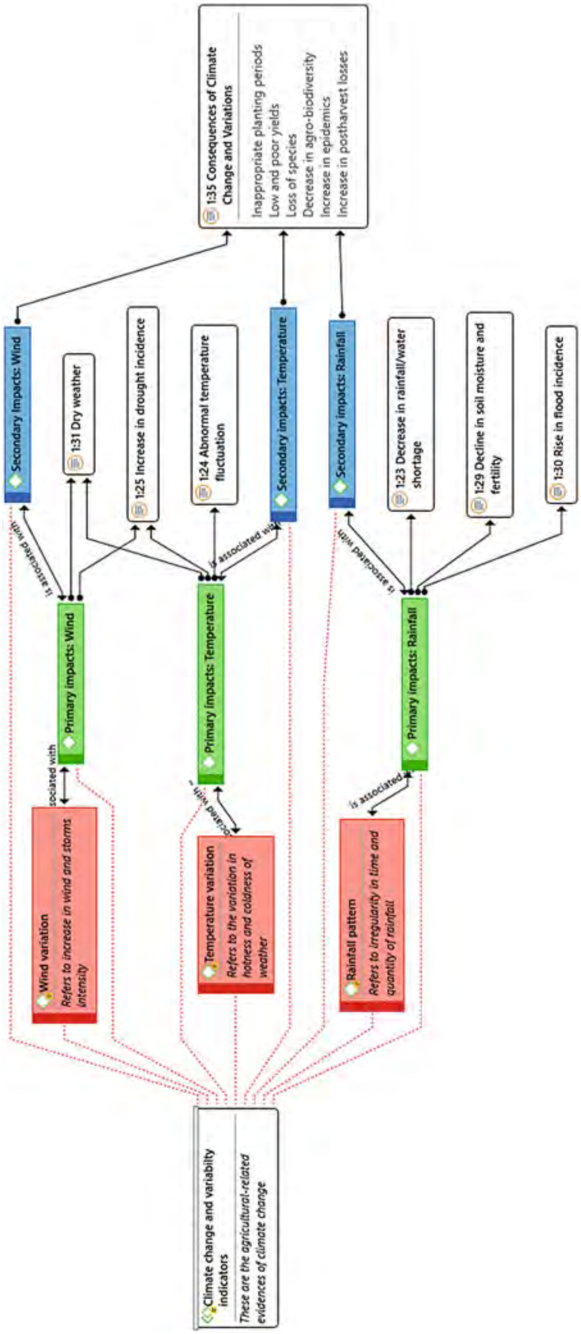

Fig. 3 Climate change and variability indicators. (Source: Deji 2019)

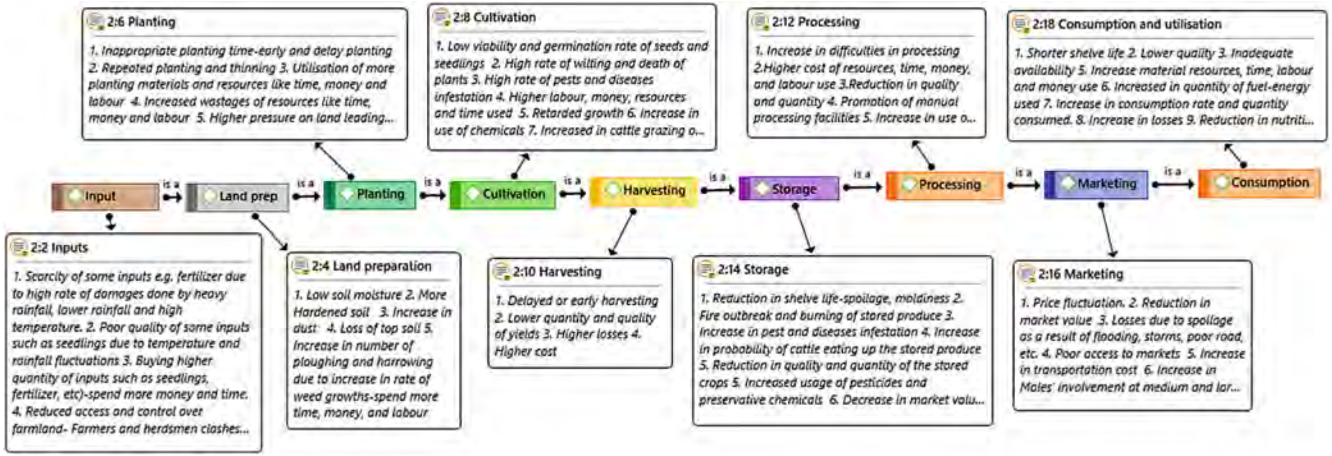

Fig. 4 Climate change impacts along Agriculture Value Chain (Source: Deji 2019)

4. Cultivation: Climate change influences low viability and germination rate of seeds and seedlings; plant growth retardation; high rate of wilting and death of plants; high rate of pests and diseases infestation; higher cost in forms of labor, money, resources, and time used; increase in use of chemicals; and increase in cattle grazing on the crops/farmland.
5. Harvesting: Climate change influences delayed or early harvesting, lower quantity and quality of yields; higher losses; and higher cost of harvesting.
6. Storage: Climate change significantly contributes to the reduction in shelf life of farm produce. It contributes to increased fire incidence and burning of stored produce, increase in pest and disease infestation, increase in the probability of cattle eating up the stored produce, and reduction in quality and quantity of the stored farm produce. It enhances the usage of pesticides and preservative chemicals; and decrease in nutrient and market value.
7. Processing: There is an increase in difficulties in processing farm produce; higher cost; reduction in quality and quantity of finished farm products; and promotion of manual processing facilities. It increases the use of preservatives and other chemicals.
8. Marketing: There is an increase in price fluctuation; reduction in market value; loss; poor access to markets; increase in transportation and other costs; increase in males' involvement at medium and large-scale marketing.
9. Consumption and utilization: At the household level, climate change influences shorter shelf life. It enhances low quality, inadequate availability of food materials; increase in cost of food preparation and readiness; increase in consumption rate and quantity consumed; increase in losses; and reduction in nutritional benefits, meal/food security.

Factors Influencing the Vulnerability of Agriculture in Nigeria to Climate Change Impacts

(i) Rain-fed agriculture
(ii) Subsistence farming
(iii) Gendered division of labor and access to resources
(iv) Lack or inadequate social insurance for farmers
(v) Unfavorable gender norms against women who are the major workforce
(vi) Patriarchal culture: practiced as males' domain
(vii) No formal insurance plan for farmers
(viii) Small scale and low literate by majority
(ix) Low awareness of the agriculture-based sources of greenhouse gases (GHG) among the farmers
(x) Limited modern effective adaptive and mitigation capability
(xi) Limited access to scientific meteorological information and technologies
(xii) Inadequate political will and enabling environment for climate smart agriculture

Gendered Indigenous Climate Change Adaptation Strategies Along Agriculture Value Chain

Climate change and variability impact are not gender neutral; they affect both males and females differently. There are complex and dynamic links between climate change and gender in terms of vulnerability to the adverse impacts of climate change and adaptation to climate change. Within countries, vulnerability to climate change impacts links to poverty and economic marginalization (UNDP 2014).

Adaptation is a process by which individuals, families, communities, and countries minimize the negative impacts of climate change and variability on their socioeconomic livelihoods. It means the strategies or methods adopted in coping with the threats resulting from the unavoidable climate change and variability impacts. On the other hand, mitigation means actions, practices, steps taking or adopted to reduce the greenhouse gases (GHG) in order to minimize their effects on global warming.

Indigenous adaptation strategies are the traditional conservative knowledge, experience, and practices that are products of repeated activities, communicated from parents and elders to younger ones through the socialization process, adopted as coping strategies to reduce the vulnerability and impacts of climate change. Indigenous adaptation strategies for alleviating the climate change impacts on agriculture and AVC actors' livelihood varied basically on the gender roles (direct and indirect) along the AVC. Indigenous adaptation and mitigation strategies are products of the repeated process of informal *observation, trial, experimentation,* and *validation,* which naturally promotes/popularizes the indigenous knowledge, experiences, and practices over time.

Roles are responsibilities carried out or performed by the primary or secondary owner of the responsibility. Gender roles are activities carried out or performed by an individual based on his/her sex as constructed by the norms and values of the society.

The concept of gender roles is significant and most applicable in agriculture discipline, because it helps to understand that some activities are carried out by individuals outside the assigned responsibilities as constructed in the norms and values of the society (Figs. 4a–e). Direct gender role refers to the activity personally carried out by an individual based on his/her sex as determined by the norms and values of the society. Indirect gender roles are activities carried out by a male or female (paid or free of charge) on behalf of another person, which may not necessarily be according to the norms and values about gender roles in the society.

Climate change significantly influences gender roles along the AVC (Figs. 5a–e). As a response to the negative impacts of the climate change on agriculture productivity along the value chain and the general livelihoods of the farm household, there are observed dynamics of roles between the male and female AVC actors. Such gender role dynamics include role delegation, role diversification, role commodification, and role intensification.

The dominant indigenous adaptation strategies among the AVC actors in Nigeria are as follows:

1. **Preproduction phase:** Bulk purchase of inputs at the group level, bush fallowing, zero tillage, fragmented planting, late and early planting, and land intensification
2. **Production phase:** Mulching, thinning, supplanting, manual irrigation, nursery and transplanting, organic fertilizer and micro-dozing application, staking, use of local herbs, mixed cropping, multi-cropping, crop rotation, mixed farming, dry season farming, traditional greenhouse farming, crop diversification, varying planting dates, increase in irrigation, soil and water conservation techniques, shading and shelter, and shortening the length of the growing season
3. **Harvesting phase:** Early/late harvesting, fragmented/installment/selected harvesting, on-farm sales of fresh crops, harvesting fresh
4. **Storage:** Air drying, sun drying, heat drying, e.g., over kitchen roofs, application of pepper, storage under the roof, over the kitchen, in gourds, earthen pots, storing below room temperature overnight on the roof, to mention a few
5. **Processing:** Value addition, repackaging to enhance economic value, group purchase of materials
6. **Marketing:** Online marketing, e.g., mobile phone, group-marketing of produce, value-addition, selling on the farm and at the farm gate, direct sales to bigger companies and consumers
7. **Consumption:** Avoiding bulk purchase, cooking what can is consumed at once, storage of used water for other purposes

The Indigenous and Expert-Based Artificial Adaptation Strategies

Male and female farmers and other value chain actors acquired indigenous adaptation and mitigation intelligence/strategies through experiences and socialization. The indigenous intelligence/strategies are popular local knowledge asset bases among the African AVC actors because they are available, cheap, and simple to understand and practice with limited gender discrimination. The indigenous adaptation intelligence/strategies are products of informal, unregulated observations, experimentations, and validation.

The indigenous knowledge/intelligence/strategy is different from the expert-based human intelligence (e.g., through extension agency) and the artificial intelligence (human-embedded machine intelligence). The indigenous knowledge/intelligence/strategy is not regulated, lacks accuracy, hence not usually efficient and effective.

There was low awareness and adoption of expert-based/artificial intelligence-based climate-smart agricultural/adaptation strategies. It may be due to their inherent low cultural compatibility, high cost, inadequate availability, gender limitation, and complexity that require high technicality and competence.

The indigenous adaptation strategies have the potentials to provide an enabling environment that could enhance the popularity and adoption of artificial intelligence

Fig. 5 (continued)

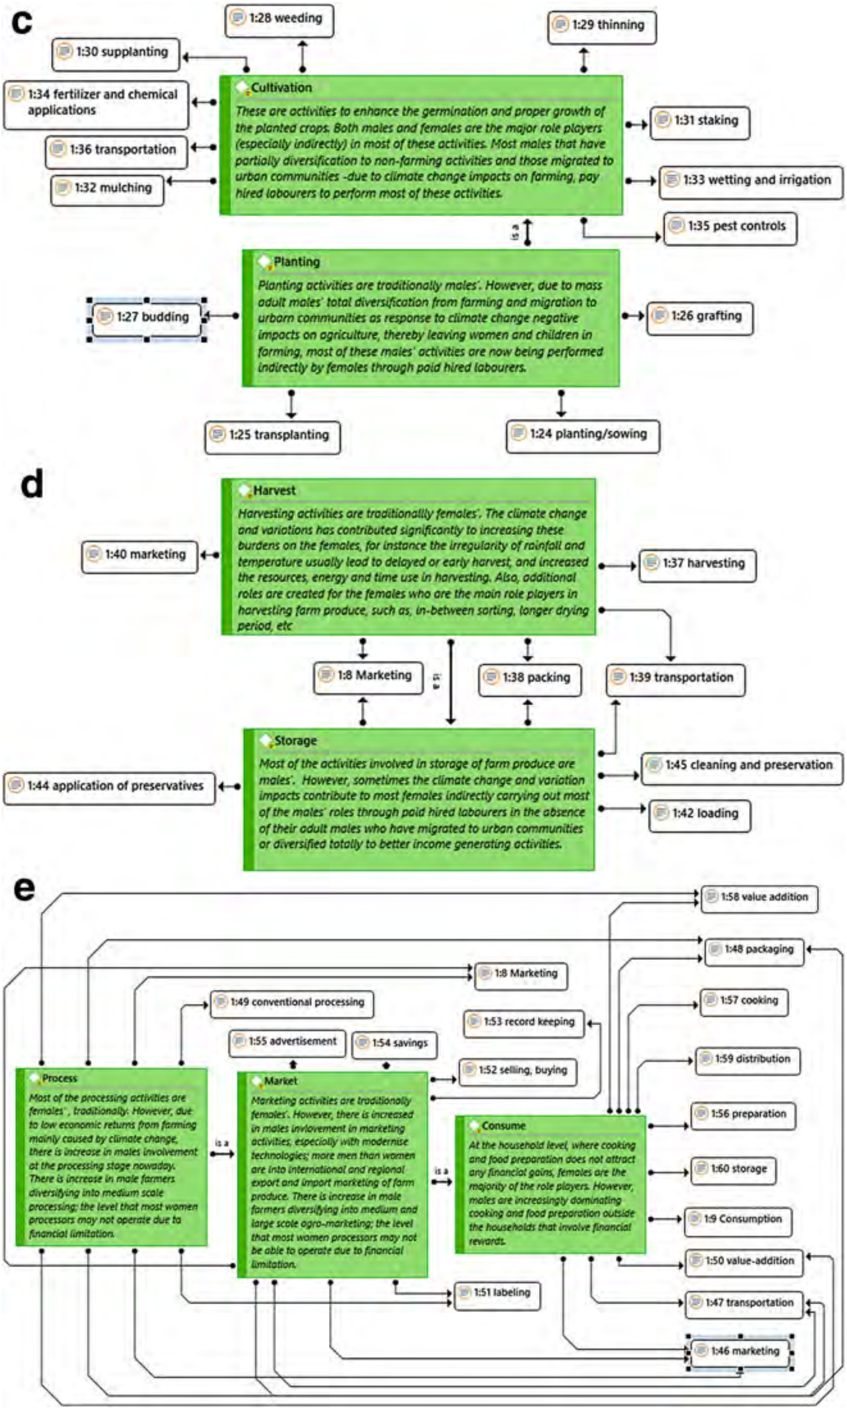

Fig. 5 (continued)

(AI) if adequately integrated. However, adequate integration will require an interdisciplinary scientific reinvention process that engaged both male and female AVC actors and the extension professionals (expert-based human intelligence).

Gendered Indigenous Adaptation Strategies to Climate Change/Variability

The popular indigenous adaptation strategies among Nigerian male and female AVC actors are in two categories: (i) resource-based indigenous adaptation strategies and (ii) relation-based indigenous adaptation strategies. Resource-based indigenous adaptation strategies target the factors of production-related adaptation strategies, such as land, finance, labor, and time (Fig. 5). The relation-based adaptation strategies focus on social capital and relations. The resource-based and relation-based indigenous adaptation strategies are:

1. **Land**: *Land fragmentation* for *multi-cropping* and *mixed farming*; *land commodification*: sales of farmland for money; *land intensification*: repeated cultivation on farmland leading to *shorter fallow period*; intensive practice of *inorganic soil fertilization and conservation* methods; and *land use diversification*: using the farmland for nonagricultural income-generating activities.
2. **Finance:** *Financial diversification*: investing financial resources in other income-generating activities such as farming and nonfarming activities; *multiple sources of finance*: to increase financial stability and security; increase in *contract farming*: an organization supplied farmers all essential inputs to produce certain crops that will be purchased in kinds by the organization; and *community-based cooperative or group saving, credit, and loan system.*
3. **Labor:** *Migration* of nondisabled males (spatially migrating from farming communities to urban cities in search of alternative sources of income, or livelihood-wise migration to other jobs, especially, nonagricultural income activities); *use of family and child labor*; *livelihood diversification* to other activities along AVC (for example, a crop farmer diversifying into retailing/marketing of farm produce) or to nonfarming activities; and increase in use of *hired labor*, especially to carry out strenuous and abandoned agricultural activities.
4. **Soil conservation management practices:** Most of the indigenous soil conservation management measures are both adaptive and mitigating in nature, e.g.,

Fig. 5 **(a)** Climate change impacts on gender roles along Agricultural Value Chain – input node. (Source: Deji 2019). **(b)** Climate change impacts on gender roles along Agricultural Value Chain – land preparation node. (Source: Deji 2019). (**c**) Climate change impacts on gender roles along Agricultural Value Chain – planting and cultivation nodes. (Source: Deji 2019). (**d**) Climate change impacts on gender roles along Agricultural Value Chain – harvesting and storage nodes. (Source: Deji 2019). (**e**) Climate change impacts on gender roles along Agricultural Value Chain – processing, marketing, and consumption nodes. (Source: Deji 2019) agroforestry. *The fallow system* encourages forest development; the forest is a carbon sink. *Agroforestry* is effective in carbon sequestration; it is a rational land use planning system that tries to establish a balance in food crop cultivation and forestry, leading to an increase in organic matter in the soil, which indirectly reduces the pressure exerted on forests. *Bush fallowing*: the use of natural fallows – leaving the land uncultivated for more than 2 years to regenerate or restore soil fertility to regenerate or restore soil fertility. *Organic manure application*: the application of compost, animal waste, and domestic wastes to the soil to maintain soil microbial activities and promote absorption of nutrients by plants. *Intercropping*: cultivation of more than one type of crop on a piece of land at the same time to reduce the risk of total crop loss/failure as well as providing good soil cover that minimizes soil erosion. *Conservation tillage*: minimal or no disturbance of soil; minimum or zero tillage; to respond to rapid soil deterioration and degradation caused by conventional tillage under harsh weather induced by climate change and variation.

5. **Water conservation/management practices:** *Rain harvesting* in pits and wells, barrels, to mention a few; *reuse of used water*; *rehabilitating degraded land*, planting of *drought-resistant crops* such as cassava, sweet potatoes, indigenous finger millet, to mention a few.
6. **Crop and farm management measures (risk-aversion practices):** Most farmers in developing countries like Nigeria do not enjoy formal insurance for risk aversion on their farms. Instead, they employ indigenous crop and farm management measures as climate change adaptation strategies, including *fragmented planting and harvesting; mixed cropping; multi-cropping; multiple investments; group farming; contract farming; decentralized or dispersed farming* – farming in one than one location at a time.
7. **Social capital/relation conservation measures:** Along the AVC, most male actors adapt to the unfavorable economic consequences of the climate change impacts through *role delegation; role commodification; role diversification; child commodification/child labor*; *rural-urban migration*: total or partial, economic or spatial, dual residency; and *livelihood diversification* to nonagricultural-related activities (vertical). *Role delegation* is a practice whereby most men delegate (substitution) their farming and family roles to the females, leading to extra burdens (addition) on the females' time, energy, and resources (Gender Response Theory). *Role commodification* means the strategy whereby most male AVC that have partially migrated or diversified to other jobs pays someone else to carry out their agricultural roles on their farms. *Child commodification* refers to the practice of exchanging children for money or material resources.

   Horizontal role dynamics (by substitution) is popular among the males, while *vertical role dynamics* (by addition) is predominant among the female AVC actors. However, in livelihood diversification, male AVC actors diversify more into nonagricultural-related activities (*vertical livelihood diversification)*. In contrast, the female AVC actors diversify mostly into agricultural-related activities (*horizontal livelihood diversification*) (Fig. 6).

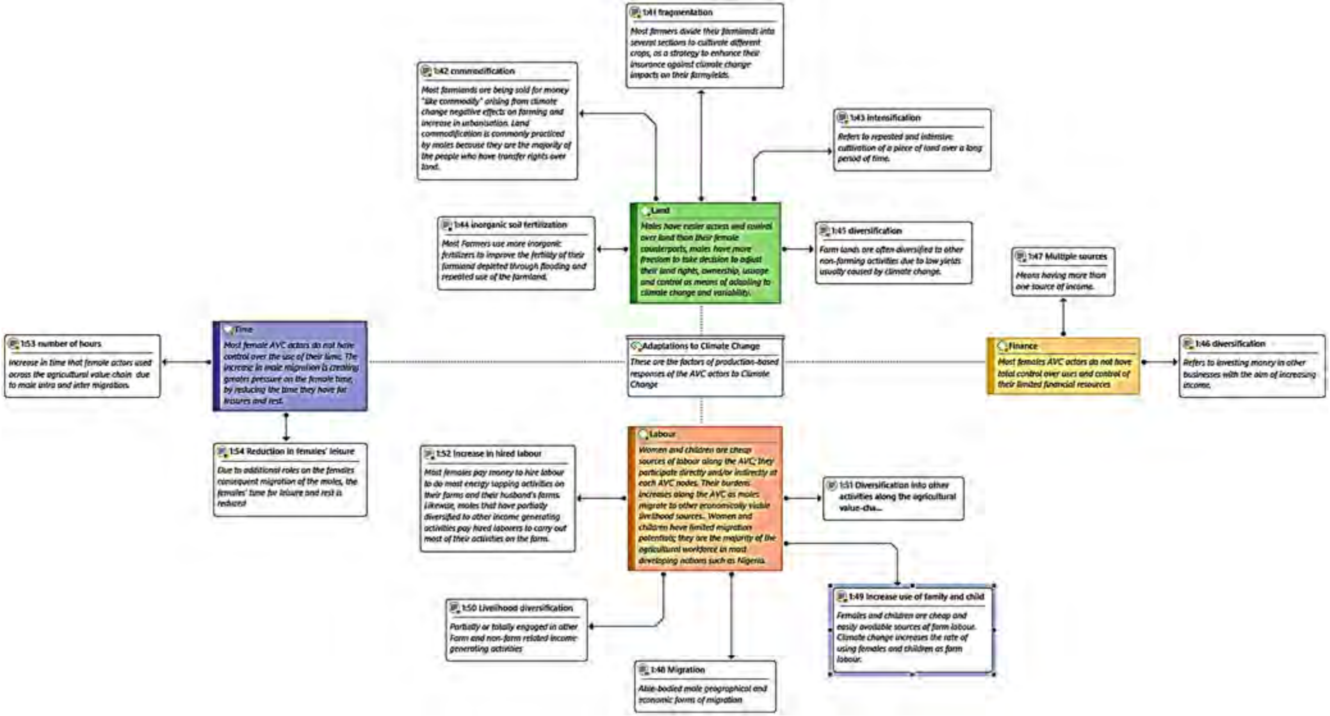

Fig. 6 Gendered resource-based adaptation strategies to climate change impacts. (Source: Deji 2019)

Indigenous Early Warning Meteorological Adaptation Strategies

Most farmers in Nigeria do not have adequate access to scientific meteorological information; they often depend on their indigenous early warning strategies. In the face of growing climate change that makes accurate prediction of weather and weather forecasting very difficult, most farmers continue with their indigenous early warning knowledge as adaptation strategies to the climate change impacts.

The indigenous meteorology practices on early warning measures and knowledge are products of years of farming experience and acquired knowledge from parents and elders in the farming communities (Table 1). Most scientific meteorology knowledge is costly and requires technical skills to understand and adopt. On the contrary, indigenous meteorology practices are readily available and straightforward to understand and adopt by an average African farmer characterized by low literacy and socioeconomic power.

Gender Implications of the Indigenous Climate Change Adaptation Strategies

Climate change is a significant threat to agricultural productivity and profitability, especially in a rain-fed agricultural nation like Nigeria. There is an increase in poor

Table 1 Some common African indigenous early warnings and weather prediction. (Source: Deji 2019)

Indigenous early warning	Weather prediction
1. General yellowing and falling of tree leaves	Onset of Harmattan season (winter)
2. Flowering of the peach tree (*Prunus persica*)	It is time to plant
3. Blooming of pear flower (*Pryus communis*) *or* roses (*Rosa damascene*)	Time to plow
4. Regular chanting of red-chested birds (*Cuculus solitaries*)	Time to plant regardless of the season
5. Half-moon facing east/full moon/rainbow on the sky	No rain to come
6. Increase in pests	More rain to fall
7.Increase in worms in the subsoil/surface of the soil	Season of summer and excessive rain/high water table/flooding possibility
8. Increase in frogs	Onset of thunder storms
9. Fruiting of brandy bush tree (*Grewia flava*):	
(a) Fruiting between November and December before the first rain in the year	Scanty or low rainfall
(b) Fruiting between February and March	Abundant rainfall
(c) No fruiting throughout the year	Drought
10. Flowering and fruiting of shepherd tree (*Boscia albitrunca):*	
Flowering and fruiting before the first rain	Year of abundant rainfall

agricultural yield leading to social and financial insecurity, reduction in farm-based income, and economic instability of the farm households. Indigenous adaptation strategies are commonly used among the AVC actors to reduce the negative impacts of climate change on their livelihoods. However, most of the indigenous adaptation strategies have implications on the social and gender relations, especially at the household levels, including:

1. Role: There is an increase in adult males' migration and diversification to nonagricultural income activities; female actors are more prominent at all the nodes along the AVC. Along the AVC, there is the high mobility of males from the production phase to the marketing phase, which promised better economic gains.
2. Reordering of social and gender relations: The male actors' spatial (rural-urban) and livelihood (from agriculture to nonagriculture) migration trend initiated by climate change is creating reordering of social and gender relationships within the farming households. Female AVC actors are increasingly occupying the spaces left along the AVC by most migrated males. Hence, there is an increase in females' involvement in decision-making, especially at the household level. Likewise, there is an improvement in females' access and control of resources at the household level.
3. Responsibility: There is an increase in responsibilities of and burdens on the female AVC actors. There is an increase in child labor and commodification (both males and females). Women and girls wake up early to fetch water for food preparation and irrigation of crops before herds come around the water to satisfy their increasing thirst due to an increase in temperature caused by climate change (which often results in herdsmen/farmers' conflict). Consequently, there is a reduction in the resting period for the females, which, in the long run, has negative health implications.

Conclusions

Climate change has the potentials to increase the vulnerability of the poor. The unfortunate situation and conditions of most agricultural value actors, especially the females, exposes them to negative phenomena and make them hard-bitten. Climate change impacts are felt more on the poor living in the rain-fed regions such as Nigeria. The chapter confirms that:

1. Agriculture in Nigeria is rain-fed in nature; hence it is significantly impacted negatively by climate change and variability.
2. Climate change is threatening the livelihoods of Nigeria Agriculture Value Chain (AVC) actors, the majority of whom are the female small-scale holders with limited access to scientific expert-based adaptation and mitigation practices, hence increased food insecurity and poverty.

3. The female AVC actors are mostly affected by the climate change impacts due to their domestic and cultural roles, limited migration potentials, and the discriminating gender norms that limited their easy access and control over production resources and decision-making.
4. More of the female than male AVC actors experience difficulty in accessing resources due to gender discrimination and gender irresponsive policies and criteria dictated by the traditional and legal norms in the society.
5. Climate change and variability are influencing the reordering of social and gender relations among the AVC actors, especially at the household levels, most of which have implications for women empowerment and gender equality.
6. The indigenous adaptation strategies are different from the expert-based human intelligence (provided through extension service) and the artificial intelligence (machine intelligence); the indigenous intelligence is not regulated, lack accuracy, and hence not efficient and effective.
7. The low awareness and adoption of artificial intelligence-based climate-smart agricultural/adaptation strategies among the AVC actors were due to their low cultural compatibility, high cost, inadequate availability, gender limitation, complexity that requires high technicality, and competence.
8. Both male and female AVC actors adopted indigenous adaptation strategies because they were culturally compatible, available, low cost, and simple to understand and apply, while expert-based artificial adaptation strategies were not common among the AVC actors.
9. Mobility, especially rural-urban, was a typical indigenous adaptation strategy among the male AVC actors. Females have limited mobility/migration potentials being the dominant workforce in the domestic and caregiving services, especially at the household level.
10. Role commodification, role diversification, role delegation, and land commodification were popular strategies among males.
11. Horizontal role dynamics (by substitution) were most common among the male AVC actors, while the vertical role dynamics (by addition) were most common among the female AVC actors as indigenous adaptation strategies to climate change. In response to climate change and variability impacts, there was significant role-based social mobility (vertical and horizontal) within each AVC node among the male and female value chain actors.
12. Most male AVC actors adapted to climate change and variability by substituting activities and roles along the AVC and diversifying, mostly, into nonagriculture livelihood sources. On the contrary, most female AVC actors adapted to climate change and variability by taking up additional activities and roles (role intensification), usually within the agricultural value chain, as confirmed by the "Gender Response Theory – GRT."
13. According to Gender Response Theory, indigenous knowledge/ strategies could provide an enabling environment for the sustainable adoption of modern artificial knowledge and strategies.
14. The theory further reveals that males are more likely to substitute new knowledge/strategies for their indigenous adaptation knowledge/strategy, and adapt

faster than the females due to their higher economic and decision-making potentials. However, a response by addition (females' response) is usually more sustainable than a response by substitution (males' response).

15. Climate change is challenging social relations, especially at the household and community level. Examples are an increase in conflict between herdsmen and farmers, land-based conflicts, and child commodification.
16. Climate change is challenging the gender relations; female AVC actors are increasingly prominent and active in most activities along the AVC and decision-making and agency at the household and community levels due to the prevailing migration and livelihood diversification among active-aged males.

Recommendations

Intervention programs and expert-based/artificial intelligence technology for climate change adaptation that will effectively enhance food security must recognize the indigenous strategies, knowledge, experiences, and practices, of the male and female AVC actors. Such programs must have in-built potentials to improve the social and economic situation and conditions as well as reduce the stress and burdens of the female actors along the AVC.

Furthermore, the male or female gender group is not homogenous on the bases of social variables such as age, education, ethnicity, social and economic status, marital status, family size, to mention a few. By implication, there might be variations in climate change impacts within each gender category at the different nodes along the AVC. Hence, there is a need for further gender analysis in AVC research using the intersectionality concept and methodology to enhance the inclusive understanding of the impacts and adaptation strategies within each gender group.

Also, research on climate change/variability must adopt an interdisciplinary approach using gender analysis methodology and theories for an inclusive understanding of the experiences and adaptation strategies among the different categories of the male and female AVC actors.

Abstract

The threat of climate change and global warming is gaining worldwide recognition. The African continent, because of its size, diversity, and its new status as a "hub" of livestock production, need to gear up to mitigate the possible impacts of climate change on animal health. The aim of this review article is to summarize the current state of knowledge regarding the influence of climate and climate change on the health of food-producing animals. Depending on its intensity and duration, heat stress may directly affect livestock health by causing metabolic disruptions, oxidative stress, and immune suppression, causing increased disease susceptibility, and death. Animal health could also be affected by emergence and re-emergence of vector- and non-vector-borne pathogens that are highly dependent on climatic conditions. The response to these challenges requires community participation in the adaptation of animal production systems to new environments and strengthening the efficiency of veterinary services delivery combined with well-coordinated public health services, since many emerging human diseases are zoonotic.

Keywords

Global warming · Extreme weather · Livestock vulnerability · Adaptation strategies

Introduction

Agriculture serves as the backbone of the economy of most African countries and is the largest domestic income producer. Moreover, it employs about 70–90% of the total working population (Chauvin et al. 2012). Interestingly, this sector supplies up to 50% of household food demand in addition to their income. The livestock subsector provides over half of the value of global agricultural output and one-third in developing countries in Africa. The demand for livestock products in the developing countries is increasing with increasing human population (Steinfeld et al. 2006). However, the livestock subsector is highly susceptible to extreme climate variability. The effect of climate change is anticipated to heighten the susceptibility of livestock production systems to emerging and re-emerging diseases. Climate change is arguably the most important environmental issue currently affecting the livestock sector, but also ecological systems, peoples' livelihoods, and species survival (Zougmoré et al. 2016). Documented effects of climate change are: increasing number of warmer days and nights in a year; changes in rainfall pattern and volume; longer summer seasons; rising sea-levels; and increasing frequency and intensity of floods, droughts, and heat waves (Field et al. 2012; Hughes 2003). Several African governments and regional organizations are aware that increasing demand for livestock products in Africa is not matched by similar growth in local livestock production and are working towards addressing this mismatch in order to reduce dependence on imports.

Unfortunately, there is a lot of emphasis on the impact of climate change on crops in global discussions on climate with little attention paid to livestock production. There is urgent need for a paradigm shift, since it is a fact that even when there is severe crop failure, indigenous livestock have helped vulnerable communities to survive. However, the resilience of indigenous livestock is also threatened by various factors, including extreme climate variability coupled with indiscriminate cross-breeding. With climate change taking the center stage, there is merit in developing indigenous livestock due to their ability to adapt to stressful environments.

The risks associated with unmanaged livestock production in the face of climate change are causing decision-makers in Africa to raise a number of questions such as: What kind of policies would expand livestock production and give societies equal benefits? What is the best way to ensure good health for the people? What choices can ensure that livestock production is socially, biologically, economically, and climatically sustainable? Therefore, the objective of this chapter is to provide some answers to these questions by reviewing the impact of climate change on livestock production, emerging and re-emerging diseases, and adaptation strategies.

Africa's Current Climatic Zones

Climate is a long-term pattern of weather, which is the sum of sunshine, temperature, rainfall, and wind. The amount of heat from the sun plays a significant role in determining climate. The equator cuts across the center of Africa, making it the most tropical continent in the world with different regional climatic conditions (Cooper et al. 2008). The northern to north-eastern parts of the continent and the south-western part of southern Africa have hot and dry climate with unreliable summer rainfall and arid to desert landscape (Gasse 2000). Countries along the equator experience warm and humid climate with heavy summer rainfall for most part of the year and characterized by tropical rain forests. The tropical but not equatorial regions have warm and moist climate with summer rainfall and savanna vegetation. Small areas at the northern and southern tips of Africa have Mediterranean climate, characterized by hot, dry summers and cool, wet winters.

Most of the rain in Africa occurs in the middle of the continent in the north-west to south-east direction (Fig. 1). The influence of cool-drier south-westerly prevailing

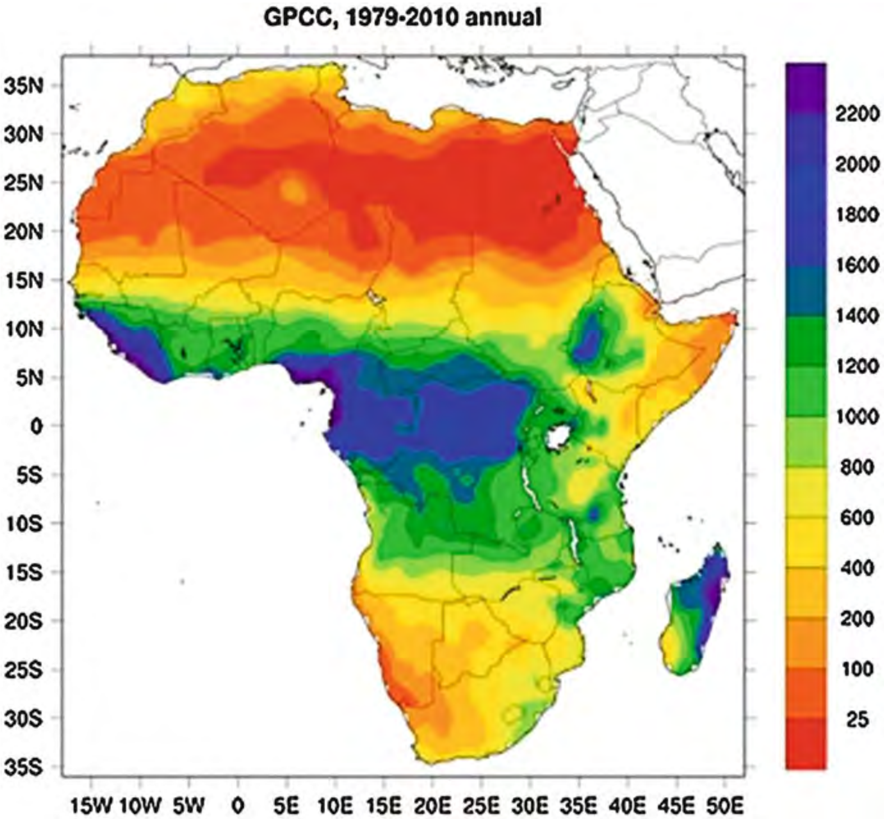

Fig. 1 Map of Africa showing annual average rainfall (mm) averaged between 1979 and 2010. (Siebert 2014)

winds reduces rainfall in the south-western part of Africa while the hot-drier north-easterly trade winds reduce rainfall in the north to north-east Africa.

Expected Impacts of Climate Change on Livestock Production and Health

Africa's contribution to global warming is low while the people living in Africa may be hit hardest by its impact. The overall impact of climate change on animal production and health is far greater than, a mere increase in average annual temperature. The effects of climate change on animal health may be direct or indirect. The direct effects are mainly due to changes in environmental conditions such as air temperature, relative humility, precipitation, drought, and floods (Lacetera 2019). These environmental conditions are responsible for temperature-related animal morbidity and mortality. Indirect effects of climate change on animal health and production are due to microbial density and distribution of vector-borne diseases, food and water shortages, or foodborne diseases (Lacetera 2019). The impact is characterized by: reduced feed quantity and quality; reduced feed intake; water scarcity; increased frequency and severity of diseases and deaths; poor growth rate; decreased quantity and quality of meat and milk; poor reproductive performance; increased costs for disease control and animal production (Thornton et al. 2009). All these culminate into decreased animal health and productivity, decreased animal welfare, and reduced income for affected communities and countries at large.

Vulnerability of Livestock Production Systems to Climate Change

Resilience to the impact of climate change depends on the vulnerability of affected animals and communities. Such vulnerability is the degree to which African livestock production systems are susceptible or incapable of coping with the adverse effects of climate change. In general, developing countries are more vulnerable to the impacts of climate change because they are exposed to many challenges at any time and have limited capacity to adapt. The African livestock sector is particularly vulnerable because of variability of climate, existing disease burdens, culture and economic circumstances, strong dependence on natural resources, weak infrastructure, institutional weaknesses, political and social instability (Thornton et al. 2007).

Direct Effects of Climate Change on Animal Physiology: Metabolic Alterations, Suppressed Reproduction, Oxidative Stress, Immune Suppression, Morbidity, and Mortality

New et al. (2006) analyzed the daily maximum and minimum temperatures and precipitation data from Southern and West African countries for the period 1961–2000. They found a consistent trend of increasing number of hot days and nights and decreasing extremely cold days and nights. Heat stress can occur in animals when a combination of animal and environmental factors increase body heat beyond the normal range (Young 1993). Cattle respond to acute periods of excessive heat in many ways, including decreased feed and increased water intake and increased respiratory rate (Gaughan et al. 1999). On the other hand, Beatty et al. (2006) showed that *Bos taurus* cattle experienced significant physiological changes while similar but less pronounced changes were experienced by *Bos indicus* but without a decrease in feed intake, when exposed to prolonged heat and humidity.

Heat stress due to fluctuating environmental temperatures that exceeds the thermoneutral zone for an animal is the most common stressor that can cause physiological, endocrine and immune responses that may lead to morbidity and reduced animal production (Carroll et al. 2012). Similarly, there was an increase in oxidative stress in dairy cows during the hot season (Tanaka et al. 2007). An increase in oxidative stress has been shown to increase the pathogenesis and severity of many diseases (Halliwell and Gutteridge 1990).

Thus, direct effects of climate change on livestock physiology are observed through the increase in heat stress and have been shown to reduce resistance to diseases and reduce reproductive efficiency and productivity in general. However, heat-tolerant local animals easily adapt compared to heat-susceptible ones.

Pathogen and Vector Ecology

The life cycle of most pathogens involves a free-living stage in the environment while most vectors spend most of their time off the host and only come in contact with animals at the time of feeding.

Pathogen Transmission Ecology and Climate Change

Animal pathogens can live in the body of a host/vector or be free-living in the environment. These pathogens are more susceptible to direct effects of weather change when they are free-living in the environment. The major climate-related factors limiting pathogen survival in the environment are temperature and humidity. Climate change in Africa is causing an increase in the number of days that are hot compared to those that are cold in a year (New et al. 2006). The increasing numbers of hotter days in turn reduce humidity thereby reducing the survival of free-living pathogens in the environment. For instance, the survival of viruses during aerosol transmission or by surface contact is influenced by humidity and ambient temperature (Lowen et al. 2007). Since drought is associated with higher temperatures and low humidity and reduced availability of water, it tends to reduce the survivor and transmission of free-living pathogens into host animals.

Floods increase air humidity and create conditions favorable for survival and transmission of free-living pathogens. For example, the transmission of avian influenza viruses involves the ingestion of water containing the virus (Domanska-Blicharz et al. 2010). Similarly, helminthes and other larger parasites that have a long free-living stage thrive better during weather conditions that increase water availability (van Dijk et al. 2010). Therefore, the effects of climate change on free-living pathogens may take different forms due to fluctuations between drought and flood years. Each pathogen in an area must be assessed on its own merit in order to have a practical adaptation strategy. Furthermore, many pathogens have short generation intervals and high rates of mutation, increasing their ability to evolve over decades and cause emerging diseases (Koelle et al. 2005).

Vector Ecology and Climate Change

In Africa, disease-transmitting vectors are equally affected by increasing number of days with hot weather and low humidity. For vectors whose life cycle involves egg, larval, nymph, and adult stages, the egg and larval stages are the most susceptible to changing weather patterns. It has been shown that the hatchability of *Rhipicephalus decoloratus* eggs reduces when temperatures are low during cold season or flood periods, while larval survival decreases when humidity is low during hot months (Leal et al. 2018). This means that warmer cold seasons and drought increase the population of these ticks and increases the risk of anaplasmosis and babesiosis, while hot seasons with low humidity decrease the population and the risk of these diseases. Similarly, higher temperatures observed during cold seasons (Elbers et al. 2015) and flooding (Ivers and Ryan 2006) may be linked to increased mosquito and Culicoides midge populations, thereby increasing the risk of diseases that they transmit such as lumpy skin Disease, Rift Valley Fever among others.

Vector-Borne Infections as Models of the Effect of Climate Change on Animal Health

There is ample literature on the effects of climate change and the epidemiology of several vector-borne species on animal and human diseases. Vector-borne animal diseases in Africa fall into two main categories: (1) Insect-borne diseases spread by mosquitoes, midges, biting flies, and Tsetse fly which transmit diseases such as Trypanosomiasis and Rift Valley Fever; (2) tick-borne diseases such as East Coast Fever (Bengis et al. 2002).

The mechanisms involved in the emergence of such diseases relating to climate are complex. Vector-borne diseases are usually transmitted by interaction between the hosts and the infected vectors. Infection prevalence is dependent on the interrelationship between hosts, pathogens, and vectors. Any climate-related factor affecting this triangular relationship will affect the vector-transmitted disease epidemiology. In this respect, the survival of the vector, its replication, distribution, density, the vector biting rate, and the pathogen's incubation rate within the vector are of particular importance.

A rise in temperature can allow some vector-borne illnesses to spread in areas with adequate rainfall. Indeed, in the absence of effective veterinary services, the spread of vector-borne diseases is largely determined by a natural boundary where environmental or climatic conditions limit the distribution of the vector and, therefore, the pathogen. Small changes in climatic conditions can have significant repercussions for disease transmission at the fringes of this natural distribution and interfere with endemic stability.

Insect-Borne Diseases

These include (a) arboviral diseases, for example, Rift Valley Fever, Lumpy Skin Disease and African Horse Sickness (b) protozoa diseases, for example, Trypanosomiasis. In the following sections, we will provide evidence, linking climate change to the spread of these diseases.

Mosquito-Borne Diseases

Rift Valley Fever (RVF) is a significant arboviral disease already linked to climate change. It is a peracute or acute zoonotic disease, but affecting mainly domestic ruminants in Africa and transmitted by the mosquito (Mellor and Leake 2000). It is most serious in sheep and goats, resulting in death in newborn animals and abortion in pregnant animals. Epidemics associated with heavy rainfall at irregular intervals of 5–15 years tend to occur in eastern and southern Africa but some outbreaks in Sudan, Egypt, Senegal, and Mauritania are not related to any change in rainfall pattern. Heavy rainfall causes flooding of often dry areas and contributes to the hatching of dormant, drought-resistant, infected Aedes mosquito eggs responsible for the maintenance of the infection in dambos. Emerging mosquitoes infect an amplifying host that becomes a source of infection for many other mosquitoes that spread the disease rapidly.

Rift Valley fever outbursts are accompanied by unexpected heavy rains and flooding, mostly caused by El Niño. For example, the 1997–1998 and 2007 El Niño events were associated with very heavy rainfall in north-eastern Kenya and southern Somalia, resulting in a significant outbreak of RVF (Sang et al. 2010). Rift Valley Fever outbreaks in North and West Africa are not associated with heavy rainfall but with large rivers and dams providing ideal breeding grounds for mosquito vectors. In these areas, increasing the water storage ability for agricultural development and irrigation, in response to the drying climate, is likely to provide new suitable breeding sites for mosquitoes and may make these areas more vulnerable to RVF epidemics. In addition, RVF may become prevalent in areas where the disease has not been previously reported. Wessel born disease (WSL) is another mosquito-borne viral disease of cows, sheep, and goats that largely depends on floodwater breeding Aedes mosquitoes, and has very close epidemiological characteristics to RVF. Lumpy skin disease is a cattle disease of economic importance in Africa, causing severe losses such as damage to hides, mortality, and losses in productivity and reproduction (Krauer et al. 2016).

Midge-Borne Diseases

Wet conditions also promote the breeding of biting flies (e.g., Culicoides (Midges), Stomoxys and Tabanus spp.). African horse sickness (AHS) and bluetongue (BT) viruses are triggered by Culicoides biting midges. Therefore, the dissemination of both diseases is greatly affected by the availability of favorable conditions for breeding of midges. Blue Tongue disease was originally restricted to a belt between 40°N and 35°S worldwide. Its spread to other parts of the world has been attributed to climate change. Some major AHS outbreaks in South Africa have been linked to the combination of drought and heavy rainfall caused by El Niño-Southern Oscillation's (ENSO) warm phase. Many global climate models predict that, in the future, ENSO will occur more often.

Tsetse Fly-Transmitted Diseases

The direct and indirect effects of climate change on tsetse fly distribution and abundance would help to determine the possible spread and prevalence of trypanosomiasis in livestock (Bett et al. 2017). However, a recent study forecasting the expected impact of climate change on the distribution of tsetse flies suggests that the impact of climate change on population results is minimal in comparison with the consequences of population growth and the concomitant shifts in land use and tsetse natural habitat. The biggest shifts in tsetse fly distribution are predicted in the drier areas of western, eastern, and southern Africa (McDermott et al. 2002). Climate change will have less impact on tsetse fly distribution in the tropical regions of Africa. Nevertheless, the potential consequences of increased temperatures and habitat suitability changes on the vector capability of tsetse flies are not clear, and further research is needed.

Tick-Borne Diseases

Diseases which are caused by tick-transmitted pathogens in Africa include: (a) protozoal diseases (Theileriosis and Babesiosis), (b) ricketssial diseases (Anaplasmosis and Heartwater disease), and (c) viral diseases (African Swine fever).

Ticks spend a significant portion of their lives feeding off their host(s) and are therefore prone to atmospheric temperature and humidity. The climate and vegetation influence the environment and determine the distribution and abundance of ticks. Rising temperature, as a result of climate change can shorten their life cycle yet increase their reproductive rate (Estrada-Peña et al. 2012). Rather high temperatures are likely to reduce their longevity, and under drier conditions, mortality may increase. A model developed for the brown-ear tick *Rhipicephalus appendiculatus*, the main vector of East Coast fever (ECF), forecasts that ideal environments for the tick will have vanished in most of the southeastern portion of its distribution by the 2050s. Conversely, in western and central parts of southern Africa, more ideal places for tick survival could appear. A strong correlation between El Niño occurrences and an enhanced ECF seroprevalence has been identified in southern Zambia as a result of the increased tick vector survival (Fandamu et al. 2005). Consequently, temperature strongly affects the nature of the tick population and the diseases they spread by influencing tick distribution and seasonal incidence. Regulation of the big tick-borne diseases in large areas of Africa should focus on preserving an endogenous stable situation.

Therefore, the growth and survival of infectious immunity in bovine with tick-borne diseases is dependent on an optimum interaction between cattle, disease agents, and ticks. Disruption of this optimum relationship due to climate change and subsequent changes in the distribution and availability of certain types of ticks is likely to affect endemic stability and could trigger disease outbreaks.

Non-Vector-Borne Diseases as Models of the Effect of Climate Change on Animal Health

Non-vector-borne diseases are transmitted directly after infectious organisms from the environment enter the animal, usually through inhalation (aerosol) and/or ingestion (water or feed) or through open wounds.

Terrestrial Non-Vector-Borne Diseases

The effect of climate change on the spread of non-vector-borne diseases and their occurrence varies greatly. Changes in environmental conditions may increase or decrease the survival of the infectious agent in the ecosystem or predispose the susceptible animals to infection, as a direct or indirect result of climate change. A changing environment can also lead to increased or decreased interaction between contaminated and vulnerable species, and therefore influence transmission. Changes in temperature and humidity may influence the spatial and temporal distribution of non-vector-borne disease pathogens that spend time outside the host (Van den Bossche and Coetzer 2008). Such infections include: anthrax and blackleg, peste des petits ruminants (PPR), and foot and mouth disease (FMD) found in wind-borne aerosols, dermatophilosis, haemorrhagic septicaemia, coccidiosis, and helminthiasis (Van den Bossche and Coetzer 2008). The increase in rainfall in some areas of Africa creates temporary water bodies or permanent water bodies for irrigation in drier areas in which the intermediate snail host of *F. hepatica* survives (Van den Bossche and Coetzer 2008). While disease spread directly between animals in close contact is less climate-related, changes in the environment resulting in the loss or sporadic availability of water resources or grazing land lead to mass migration of livestock and wildlife in pursuit of water or pasture. Such movement enhances the interaction between livestock from different areas, and between wildlife and livestock, and can contribute to pathogens being transferred. Such population gatherings, animal congregations, and exchange of water and food supplies are considered to significantly contribute to the dissemination of major transboundary African diseases such as FMD, PPR, and contagious bovine pleuropneumonia. Drought, overgrazing, and extreme environmental stress arising from climate change and/or mass migration can become significant trigger factors for soil-borne disease epidemics, such as anthrax which remains dormant and viable in the soil for several decades.

Foot rot is a flood-related bacterial condition that affects ruminant interdigital tissue. Changes in the quality of the interdigital surface, due to exposure to wet conditions during floods, provide a favorable environment for bacterial growth and foot rot (Hiko and Malicha 2016). Changes in the environment as a result of climate change will also affect the migratory paths of a large range of bird species, both within and across continents. These movement path modifications can play a role in the spread and distribution of avian influenza and West Nile virus (Altizer et al. 2011).

Aquatic Non-Vector-Borne Diseases

Epizootic Ulcerative Syndrome (EUS) is a disease characterized by red spots and ulcers on the skin and often high mortality of various fish species (Songe et al. 2011). The lesions of EUS are caused by *Aphanomyces invadans,* and poor water quality parameters predispose fish to EUS (Pathiratne and Jayasinghe 2001). The first outbreak of EUS in Africa was recorded in 2006 in Botswana, Namibia, and Zambia in the Chobe-Zambezi river basin (Andrew et al. 2008). This was associated with

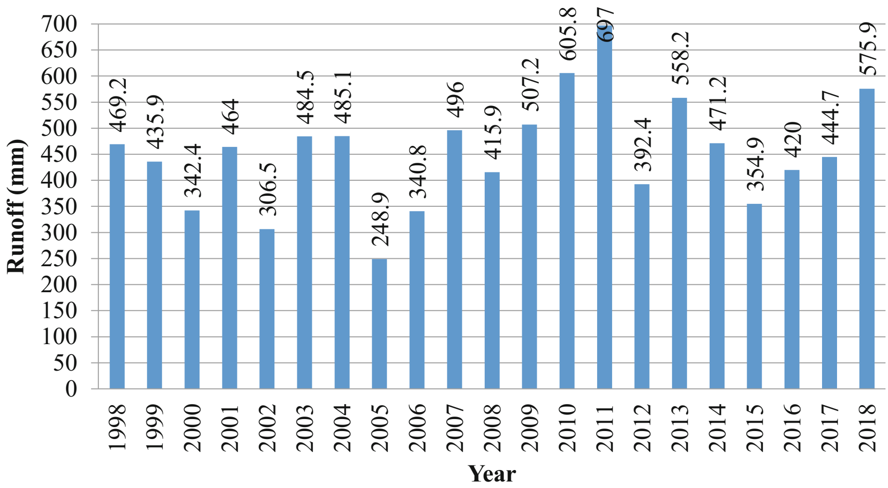

Fig. 2 Total annual water runoff on Zambezi River in Mongu, Zambia from 1998 to 2018 showing the lowest ever water runoff below 250 mm in 2005 due to severe drought. (Source of data, Brakenridge 2020)

river basins having thionic gleysols, soils with enough sulfur content to cause acidification of the soil upon oxidation (FAO/UNESCO 1970), and the severe drought of 2005 (Fig. 1; Brakenridge 2020) that drastically reduced the water table to expose the sulfide/sulfur horizon to air oxidation, resulting in acidic pH and poor water quality (Choongo et al. 2009). The high rainfall of 2006/2007 season flushed the acidic underground water to the surface, creating favorable conditions for the disease. It was observed that the disease was spreading upstream towards the underground source of the water, rather than downstream where all the dead and infected material were being washed to by the water. It is interesting to note that the water runoff on the Zambezi River has up until 2018, never reduced to the 2005 level of less than 250 mm and the EUS disease is so far naturally under control.

Thus, it would be important to use river water runoff data and any other meteorological data that can be used to predict future outbreaks of EUS in areas with underwater sulfur content that can be acidified when exposed to air due to lowering water table during severe drought. This would enable aquaculture farmers in such areas as the Chobe-Zambezi river basin prepare their fish ponds for sufficient alkalinization with lime in order to mitigate the possible outbreak of EUS (Fig. 2).

Determination and Use of Meteorological, Vector and Health Data for Assessing and Mitigating Impacts of Climate Change on Animal Health

The availability of reliable meteorological and disease data is necessary to design effective disease monitoring, surveillance, and early warning and response systems. The major sources of meteorological data, including temperature and precipitation, are obtained from ground-based and satellite measurements or interpolated gridded datasets (Heaney et al. 2016).

A web search for articles published between 1970 and 2015 on meteorology and infectious diseases in Central Africa by Heaney et al. (2016) concluded that in Central Africa, meteorological data is limited because of sparse ground-based recording stations and the lack of proper validation of available satellite data. Therefore, most studies done on the link between infectious diseases and meteorological variability may not be reliable unless infectious disease data are linked to high-quality spatially matched weather data. Spatial mismatch happens when humidity, temperature, and rainfall estimates are obtained from a place that was far from the area where disease data was collected. They advised the scientific community to be aware of the limitations of meteorological data available in Africa and ensure that there is an improvement in the quality and quantity of both meteorological and infectious disease data collected.

"Environmental change vulnerability," which includes community exposure to climatic change, its sensitivity and ability to adapt (McLeman and Hunter 2010), is considered to be very high in African countries. Thus, the need to have quality meteorological and disease data cannot be overemphasized.

Animal and Farmer Resilience and Adaptation to Effects of Climate Change on Animal Health

Coping and adapting to negative effects of climate change on animal health requires that the farming community adapts to changing circumstances, animal management systems are adapted and animal disease preventive measures are strengthened. It should no longer be business as usual.

Community Resilience and Adaptation

Most of the climate-associated emerging and re-emerging animal diseases are transmitted by agents that do not respect any boundaries and therefore, require collective stakeholder participation if effective control for improved productivity is to be achieved. In most African countries, government infrastructure meant to support farmers in livestock production and health is either very poor and unreliable or nonexistent at all. However, when assistance from government or NGOs exist, most of it focuses on the usual aspects of disease control and animal production and not really mitigating effects of climate or weather changes that increase effects of diseases on their animals. Therefore, empowering communities with knowledge and skills to adapt to climatic and weather patterns should now be a priority. Community participatory disease control and surveillance have been practiced in some areas and when supported by government projects or NGOs may yield variable results, which usually disappear when the project or support ends. This is normally the case when project activities are compromised by poor objectives and subjective practicality

(Ayal and Muluneh 2014). In order to have really lasting benefits, there is a need to implement sustainable community based herd health programs that integrate all activities such as vaccinations, deworming, etc., into the day-to-day husbandry, with increased livestock off-take where, there is government marketing support. It has been shown that when farmer livelihood sustainability through improved income becomes the goal of their community participation, tangible results are usually obtained. The rinderpest eradication program was one such success story because livelihood sustenance was the ultimate rationale for collective community efforts (Rich et al. 2014). Therefore, resilience and adaptation to effects of climate change in Africa require that the affected communities are directly involved in adaptation strategies that are practical and centered on livelihood sustenance.

Animal Management Adaptations

Although severe droughts and floods are all considered to be a result of climate change, drought by far has the greatest impact on animal production because it drastically limits both feed and water availability. Limited feed, both in terms of quality and quantity, reduces the competence of the immune system thereby making the animals more susceptible to diseases. In most parts of Africa both feed and water are abundant during flood years. Therefore, in most cases, climate change livestock production adaptation strategies that are usually considered are those responding to the impact of drought. Floods may affect animal production more through diseases than through nutrition. Adaptation strategies can be short-term or long-term.

Unfortunately, most farmers tend to implement short-term adaptation strategies because they have immediate visible impact although they are not usually sustainable in many cases especially for large flocks or herds. Short-term strategies include increasing spending on veterinary services, destocking, trekking animal's long distances in search of water and pasture, constructing fences to protected farmland, as well as feeding through cut-and-carry and other zero-grazing practices.

Long-term resilience to effects of climate change should make management of animals according to local conditions priority number one (Nyamushamba et al. 2017). This should start by ensuring that there are a large percentage of genes from local animals in the breeding stock. Indiscriminate cross-breeding should be discouraged as it produces offspring that are not well adapted and succumb easily to any emerging diseases. Even in the midst of climate change, local breeds have traits for genetic resistance to disease and other traits for quickly adjusting to local conditions. Other management practices like feeding and housing play an important role in the maintenance of resilient, healthy, and productive animals. In fact, continuous breeding of the best performing animals under the harsh local environmental conditions is the more sustainable long-term adaptation strategy. There are many examples of resilient animal breeds that have been developed with mainly local genetics that are performing very well even in the midst of climate change. These include the Tuli and Boran cattle breeds. However, livestock farmers that have maintained their indigenous cattle breeds such as Sanga in Southern Africa (Norval et al. 1988), East

African zebu (Scarpa et al. 2003), and the N'dama in West Africa (Mattioli et al. 2000) suffer less from the impact of environmental changes compared to those that keep breeds with a large percentage of exotic genetics.

Thus management adaptation to changing climate requires committed allocation of resources and improvements in the way land is used for livestock production, coupled with the promotion of local genetics.

Adaptation by Strengthening Disease Prevention Practices

The impact and prevalence of many diseases such as FMD, theileriosis, anaplasmosis, etc., have been increasing while the budget for controlling the diseases has been reducing in most African countries. Sufficient resources must be allocated while ensuring that the whole community is involved in improving sanitation and biosecurity. Usually disease risk factors vary with animal management systems. However, irrespective of the management system, early warning, detection, and quick response are key to preventing and controlling both emerging and re-emerging animal diseases (Black et al. 2008). Prevention and stopping the spread of diseases across an area and country should be the cornerstone of all preventive mechanisms. In addition, in order to stop the spread of high impact infectious diseases such as FMD and ASF, transboundary control measures by African countries are required. The success of the rinderpest eradication program was a result of early detection and early response globally. The world was declared to be free of rinderpest by both FAO and OIE in 2011 because of commitment to early detection and early response (Mariner et al. 2012). Unfortunately, in Africa, new diseases continue to emerge and the impact and persistence of endemic diseases is still a major challenge. In order to achieve early detection and early response, African countries must have functioning laboratories that give real time results of disease confirmation which are well coordinated with field veterinarians.

Conclusion

Climate change has certainly increased land and sea surface temperatures, leading to an increase in the number of warmer days and nights in a year. These changes have been shown to increase the severity of droughts and floods. The manner in which these climatic changes affect animal health and production has been highlighted in this review. The impact can be directly, by affecting the animal's thermoneutral zone thereby inducing stress and its subsequent effects. The effect can also be indirectly by increasing the survival of pathogens and vectors in the environment resulting in increased severity and frequency of diseases. The use of meteorological data that are spatially matched to disease data can help in achieving early warning, detection, and response to eminent diseases. In Africa, adaptation measures should include livelihood-sustenance based community participation in managing animal production according to local conditions and strengthening disease preventive practices.

Contents

Abstract

Since the mid-1970s, the high plateaus of eastern Morocco have experienced proven trends of climate change (CC) such as a significant decrease in rainfall amounts and an increase in the droughts' frequency. Consequently, the CC threatens the sustainability of this pastoral ecosystem and negatively affects the

breeding of small ruminants, the main local-level livelihood, which becomes more vulnerable due to its high dependence on climatic conditions. This chapter aims to analyze breeders' adaptation practices by taking into account their social stratification based on the size of the sheep flock in possession. Data were analyzed using descriptive statistics, Kruskal-Wallis and Mann-Whitney tests to examine the differences in the adoption' frequency of CC adaptation measures according breeders' classes and Chi-square independence test to identify the factors explaining these observed differences. The analysis of local adaptation practices reveals that they are endogenous but above all curative, aiming at a short-term logic and have a low to medium relevance compared to the specific objective of adaptation to CC. In addition, there are significant differences in the frequency of adoption of CC adaptation strategies (chi-square value = 8.1112, $p = 0.017$, df = 2) within categories of breeders, in particular between small and larger breeders (U statistic = 58.000, p = 0.008). The significant factors explaining these differences are socioeconomic (age, household size, equipment, training, and membership of a basic professional organization). It is therefore recommended to target small breeders as a priority and to set up support measures (equipment, training, funding, organization of breeders).

Introduction

Currently, climate change (CC) has become obvious, due to its manifold effects on human and natural systems, affecting all countries of the world (IPCC 2014). Africa is considered one of the most vulnerable continents to climate change and extreme events (Garcia 2008). This vulnerability is principally attributed to the low level of economic development in its countries, thus generating a weak and limited adaptive capacity to deal with the negative physical, human, and socioeconomic impacts of CC (Besada and Sewankambo 2009; Bruckner 2012).

Within North African countries, Morocco is seen as the most vulnerable to climatic change and extremes, due to the combination of high exposure to climate consequences, marked climate sensitivity (high dependency on rain-fed agriculture, recurrent water stress), and a weak generic adaptive capacity (low income per capita and its unequal distribution) (Yohe et al. 2006; Schilling et al. 2012). Indeed, Morocco has already suffered the impacts of climate change, evidenced by the climate trends observed during the period from 1960 to 2005. Thus, aridity has increased from the south to the north of the country (Mokssit 2012), rainfall had seen a widespread decline (Schilling et al. 2012) of between 3% and 30% (Ezouine and Bouaza 2019), while the temperature has risen (Hulme et al. 2001) from 1.0 to more than 1.8 °C (Morocco 2016). In addition, the frequency, intensity and duration of droughts have increased during the last three decades (Moroccan Meteorological

Office 2007; NIC 2009). Climate change projections for Morocco, exhibit a decrease in annual rainfall amounts of 10–20% by 2100 (Mokssit 2012; Morocco 2016) and an increase in temperature until 2050 between 1.0 °C to 1.2 °C (Schilling et al. 2012) or ranging from 2 °C to 3 °C according to Paeth et al. (2009). Also, the frequency and the duration of droughts are forecasted to rise (Beniston et al. 2007; Bzioui 2012; Schilling et al. 2012). In short, negative climatic changes already observed are likely to continue in the twenty-first century, resulting in warmer and drier conditions (Schilling et al. 2012). Agriculture, the key economic sector and the main provider of jobs, is the most negatively affected by the effects of CC (Morocco 2016). Thereby, rural populations whose rain-fed agriculture is the major source of income are hardest hit because of their high vulnerability to the harmful consequences of climate change (Morocco 2011).

In this context, the study area, namely, the high plateaus of eastern Morocco (HPEM), has experienced proven climate change trends since the late 1970s, such as a substantial decrease in rainfall (Fink et al. 2010; François et al. 2016; Melhaoui et al. 2018) and an increase in temperature and frequency of droughts (Moroccan Meteorological Office 2007; François et al. 2016; Melhaoui et al. 2018). Livestock breeding on rangelands, based mostly on the sheep farming, is the main livelihood and job provider for the local population. This economic activity is vulnerable to CC due to its high dependence on climatic conditions (Bechchari et al. 2014), which are characterized by high intra- and inter-annual variability in rainfall and recurrent droughts (Mahyou et al. 2010; Bechchari et al. 2014). In fact, livestock breeding on arid rangelands is severely affected by the adverse impacts of extreme climate change events since it depends on natural resources and practiced in a fragile and marginal environment such as the pastoral ecosystem of the study area. As highlighted by Hassan (2010) drylands present an intrinsic natural vulnerability generated by a high exposure to significant water stress. Indeed, climate change and extremes in the high plateaus of eastern Morocco threatened the sustainability of pastoral livestock rearing, accentuated the precariousness of the poorest rural households and increased the flow of potential emigrants. Also, extreme climatic events (drought in particular), that have occurred in the HPEM in the past, have caused fodder and water scarcities leading to higher competition for available natural resources and to sometimes brutal pastoral conflicts (Bourbouze and El Aich 2000).

The increase in the occurrence and intensity of climate change-induced droughts and their prolongation over time exacerbated social inequalities among local breeders (Schilling et al. 2012). Indeed, at the time of drought event, small-scale livestock owners face both increased pressure on available pastoral resources and an inability to purchase higher-priced livestock feeds. Thereafter, the size of their herds decreases considerably, while large breeders, their strategy of decapitalization seems to be well under control and their ability to replenish herds is much greater (Bourbouze 2000; Bechchari et al. 2014). In fact, better-off herders are slightly less vulnerable because they are not exclusively or largely dependent on natural resources, have the financial resources to buy livestock feed, and can even take advantage of this opportunity created by the decapitalization of the poorest livestock owners (Kuhn et al. 2010; Bechchari et al. 2014).

In addition, decrease in rainfall and increased droughts' frequency have contributed to the degradation of rangelands in the HPEM, which has also been caused by overgrazing, plowing and anarchic cultivation of marginal areas, uncontrolled land clearing and sedentarization (Mahyou et al. 2010; Maâtougui et al. 2011; Schilling et al. 2012). Furthermore, climate change and extreme weather events, especially, have often limited the success and sustainability of local public interventions in terms of development and poverty reduction.

To deal with or overcome the negative impacts of climate variability and change, livestock herders in the HPEM have undertaken a diversified range of coping and adaptation practices such as pastoral mobility (transhumance), reciprocal grazing agreements with distant pastoral tribes, rearing of mixed species herds, social networks, and intracommunity solidarity to mitigate income shocks (Bourbouze 2000; Bourbouze and El Aich 2000; Schilling et al. 2012). Complementing these traditional coping actions, contemporary adaptation strategies, which are widely implemented in the study area, include: association of cereal crops and livestock farming, breeding of mixed herds of sheep and goats, new form of mobility based on motorization, income diversification and use of emigrants' remittances, commercializing of livestock, storage of livestock feed, using subsidized livestock feed and public programs against drought effects, sale of animals to purchase supplementary livestock feed (Bourbouze 2000; Bourbouze and El Aich 2000; Schilling et al. 2012), and recently the subscription to insurance climatic multi-risks which covers land cultivated with cereals, but not mobile or sedentary livestock rearing.

Nevertheless, these adaptation strategies are in large part of curative scope, low efficient and are less sustainable over time (Bourbouze 2000; Bourbouze and El Aich 2000). In addition, many of these adaptive practices show a relative or low relevance regarding to the specific objective of adapting to climate change and extremes, since they are seen rather as alternative livelihoods more than adaptation actions itself. Thus, they are undertaken by some breeders in order to secure or diversify their livelihoods, for instance, casual work, emigration and the practice of income-generating activities in complement to livestock rearing.

In addition, the adaptive capacity of the herders in the HPEM's area to climate variability and changes depends on the size of the livestock held and the financial and material resources available. So, their adaptive behaviors rely on their respective socioeconomic status (Bechchari et al. 2014). Thereby, small-scale breeders have less options for adaptation, are more severely affected by the observed adverse climatic trends, and are more threatened by the abandonment of livestock rearing (Bourbouze 2000). More globally, Lazarev (2008) pointed out that the main criteria for differentiation between categories of breeders in the study area are socioeconomic characteristics such as the size of the herd exploited and the capital available. Similarly, it is accepted that the susceptibility to the effects of CC and the adaptation capacities differ according to the farmers. In fact, since that the farmers' CC adaptation depends on their respective specific socioeconomic conditions (Below et al. 2012), the design of an effective and appropriate adaptation CC policy and strategies, must take into consideration these differences within human contexts (Fussel 2007) by using local-level analyses (Below et al. 2012).

In view of all of the above, the study is aimed at filling the knowledge gaps relating to the adaptation of breeders in the study area to CC, mainly with regard to the effect of social differentiation within livestock herders on the adoption (implementation) of adaptation strategies to this phenomenon. Concretely, the specific objective is to analyze breeders' practices in adapting to climate variability and change, by taking into account their contrasting socioeconomic conditions mainly the existing differences in the size of the sheep flock in ownership.

Materials and Methods

Study Area

Located in the northeast of the country (30S UTM zone), the high plateaus of eastern Morocco (HPEM) are one of the largest pastoral areas in Morocco, covering about 3.5 million hectares. Their soils are generally shallow, low in organic matter and therefore susceptible to wind and water erosion (Mahyou et al. 2016). Water resources are very limited. The HPEM have two gradients going from north to south: the altitude increases regularly from 900 to 1400 m and the climate fluctuates from semi-arid to lower arid and pre-Saharan. Indeed, the climate is of Mediterranean type, but under of a great influence of the Sahara. Average annual rainfall is highly variable, ranging from 143 mm in the south to 201 mm in the north, with respective coefficients of variation of 45% and 34% (Melhaoui et al. 2018). Dry and hot winds which can cause real sandstorms, especially in summer, are frequent. The rangelands of the HPEM are dominated by specific steppe vegetation consisting of steppes at *Stipa tenacissima*, Chamemic steppes at *Artemisia herba alba* and steppes at Chenopodiaceae (*Artrophytum scoparium*). The vast majority of local population derive most of their income from livestock farming, in particular sheep breeding. The herds in the possession of the breeders in the study area are made up of more than two million heads of small ruminants, usually conducted according to an extensive to semi-extensive rearing system. The HPEM area can be seen as a suitable and representative site for better understanding of adaptation to CC in Morocco's pastoral ecosystems.

Data Collection

Data collection method consisted of a literature review and a survey of 167 breeders, heads of pastoralist households. Relevant literature available from local extension and agricultural development agencies were consulted to acquire a complete and clear overview about the CC issue in the HPEM's area, mainly with regard to livestock practices and core endogenous adaptation measures implemented by the breeders in response to climate variability and change. The survey of herders focused on the socioeconomic characteristics of households and the adaptation practices embraced to reduce the effects of perceived CC. The basic study unit is the pastoralist household, as at this level, decisions relating to adaptation to climate variability and change are taken (Below et al. 2012).

Given that sheep farming is the main activity of the pastoralist households in the study area, the size of the sheep flock in ownership was chosen as the criterion of discrimination between herders. Thereby, three classes of livestock breeders have been identified and this in agreement with local agricultural extension agencies. Large breeders are those with a sheep herd exceeding 300 heads, medium breeders with own sheep flocks of between 101 and 300 heads and the small livestock owners with the number of sheep in possession is less than or equal to 100 heads. Based on the respective representativeness of these three breeders' categories in the study area (Bechchari et al. 2014), respondent herders were randomly selected. The distribution of breeders surveyed by class is as follows: 96 small, 47 medium, and 24 large breeders to give a total of 167 livestock producers.

Data Analysis

Data collected on the adaptation practices implemented by the livestock herders in the study area were analyzed using descriptive statistics and the tests of Kruskal-Wallis, Mann-Whitney U and of Chi-square independence. Descriptive statistics have been made, with regard to the socioeconomic characteristics of breeders surveyed and the different local adaptation measures. The Chi-square independence test was used to highlight the relationship that may exist between the developed endogenous practices and the categories of herders (small, medium, large). In addition, the strength of this possible statistical association was measured using Cramer's V. coefficient. This test was also carried out to verify whether the observed differences within the three breeders' classes is linked to their respective socioeconomic conditions at household level. Furthermore, Kruskal-Wallis test is an appropriate nonparametric test for comparing more than two independent samples. It is a rank-based test which can be used to test whether such samples come from the same distribution (Ostertagova et al. 2014). The null hypothesis is the following: all the populations have the same median or no significant difference between the groups (samples). In our case, the Kruskal-Wallis test was used to testing for difference in the frequency of adoption of adaptation strategies among three livestock breeders' classes. If the Kruskal-Wallis statistic is significant, a nonparametric multiple comparison method (Mann-Whitney U test) is used to find out which classes of herders are different from the others. Also, using the Mann-Whitney U test, we assessed if the adoption of adaptation practices to CC differed significantly between the three classes of breeders which are based on the size of the owned sheep herd. Indeed, this test was realized to show if there is a significant difference between the "adoptive" and "non-adoptive" groups according to the number of sheep in possession. Generally, the Mann-Whitney U test is a non-parametric statistical test used to determine if two independent samples come from the same population or from 2 different populations. Indeed, this test was used because the assumptions of use of the Student's t test were not verified (non-comparable variances and non-normal distribution of the dependent variable).

Results and Discussion

Socioeconomic Characteristics of Breeders Surveyed

The average age of breeders is 52 years with almost 60% of them who have an age greater than or equal to 50 years. Livestock breeders are in large part without level of education (70%). The rearing of small ruminants is the main economic activity for 83% of herders sampled. Approximately 35% of respondents are engaged in an ancillary activity (mainly the temporary employment: 26%). The size of households is an average of 8 people. The average number of labor force by household is around 2 persons. The employ of shepherds is observed in 36% of cases. The rate of emigration is low and is close to 17%. The types of dominant habitat are the tents and concrete houses with respectively 36% and 24%. The rate of connection to the public electricity network is low, either almost 20%. The distance to the nearest market is relatively long and is 60 km.

The majority of the breeders (83%) had agricultural land, but only 16% of the herders surveyed owned an irrigated plot. In effect, on average, arable land was about 31 ha and irrigated area did not exceed the 0.37 ha. Breeders are moderately equipped, since more than 61% of them possesses at least one agricultural equipment and/or transport (possession trucks: 27%, tractors: 14% and water tanks: 50%). The average number of sheep and goats are respectively of 166 and 33 heads/breeder. More than 52% of the herders have at least one head of bovine cattle.

Access to formal credit is low not exceeding 23%.

Analysis of Pastoralists Adaptation Practices in the HPEM

Table 1 showed that the breeders in the HPEM have implemented, over time, a wide and diversified range of adaptation practices to cope with the harmful effects of hazards and climate changes.

These adaptation and coping measures are almost all of endogenous origin, thus attesting on a great intrinsic capacity for adaptation based on the accumulation of experiences and initiatives of the breeders in this arid pastoral ecosystem where climatic conditions are difficult and unpredictable. Local adaptation practices to climate variability and change can be grouped into two main categories: (1) Adjustment of farm management and pastoral practices and (2) Partial shift to alternative livelihood options. A large part of the adaptation actions identified concerns the first dimension.

Contemporary adaptive strategies in the study area are mostly individualized. This testifies to the spectacular rise of an individualism of spirit and action and of refocusing on the individual to the detriment of the social group to which he belongs (Bourbouze and El Aich 2000). These authors added that it is now at the individual level that one must know how to protect oneself from environmental and economic risks and no longer at the community level. Whereas during the first half of the last century, local customary institutions organized the access and use of collective

Table 1 Distribution of herders surveyed according to adaptive measures implemented (in %)

Adaptation practices	Freq.	Perc.	Dur.	Inten.	Adeq.

pastoral resources and guaranteed intra- and inter-tribal solidarity for the survival of their ethnic groups in times of climate crisis. The decline of these traditional structures for several decades has been caused mainly by a public policy which has fragmented tribal organizations in favor of modern administrative and elected institutions and encouraged sedentarization (Rachik 2007). Negative practices of breeders, especially the large and influential among them, such as the cultivation of rangelands and their appropriation for private use, have also contributed to the weakening of these tribal structures (Bourbouze 2000; Bechchari et al. 2014).

In addition, the majority of the adaptation measures adopted are part of a short-term temporal perspective, thus allowing breeders to buffer climate risks and reduce their negative consequences through the practices of curative type (for example the regular sale of animals to purchase livestock feed, benefit from public interventions such as subsidized fodder). This testifies to the predominance of short-term and reactive vision of adaptation at local level. Furthermore, most local adaptive practices show a low to medium adequacy in relation to the main objective of adaptation to CC, as their purpose is not a specific response to this phenomenon. They are embraced by breeders either to improve their rearing productivity and, thus, contribute to reducing their vulnerability to hazards and hostile climatic changes, such as diversification of livestock species and practice of fattening (medium adequacy) or to increase their income, meet the financial needs of their farms and maintain their economic activity, e.g., regular sale of animals to purchase livestock feed, credit from resellers of livestock feed and casual employment (low adequacy). Only four adaptation measures which were highly relevant in relation to climate change. They are: transhumance or herd mobility, storage of livestock feeds, subscription to climate insurance and the integration of livestock breeding and irrigated agriculture. However, these adaptive actions depend on the socioeconomic status of the breeder (mostly implemented by large herders) or they are very spatially localized like irrigated agriculture.

In line with our findings, Bourbouze (2000) and Bourbouze and El Aich (2000) highlighted that most adaptation practices to variability and climatic risks (drought in particular) implemented by the breeders in the HPEM are of curative type and provide only relative protection. The only really effective strategies against climatic hazards were the cereal-livestock association, livestock feed supplements purchased through animal sales, remittances of emigrants and irrigated agriculture by pumping, but even these are little effective in a sustainable way. Bechchari et al. (2014) emphasized that the adaptive capacity of herders in the HPEM's area with regard to climate-related risks and changes, closely depends on their respective socioeconomic characteristics. In fact, the socioeconomic status of breeders in the study area largely affects their drought adaptation responses and more generally their pastoral practices and their way of using the rangelands (Mahdi 2007; Lazarev 2008).

Differentiation of Adaptation Measures According to Breeders' Classes

The Table 2 showed general divergence in the frequencies of adaptation measures implemented within the categories of breeders (small, medium and large) which are based on the size of the sheep flock in ownership. Thus, large livestock owners adopt with higher frequencies, most of the endogenous adaptation practices in response to perceived climate variability and change, compared to the two other categories. In addition, practices of the first dimension of adaptation measures are more frequently implemented by large breeders. They include strategies for the diversification of the productions (integration of livestock breeding and cereal farming, breeding of mixed flocks of sheep and goats), improvement of rearing productivity (practice of the fattening, selection and reproduction of powerful races), transhumance and market orientation (finished products of good taste quality). In fact, all of these adaptation strategies require considerable financial resources, which manifests itself in much lower adoption frequencies among small and medium-sized breeders.

By relying on their social status and their relationship networks, large breeders adopt an opportunistic land strategy by constantly conquering vast new areas of collective rangelands for their private use. As evidenced by the significant differences between the average available agricultural areas, which are 86, 37 and 15 hectares respectively for great, medium and small breeders. Recently, large herders and some medium breeders have massively subscribed to climatic multi-risk insurance. The adoption of this practice has two objectives. First, climate insurance contracts represent, in the eyes of local breeders, justifications approving the legitimacy of the ownership of conquered rangelands in order to annex them definitively

Collection of truffles as additional income[a]	13.5	2.1	0	7.917 (0.019)	0.218[M]

Note: Cramer's V. value: S: Strong (between 0.40 and 0.80); M: Moderate (between 0.20 and 0.40); L: Low (between 0.10 and 0.20). Values in parentheses in χ^2 Pearson represent the asymptotic significance (bilateral)

[a]Significant at 5% level

later. Also, this measure (insurance) allows subscribers significant financial compensation following of climatic hazards (drought in particular) equals to 600 MAD per hectare.

Large livestock owners have benefited from contracts of sale with supermarkets of many urban agglomerations in the north of the country during the feasts of sacrifice, thanks to the USAID' initiative. Thus, they were able to achieve very interesting butcher performances (well-finished animal products with appreciable gustative qualities). This explains the strong orientation of their breeding activity towards the market. In addition, thanks to their accumulated savings, large livestock keepers invest more and more in activities of speculation, including the real estate, in order to overcome the unfavorable climatic and economic conditions affecting their livestock rearing activity.

As for small herders, they frequently shift to additional off-farm livelihoods to complete or diversify their income sources. Thus, they are forced to engage in other small-scale activities in addition to the livestock breeding, such as temporary labor, collecting truffles and small trades, in order to satisfy both the needs of their families and those of their meager herds especially in the event of climatic vagaries (drought) prolonged in time. The poorest of them, after the sale of all their herds, find themselves decapitalized. In the absence of support from relatives or the State, they opt for rural exodus as the final solution.

In addition, the results of the Chi-square independence test revealed that there was a statistically significant relationship between most adaptation practices (11/16 measures identified) and livestock breeders' classes (Table 2). The Cramer's V. coefficient measuring the strength of this statistical relationship has medium to high values. This association of significant magnitude indicates, thereby, that the larger the size of the sheep herd in possession, the higher the frequency of adoption (implementation) of adaptation practices.

As highlighted by Bourbouze (2000), the choices for small breeders regarding adaptation to adverse impacts of climate variability and extremes are much narrower and their most common strategy is to regularly sell animals in the souk so that they can buy livestock feed, water their herds and feed their families. Thereafter, either they abandon livestock rearing after having sold all their flocks, or they migrate to the nearest urban centers in search of small trades. Whereas the decapitalization strategy seems well controlled among large breeders (Bourbouze and El Aich 2000), they can even take advantage of periods of climatic crisis to increase the size of their herds to the detriment of the poorest breeders (Schilling et al. 2012). Bechchari et al. (2014) underlined that the portfolio of strategies for adapting to variability and climate change implemented by large breeders is much denser and more diversified. It includes the acquisition of equipment (trucks, tractors, water tanks), the appropriation of large areas of rangelands, the profit of the best grazing sites and the commercial speculation in livestock in order to make a good profit on their invested capitals. In contrast, the possibilities offered for small breeders, are very limited and mainly boil down to the regular sale of their herds, the search for additional activities to breeding and rural exodus.

The Kruskal-Wallis test was conducted to examine the differences in the frequency of adoption of climate change adaptation practices according to the classes of breeders. Significant differences (chi square $= 8.1123$, $p = 0.017$, df $= 2$) were found between the three categories of herders. In addition, the distribution of the majority of adaptive measures differs significantly between classes of breeders (Table 3).

After the Kruskal-Wallis test led us to reject the null hypothesis of similarity between breeders' categories in terms of frequency of adoption of adaptation and coping actions, we performed pairwise comparisons using the Mann-Whitney test to

Table 3 Results of the Kruskal-Wallis test

determine which classes of breeders are different. The results of this test show that there is a highly significant difference (U statistic = 58.000, $p = 0.008$) between small and large breeders in adopting CC adaptation practices. The other differences between on the one hand small and medium breeders (U = 92.000, $p = 0.174$) and between medium and large herders on the other hand (U = 79.500, $p = 0.067$) were found not to be significant. This shows that breeders' adaptation in the study area depends mainly on their social status or economic power, expressed by the size of the sheep herd in possession.

Factors Influencing the Adoption of Climate Change Adaptation Practices

In order to confirm this relationship between the adaptation measures to climate variability and change implemented by the breeders in the study area and the size of the sheep herd in possession, we carried out the Mann-Whitney U test. This test is often employed to compare differences between two independent groups when the dependent variable is continuous, but not normally distributed. In our case, the two independent groups are the "adopters" and "non-adopters" of CC adaptation practices, while the continuous dependent variable is the sheep herd size. The mean rank column shows mean rank for the two groups tested (adopters and non-adopters groups). This column is very useful because it indicates which group can be considered as having the higher size of sheep herd, overall; namely, the group with the highest mean rank. In this case, the adopter group had the highest size of sheep herd. Indeed, the first group (adopters) have higher mean ranks than those of non-adopters, except for the case of two coping actions, namely, "Casual labor" and "Collection of truffles as additional income" (Table 4). In fact, these two practices are usually pursued either as a complement to a breeding activity that does not allow the household to meet its needs or in the event of abandonment of livestock farming (decapitalization frequently caused by successions of prolonged episodes of drought). They are practiced mainly by the small breeders with respectively 75 and 93%.

Furthermore, the Test Statistics column shows us the actual significance value of the Mann-Whitney U test. Specifically, this column provides the test statistic, U statistic, as well as the asymptotic significance p-value. From our data, it can be

Conversion of livestock capital into land capital	101.54	72.25	(2174.5, 0.000)	−3.841
Casual labor	59.39	96.08	(1726.5, 0.000)	−4.612
Internal or external emigration in search of jobs	94.36	81.91	(1656, 0.214)	−1.243
Collection of truffles as additional income	27.46	89.17	(279.5, 0.000)	−4.574

Note: U: U statistic of Mann-Whitney test, *p*: the value of p of the test concluded that the size of the sheep herd in the adopter group was significantly higher than in the non-adopter group for the majority of adaptation strategies practiced by the livestock owners in the study area.

In line with our findings, herd size influences positively and significatively the likelihood that pastoralists implement adaptation strategies in the face of climate change (Balew et al. 2014; Berhanu and Beyene 2015; Opiyo et al. 2015).

Other socioeconomic characteristics at household-level, using the category of the breeder as a classification variable, could explain significant observed differences in the frequency of climate change adaptation practice's adoption (implementation) within breeders' classes (small, medium, large). The results of chi-square independence test contained in the Table 5 show that there is a significant relationship between the category of herder and the following factors: age of breeder ($\chi^2 = 19.020$, $p = 0.000$), household size ($\chi^2 = 30.720$, $p = 0.000$), no practice of ancillary activity ($\chi^2 = 25.662$, $p = 0.000$), employment of shepherds ($\chi^2 = 42.124$, $p = 0.000$), land ownership ($\chi^2 = 14.384$, $p = 0.001$), possession of truck ($\chi^2 = 17.754$, $p = 0.000$), possession of tractor ($\chi^2 = 49.740$, $p = 0.000$), possession of water tank ($\chi^2 = 33.902$, $p = 0.000$), possession of a motor pump ($\chi^2 = 39.048$, $p = 0.000$), veterinary care ($\chi^2 = 16.005$, $p = 0.000$), training received ($\chi^2 = 7.850$, $p = 0.020$) and membership to a technical supervisory structure, namely, National Association of sheep and goat breeders- ANOC ($\chi^2 = 27.454$, $p = 0.000$).

Large livestock producers have a higher average age, 62 years, compared to 49 years for small breeders (Table 6). They are ones who benefited the most from training actions in livestock rearing, development and management of rangelands and other technical topics of interest (42% vs. 17%), adhered massively to the breeders' organization, namely, ANOC (58% vs. 11%). These elements indicate that large herders have accumulated a great pastoralism experience compared to small-scale breeders. Piya et al. (2013) and Tiwari et al. (2014) pointed out that the training received improved the adaptive capacity of farmers in the face of climate change. As highlighted by Tiwari et al. (2014) and Taruvinga et al. (2016), membership in the community-based organizations increases the adoption of climate change coping strategies. Yila and Resurreccion (2013) and Mabe et al. (2014) underlined that farming experience significantly and positively influences the implementation of CC measures, respectively in the semiarid Nguru Local Government Area, Northeastern Nigeria, and in Northern Ghana. In addition, large breeders are far largely more endowed with production factors than small breeders such as labor force (4 vs.. 1 people), employment of shepherds (88 vs. 19%), land size (86 vs. 15 ha), small ruminants herd size (684 vs. 72 heads), bovine cattle flock size (7 vs. 1 head), number of equipment owned (5 vs. 1) and veterinary care (83 vs. 45%). In line with our findings, Yila and Resurreccion (2013) pointed out that labor force was a significant determinant for farmers' adaptation practices to climate change in the semiarid Nguru Local Government Area, Northeastern Nigeria. Debalke (2011) and Ndamani and Watanabe (2016) highlighted that land size was a determinant factor that influences farmers' climate change coping strategies, respectively, in north shoa zone of Amhara region Ethiopia and Lawra district of Ghana. Berhanu and Beyene (2015) and Opiyo et al. (2015) have found that herd size affected positively and

significantly the probability that pastoralists put in place CC adaptation measures. Hassan and Nhemachena (2008) and Ouédraogo et al. (2010) stressed that ownership of heavy machinery or agricultural equipment improves the coping capacities of farmers to deal with the negative effects of climate variability and extremes.

Furthermore, large breeders have specialized over time in the extensive breeding of small ruminants, while small-scale herders have been forced to practice non-farm activities such as casual labor, small trades, and the collection of truffles to obtain additional income necessary for their survival. In fact, almost all large livestock owners (92%) do not carry out any ancillary activity generating additional income, unlike 53% for small herders. Given that the occupation of the farmer was an indication of the total amount of time available for farming activities (Gbetibouo 2009), the off-farm employment may present a constraint to the adoption of technology because it consumes time which must be devoted to the management of agricultural activities (McNamara et al. 1991). Also, large breeders are the ones who benefit most from the best grazing sites (38 vs. 14%). Berhanu and Beyene (2015) expressed that the traditional pastoralism represents a resilient and unique system of adaptation to hostile and unpredictable climatic variability in dryland ecosystems.

In accordance with the results presented above, several previous studies showed that the significant factors influencing African farmers' adaptation to climate change are socioeconomic household-level variables, and this in many countries such as Ethiopia (Balew et al. 2014; Berhanu and Beyene 2015), South Africa (Taruvinga et al. 2016), Ghana (Ndamani and Watanabe 2016), Tanzania (Below et al. 2012), Nigeria (Obayelu et al. 2014), Kenya (Opiyo et al. 2015), and Uganda (Nabikolo et al. 2012).

Conclusion

In response to perceived climate changes and extremes, livestock breeders in the high plateaus of eastern Morocco have implemented differently many adaptation practices, depending on their respective socioeconomic conditions at household level. Thereby, contrasting socioeconomic characteristics, mainly the size of sheep flock in ownership, allowed large breeders to adopt (put in place) with higher frequency most of adaptive measures compared to small-scale herders who have much more limited possibilities or choices. This social inequality could be exacerbated in the future due to adverse climatic trends (increase in the frequency and intensity of droughts, reduction in rainfall amounts) caused by current and future climate change, in the absence of support measures targeting primarily small breeders who are the most vulnerable group to this climatic phenomenon.

In addition, future studies relating to climate change adaptation in the study area should first investigate the perceptions of livestock producers. Indeed, local perceptions toward climate change influence farmers' decisions on whether or not to adapt (Deressa et al. 2009), are useful for the development of relevant and appropriate adaptation policies and strategies (Opiyo et al. 2015), and are also an important factor influencing the success of the adaptation actions to be implemented (Tesfahunegn et al. 2016).

Abstract

The lack of affordable, clean, and reliable energy in Africa's rural areas forces people to resort to poor quality energy source, which is detrimental to the people's health and prevents the economic development of communities. Moreover, access to safe water and food security are concerns closely linked to health issues and children malnourishment. Recent climate change due to global warming has worsened the already critical situation.

Electricity is well known to be an enabler of development as it allows the use of modern devices thus enabling the development of not only income-generating activities but also water pumping and food processing and conservation that can promote socioeconomic growth. However, all of this is difficult to achieve due to the lack of investors, local skills, awareness by the community, and often also government regulations.

All the above mentioned barriers to the uptake of electricity in rural Kenya could be solved by the coordinated effort of government, private sector, and academia, also referred to as Triple Helix, in which each entity may partially take the other's role. This chapter discretizes the above and shows how a specific county (Marsabit) has benefited from this triple intervention. Existing government policies and actions and programs led by nongovernmental organizations (NGOs) and international agencies are reviewed, highlighting the current interconnection and gaps in promoting integrated actions toward climate change adaptation and energy access.

Keywords

Triple helix · Rural electrification · Wealth creation · Climate change adaptation · Suitable policies and regulations

Introduction

Energy poverty is a serious concern in developing countries which often are the ones to bear most of the negative consequences of climate change. Currently, about 2.6 billion people have no access to clean cooking and about 850 million do not have access to electricity (International Energy Agency (IEA) 2019a). Some of these consequences are deficient healthcare systems, lack of access to education, and lower economic growth leading to political instability and migratory flows. Despite of international agencies' support and local government fund allocation, still 500 million people are expected to have no access to electricity by 2030 (International

Energy Agency (IEA) 2019b). All of the above are worsened by climate upheaval such as droughts, floods, and rain shortage (Trenberth et al. 2014).

Energy, food, and water are scarce and of low quality for people living in rural areas of developing countries. Food insecurity affects about 10–11% of people worldwide with peaks of 30% in east Africa (FAO 2019), or even beyond as confirmed by the surveys performed by Fraval et al. (2019). Food is often cooked without proper cooking facilities, often with firewood or charcoal, and exhaust gases are released inside the rooms without a proper ventilation system (Goldemberg et al. 2018). This affects the healthy conditions of inhabitants and especially children (Smith et al. 2014). Moreover, according to UNICEF, only about 30% of people in Sub-Saharan Africa had access to safely managed drinking water in 2017, whereas 30% of them had limited or inadequate access (UNICEF and WHO 2019). Often, water is far from settlements and unemployed people, usually children or women, have to walk several kilometers a day for procuring water for the family (UNICEF and WHO 2019). Furthermore, lack of water and scarce hygiene can facilitate the widespread of diseases (UNICEF and WHO 2019). Energy poverty, hunger, and no access to clean water are extremely correlated not only among themselves but also with low hygiene and low development rates (FAO 2019).

Electricity is widely recognized as a major determinant for social and economic development (Gambino et al. 2019), as it can allow the use of modern devices to be used for commercial or small industrial activities. The attention that African governments have paid on fostering access to electricity is justified by the correlation between electricity and income, as well as with the social development index (Zhang et al. 2011; FAO 2019). In fact, access to modern energy can have significant effects on poverty and access to water and reduce hunger, which are all significant priorities stated by United Nations (International Energy Agency (IEA) 2019a). Renewable energy–based electricity can provide reduction in CO_2 emissions by reducing the recourse to coal-based electricity in communities already reached by the national grid, by hybridizing with renewable sources existing mini grids mostly powered by diesel gensets (Micangeli et al. 2017), and by displacing the use of traditional fuels for lighting (Micangeli et al. 2017; Ambition to Action 2019). As an example, small-scale irrigation can contribute to income diversification and livelihood resilience (Murphy and Corbyn 2013).

Governments in developing countries often cannot enforce a fast development of rural electrification alone, due to lack in financial resources, know-how, or human capacity (Franz et al. 2014). On this regard, the involvement of the private sector as well as know-how holders, such as universities and international entities, is considered crucial (Franz et al. 2014), also to prevent the consequences that climate change may cause on already critical situations. Recent modern business models exploit the benefits of the integrated approach of the so-called energy-water-food nexus, by which the developer brings in electricity service, which in turn avails services like water and food through irrigation (Res4Africa 2019).

Universities produce knowledge and promote long-term growth through innovation and technology transfer to private and public sector. On the other hand, governments develop guidelines and policies in order to guide the industry toward the long-term social benefits for society. By considering the above, it is clear that significant synergies among the three entities can be explored and this cooperation is called “Triple Helix” (Leydesdorff and Etzkowitz 1995; Carayannis and Campbell 2010), which is proposed in this chapter as a tool to foster climate change adaptation in Kenya, with the special attention to the Marsabit County, an area heavily hit by climate change and subject to draughts and floods.

In section “The Triple Helix,” the Triple Helix concept is detailed, including applications for rural electrification, Africa, and sustainability concerns. In sections “Energy Access and Climate Change in Kenya” and “Case Study – Marsabit County, Kenya,” the case study is introduced and in section “Discussion” the major discussions are proposed. Finally, the conclusions are made.

The Triple Helix

The concept of Triple Helix (TH) has been proposed in the 1990s (Leydesdorff and Etzkowitz 1995) as a new framework to conceptualize relationships between university, government, and industry, to address the need of organizational innovation in a knowledge-based society. Innovation, defined as “reconfiguration of elements into a more productive combination” (Etzkowitz 2008), requires, in this view, a central role of the university, since innovation is not merely attributable to new product development by the industrial sector (Etzkowitz 2008).

The Role of the University

It has been acknowledged, in a seminal work made by Gibbons et al. (Gibbons et al. 1994), that the very production of knowledge has transitioned from a “traditional” framework, labeled Mode 1, driven and administered by classic academia in a disciplinary context, to a new mode, labeled Mode 2. In this new framework, knowledge is produced in the context of application, by a variety of actors coming from different disciplines, in an interactive relationship with society as a whole, both in defining the problems and research goals, and in diffusion of results. In recognition of the different way of knowledge production, and the role that it acquired in innovation, the university reshaped its mandate. The first modern universities were created in the twelfth century with the purpose of preservation and dissemination of knowledge (teaching mission). In the nineteenth century a second mission – research – was added, and more recently a third mission, that of contribution to economic development (Etzkowitz 2003). This mission requires an entrepreneurial model to be adopted by academia, that is not limited to preservation and transmission of knowledge but is involved proactively in technology transfer and incubation activities (Etzkowitz 2003). Furthermore, Carayannis et al. proposed the concept of “Mode 3” in which knowledge is produced by pluralism and diversity of knowledge, in a Triple, Quadruple, or Quintuple Helix framework, also including a combination of modes 1 and 2 (Carayannis and Campbell 2010).

The Relationships between University, Government, and Industry

The relationships among these three entities can be visualized as lying among two extremes: a centralized model where the government guides science policy and industrial development ("statist model") or a situation of very limited interaction, where each entity attains its core mandate separately from the others ("laissez-faire model") (Etzkowitz 2008). To visualize the interactions typical of the TH, Fig. 1 shows the "field interaction model" proposed by Eskowitz (Etzkowitz 2008) that schematizes government, industry, and university as three spheres with an inner core, representing their specific functions, and outer cores that overlap as each entity "takes the role of the other on a synergetic manner."

It is argued that the TH concept could act as a flywheel in pursuing a path of compliance with the objectives set out by the Sustainable Development Goals (SDGs) for rural areas of developing countries. However, TH dynamics has usually referred to a context of discontinuous innovation in advanced technological sectors such as ICT (Information and Communication Technology), semiconductors, or biotechnology. The most iconic example of regional development led by TH dynamics is the one of Silicon Valley, an international hub for high-tech companies animated by Stanford University's knowledge development (Etzkowitz 2012). In the following section, we will look at how the TH framework has been applied and discussed in the African context and how it has been integrated or reformulated to embed the sustainability issues underpinned by the SDGs.

Triple Helix in Africa

Rarely TH applications have been found in Africa. As noted by Outamha and Belhcen (Outamha and Belhcen 2020), the core mission of university in the

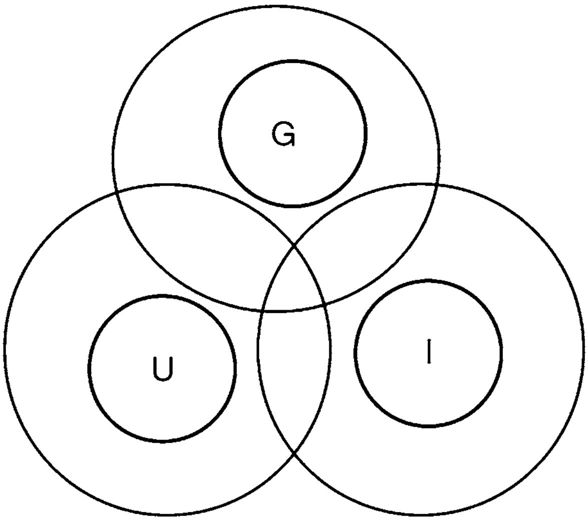

Fig. 1 Triple Helix field interaction model (Etzkowitz 2008)

continent is still the provision of human capital to industry and government, hence it is not on par with the global standards of knowledge-based societies. The historical reasons for this have been identified by some authors in the focus on mass primary and universal education over higher education in aid programs, at the expense of higher education (Dzisah 2011).

In Outamha and Belhcen (2020), a list of challenges that interconnections between university and industry are facing in Africa is given and shown in Fig. 2, together with the challenges for the implementation of mini-grids for rural electrification (African Development Bank Group et al. 2016). The different points are shown below:

- The lack of data regarding mini-grid projects reflects the lack of interest and commitment from industry to share information and collaborate in knowledge creation and diffusion, aggravated by confidentiality and property right concerns.
- Lack of capacity for mini-grid development reflects the lack of interest and lack of communication platforms to socially disseminate results of application-oriented curricula (Perez-Arriaga et al. 2018).
- Lack of access to finance reflects the lack of entrepreneurial prowess on the university side, resulting in lack of interest and aggravated by lack of mutual trust and lack of communication platforms bringing together the other two sectors.
- Gaps in policy and regulation reflect that academic curriculums in universities, prioritizing human capital formation, tend to not address the training of leaders that can give an answer to structural problems undermining the development of countries.
- Lack of viable business models is also a consequence of a lack of coordinated effort from governments planning for electrification plans, state-owned utilities, private actors, and academics in analyzing and reviewing current on-field experiences and contributing to develop improved models, overcoming contradictions

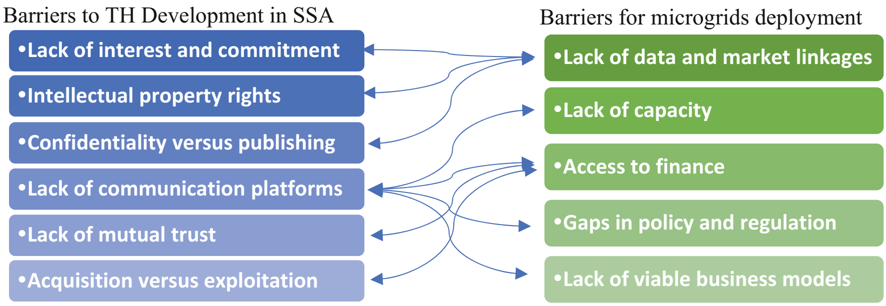

Fig. 2 Proposed linkages between barriers to university-industry linkages in SSA (Outamha and Belhcen 2020), on the left, and the barriers to development of Green Mini-Grids in SSA (African Development Bank Group et al. 2016), on the right

between knowledge acquisition by universities and commercial exploitation by private sector players.

The adoption of a TH framework has been proposed for the energy sector in SSA, specifically for the development of photovoltaic installations in Uganda (Da Silva and Wassler 2011). There are examples of spin-off companies operating in the Solar Home System sector in SSA, such as BBOXX (from Imperial College of London) and Azuri Technologies (from Cambridge University) (Bagley et al. 2018). By looking at these two companies, it is worth highlighting the issue of the "localization" of TH dynamics for the specific case, as they are firms born from non-African universities but working on African ground with local government and international entities.

In tackling the issue of electricity access conjointly with the food and water security and climate change adaptation issues, it has to be kept in mind that is a sector of intervention with serious concerns of bankability of investments (Kottász and Draeck 2017), especially for the realization of mini-grids, and in which international organizations and NGOs play a leading role. Therefore, there is, on the one hand, a multiplicity of stakeholders (i.e., NGOs) that are not present in the classic TH model, and on the other hand, a geographical globalization by which interventions directed at rural communities of developing countries involve not only local governments, universities, and industries but also international counterparts, mobilized by the concerns and goals of international agencies and non-profit organizations. As an example, in Moore et al. (2015) a program for ICT (Information and Communication Technology) education for Rwandan teachers is discussed as a possible example of TH development, albeit "loosely" not only because of the leading role of the local government in proposing the program, supported by local academia and privates, but also for the role of UNESCO and foreign cooperation agencies, factors that "are missing from the model."

Triple Helix for Sustainability and Climate Change

The original TH model did not entail sustainability issues linked to innovations. Etzkowitz and Zhou (Etzkowitz and Zhou 2006) proposed to consider a second TH system, one of university, government, and public to act as a counterbalance to technological innovations introduced by the university-government-industry triad, by representing the "dynamic of controversies over technological innovation." This picture of twin helices was chosen to maintain the triadic nature of each one, whereas other authors have proposed to the inclusion of a fourth helix – representing civil society, in form of NGOs or other associations of citizens – and a fifth helix, accounting for the natural environment of society (Carayannis et al. 2019). A quadruple helix approach has been proposed specifically for Africa (Kimatu 2015), as it could provide the needed "sustainable innovation ecosystem" to accelerate economic development. Similarly, a quadruple helix approach is advocated in (Amaro et al. 2014) for Guatemala, a country vulnerable to extreme climate events that shows a lack of awareness for climate change effects and related action systems, and that could therefore benefit from a TH intervention integrated with civil society actors.

Finally, other authors criticized the underlying paradigm of the university role in a TH model, namely the concept of third mission pursued by an entrepreneurial university, highlighting how the adoption of market logics promoted profit over the technology transfer; the new mission for academic institutions should be that of "creating societal transformations in pursuit of realizing sustainable development" (Trencher et al. 2014). In this perspective, with the goal of materializing sustainable development in a specific context, a function of "co-creation for sustainability" is proposed for the university, beyond the conventional research and development and product improvement through innovation.

Energy Access and Climate Change in Kenya

Country Overview

Kenya is an equatorial country of about 580,000 km^2 located in East Africa with significant different climate conditions varying from desertic to humid areas. With a gross domestic product (GDP) of 87.9 billion USD in 2018 with an average growth rate of about 9% in the past 10 years and a population of about 51.4 million people in 2018, Kenya is experiencing a strong economic growth (World Bank 2020). In the last 20 years, the GDP per capita has grown steadily and even poor people have benefited as the poverty ratio decreased by 36% over the period.

However, the Sustainable Development is not achieved in Kenya; still many people live below the poverty line, rarely water is safely managed with even no basic service in 40% of cases (UNICEF and WHO 2019), hunger significantly affects 10–40% of the children 5 year old or younger (FAO 2019), and sanitation and hygiene is even worse, also affecting maternity-related concerns (UNICEF and WHO 2019). Energy access is still limited: about 25% of people do not have access to electricity and an even larger proportion (75%) have no clean cooking facilities (World Bank 2020). Altogether, inequalities are significant, as also proven by the high 40% Gini index (2015) (World Bank 2020). Nevertheless, these problems have been decreasing.

In order to promote growth and tackle these challenges, the government has developed and implemented the Kenya Vision 2030 program in 2007 (Ministry of Planning and National Development 2007) with significant pillars based on macroeconomic stability, measures for the poor, capacity building, research, infrastructures, and energy. A new constitution was promulgated in 2010 and the corresponding legislation and administrative procedures have been set up the following year. The reform laid the bases for the decentralization of power into county-level governments able to develop local policies and tax reform accounting for the specific problems of the territory (Ministry of Planning and National Development 2007; Ngigi and Busolo 2019). The Devolution, which was ushered in 2013, has benefits in terms of a more equitable distribution of resources, economic and social development, political participation of citizens, enhanced transparency and accountability of governments, and even unity (Ngigi and Busolo 2019).

Climate Change

Kenya is vulnerable to climatic events, mainly droughts and floods. According to the National Adaptation Plan (NAP) launched in 2016 (Government of Kenya 2016), droughts have been recurring in the past 40 years, affecting millions of people by disrupting pastoral and agricultural activities, causing famine and population displacement. Floods, which are recurring phenomena as well, cause loss of human lives and damages to infrastructure, such as roads or power lines, hence potentially leading to problems to the transportation sector and the supplying of basic services to the population. Moreover, the areas subject to floods can experience the spreading of waterborne or sanitation-related diseases in the subsequent period (Government of Kenya 2016), as humid conditions ease the widespread of diseases, excrements and sewage are difficult to contain, especially in case of open defecation (UNICEF and WHO 2019), and the damaged infrastructure delay possible aid (Bündnis Entwicklung Hilft (Alliance Development Works) and United Nations University – Institute for Environment and Human Security (UNU-EHS) 2016). Given the damage and risks due to these extreme events, local and international entities have developed policies and dedicated programs for droughts and disaster risk management in Kenya, as detailed in Global Water Partnership Easter Africa (GWPEA) (2015).

Rural Electrification in Kenya

In Kenya Vision 2030, the "long-term development blueprint for the country" launched in 2007 (Ministry of Planning and National Development 2007), energy is considered a foundational infrastructure to enable the goals set out by the government on the economic, social, and political governance pillars. To address the specific issue of electricity access in rural areas, the Rural Electrification Authority (REA) was created in 2007, and then with the 2019 Energy Act adopted in March 2019 (Republic of Kenya 2019), REA has been changed to Rural Electrification and Renewable Energy Corporation (REREC). REREC has the mandate to develop and implement the rural electrification program of Kenya and to manage a dedicated Rural Electrification Programme Fund, also established by the Energy Act.

This choice reflects the change of pace in the country's objectives: the target for 100% electricity access in rural areas originally set out for 2030 (Rural Electrification Authority (REA) 2008) has been moved to 2022 in 2013 (Kenya Ministry of Energy 2018), as electricity is considered a key backbone for the achievement of the "big four agenda" (Republic of Kenya – The National Treasury and Planning 2018) pivoted on enhancing food security, universal healthcare, affordable housing, and increasing the GDP share of manufacturing and agri-processing activities. Kenya has been the fastest African country in closing the access gap, with an annualized increase in access of 6.4 percent points between 2010 and 2017, with a remaining deficit of 18 million people without access, corresponding to a 63.8% access rate in 2017 (IEA et al. 2019).

According to the national electrification strategy, universal access will be achieved mostly via grid intensification and densification (2.77 million connections), standalone solar systems (1.96 million connections), grid expansion (269,000 connections), and mini-grids (35,000 connections) (Kenya Ministry of Energy 2018).

Research showed that the mere presence of grid infrastructure in Kenya does not translate to high rate of consumer takeoff, even for "under grid" households that are within 200 m of a low voltage power line (Lee et al. 2014). To address this issue, the Last Mile Connectivity Program has been launched, to tackle the key issue of affordability of the connection fee, lowered from 398 to 171 USD, including the opportunity of paying in monthly installments.

On the other hand, the construction of the mini-grids, foreseen by the national electrification strategy, will fall under the Kenya Off-Grid Solar Access Project (KOSAP), started by the Ministry of Energy in July 2017 and financed by the World Bank (Ministry of Energy 2018). The project benefits 14 underserved counties in the northern and eastern regions of Kenya, including the Marsabit County, and envisages providing standalone systems, for dispersed users and public facilities, clean cookstoves, solar water pumps for community facilities, and mini-grids in selected target communities. As per government data, the number grew to 151 after the field surveys (Ministry of Energy 2019a). It is worthy noticing that KOSAP integrates environmental concerns, citizen engagement, a capacity building component – also directed at county governments – and incentives for private sector involvement. The mini-grids to be developed under this framework, in fact, will be developed under a public-private partnership (PPP) lasting 7–10 years by which generation facilities will be co-funded by public and private actors, and distribution networks will be built with public funds only (KP and REA 2017). Until the PPP lasts, the O&M of generation and distribution assets will be performed by a single private service provider (PSP), while the final users will be KP customers subject to the national tariff (KP and REA 2017); thereafter, all the assets, hence both the generation and distribution ones, will be owned by the Government of Kenya.

According to the National Electrification Strategy, the funding allocated on improving the national grid are about 2.3 billion USD over five years, accounting for about 82% of the total. The interventions are expected to focus on the installation of new transformers (grid densification), on the extension of existing MV lines up to 2 km to reach new customers (grid intensification) and also on the extension of the distribution system with longer lines expansion within 15 km the existing backbone (grid extension). These measures focus on areas relatively close to the existing network; yet, rural areas are not overlooked. In fact, about 18% of the funding will fund mini-grids and solar home systems (SHS) with the goal of reaching the people that cannot be reached by the other measures. SHS will receive more than ten times the funding with respect to mini-grids (Kenya Ministry of Energy 2018); yet, the potential for mini-grid development in Kenya may have been underestimated in the national planning strategy, as detailed in a series of technical reports and scientific papers (Ambition to Action 2019).

Case Study – Marsabit County, Kenya

In this section we describe the major activities in the view of the TH concept that have been developed in Marsabit, Kenya. The information reported here are based on the available literature and the knowledge of the experienced authors, also based on field work. Three case studies have been chosen for this book chapter due to the different types of conditions and information they represent.

Overview

Marsabit is one of the 47 counties created with the 2010 Constitution of Kenya, located in the northern part of the country, bordering Ethiopia. According to the most recent census, held in 2019, Marsabit has 459,785 inhabitants occupying a total of 67,000 square kilometers, making it the least densely inhabited county in Kenya, with an average population density of 6 persons/km^2 (Kenya National Bureau of Statistics 2019). The agroclimatic zones range between very-arid (zone VII) to semi-humid/semi-arid (zone IV). The prevalent land cover is barren land (65.4% of the total area), which is only fit for pastoralist activities (Wiesmann et al. 2016). Rural population engaged in agri-pastoral activities is largely nomadic, moving around the countryside according to the seasons in search of food, water, and grazing land.

The poverty rate in Marsabit registered with the 2009 census was 75.8%, the fourth overall highest among Kenya, with a poverty severity of 8.8% with respect to a 4.89% national average (Wiesmann et al. 2016). The living conditions are very different among the various sub-counties and among towns and rural areas. All the settlements around the main northern road, which goes from Merile to Moyale and connects Kenya to Ethiopia, have the advantage of increased access to goods coming from all the county and benefit from the presence of numerous investors, which started setting foot in the region since devolution and significantly increased their presence during the last few years. In a comparative analysis done among Isiolo, Marsabit, and Meru counties, Marsabit exhibited the lowest resilience capacity index (FAO 2017). The main reason was a poor adaptive capacity, linked to low education levels and low income diversification, given the predominance of pastoral activities (FAO 2017).

Although the region is one of the lowest developed in Kenya, food insecurity affects a limited share of the population (10–15%) given the large consumption of milk, but there is serious/critical malnourishment among above 15% of children and it is also stated that the whole population is even at significant risk of food insecurity in case of drought emergency (UNICEF 2017). Moreover, despite improvement in the years, water access is still a problem. Socioeconomic analyses revealed that only 26.4% of population above 3 year old is currently enrolled in school, whereas 63.4%

of the population has never attended one (Kenya National Bureau of Statistics 2019). The typical economic activities are farming and livestock production, with a minority practicing fishing (1295 households out of 77,495), yet with no commercial-oriented business as the majority of households conduct these activities for subsistence (Kenya National Bureau of Statistics 2019). At the time of writing, the release of the 2019 census is still incomplete, so for other relevant data figures provided will refer directly or indirectly through secondary literature, to the 2009 census.

Given the climate and soil conditions, about 80% of the population is involved in pastoral production, a sector extremely vulnerable to not only recurrent droughts that have caused losses for over 60% of livestock in recent years but also floods that have also caused sweeping the cattle and killing them (The Ministry of Agriculture Livestock and Fisheries (MoALF) 2017). There are no perennial rivers but only four seasonal drainage systems (Marsabit County Government 2018); therefore, only 38.2% of the households have access to safe water (Wiesmann et al. 2016). The county is dependent on short rains for 80% of food security and on long rains for 20% (Kenya Food Security Steering Group (KFSSG) and Marsabit County Steering Group 2017). Moreover, the irrigated areas for the major crops (maize, tomatoes, and kales) declined also due to high maintenance costs for irrigation and low recharge of surface water sources (Kenya Food Security Steering Group (KFSSG) and Marsabit County Steering Group 2017).

Aiming to adapt to these challenges, some locals have attempted to develop activities such as water harvesting, value addition to local products, conservation of soil and water, tree planting, business diversification, selection of more resistant livestock types, yet in an insufficient and uncoordinated way, and the lack of access to electricity and good infrastructure are clearly additional barriers (The Ministry of Agriculture Livestock and Fisheries (MoALF) 2017). Deforestation in the lowlands in combination with droughts contributes to reduced water flows, health issues, and undermining of food security and strongly affects not only the living condition of the population but the farming businesses, agriculture targeting programs, and pastoralist pathways and lowers drastically the level of security due to land use conflicts (The Ministry of Agriculture Livestock and Fisheries (MoALF) 2017). Armed fights, which can also have a tribal nature across counties, result in human and livestock deaths, destruction of crops and homesteads, fear, and poverty.

Energy Access in Marsabit

Energy access in Marsabit County is restricted to urban centers, always supplied by off-grid solutions with the exception of the towns of Sololo and Moyale, which are interconnected to the Ethiopian national grid, thanks to their proximity to the border (Republic of Kenya and County Government of Marsabit 2018). A list of public mini-grids active in the county is provided in Table 1, the only known active private mini-grid in Table 2, and the list of 13 sites in which mini-grids will be built under KOSAP in Table 3. Also, a list of 26 medical, school, and public facilities to be

Table 1 Operational public mini-grids in Marsabit (Nygaard et al. 2018; Ambition to Action 2019)

Off-grid station	Diesel (kW)	Solar (kWp)	Wind (kWp)	Battery capacity (Ah)	Connections	Commissioning date
Marsabit	2900	0	500	0	8200 (June 2016)	1977
North Horr	184	0		0	160 (June 2016)	2016
Laisamis	264	80		27,816	160 (June 2016)	2016
Illaut	50	60	0	76,800	200	2019
Ambalo	50	60	0	76,800	200	2019
Balesa	50	60	0	76,800	n/a	2019
Total	3498	260	500	258,216	8920	

Table 2 Operational private mini-grids in Marsabit (Blodgett et al. 2017; Nygaard et al. 2018)

Mini-grid	Developer	Solar (Wp)	Commissioning date	Customers
Merile	Vulcan Inc.	1.5	2014	27

Table 3 Mini-grids to be built in Marsabit County under KOSAP (Ministry of Energy 2019a)

Mini-Grid	Potential customers
Bubisa	329
Kargi	379
South Horr	496
Loiyangalani	1051
El Gadhe	108
Gatab	299

benefited by KOSAP intervention in the county has been published (Ministry of Energy 2019b). Finally, there are also private projects, however, often supported by international cooperation (KfW/GIZ/EnDEV) such as for the mini-grids to be developed in Dukana, Illeret, Ngurunit, Dabel, and Diridima (Energies Development 2018; Nygaard et al. 2018).

Moreover, although being a low developed area, there have been developed some large-scale projects in recent years. First of all, given the large wind power potential available in areas of the region, a large scale 310 MW wind farm, representing about 15% of the installed capacity, has been developed close to lake Turkana and connected to the national grid in September 2018 (LTWP 2018). Furthermore, given the proximity with the Ethiopian border, a 263-km HVDC transmission line has been developed as part of the Eastern Electricity Highway Project interconnecting Kenya and Ethiopia (KETRACO 2018). Despite the location of these large electrification projects, the County has not benefited from them in terms of increased access to electricity because low energy demand does not justify the installation of substations. However, the projects have led to enhance and tarmac the 195-km road infrastructures connecting South Horr with Laisamis (code D371) and with Loiyangalani (code C77), with the objective of easing the transport of materials and equipment for the construction of the wind farm (Lake Turkana Wind Power Limited 2011). Moreover, under the LAPSSET project the tarmacking of the Isiolo-Moyale highway has been completed, with significant economic benefits and enhanced accessibility for the region (Republic of Kenya and County Government of Marsabit 2018). The next step of the project, to be developed in future years, is the development to complete the corridor with a railway line (Republic of Kenya and County Government of Marsabit 2018).

The increased level of economic activities along the Isiolo-Moyale road is also visible as shops and residential houses are quickly sprouting by the highway. Local people are moving slowly from pastoralism to different types of business in this area or are using part of their herd to try and invest in diverse activities.

The Marsabit County set out the development of renewable energy sources as a recommendation for climate change mitigation and adaptation, aspiring to exploit the solar and wind potential of the region (Republic of Kenya and County Government of Marsabit 2015). However, the same document stated the lack of human capacity and investment opportunities as barriers for development of energy projects, as well as high fuel costs in construction machineries that hinder investments (Republic of Kenya and County Government of Marsabit 2015).

During the 2013–2017 period, the county provided over 2000 energy saving charcoal burners (*jikos*) to households, 417 solar street poles, and distributed solar panels to schools with the goal of improving the household reliance on biomass and kerosene that can significantly affect the health of people (Republic of Kenya and County Government of Marsabit 2018). While the goal for solar street poles set out in the previous integrated development plan has been exceeded, the other targets for the distribution of 500,000 jikos, start-up of a solar equipment enterprise, installation of solar pump driven boreholes, and construction of a power station per constituency have not been fulfilled yet (Republic of Kenya and County Government of Marsabit 2015, 2018).

In the current development plan, not only the previous targets have been restated and expanded but also specific funds have been dedicated for Centre for Renewable Energy Studies and Research of Marsabit County (Republic of Kenya and County Government of Marsabit 2018) to help overcome the knowledge gaps limiting the supply of energy to the population.

Marsabit Town

Marsabit Town is the main town in the county and is situated on an isolated extinct volcano, Mount Marsabit, where the environmental conditions are completely different from the rest of the region.

Devolution, started in 2013, had a broad impact on the development of Marsabit Town that became the county government headquarter, thus, not only the center of all international organizations operating in the county but even of all the various ministries of regional government. As a result, the town is attracting a growing number of investors with several companies setting up business and effectively opening up the northern frontier region market. Marsabit market, especially during Saturdays, became the first market in the County. Cereals and legumes are imported directly from Ethiopia, while vegetables come from the area around Meru. Between 2013 and the 2019 more than 40 schools were built and one level 5 hospital, in addition to the one run by CARITAS. In the town there is the presence of numerous clinics and dispensaries, mostly in the scattered sublocations. Marsabit Town currently has more than 50 primary schools, 15 secondary ones, and 2 technical institutes, accounting both public and private institutions. All the secondary schools and most of the primaries are electrified, reflecting as per the first phase of REA's strategic plan for 2008–2012 (Rural Electrification Authority (REA) 2008).

The town is served by a mini-grid installed by REREC and operated by Kenya Power with an installed capacity of 3.1 MW (2.6 MW from three diesel generators and 500 kW from wind turbines). The system was commissioned in 1977, with the generation capacity growing steadily and number of connections steeply rising, especially after devolution came into place. As most of the public infrastructure has then been built and reaching around 8200 customers as per June 2016. The medium voltage lines used to connect the public facilities have then been used to give access to households located within 600 meters of an existing transformer, with the uptake from final users facilitated by the Last Mile Connectivity Program which lowered the upfront cost of connections. Consequently, most of the connected households are either located in the town center where most of the business activities take place, or in the vicinity of schools, hospitals, or dispensaries and county government buildings, but also the areas surrounding the town are slowly benefiting from the ramp-up in electricity access.

Water access is the primary issue of the population residing in the town. The water table is very deep, due to the characteristics of the volcanic soil, and the main source of water are shallow wells in the forests, water boozer coming from boreholes in the nearby settlements or through water harvesting.

National government programs focusing on floods and droughts resilience were already deployed before devolution, but through the county government presence in the town, the solutions have been increasingly adapted to the specific context collaborating directly with the NGOs operating locally, local associations and cooperatives. Numerous projects and training programs have been carried out on water harvesting, water management, and small-scale agriculture as focused programs on seeds restocking and drought-resistant crops.

Illaut

Illaut is a town located in the south-western part of Marsabit, near the border with Samburu county. Illaut, after the rehabilitation of the existing Laisamis–Ngurunit–llaut–South Horr–Loiyangalani road, funded by the African Development Bank and the Government of the Netherlands to connect the Wind Farm developed on the shore of Lake Turkana, became a central point of connection for all the surrounding areas. The chief of Illaut is responsible for everyone living in all the nearby villages.

In consideration of its relevance, Illaut has been selected as one of 26 sites for the installation of hybrid mini-grids by REREC (REREC 2019). The system was commissioned in October 2019, with around 20 customers connected (two shops, one church, and one dispensary plus households). Due to the lack of Internet connectivity, the smart-metering system is still not operating at the present time, while power generation and consumption is steady. Having network access is in fact mandatory for the KP metering systems, as to collect the revenues, monitor consumption, and bill collection is a big hurdle for most of the new hybrid mini-grids operated by Kenya Power. However, Safaricom started building a repeater tower in the end of 2019, which is supposed to start working during spring 2020, to grant network access to the Illaut and the nearby villages. Access to the network has been proven to bring direct economic and social benefits for everyone: mobile and Internet services have a transformational impact, offering life-enhancing financial and health services, as well as the simple ability to enhance communication within families and within the whole community.

Most of the houses are made out of bricks and the Tuesday market became the main trading post for goods coming from Meru and Nairobi, through Marsabit and Nyeri, and for local handmade products. The presence of a nearby shallow well provides access to water that has to be treated to be drinkable. This is not perennial and depends on rainfall, making it hard for people to access water during the long-lasting dry season.

Firewood is the primary source for cooking, followed by charcoal. In Illaut town local government is creating awareness regarding the negative that open fire has on the health of mainly women and children.

In the end of 2019 the county government, following the access to water plan of the Water Resources Management Authority (WARMA), started building a borehole in the town that will be completed in early 2020. Thanks to this borehole the town, and the nearby settlements, can have access to clean water that can be used for irrigation and cattle survival during the dry season. The chief of the village, together with key personalities of the community, has been engaging both the farmer communities in Marsabit and Laisamis, NGOs like PACIDA, and some SACCOs to obtain training, seedlings, and agriculture machines to open up the possibility of unlocking the potential of local farmers.

Illaut can be considered as an example of sustainable development and climate change resilience through the TH model, due to:

- Improvement of the infrastructure by the government (Laisamis-Loiyangalani road funded by AfDB).
- Electrification through a hybrid system by REREC (60 kW) (Rural Electrification Master Plan).
- Construction of a borehole and installation of a pumping system for human and agriculture use by the county government (WARMA access to clean water program).
- Installation of a repeater for the network access by Safaricom (private company intervention).

Laisamis

Laisamis is the main town of Laisamis constituency. It is situated between Merile and Log-logo, on the road from Isiolo to Marsabit Town. In Laisamis most of the buildings are made out of bricks, but most of the people in the surrounding areas are living in huts. Along the road there is the presence of schools, hospitals, shops, hotels, and other business which are benefiting from affordable and reliable energy access.

Laisamis is served by a hybrid mini-grid commissioned by REREC in 2015 that currently serves 170 connected customers, mostly concentrated around the tarmac road and near the town center, where the majority of shops and activities are located. The system that combines 264 kW of diesel generators, 80 kW of solar photovoltaic, and a battery storage system experienced a significant growth of connections thanks to the implementation of the last-mile project. Furthermore, an expansion of the system to reach the communities of Log-logo and Merille started 2 years ago, and the main distribution infrastructure, transformers, and low voltage lines have been put in place in early 2020, but are not yet operational.

Merille and Log-Logo are two urban centers located, respectively, 23 km south and 47 km North of Laisamis. In both towns there is presence of numerous boreholes that are powered by PV systems or diesel generators for shops, dispensaries, and schools. The interconnection of the systems foresees the installation of an additional 500 kW diesel generator to provide adequate electricity supply. This is creating a big opportunity for people to benefit from energy access through income-generating activities.

In Laisamis, access to water is granted by a seasonal river and different private and public boreholes scattered around town. In fact, the water table is not deep, and as results of surveys by the county government and WARMA suggest there is a good potential to dig boreholes. During dry season the sources of water, for the majority of the people, are two public boreholes in the north west of the main settlement, where they can access water for free, but in limited quantities. The salinity level of the water extracted is high and has to be treated accordingly.

Discussion

The selected case studies in Marsabit are evaluated with respect to the theoretical framework laid out in section “The Triple Helix,” and in consideration of the literature review detailed in section “Energy Access and Climate Change in Kenya.” Although the analysis has been carried out for Marsabit County, a great part of it can be replicated in the other 13 underserved counties identified by KOSAP.

An interesting aspect of this ecosystem is that NGOs have been attempting to improve local conditions by capacity building which can be done by locally present technical schools, vocational training centers, and Technical and Vocational Education Training (TVET) centers. In the proposed cases, in fact, NGOs have developed projects on agriculture and drought resilience species. It was also noted that some electrification activities have also been directly promoted by NGOs, but some projects have failed because the system has not been maintained. Here is when one sees the difference between NGOs and private sector partners. The latter will not leave as long as there is a market for the goods or services rendered.

In the three case studies reported above, water pumping from boreholes or close water sources is significant priority and is usually performed when the village is electrified and water is available nearby. The devolution that started taking place in 2013 has actually helped the county in addressing these problems.

The positive example of Laisamis has shown that combining energy with a safe source of water for people and animals has reduced the nomadism of the area, thus making the electric system more sustainable. Another useful information is an accurate estimate of the population able and willing to purchase energy from the mini-grid. As a matter of fact, load assessment is one of the most critical challenges in mini-grid development.

From the case study analysis, it appears that there is a growing attention in policymaking to the transversally and interdependence of key rural challenges such as energy access, climate change adaptation, and water and food security. Even if not explicitly mentioned, partial references to the TH approach are each day more present in the planning phase though the “silo mentality” that persists.

Education plays a significant role in terms of both enhancing awareness of technologies, opportunities, safe practices, and hygiene in the area and developing skills to promote growth. Currently there are eight vocational training centers (VTCs) in the county that provide above-basic education, four of them instituted by the county government. These centers nonetheless are not yet accredited by the Technical and Vocational Education and Training Authority (TVETA).

It is worth noticing the case of Illaut in which a repeater has been installed shortly after the mini-grid was installed. In fact, people look for connection as a modern mini-grid operator needs connectivity to operate, monitor, and manage the smart-metering system.

Considering this, universities can support and study all the above and identify best practices as well promote new solution to tackle the issues. For example, in Laisamis, the electricity service suffers from poor quality and outages, and the system will be soon enlarged to electrify the nearby villages. However, this may lead to increased number of outages and reduced quality given the long lines to reach the communities. This could be an opportunity for a university research center to provide support by analyzing the data in the field and promoting innovation also by field experience (mode 2). Social data combined with electrical data from the villages can be analyzed in order to estimate and promote the major determinants for load growth and even support the expansion of the mini-grid (Lee et al. 2014).

From the literature review on the TH, it is evident that when government, university, and industry work together in good coordination, rural electrification and climate change adaptation problems are easier to solve.

In a society in which innovation is one of the major drivers for growth, a good application of TH to rural electrification can be not only a promising solution but also promote growth by developing innovation in a challenging and new sector in which few players operate. Besides, electricity provided by decentralized solutions such as mini-grids can be not only an economic solution for areas but provide services that can help people to stop the nomadic lifestyle. Many Turkana people are building permanent houses where the wives and children can stay in a place and profit from education, health service, and electricity while their husbands move around in search of water and grazing fields for their animals.

Rural electrification is a very risky business and rarely can achieve bankability without external funds. However, it brings significant benefits to society in terms of externalities such as local growth, the development of business activities, higher education for children, improved healthcare conditions, and connectivity, to quote but a few services. Therefore, the public sector that looks at society as a whole should be interested in fostering activities and reduce barriers to rural electrification, with tools such as tax exemption, green line of credit, and grants by developing agencies.

The involvement of university in the process can promote innovation by pre-existing knowledge (mode 1), exploiting the field experience (mode 2), and also promoting capacity building for engineers, technicians, and students to provide the desired skills at county level. Therefore, alongside the "mode 2," which justifies the recourse of case studies, the "mode 3" of knowledge production that is based on pluralism and diversity ought to be used.

Additionally, it turns out that the TH concept for rural electrification and climate change might be extended including civil society and concern for natural environment conservation, which have been included respectively as the fourth and fifth helices, respectively, in the work described in Carayannis et al. (2019). Also the concept of "bottom-up triple helix" (Haas et al. 2016) is a valuable contribution toward a better understanding of the role of connector agents, financing institutions, market facilitators, and knowledge brokers. In short, a TH intervention for the development of vulnerable areas promotes the joint action of several entities.

In fact, there is for local universities not only the need to improve their research standards and improvement of curriculums to go beyond the training of workforce but also the mandate to carry out the capacity building of technicians and governmental actors (Perez-Arriaga et al. 2018) and to act as knowledge brokers in order to reach the final rural beneficiaries. In this sense, if we consider that, for example, Nairobi and Marsabit town are located more than 500 km apart, connector agents are needed even within a country in order to promote innovation by experience (mode 2). This specific issue has been addressed in Da Silva et al. (2018) that describes an outreach program to train solar PV technicians on the standards of the Kenyan Energy Regulatory Commission (ERC). The project represents a multi-stakeholder interaction involving academia (Strathmore Energy Research Centre (SERC)), donor agencies (USAID, GIZ), regulatory institutions (National Industrial Training Authority (NITA), ERC) and technical training institutions (TTI) which through "training of trainers" received the capacitation from SERC to train technicians in locations distant from Nairobi.

Conclusions

This chapter has shown that the collaboration of government, universities, and industry in a Triple Helix (TH) framework can be a promising tool for tackling rural electrification and climate change adaptation, using as example the Marsabit County, Kenya, case study.

One such lesson was the need to add to the traditional TH concept the civil society which can provide a soft landing for the private sector partner which at the initial stage may not see significant opportunities for business sustainability.

In modern knowledge-based society, the role of academia in promoting innovation is crucial, and rural electrification sector is not an exception. The university can identify best practices, develop research studies on the possible outcomes of different actions, and even support the development of novel devices, by working closely with the two other partners and having enough data to work with, which are very precious for the effectiveness of the studies.

In Marsabit, which is one of the least developed counties in Kenya, there have been limited examples of TH interventions, but the potential can be significant. Government can provide an adequate policy framework and/or fiscal stimulus, driven by the industry's needs, lowering barriers and reducing risks, after being discussed and agreed with the other stakeholders. Industry can make use of the innovation created by this environment and thrive, hence employing local people and boosting the economy.

The concepts discussed in this study can be useful for policy makers and players in the rural electrification, since they can be easily generalized for different areas in Kenya and Sub-Saharan Africa.

Climate Change Adaptation Mechanism for Sustainable Development Goal 1 in Nigeria: Legal Imperative

93

Erimma Gloria Orie

Contents

Abstract

Despite international efforts on poverty reduction in the last decade, poverty is rampant in many countries including Nigeria. Poverty remains a principal challenge for development in twenty-first century and a threat to achievement of Sustainable Development Goal (SDG) 1, which is a global attempt, among others, to end poverty by 2030. Meanwhile, 13 out of the 15 countries where extreme poverty is rising are in Africa. According to the World Poverty Clock, Nigeria, by 2018, had the largest extreme poverty population of 86.9 million, thus making the people vulnerable to malnutrition, armed conflict, migration, and other socioeconomic and environmental shocks. Whereas these impacts are exacerbated by climate change (CC), unfortunately, Nigeria's adaptation efforts are inadequate due to certain impediments. The chapter finds that Nigeria lacks the CC law to properly regulate institutional and policy interventions to impacts of CC. It argues that although adaptation as opposed to mitigation is interim, yet integrating adaptation measures into Sustainable Development (SD) framework and poverty reduction strategies is a potent means of addressing CC impacts on the poor and achieve SDG1 target. The chapter therefore recommends the establishment of CC

law in Nigeria that incorporates adaptation measures in poverty reduction strategies and mainstreaming of CC issues.

Keywords

Poverty · Adaptation · Sustainable development (SD) · Sustainable Development Goals (SDGs) · Climate change (CC)

Introduction

Since the turn of the twenty-first century, there has been an unrivaled concern of the international community to achieve sustainable development (SD). From Stockholm Declaration through Rio +10, Agenda 21 to the United Nations Conference on Sustainable Development held in Rio 2012, and the Millennium Development Goals (MDGs), the Paris Agreement, and the recent UN Conference of Parties (COP 24) at Bon, Germany, the focus has been to combat environmental damage and reduce poverty and diseases through global cooperation on common interests, mutual needs, and shared responsibilities. Even the United Nations 2030 Agenda for Sustainable Development is an action plan focused on people, planet, prosperity, peace, and partnership (5Ps) with a mandate that no one should be left behind. The first Sustainable Development Goals' Report published in 2016 (Portugal 2016) reveals that about 1 in every 8 persons in the world still lives in extreme poverty; some 800 million people are suffering from hunger; the birth of nearly 1 in 4 children under the age of 5 years is still unregistered; women spend about 2.4 times more hours per day on caregiving and household tasks than men; 1.1 billion people live without electricity; and that water scarcity now affects more than 2 billion people in the world (Ibid). Furthermore, the UN has launched the 2018 version of the yearly Sustainable Development Goals (SDGs) Report (SDG Report 2018) which finds that conflict, climate change, and inequality are major factors in growing hunger and displacement, and are hindering progress toward the SDGs. The implication of these reports is that the world, particularly Africa and of course, Nigeria, is not on course to ending poverty at least by 2030. This could undermine the attainment of SDG 1 which deals with poverty reduction.

The major objective of the World Bank since the 1970s has equally been to reduce poverty. In 2013, the World Bank Group announced two all-embracing goals: the end of chronic extreme poverty by 2030; the promotion of shared prosperity, defined in terms of economic growth of the poorest segments of society (to reduce extreme poverty to 3% of the world population by 2030 and, for the first time, including a distributional goal, "share prosperity" by promoting the income growth of the poorest 40%). However, the global proportion of people living in extreme poverty is three times lower than in 1970; it fell from 43% in 1990 to 19% in 2010 and further to 17% in 2011 (Ending Extreme Poverty 2013).

Despite commitments to inclusive, pro-poor, and broad-based growth, the poorest 20% of people still receive just 1% of global income causing the gap between the poorest 20% and everyone else to continue to widen. Indeed, 13 out of the 15 countries where extreme poverty is rising are in Africa. According to the World Poverty Clock, by 2018, Nigeria had the largest extreme poverty population of 86.9 million due to drought, flood, heatwaves, ocean surges, reduction in crop yield, decreased fresh water availability, disruption of economic activities, destruction of infrastructure, etc. These challenges are exacerbated by the impact of climate change (Orie 2015), the end state of which is that the people are made vulnerable to malnutrition, armed conflict, migration, and other socioeconomic and environmental shocks. The National Bureau of Statistics figures showed that poverty incidence worsened between 2004 and 2010, despite impressive growth record over this period (Olofin et al. 2015). Poor farmers also risk losing crops as the flood season occurs when crops ripen for harvest. In the longer term, poor households also risk losing wage opportunities as the sick and injured cannot work or as the disaster destroys the need for labor. Recovery strategies, like selling assets, can leave the poor without income and thus more vulnerable.

Nigeria's extreme poverty population of 86.9 million can be scary. Specifically, for Lagos, Osun, Anambra, Ekiti, Edo, Imo, Abia, and Rivers States, the poverty level hovers between 8.5 and 21.1%; Plateau, Nassarawa, Ebonyi, Kaduna, Adamawa, and Benue States have poverty level that hovers between 51.6 and 59.2%, while the poverty level for Niger, Borno, Kano, Gombe, Taraba, Katsina, Sokoto, Kebbi, Bauchi, Jigawa, Yobe, and Zamfara States hovers between 61.2 and 91.9% (Olawale 2018). Certainly, these degrees of poverty make the people vulnerable to malnutrition, armed conflict, migration, and other socioeconomic and environmental shocks. Whereas these impacts are exacerbated by climate change, unfortunately, Nigeria's adaptation efforts to counter poverty are inadequate due to certain legal impediments. Nigeria, for instance, lacks the climate change law to properly regulate institutional and policy interventions to impacts of climate change. The crux of the matter is that without a legally binding framework, integrating adaptation measures into SD framework and poverty reduction strategies, it will be difficult to address climate change impacts on the poor and achieve SDG1 target. Moreover, the commitment to all-inclusive zero poverty has no global or national framework of measurement. These are some of the challenges Nigeria has been grappling with and must overcome in order to attain SDG 1 target. Perhaps, leveraging international best practices, the establishment of climate change law in Nigeria that incorporates adaptation measures in poverty reduction strategies could present a way forward and that is the motivation and what this chapter purposes to achieve. The chapter is limited mostly to document analyses of the relevant UN and other international conventions/documentations as well as national policies on the subject matter in the last decade when climate change, MDG, and SDG issues assumed more global attention and priority. The focus of this work remains the legal dimensions to Nigeria's efforts regarding climate change adaptation mechanism.

Therefore, the chapter begins with conceptual clarifications of key words to set the work in proper perspective leading to establishment of nexus between climate change adaptation and poverty. This is followed by a highlight of global efforts to combat poverty through Adaptation mechanism. Next is an examination of the policy, legal, and institutional framework for fighting poverty in Nigeria leading to a discussion on the legal issues, challenges, as well as strategies in the application of climate change adaptation mechanism to achieve SDG 1. Thereafter the chapter concludes with salient recommendations.

Conceptual Clarification

It is necessary to conceptualize the key words in order to put the paper in proper perspective and to aid understanding. The words and phrases to be conceptualized are climate change, sustainable development, adaptation, and poverty.

Climate Change

The United Nations Framework Convention on Climate Change (UNFCCC) defines climate change as a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods (UNFCCC Art 1.2). The impact of climate change include rise in sea levels, rise in temperature, and change in weather patterns resulting in decline in overall biodiversity, implications for agriculture and food security, human health, unpredictable rain pattern and floods, prolonged drought and subsequent crop failures, water shortages, and homelessness (Orie 2017).

Sustainable Development

Sustainable development is the universally adopted plan to promote prosperity and social well-being while protecting the environment. The 2030 Agenda for SD is “our shared vision of humanity and a social contract between the world’s leaders and the people” (Ban Ki-Moon), which sets an ambitious but achievable, universal, and holistic agenda for all. As a universal agenda, based on 17 SDGs and 169 targets to be implemented by all countries, the 2030 Agenda calls for the integration of the SDGs into the policies, procedures, and actions developed at the national, regional, and global levels. There is a clear call for action to dramatically scale up development finance and improve the development impact of all financial flows. But its goals are at risk of not being realized as the gap between the poorest people and the rest of the world continues to widen.

In several ways, the SDGs brought a novel tactic to the manner in which the world approaches the subject matter of development. These include, for example:

(i) Integrating the three dimensions of SD (economic, social, and environmental).
(ii) Being based on universal goals and targets to be implemented by all countries (and not only by developing countries).
(iii) Having a greater potential for tackling inequality and promoting human rights as a cross-cutting concern across all SDGs.

(iv) Involving new dynamic concerted efforts from a wide range of actors, including nongovernmental organizations (NGOs), the private corporate sector, academia, social partners, and other members of civil society, including the cooperation between parliament, government, regional, and local authorities. In fact, this is a challenge which concerns us all (Portugal).

Adaptation

The term adaptation according to the UNFCCC refers to "adjustments in ecological-social-economic systems in response to actual or expected climatic stimuli, their effects or impacts, and the building of a climate-resilient society that is able to withstand or recover quickly from difficult conditions caused by the adverse effects of climate change" (Medugu et al. 2011). Examples of adaptations include building flood defenses, planning for heat waves and higher temperatures, and installing water-permeable pavements to better deal with floods and storm water and improving water storage and use (Ibid; Orie 2015). Adaptation also encompasses making the most of any potential beneficial opportunities associated with climate change (for example, longer growing seasons or increased yields in some regions) (global climate change). However, the major challenge to adaptation includes the fact that adaptation is fundamentally about climate change risk management, and it is not a long-term solution, hence the need for reinforcement which mitigation offers (IPCC report).

A major benefit of adaptation is the fact that it is usually imbued with the prospects of reducing the negative impacts of climate change. However, the capacity to adapt is principally a factor of the socio-economic characteristics, and the likelihood of adaptation needs to be carefully analyzed given the peculiar circumstances of the developing countries and their obvious disadvantage with respect to technological, financial, and institutional provisions (McGuigan et al. 2002).

Poverty

The World Bank defines extreme poverty as living on less than 1.90 international dollars (int.$) (Roser and Ortiz-Ospina 2019). Poverty is the result of economic, political, and social processes that interact and frequently reinforce each other in ways that exacerbate the deprivation in which poor people live (Ibid). The United Nations has also now declared the eradication of poverty by 2030 as a primary development goal. Poverty is at the same time stark and conceptually elusive, especially when we try to track it statistically across nations and over time. The World Bank Group has been at the vanguard of developing measures of living standards and it sets the International Poverty Line (IPL). The poverty line was revised in 2015 and since then persons are considered to be in extreme poverty if they live on less than 1.90 (int.-$) per day. The measurement of this poverty is based on the monetary value of a person's consumption while the application of income measures is employed for countries without available reliable consumption measures (World Bank 2015). Alternative starting points for measuring welfare include subjective views (e.g., self-reported life satisfaction), basic needs (e.g., caloric requirements), capabilities (e.g., access to education), and minimum rights (e.g., human rights) (Ibid). There is also the national accounts method to estimate poverty which is based on academic studies that reconstruct historical income levels from cross-country macro estimates on economic output and inequality. Therefore, while the IPL is useful for understanding the changes in living conditions of the very poorest of the world, one must also take into account higher poverty lines reflecting the fact that living conditions at higher thresholds or well above the IPL can still constitute a destitute.

Nexus Between CC Adaptation Mechanism and Poverty (SDG 1)

The 2007 and 2014 IPCC reports state that due to the effect of climate change, both distributional impacts of increased temperature and precipitation changes will vary from region to region, affecting higher and lower latitudes disparagingly and asymmetrically (IPCC Fourth Assessment Report). The IPCC Report predicts further that global warming resulting from carbon emissions will cause a rise in sea levels and may lead to an increase in the frequency and severity of natural disasters. In addition, incidences of natural disasters such as droughts and floods, which affect agricultural production, fisheries and marine life, water resource availability, industry, and human health will continue to be on the increase and indeed exacerbated by climate change.

Coastal areas are most at risk to the changes outlined above. Increased sea levels will bring salinization and an intrusion of seawater into freshwater sources, flooding and loss of land, erosion, loss of wetlands and mangroves, and loss of soil fertility. Furthermore, changes in temperature will alter ocean circulation patterns, vertical mixing of water and wave patterns which will impact on marine productivity, availability of nutrients, and disturb the structure of marine and coastal ecosystems (IPCC 2001). While there is no data on the frequency of disasters due to climate change, Messer estimates that with a 70 cm sea level rise, the number of people at risk of annual flooding could increase from 46 million to 90 million. With such disasters come the urge need for interim relief assistance (like artificial irrigation in drought areas) to enable the people adjust to the impact of the disaster. Thus, adaptation enables the victims to access immediate and or interim assistance as opposed to a long-term relief which mitigation provides (Messer 2003).

Furthermore, the disasters are expected to increase the disparity in wealth between the developed and developing world, and redistributive impact is one of the major reasons for concern about the climate change phenomena as expressed by the IPCC in its 2001 report. Due to these differential effects, developing countries like Nigeria are likely to suffer more from the economic impacts of climate change, as well as being the least able to adapt to new climatic conditions. Moreover, poorer communities also have limited means to cope with the losses and damage inflicted by natural disasters. Lack of adaptation option like insurance policies, savings, or credit make it almost impossible to replace or compensate for the numerous things lost or destroyed, including houses, livestock, food reserves, household items, and tools (IPCC 2001), which in turn will threaten the chances of effective reduction in poverty level.

Developing countries often do not have the resources for these and consequently are ill-prepared in terms of coastal protection, early warning and disaster response systems, and victim relief and recovery assistance, hence the disproportionate level of climatic impact. For example, it has been asserted in some quarters that even when developed countries experience a larger proportion of property damage (75%), that recovery costs are higher for developing countries. Also, that whilst developed countries pay 0.1% of GDP in losses, developing countries pay 2–3%, or sometimes as much as 15% as seen with hurricanes in the Caribbean (Gurtner 2010). Developing countries also experience greater loss of life, about 90% of all deaths (Bankoff 1999). For example, the risk of drowning in Fiji due to dyke failure is one in 100,000, whereas in the Netherlands it is one in ten million (Olsthoorn et al. 1999). Notwithstanding the degree of risks exacerbated by climate change for these poor and marginalized populations, lots of uncertainties exist for developing countries regarding scientific predictions, levels of vulnerability, and the ability to adapt to these developments. Recent estimates suggest that, in the absence of adaptation, climate change could result in a loss of between 2% and 11% of Nigeria's GDP by 2020, rising to between 6% and 30% by the year 2050. This loss is equivalent to between N15 trillion (US$100 billion) and N69 trillion (US$460 billion) (National adaptation strategy). Several legal barriers, poor access to location, lack of services and infrastructure, and poor building structures all increase the vulnerability to flooding, storm surges, drought, and rain. The result is the accentuation of poverty, hunger, lack of quality education, gender inequality, loss of basic shelter, and jobs. These challenges are a threat to both the global and national efforts toward the attainment of the SDGs especially that of eradicating poverty.

The SDGs comprise 17 goals spliced into 169 targets. For example, the focus of SDG #1 is to end poverty and SDG #2 is to end hunger. Poverty breads hunger which in turn affects the general well-being of a person by reducing the coping capacity to environmental challenges. A poor man is usually hungry and thus cannot achieve SDG #3 which is on well-being. When the stomach is empty, nothing can enter the brain, but if the first three goals are achieved, one can make use of SDG #4 Quality Education and learn to respect others and internalize SDG #5 Gender Equality. Thus, the SDGs are interrelated and interconnected.

It has been noted that giving priority to SD and meeting the SDGs is in tandem with efforts to adapt to climate change. When SD promotes livelihood security, it enhances the adaptive capacities of vulnerable communities and households. Examples include SDG 2 and its targets that promote adaptation in agricultural and food systems (Lipper et al. 2014) and SDG 11 which supports adaptation in cities to reduce harm from disasters (Kelman 2017). The overall success of SDGs 2 and 11 will assist in reducing poverty which is SDG 1. Indeed it has been submitted by various scholars that a well-integrated adaptation supports sustainable development (Weisser 2014). Substantial synergies are observed in the agricultural and health sectors and in ecosystem-based adaptations. However, a particular adaptation strategy can equally lead to adverse consequences for developmental outcomes.

Furthermore, adaptation strategies that advance one SDG can result in tradeoffs with other SDGs. For instance, agricultural adaptation to enhance food security (SDG 2) causes negative impacts on health, equality, and healthy ecosystems (SDGs 3, 5, 6, 10, 14 and 15). Notwithstanding this important role that adaptation could play to ensure that achievement of SDG 1 remains on course, Nigeria has no climate change law for the implementation of adaptation policy to achieve SDG 1. This is quite a challenge that must be addressed in order to make progress.

This segment has so far established the nexus between climate change adaptation and poverty. It has argued that incidences of natural disasters such as droughts, floods desertification, etc. which continue to increase and indeed are exacerbated by climate change can be checkmated, albeit, in the interim by adaptation measures to ensure the eradication of poverty (attainment of SDG 1) by 2030. In the case of Nigeria, it is therefore imperative that her adaptation measures are strengthened legally to ensure that the stated target is achieved. The next section will examine the global perspective to this.

Global Efforts to Combat Poverty Through Adaptation Mechanism

There is increasing global efforts to address poverty based on our interconnectedness as peoples living on mother earth and the understanding of the need to save the environment for use by future generations. From around 1820, there was widespread poverty with more than a billion people that lived in extreme poverty, but this has changed over the last two centuries due mainly to economic growth not withstanding that the population increased sevenfold over the same period. According to these household surveys, 44% of the world population lived in absolute poverty in 1981, whereas in 32 years, the share of people living in extreme poverty was divided by 4, reaching levels below 11% in 2013. There were 2.2 billion people living in extreme poverty in 1970, while people living in extreme poverty in 2015 were 705 million (Roser and Ortiz-Ospina 2019).

The global incidence of extreme poverty has gone down from almost 100% in the nineteenth century to 10.7% in 2013. Some analysts have submitted that this substantial reduction of global poverty is not unconnected with the poverty reduction in China where in 1981 almost one third (29%) of the non-Chinese world population was living in extreme poverty, but by 2013, this share had fallen to 12%. Others believe it has to do with sustained economic growth, driven by industrial development and their ability to benefit from globalization. While this is a great achievement, there is absolutely no reason to be complacent: a poverty rate of 10.7% means a total poverty headcount of about 746 million people (Ibid). The breakdown by continent is as follows: 383 million in Africa, 327 million in Asia, 19 million in South America, 13 million in North America, 2.5 million in Oceania, and 0.7 million in Europe. Africa is the continent with the largest number of people living in extreme poverty. On the other hand, India is the country with the largest number of people living in extreme poverty (218 million people), while Nigeria and the Congo (DRC) follow with 86 and 55 million people, respectively (Ibid).

In line with the global fight against poverty, it has been suggested in some quarters that the most direct method to measure poverty is to use the poverty headcount ratio. This method requires the setting up of a poverty line and then counting the number of people living with incomes or consumption levels below that poverty line. A major advantage of this system is that it offers information that is candid to interpret; by definition, it shows the percentage of the population living with consumption (or incomes) below some minimum level (Ibid).

The World Bank Group has also published a new set of poverty estimates, as part of their report on poverty and shared prosperity. These estimates, explained in details in two related background papers (Ibid), are consistent with the official World Bank poverty figures published in Povcal and the World Development Indicators, but they are disaggregated by key demographic characteristics such as age and educational attainment. Furthermore, the UN projection through the SDGs is an extremely ambitious target of ending extreme poverty by 2030, a target which many analysts have observed is likely to require growth with declining inequality. Globally, many governments tend to adopt short-term interventions programs as a means of reducing poverty. In fact, a multilayered program offering short-term support along various household dimensions has been shown to cause lasting progress for the very poor in six different countries. This intervention comprises six elements; a productive asset grant, temporary cash consumption support, technical skills training, high frequency home visits, a savings program, as well as health education and services.

Regionally, the European Union in a show of commitment to the SD across borders published, through the European Commission on November 22, 2016, a Communication on the "*Next steps for a sustainable European future*" that sets out how the 2030 Agenda is to be implemented within the EU. This internal implementation of the Agenda includes two work streams: the first is to fully integrate the SDGs in the European policy framework and the Juncker Commission's ten priorities for its current term, identifying the most relevant sustainability concerns, and also assessing European policies and the efforts to achieve the 17 Goals, while the second one will work on further developing a long-term European vision and focus on sector-based policies after 2020 which will enable the long-term implementation of the SDGs. The new Multiannual Financial Framework beyond 2020 shall also reorient the EU budget's contributions toward that same end (Ibid). Furthermore, for the external implementation of the 2030 Agenda, the Commission also presented on November 22, 2016 a communication on the review of the European Consensus on Development (2017), seeking to adapt the development policy of the EU to the new international development architecture. European Consensus was adopted in 2017, and it is organized around the 5Ps of the Agenda 2030. It is expected to impact on the elaboration of development instruments and programs of the EU and its Member States, fostering their alignment with the SDGs and the Addis Ababa Action Agenda (Addis Ababa 2015).

The implementation of the Agenda at the national level brings new challenges which require some reshaping of institutional models to reflect and meet the inherent cross-sector coordination requirements. In this process, it is also relevant to create mechanisms that provide the necessary coordination between the various institutional stakeholders, with a view to present progress reports in a number of different fora in which the implementation of the 2030 Agenda is discussed. On the other hand, the EU's impact outside its borders is not limited to its external action agenda. Many EU policies contribute to the implementation of the SDGs worldwide. Therefore, achieving coherence across all EU policies is crucial to achieving the SDGs. With respect to bilateral and multilateral donor programs, the centerpiece of USAID's climate change policy is the Climate Change Initiative (CCI) with projects in three target areas, reducing GHGs, increasing developing countries' participation in UNFCCC, and decreasing vulnerability. The Canadian Government also established the Climate Change Development Fund (CCDF) in 2000, which allocates US$100 million to assisting developing countries combat the causes and effects of climate change. The CCDF has four priority areas, namely emissions reduction, carbon sequestration, adaptation, and capacity building. Key recipients for the emission reduction include Brazil, China, Egypt, India, Kazakhstan, Nigeria, and South Africa (37–42% of funds), while the key recipients for adaptation are Bangladesh, sub-Saharan Africa, and Small Island States (10–15% of funds) (Climate change 2016). Thus, for Nigeria to remain a beneficiary of these foreign aids and attract foreign investment to complement her efforts, she must align her policy frameworks to SDGs to meet international standards in terms of harmonization of policies and legality of initiatives while keying into the priority project target areas set by donor countries and agencies.

In sum, poverty-induced climate change is widespread and has become a global phenomenon which requires international commitments for it to be curbed through adaptation mechanism. The aforementioned efforts have provided the global community with a template for the implementation of adaptation mechanism. In all of these, it will be interesting to examine how Nigeria has fared in employing adaptation mechanism, and this will form the subject of discussion for subsequent segments of this chapter.

Policy, Legal, and Institutional Frameworks for Fighting Poverty in Nigeria

Nigeria can boast of numerous policies, legal, and institutional frameworks which directly and indirectly deal with climate change and poverty reduction. The frameworks for alleviating poverty in Nigeria include:

(i) Nigeria's Constitution, particularly its Chaps. II and IV on the protection of citizen's right and the Directive principles of state policy.
(ii) Nigeria Climate Change Policy Response and Strategy: The focus of the policy is to:
    (a) Implement mitigation measures that will promote low carbon as well as sustainable and high economic growth
    (b) Enhance national capacity to adapt to climate change

(c) Strengthen national institutions and mechanisms (policy, legislative, and economic) to establish a suitable and functional framework for climate change governance

(iii) The National Adaptation Strategy and Plan of Action on Climate Change for Nigeria (NASPA-CCN). This is the principal National Adaptation Strategy and Plan of Action on Climate Change for Nigeria. The objective of the policy is to integrate climate change adaptation into national, sectoral, state, and local government planning and into the plans of universities, research, and educational organizations, civil society organizations, the private sector, and the media; mobilize communities for climate change adaptation actions through the provision of appropriate user-friendly information; and reduce the impacts of climate change on key sectors and vulnerable communities, among others. Specifically, with respect to agriculture (crops and livestock), the policy seeks to adopt improved agricultural systems for both crops and livestock and to provide early warning/meteorological forecasts and related information.

(iv) The National Policy on Environment which supports “the prevention and management of natural disasters such as floods, drought, and desertification.”

(v) Nigeria’s Agricultural Policy whose objectives include the protection of “agricultural land resources from drought, desert encroachment, soil erosion, and floods.”

(vi) The Nationally Determined Contributions (NDC) which is a determined contribution of Nigeria as regards her target of carbon emission reduction.

(vii) Nigeria’s Drought Preparedness Plan.

(viii) National Policy on Erosion and Flood Control.

(ix) National Water Policy, National Forest Policy.

(x) National Health Policy.

(xi) Nigeria’s Sovereign Green Bond – Nigeria embraced the issuance of its Sovereign Green Bonds as an innovative and alternate way of raising finance both locally and internationally. This is a financing mechanism to facilitate and assist Nigeria meet its Nationally Determined Contribution target and low carbon pathway for socio-economic development in line with the Economic Recovery Growth Plan (ERGP).

(xii) Development of Sectoral Action Plan for Nationally Determined Contribution (NDC) implementation road map.

(xiii) Other programs/efforts are as follows:

(a) Energizing Education Program(EEP) for seven universities in Ebonyi, Delta, Anambra, Sokoto, Kano, Benue, and Bauchi states at the cost of N8,553,600,827.75 for 12.5 MW (off grid).

(b) Afforestation programs in Borno, Bauchi, Gombe, Jigawa, Kastina, Adamawa, Kano, Oyo, Plateau, Zamfara, Kaduna, Niger, Oyo, Ondo, Ogun, Abia, and Edo States for N1, 990,331,366.00 covering 1178 Ha.

(c) Renewable Energy Micro Utility (REMU) at Sokoto for N146, 067,806.25 for 60KW (grid connected).

(d) National Trader Moni program under which low income business people are given interest free sum of ten thousand (to inject into their businesses) repayable over a specified period.
(e) Establishment of Climate Change Desk Officers across the states of the federation.
(f) Commencement of the implementation of the NDC with the support of UNDP.
(g) Capacity Building on Measurement, Reporting and Verification (MRV) and GHG Inventory achieved on sector mapping.

(xiv) Nigeria has a number of bilateral and multilateral agreement cooperation with World Bank, Global Environment Fund (GEF) Green Climate Fund (GCF), etc.

In striving to address poverty, it is important to note that significant portions of Nigeria's population and economy are tied to activities that are climate sensitive, such as rain-fed agriculture, livestock rearing, fisheries, and forest products extraction. The heavily populated coastal areas and Northern Sahel zone are particularly vulnerable to climate change. As part of efforts to address this vulnerability, Nigeria, in June 2014, in Equatorial Guinea, together with the Heads of State and Government of the African Union put agriculture on top of Africa's agenda when they adopted the Malabo Declaration on Accelerated Agricultural Growth and Transformation for Shared Prosperity and Improved Livelihoods (Malabo Declaration 2014). In the Declaration, African leaders made several commitments, among them, to end hunger in Africa by 2025.

The discussions above reveal that Nigeria has been making domestic and international efforts at adaptation mechanism and to attain SDGs targets. She has also keyed into bilateral, multinational, and regional initiatives. Although there are policy framework arrangements to manage climate change in Nigeria, in reality, the policies are not harmonized and remain mostly on paper. This is because the legal framework specific to climate change is non-existent and therefore not legally binding. Efforts to manage climate change therefore remain ad hoc and superficial. This is due mainly to the fact that Nigeria has failed to establish a robust climate change law that should incorporate some of the global initiatives and best practices enumerated earlier. This leads us to the need to x-ray the legal issues, challenges, and strategies in the application of climate change adaptation mechanism.

Legal Issues, Challenges, and Strategies in the Application of Climate Change Adaptation Mechanism

There are many legal issues and challenges which hamper the application of climate change adaptation mechanisms in Nigeria. These are examined in this section with a view to proffering strategies to overcome them.

(i) **Lack of legal framework**: In Nigeria, there is the National Adaptation Strategy and Plan of Action on Climate Change for Nigeria (NASPA-CCN) and the

Nigeria Climate Change Policy Response and Strategy (NCCPRS). Nevertheless, despite the well acknowledged position that there is a close nexus between poverty (SDG 1) and climate change adaptation mechanism as earlier articulated in this chapter, Nigeria still lacks the legally binding law on the subject matter. It has been argued at different fora that the non-transmission of the policies into Nigerian laws is in breach of the climate change policy thrust. This is a challenge and one which makes it difficult to assess the effectiveness of such policies. It has however been suggested in some quarters that the birth of Nigeria's Intended Nationally Determined Contribution (INDC) will compel Nigeria to expedite action on establishing relevant laws and become more focused in terms of combating the impact of climate change. Unfortunately, the provisions of the INDC do not appear to have reflected this expectation.

Furthermore, apart from the absence of a law on climate change to galvanize action toward effective policy implementation, there is equally no existing law in Nigeria that provides for climate change management. In fact, until very recently actions taken by the Ministry of Environment Department of Climate Change have been largely ad hoc and divorced from a bigger picture of global fight against climate change. This is due largely to the absence of a climate change law that will regulate the management of every impact of climate change. The challenge is that without a binding climate change law, it will be difficult to achieve effective adaptation mechanism to reduce poverty in line with the SDGs. In terms of strategy to overcome this challenge, therefore, there is the need to establish a legal framework that would comprehensively and legally bind the various policies on adaptation mechanism. This, for example, is the case in Bangladesh which is a good example of the impact a climate change law can have in the struggle to achieve SDG1.

(ii) **Lack of equality:** It has been argued in some quarters that calls to eradicate poverty are meaningless without commensurate and committed policy action to reduce inequality. This is a global menace that must be conquered to stand a good chance of meeting the SDG 1 target. For instance, the income of the poorest 20% of the world's population has only moved from USD $0.94 in 1990 to $1.90 today, but that of the rest of the population has grown from an average USD $12.85 to $18.63 over the same period, thus creating great inequality. This inequality is projected to worsen with an income gap of USD $18.79 by 2030 which is almost double what it was in 1990 (Hope 2018). A recent report by the research organization, Development Initiatives, which looked at the period between 2010 and 2017, found that notwithstanding global commitments to zero poverty as per SDG 1, the attitude of the global actors is at variance with the espoused commitment. Aid donors promised in 1970 to give 0.7% of their GNI to fighting poverty, and yet the average spent up till 2017 is about 0.31%, and this is lower than it was then (0.33%) (Ibid).

In Africa where the population is expanding at a rate of more than 2% per year, a combination of double digit GDP growth and dramatic declines in inequality is a sine qua non for plummeting the level of extreme poverty to below 5% by 2030 and much more than would be expected to bring the level of poverty to 0% by 2030. Corroborating this view, the UN estimates that without significant changes in behavior, more than 7% of the global population may remain in poverty by the year 2030, including about 30% of the populations in Africa and the least developed countries (LDCs). The challenge is for the governments, including the Nigerian government, to bridge this poverty gap.

Since equality is a sine qua non to the attainment of SDG 1, a major strategy should therefore be to ensure that equality is an inclusive part of the fight to eradicate poverty. It is vital that any form of mainstreaming incorporates a poverty focus rather than viewing it as a purely environmental problem. This will ensure that aid initiatives address the vulnerability of the poor to climate changes and equally to align such aids with the priorities of the SDGs. Development partners must continue to support efforts to bridge the poverty gap and to eradicate poverty. In 2010, the International Development Association (IDA) gave almost USD $2 billion more in loans to middle-income countries (MICs) than to the LDCs, whereas in 2017, it gave over USD $2 billion more in loans to LDCs than to MICs (Dodd et al. 2019). A research also found that if actors met their commitments, an extra USD $1.5tn would be available between 2017 and 2030 to help lift the very poorest in the world out of poverty. A number of both bilateral and multilateral donors are driving these trends.

While there is no one-size-fits-all policy prescription that guarantees delivery of a more equal and prosperous society, one overarching message resonates. It is that calls to exterminate poverty are meaningless without concerted and committed policy action for dramatic decrease in inequalities (Zhenmin 2019), in income, in opportunity, in exposure to risk across gender, within countries and between countries. No doubt, well-designed fiscal policies can help smooth the business cycle, provide public goods, enact reforms that would help build resilience, correct market failures which include, for example, raising potential economic growth and its inclusiveness, and directly influencing the income distribution to bridge inequality. Specifically, Nigeria could introduce measures to bring all the poor under coverage of social protection system and anti-poverty strategy of the government through, for example, an expanded Social Safety Net Programmes (SSNP) to address risk and vulnerability as a means of reducing poverty and inequality.

(iii) **Inadequate political willpower:** This entails the lack of sufficient political willpower of government to ensure SDG 1 succeeds, and the inability to elevate SDGs to a very high political level to be able to give it the national attention and priority that climate change issues deserve. Presently, Nigeria does not even have a climate change law to give focus to the fight against climate change. Meanwhile, the political will of the government as good leadership and governance are crucial for implementation of adaptation mechanism. Akin to this is the fact that Nigeria has also not created the favorable climate environment for addressing its long-standing armed conflict or civil unrest, kidnapping, and political instability. This means that decent jobs for most citizens will become increasingly out of reach resulting in weak economic performance. The required strategy to address the problem is for the government to muster enough political courage to elevate critical decision-making for climate change matters to the presidency for needed priority and implementation directives.

(iv) **Centralization of information and services on climate change:** The issue of centralization of information and services at the Ministry of Environment and several other ministries without decentralizing to the door steps of the citizens remains a challenge. This is because adaptation is likely to be successful if people are informed about climate change, how it affects them, and options for doing something about it. Successful climate change interventions are dependent on high-quality accessible information to allow effective decision-making. As the impacts of climate change are difficult to predict accurately, adaptation activities need to be flexible and responsive to new information, and robust enough to withstand a wide range of plausible futures.

There are many examples of use of information to enhance adaptation mechanism. For instance, the use of risk management and coping thresholds is an area of applied adaptation research of growing importance (Part 2: Adaptation). In addition, agricultural climate information is now used to advise farmers about their choice of crops and methods of cultivation, which in turn has provided major benefits in terms of increased yields and preventing food shortages. Similarly, better information and early warning systems for farmers can reduce vulnerability to inter-annual climate variations and enable responses to be proactive rather than reactive. Climate information can generate substantial benefits in other areas as well, including water management, planning and delivery of health services, and improved warning for extreme weather events. The challenge for Nigeria is that in spite of what is provided for in its Nationally Determined Contribution (NDC), Nigeria has failed to decentralize the delivery of public services and take them to the doorsteps of millions of underserved citizens. It has also not actively leveraged the local knowledge of the communities. For example, in Arochukwu, in the Eastern part of Nigeria, farmers can predict a bountiful harvest merely by observing how severe the harmattan is. This highlights the importance of capturing local knowledge, reviewing and assessing its applicability, and its dissemination among other communities and relevant agencies. The strategy to overcome this challenge is to decentralize information. As the poor already have a lot of knowledge about how to cope with climate variability, adaptation activities should take account of this knowledge, where benefits are proven. Incorporating local knowledge into policy actions could help the governments of Nigeria to accommodate specific needs of poor people and ensure that strategies are taken up by local communities. Thus, relevant information must be decentralized from top to the local levels as a matter of deliberate policy.

(v) **Weak human and institutional capacity:** In Nigeria there is weak human and institutional capacity for climate change related issues. This is because climate change is fast altering the landscapes, and the inability of the various government institutions and weak human capacity to respond appropriately has created various risks due to shortages of resources such as land (Orie 2015) and water, with attendant negative secondary impacts, hunger, poverty, sickness, loss of employment, etc. The poor responses have in turn opened the door to conflict. This alteration comes mainly from the arid north; Nigeria's northern Sahel area (the transition zone between the Sahara desert to the north and the grasslands to the south) gets less than 10 inches of rainfall a year already, a full 25% less than 30 years ago; areas of southern Nigeria where recorded volumes of torrential rains increased 20% across various southern states, some of which already see up to 160 inches of rainfall a year, with wet seasons lasting 8–10 months (Odjugo 2005), and along the southern coastline, where sea levels could rise 1.5–3 feet by century's end which is a further increase over the nearly 1-foot rise observed in the last 50 years (Federal Ministry of Environment 2009). (Federal Ministry of Environment, Nigeria and Climate Change: Road to Cop15 (Abuja, Federal Ministry of Environment 2009).) In fact, in 2012 about 26 out of 36 states in Nigeria were submerged in flood water. The situation is getting worse due to inadequate experts and institutions to properly contend with the developments. In Nigeria, there is no conscious effort either toward manpower or institutional development. Most discussions on the impacts of climate change end at the federal level, occasionally at state level but never at the local government level. The implication of this is that there is disconnect between what happens at the federal and state levels and that of the local government. The result is that at the local level people are not motivated to share in the national vision. For example, the locals still engage in illegal sand mining resulting in erosion, land-slides, and other negative impacts on the ecosystem, while at the federal level government is fighting erosion and landslides.

The strategy to checkmate this challenge is to improve human and institutional capacity development at the grassroot level such that a culture of comprehensive risk reduction management would naturally evolve overtime as the locals become stakeholders and team players with the government. Government and private actors also need to ensure that particular adaptive responses do not themselves fuel violence but actively help build peace. Successful adaptation measures will be crosscutting in design and impact, based on inclusive planning and implementation and steer clear of political patronage traps. An example is the system of Payment for Ecological Services (PES) (Fagbohun and Orie 2015).

(vi) **Inadequate needs assessment and financing strategy:** This is a challenge that cuts across the various adaptation mechanisms. It is so because adaptation as a mechanism is not cheap and therefore requires a lot of funding which most of the developing countries like Nigeria do not have. For instance, for the adaptation mechanism to play its role in achieving SDG1, there must be technology transfer from the developed countries to the developing countries, and also data have to be purchased. In the last couple of years, China has been championing transfer of technology through South-South Cooperation. So many member countries of the South-South Cooperation like Bangladesh, Kenya, Ethiopia, South Africa, Angola, etc. have benefitted richly from this collaboration compared to Nigeria. Some of the identified areas are water resources, agriculture, tourism and health, etc. Nigeria should reposition itself to aggressively acquire the much needed technology to adapt to climate change scenarios. No doubt, recent years have seen evidence of China's technical assistance to Nigeria. The argument here is that such assistance would have been much more both in volume and quality had Nigeria been more proactive like some other member countries like Bangladesh and Kenya where CC is elevated to a political level.

In addition, Nigeria is also expected to have done its needs assessment and financing strategy which should be in tandem with its SDG 1. Such an assessment will ensure that aids initiatives address the vulnerability of the poor to climate changes and equally to align such aids with the priorities of achieving SDGs 1. However, the overriding challenge is that without a strong legal framework on climate change, the international community may not be willing to provide substantial aids. Thus, the strategy to overcome this challenge is to do adequate needs assessment and financial strategy, as well as have a CC law in place in order to attract the international community to support Nigeria fully in its adaptation mechanism to attain SDG 1.

Conclusion and Recommendation

In response to achieving the global target of SDG 1 by employing adaptation mechanisms, this chapter examined the legal angle to Nigeria's efforts at combating poverty. This was predicated on World Poverty Clock data that by 2018, Nigeria had the largest extreme poverty population of 86.9 million implying that the people are vulnerable to malnutrition, armed conflict, migration, and other socioeconomic and environmental shocks. It was argued that unfortunately for Nigeria, her adaptation efforts are inadequate to ensure the eradication of poverty by 2030. Consequently, Nigeria needs a comprehensive legal framework which is in line with global best practices to enhance her chances of attaining the objective of SDG 1.

The chapter also established the nexus between climate change adaptation mechanism and poverty reduction, showing a direct positive relationship, such that as climate change-induced poverty occurs, the adaptation measures alleviate the adverse consequences and thus make the attainment of SDG 1 feasible. Conversely, weak adaptation mechanism cannot effectively combat the impacts of climate change and invariably undermines the attainment of SDG 1.

It was shown that although there is a policy framework arrangement to manage climate change in Nigeria, in reality, the policies are not harmonized and remain mostly on paper. This is because the legal framework specific to climate change is non-existent and the various related policies are not legally binding. Efforts to manage climate change remain ad hoc and superficial. Therefore, a way forward was proffered based on some global best practices which Nigeria could leverage in the implementation of adaptation laws.

The legal issues and challenges militating against Nigeria's efforts at effectively employing adaptation mechanisms were discussed. They include lack of legal framework, inequality, inadequate political will, and centralization of information and services. Others are weak human and institutional capacities and lack of needs assessment and financing strategy regarding adaptation mechanism. These challenges were matched with corresponding and relevant strategies which include establishment of a robust climate change law which ought to draw from global best practices and incorporate the extant regulations and policies, curbing inequality through the introduction of social protection system and anti-poverty strategy for the poor to address risk and vulnerability. In addition, the law must provide for climate change and related issues to be elevated to a political level such that government shall muster the necessary political will to domicile climate change related issues at the presidency and give top priority to such issues. Other strategies are decentralization of information down to citizens at the local government level, human and institutional capacity building, and undertaking of needs assessment and financing strategy. The chapter therefore makes the following recommendations.

The chapter thus recommends the establishment of climate change law in Nigeria that incorporates adaptation measures and mainstreaming of climate change issues towards the attainment of SDG 1. This law should be comprehensive enough to give legal backing to the various extant policies. It should cover social protection system and anti-poverty strategy for the poor to address risk and vulnerability; elevation of critical climate change decision-making to the presidency in order to get priority attention and the needed funding; as well as decentralization of information down to citizens at the local government level. Provisions should also be made for periodic training of staff and reform of institutions to effectively undertake climate change and adaptation projects. Significantly, needs assessment and financing strategy should be undertaken to the standards required by development partners and aid givers to attract the necessary levels of foreign funds and maintain transparency and accountability. These recommendations constitute the legal imperatives to properly regulate institutional and policy interventions to impacts of climate change and if implemented will guarantee attainment of SDG 1 by 2030 and thereby enhance poverty reduction in Nigeria.

Abstract

This chapter examined the effects of climate variability on fishing activities in inland waters: the case of Owena River in Ondo and Osun States, Nigeria. The particular inland water body (Owena) was selected purposively because the Owena River crosses across the two States (Ondo and Osun States). A total of 100 respondents/fisher folks were selected randomly. Primary data was used to get information from the respondents with the aid of the structured questionnaire. Secondary data was used to get information on the climate variability existing in the locations in order to achieve the set objectives. Specifically, the effects of climatic variables such as temperature, rainfall, and wind were determined on fisher folk, fishing duration, fish catch, fishing techniques, and fishing equipment/ gears. Descriptive survey design was used to examine the demographic characteristics of respondents. The result revealed that most of the respondents (96%) were male. This chapter established that climate variability particularly strong wind, rainfall, and temperature has adverse effects on fishing activities such as reduction in fish catch, long duration of fishing, loss of fishing gear, change in fishing techniques, and effect on health; hence, the livelihoods of the residence are adversely affected on the long run. In addition to the adverse effect of poverty and loss of life for the fisher folks. Although, the fisher folks livelihoods depend mainly on fisheries resources and optimum fishing depends on favorable climate/ weather conditions. Therefore, proper preventive coping strategies against the adverse effect of climate variables should be paramount in both States (Ondo and Ekiti) to improve livelihoods and food security.

Keywords

Climate variability · Fishing activities · Inland waters · Livelihoods · Nigeria

Introduction

Climate variability is the observable change in atmospheric conditions of a given area at a particular time usually 10 years. The Intergovernmental Panel on Climate Change defined climate change or variability as any change in climate overtime, whether due to natural variability or as a result of human activities. Temperature and precipitation are the most common climate variables critical to measure with regard to food systems. Climate variability poses a threat to the effective productivity and sustainability of fishing activities and resources around the world. Climate variabilities are changes or variation in climate condition due to factors such as anthropogenic factors, e.g., bush burning, release of fossil fuel, and other biochemical activities which will consequently lead to global warming, loss of abundant fisheries resources and other agricultural resources, and also depletion of ozone layer (Cheung et al. 2009).

Climate plays an important role in the world. Because most livelihood and living resources depend on suitable climatic condition for survival and continuity, its effects can be felt directly or indirectly. The Intergovernmental Panel on Climate Change (IPCC) predicted that during the next decades, billions of people, especially those in developing countries, will face changes in rainfall patterns that will contribute to severe water shortages or flooding, rising temperatures that will cause shifts in crop growing season, and aquatic organism distribution.

Climate change and global warming will definitely cause adverse effects on the livelihoods of the populace in Nigeria if not prevented, and it will affect crop production, livestock production, fisheries, forestry, and post-harvest activities, because the rainfall regimes and patterns will be altered, floods which devastate farmlands would occur, increase in temperature and humidity which increases pest and disease would occur, and other natural disasters like floods, ocean, and storm surges, which not only damage Nigerians' livelihood but also cause harm to life and property, would occur.

Nigeria is a West African country found in the tropics; it has only two seasons which are the dry season and the raining season. The country is one of the most populated countries in the world with over 180 million people and is blessed with abundant aquatic resources. However, Nigeria is vulnerable to climate change impacts due to its geography, location, climate, vegetation, soils, economic structure, population and settlement, energy demands, and agricultural activities.

The prominence and persistence of climate change has made it a global menace with adverse effects borne by developing nations (Agbebi and Omoniyi 2011). Global disasters perpetrated by storm-surge, flood, coastal erosion, and other natural hazards have brought much anxiety and bewilderment to the world governing agencies. These impacts and implications are profound as they occur through the increasing changes in water temperature/sea levels (Adeleke and Omoboyeje 2016).

Fisheries is one of the fastest growing sectors in the world, and it provides employment, food, income, and recreation for many people globally. The dependence of the human populace on fishing activities as a major source of food and livelihood is linked to the rich nutritional composition of fisheries products (fish, crayfish, prawn, shrimps, etc.), palatability, digestibility, and high source of animal protein, omega fatty acid, and vitamins.

Despite these numerous and enviable benefits, fisheries resources, functions, and structures have come under intense threat due to the extensive and increasing anthropogenic activities that exist in and around various water bodies. These result in a wide array of problems for both the aquatic resources users and decision makers. These anthropogenic activities often lead to induced climate change which have shown to have apparent effect on aquatic ecosystems, the economic and social system that depends on them (World Fish Centre 2006; Perry et al. 2009).

Recent studies on the effect of climate change on aquaculture production and management in Akure metropolis, Ondo State, and also the occurrences of climate change and its effect on the fishing activities in the coastal region of Ondo State (Adeleke and Omoboyeje 2016; Adeleke and Balogun 2013), respectively, have revealed the occurrences of climate variability and its effect on fishing activities through alteration in temperature, wind pattern, rainfall pattern, water qualities, and availability.

Severe effects such as great reduction in aquatic resources, low fish catch, reduced fish production, slow growth rate, increase in boat mishap, loss of lives, poverty, etc. arise mainly from increased flooding, variation in rainfall pattern and intensity, and rising temperature. Idowu et al. (2011) reported that the impacts of climate change are expected to exacerbate the impacts of human pressure which will further diminish the ability of natural ecosystems to continue to provide ecosystem services and may cause invasion of strange species that are favored by climate change thereby threatening biodiversity. Also, poor adaptation strategies and high dependence on fisheries have been reported to expose small-scale fisher folks in most developing country to climate change (Allison et al. 2009). These effects impact on fish species composition, production, and yield, risk of health and life of fisher folk, and loss and damage to livelihood assets. Therefore, the fisher folk will have to seek adaptation and mitigation strategies in order to sustain their livelihood.

The inhabitants of Ondo and Osun are mostly small-scale commercial fish farmers that depend on fisheries resources as a source of food and livelihood. However, climate variability may threaten their livelihood and infrastructural development. Hence, there is the need to identify the pathways through which climate variability and change are impacting or likely to impact the fishing-dependent communities. This will also help policy makers in implementing adaptive strategies to be able to withstand and cope with these adverse climate variability. This research work will examine the effect of climate variability on fishing activities in Owena Ondo and Osun States.

The following research questions were answered in this chapter. What are the effects in Owena, Nigeria, are of temperature, rainfall, and wind variability on fish catch; rainfall, temperature, and wind variability on fishing techniques and equipment; rainfall, temperature, and wind variability on fishing duration; and rainfall, temperature, and wind variability on fisher folks.

The Chapter Design

The chapter design that is adopted in this chapter is descriptive survey designed to obtain precise information on the current status of climate change and to possibly draw a valid conclusion from the survey. It should be noted that there are no climate change nor meteorological records in the area as observed limitation of the chapter.

Owena Ondo State and Owena Osun State were used. Owena Ondo is located at geographical coordinate 7° 12′ 0″ North, 5° 1′ 0″ East, while Owena Osun is located at latitude 7.19908 and longitude 5.018267 degree. Both areas were purposively

Fig. 1 Map of Nigeria. (Source: Authors' Download: Google map, 2018)

selected based on general fishing activities, trading, accessibility, and anthropogenic activities (Figs. 1 and 2).

Chapter Design

A multistage sampling technique was used to select the samples in this chapter. The first stage involved the purposive selection of Owena Ijesa Ori Ade Osun State and Owena Market road Ondo East Local Government and Owena Ondo State. The justification of the selection is based on the fact that the two locations are close and prominent for fishing activities and have the same water body flow to both locations. The target population are fisher folk, and fishermen in Owena Ondo State and Owena Osun State were purposively selected based on their closeness of the site and the prominent fishing activities in the area. Primary data from fisher folks were collected with the aid of an interview schedule using structured questionnaire. 50 questionnaires each were administered to both locations making it 100 in total. The interview schedules were divided into sections based on the objectives of the research. Data obtained from various sources were processed before analysis. The data were edited, coded, and entered for analysis in the Statistical Package for Social Sciences (SPSS). Summary tables were then prepared to facilitate recording and further analysis. Data obtained through questionnaire were analyzed using quantitative methods. The data

Fig. 2 Map of study area. (Source: Authors' Download: Google map, 2018)

from the questionnaire were subjected to computation of simple statistics such as frequencies, percentages, tabulations, and cross-tabulations and presented in form of tables, graphs, and charts.

A multistage sampling technique was used to select the samples in this chapter. The first stage involved the purposive selection of Owena Ijesa Ori Ade Osun State and Owena Market road Ondo East local Government.

Cronbach Alpha

Cronbach alpha (α) was used to analyze the sufficiency of the survey instrument.

$$\text{Cronbach } s\alpha = \frac{N - \overline{C}}{\overline{V} + (N - 1).\overline{C}}$$

Where:

$N =$ No of items (12)
$\overline{C} =$ Average inter – item covariance among the items
$\overline{V} =$ Average variance

The survey instrument for this chapter is sufficient because Cronbach alpha is greater than 0.6.

Distribution According to Gender and Age Group of Respondent in Owena Osun and Ondo States

The distribution according to gender and age group of the populace involve in fishing activities in this chapter is presented in Figs. 3 and 4, respectively. The result revealed that all of the respondent (100%) in Owena Ondo were males, while 92% of the respondents in Owena Osun were male and 8% females. The pooled result revealed that 96% of the respondents were males while 4% were females. The high percentage of men involvement in fishing as revealed by the most of the respondents in the areas attest to high-risk associated fishing. In addition, the extensive involvement of women in post-harvest fish processing and fish trading might have accounted for their low percentage in fishing in both States inland water environs.

The mainstream of the respondent (52%) were between 21and 31 years, 38% of the respondents were between 31and 40 years, 8% <21 years, and 2% were between 41 and 50 years. This implies that the pooled age brackets were within the age group of 21–45 years. This age bracket is considered to be the most economical, vibrant, resourceful, and productive group when considering the energy required to carry out a tedious activity like fishing and the need to source for income and livelihood.

Secondary Occupation and Monthly Income of Respondent in Owena Osun and Ondo State

The secondary occupation and monthly income of the populace involve in fishing activities in the areas is presented in Figs. 5 and 6, respectively.

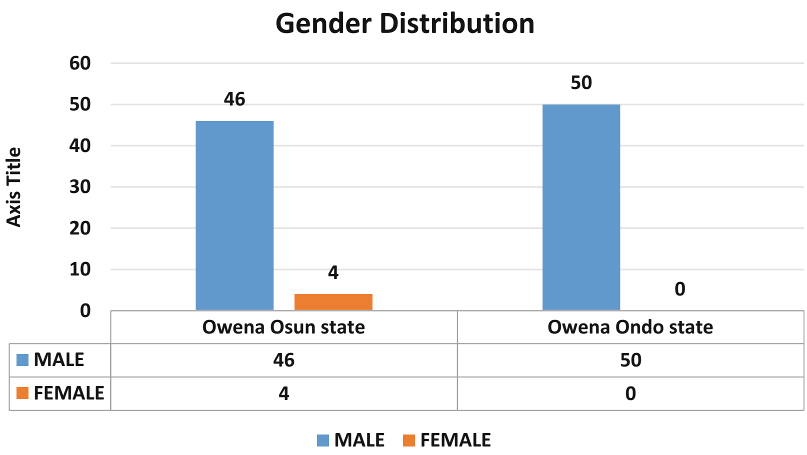

Fig. 3 Gender distribution of respondents

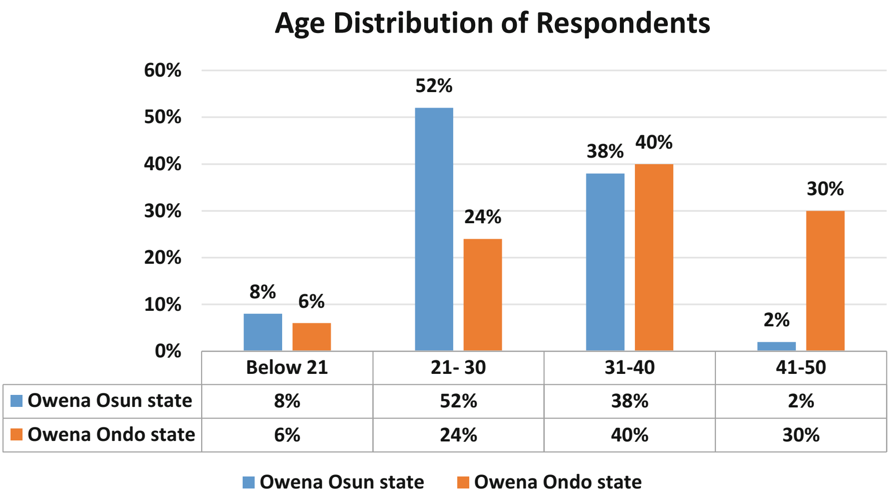

Fig. 4 Age distribution of respondents

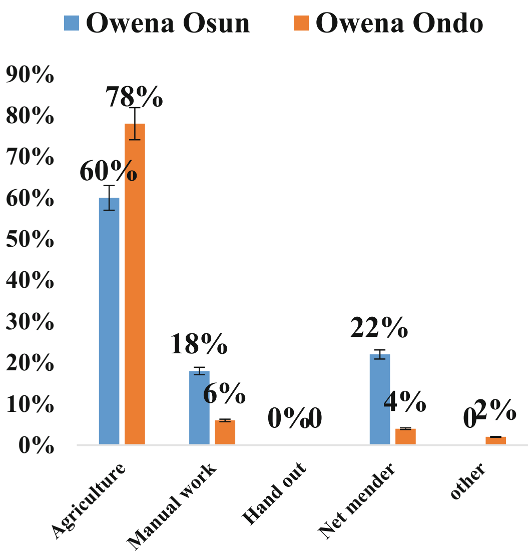

Fig. 5 Secondary occupation of respondent

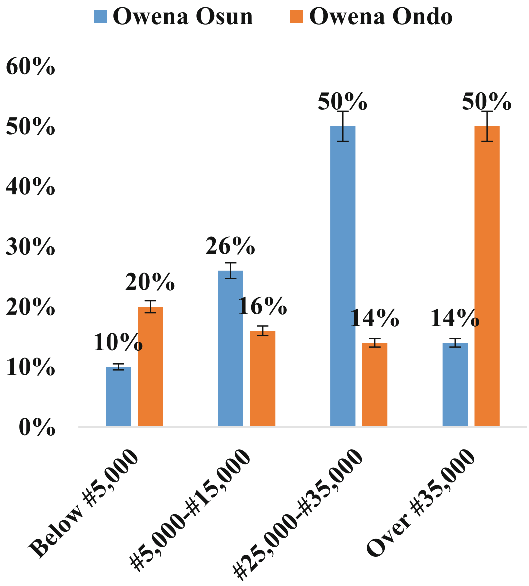
Agriculture was revealed as the major source of income in both States. The chapter revealed that 60% of the respondents in Owena Osun had their secondary occupation as agriculture (fishing), followed by net mending work (22%) and manual work (18%), while in Owena Ondo, agriculture as secondary occupation was 78%, followed by manual work (6%), net mending (4%), and other income sources (2%). The monthly incomes of the respondents from fishing activities as shown in this chapter were as follows: 50% of the respondents in Owena Osun earn

Fig. 6 Income per month of respondent



between #25,000 and 35,000, 26% between #5000 and 15,000, 14% over #35,000, while 10% earn below #5000. Likewise in Owena Ondo, 50% earn over #35,000, 20% below #5000 naira, 16% between #5000 and 15,000, and 14% between 25,000 and 35,000.

The result in this chapter implies that fishing activities in the area might not be sustaining the living standard of the populace and might be the reason why most of the respondents took agriculture as their secondary occupation.

Effect of Climate Variability on Fish Catch in Owena Ondo and Osun States

The effect of wind, rainfall, and temperature on fish catch in Owena Ondo and Osun States is presented in Table 1.

The result in this chapter revealed that variability in wind patterns often affects fish catch in the aquatic ecosystem. As shown in Table 1, 88% and 90% of the respondents observed that strong winds reduce fish catch in Owena Ondo and Osun State, respectively. During moderate wind, 2% and 10% of the respondents reported very low fish catch, 38% and 30% reported high catch, 20% and 10% observe very high catch, while 34% and 50% observe normal fish catch in Owena Ondo and Osun State, respectively. Also, the impact of waves on fish catch by respondents revealed that 52% causes regular and normal catch in the two States, while 36% and 48% cause low catch in Owena Ondo and Osun, respectively. The availability of fish for harvest in various aquatic environments is often affected by variation in wind

Table 1 Result showing the effect of climate variability on fish catch in Owena Ondo and Osun States

Variables	Very low				Low catch				Normal catch				High catch				Very high catch			
States	Ondo		Osun		Ondo		Osun		Ondo		Osun		Ondo		Osun		Ondo		Osun	
	F	%	F	%	F	%	F	%	F	%	F	%	F	%	F	%	F	%	F	%

Low temperature	6	12	2	4	21	42	33	66	23	46	10	20	0	0	0	0	0	0	0	0

patterns. This often results in the destruction of fishing infrastructure, submergence/loss of fishing boats with adverse effects on fisher folks, and reduction in the number of catches. Trotman (2009) and Crandall (2009) opined that changes in wind patterns and extreme weather conditions can be damaging to fish production, distribution, abundance, and the fisheries industries as they cause destruction of the fishing gear, vessels, and biodiversity, thus becoming a major setback to the fishing community. The findings support the report of Jallow et al. (1999) who observed changes in wind pattern and adduced it to changes in climatic regimes.

There was marked variation in the rainfall pattern across the two states with different impacts on fish catch. In Owena Ondo, 46% of the respondents observed very high catch, 26% high catch, and 18% low catch during high rainfall. During moderate rainfall, 46% of the respondents observed high catch, 26% very high catch, 22% normal catch, and 6% low catch. During flooding, 66% of the respondents observed that catch is high, while 6% observe low catch. In Owena Osun, 2% of the respondents observed very high catch, 8% high catch, and 54% low catch during high rainfall. During moderate rainfall, 50% of the respondents observed high catch, 10% very high catch, 30% normal catch, and 10% low catch. 76% of the respondents observed low catch during flooding, while 20% observed high catch. Although changes in rainfall pattern have often proof to have different impacts on the duration of fishing, the high catch observed during high rainfall could be as a result of influx of fresh water which could have led to increase in fish growth and performances. In addition, many aquatic species tend to reproduce and migrate during raining seasons due to water and nutrients availability, thus supporting high biomass and catch.

Most of the respondents in both locations reported low fish catch during high and low temperature. 40% and 88% reported low fish catch during high temperature, while 19% and 6% observed high catch in Owena Ondo and Osun, respectively. Also, during low temperatures, 54% 70% of the respondents reported low fish catch in Owena, Ondo and Osun, respectively. The low fish catch during high and low temperature implies a warming trend in the areas. Changes in temperature can change the dynamics of aquatic environments, thus resulting in changes in the migration patterns of fish and reduced fish landings (African-Action 2007).

Likely Effect of Climate Variability on Fisher Folks in Owena Ondo and Osun States

The likely effect of climate variability such as wind, rainfall, and temperature on fisher folks in both locations is presented in Table 2.

In both locations, most of the respondents (94% and 100% in Owena Ondo and Osun, respectively) observed and stated the adverse effect of strong winds on fisher folks. This impact varies from loss of fishing gear (traps and nets), sickness (body injuries), and death. Majority of the respondents (100% and 98% in Owena Ondo and Osun, respectively) preferred moderate, calm wind for their fishing activities. It was also observed by most of the respondents in both states that wave and stormy conditions lead to loss of fishing equipment.

Table 2 Result showing the effect of climate variability on fisher folks in Owena Ondo and Osun States

Variables	Might lead to fisher folks death				Sickness				Loss of fishing gears				No effect			
States	Ondo		Osun		Ondo		Osun		Ondo		Osun		Ondo		Osun	
	F	%	F	%	F	%	F	%	F	%	F	%	F	%	F	%
Strong wind	0	0	2	4	7	14	0	0	43	86	48	96	3	6	0	0
Moderate wind	0	0	0	0	0	0	0	0	0	0	1	2	50	100	49	98
Waves	1	2	0	0	0	0	0	0	30	60	34	68	19	38	16	32
High rainfall	10	2	16	32	45	90	10	20	14	28	36	72	3	6	2	4
Moderate rain	0	0	0	0	0	0	0	0	0	0	1	2	50	100	49	98
Absence of rainfall	0	0	0	0	0	0	0	0	0	0	0	0	50	100	50	100
Flooding	1	2	22	40	31	62	15	30	13	26	39	78	9	18	2	4
High temperature	1	2	6	12	0	0	1	2	0	0	1	2	50	100	42	84
Moderate temperature	0	0	0	0	0	0	0	0	0	0	1	2	50	100	49	98
Low temperature	1	2	0	0	4	8	2	4	0	0	0	0	46	92	48	96

The results in this chapter also revealed the effect of changes in rainfall pattern in both locations. In Owena Ondo State, 90% of the respondents observed high rainfall which results into sickness such as cold and malaria from mosquito bite on the fisher folks, 28% observed the loss of fishing gear in waters, while 20% revealed fisher folks might die as a result of high rainfall. In Owena Osun, the majority of the respondents (72%) observed the loss of gear during high rainfall, 32% observed that it might lead to the death of fisher folks, while 20% observed various sickness on the fisher folks. The major impact of flooding in both locations was sickness and loss of fishing gears and death.

The adverse effect of climate variability on the fisher folks was clearly evident in this chapter. The impacts of strong wind, waves, rainfall, flooding, and temperature were strongly observed by the respondents to cause sicknesses (malaria, cholera), physical injuries, destruction/loss of fishing gears, and death from boat submergence and climatic shocks. Badjeck et al. (2009, 2010) observed the same effects in their studies and noted it to be inimical to health and safety of the fisher folks and deleterious to sustainable livelihood.

Effect of Climate Variability on Fishing Techniques in Owena Ondo and Osun States

The effect of climate variability on fishing techniques in both locations is presented in Table 3.

This chapter revealed that most of the respondents observed the adverse effect of climate variability on the fishing techniques in both locations. During strong winds and storms, most of the respondents (59.38% and 83.33%) do fishing using other

Table 3 Percentage of respondents on effect of climate variability on fishing techniques in Owena Ondo and Osun States

States	Ondo				Osun			
Variables	Normal fishing method (active)		Other fishing method (passive)		Normal fishing method (active)		Other fishing method (passive)	
	F	%	F	%	F	%	F	%
Strong wind	13	40.63	19	59.38	7	16.67	35	83.33
Moderate wind	19	59.38	11	34.38	34	80.95	7	16.67
Waves	15	46.88	17	53.13	19	45.24	23	54.76
High rainfall	11	34.38	19	59.38	16	38.09	26	61.9
Moderate rain	18	56.25	14	43.75	37	88.1	5	11.9
Absence of rainfall	14	43.75	18	56.25	30	71.43	12	28.57
Flooding	14	43.75	31	62	10	23.81	32	76.19
High temperature	15	46.88	17	53.13	37	88.1	5	11.9
Moderate temperature	22	68.75	10	31.25	39	92.86	3	7.14
Low temperature	19	59.38	13	40.63	32	76.19	10	23.81

fishing method (passive method), while 40.63% and 16.67% use normal fishing method techniques (active method) in Owena Ondo and Osun, respectively. During waves, 53.13% and 54.76% use other fishing method, while 46.88% and 45.24% use normal fishing method in Owena Ondo and Osun, respectively.

The result also revealed that fishing techniques change during high rainfall as 59.38% and 61.90% use the other techniques as opposed to the usual fishing methods in Owena Ondo and Osun, respectively. During flooding, 62% and 76.19% use unusual fishing method, while 43.75% and 23.81% use normal fishing method in Owena Ondo and Osun, respectively.

Most of the respondents (53.13% and 88.10%) reported the use of other methods of fishing during high temperatures, while 46.88% and 11.09% reported the use of the usual methods of fishing in Owena Ondo and Osun, respectively.

The effect of climate variability was visible on the various methods and techniques of fishing. The techniques of fishing referred to as the normal methods of fishing include the use of cast nets, gill nets, hand lines, and beach seine nets that is the active fishing, while the other methods of fishing include trapping, long line fishing, and use of baskets, i.e., the passive fishing.

Effect of Variability in Climate on Choice of Fishing Equipment in Owena Ondo and Osun States

The effect of climate variability on the choice of fishing equipment in both locations is presented in Table 4.

This chapter revealed that strong winds destroy 88% and 66% fishing equipment, 6% and 40% causes sinking of gears in Owena Ondo and Osun state, respectively. 66% and

Table 4 Percentage response of respondents on the effect of climate variability on fishing equipment in Owena Ondo and Osun

Variables	Destruction of fishing gears				Sinking of fishing gears				No effect on equipment			
States	Ondo		Osun		Ondo		Osun		Ondo		Osun	
	F	%	F	%	F	%	F	%	F	%	F	%
Strong wind	44	88	28	56	3	6	20	40	3	6	2	4
Moderate wind	0	0	0	0	0	0	1	2	50	100	49	98
Waves	33	66	20	40	3	6	15	30	16	32	15	30
High rainfall	5	10	15	30	37	74	36	72	12	24	5	10
Moderate rain	0	0	0	0	0	0	1	2	50	100	49	98
Absence of rainfall	0	0	0	0	0	0	2	4	50	100	48	96
Flooding	18	36	30	60	26	52	34	68	15	30	5	10
High temperature	0	0	4	8	0	0	0	0	50	100	46	92
Moderate temperature	0	0	0	0	0	0	0	0	50	100	50	100
Low temperature	0	0	0	0	0	0	0	0	50	100	50	100

40% of the respondents revealed the impact of waves on the destruction of fishing equipment in Owena Ondo and Osun, respectively. Also, 74% and 52% of the respondents showed that fishing equipment sink during high rainfall and high flooding, respectively, in Owena Ondo, while 72% and 68% reported the same scenario in Owena Osun. The effect of climate variability on the fishing equipment was strongly observed in the areas. The loss of physical capital equipment (gears and nets) compounded with a deteriorating financial asset base from strong winds, waves, and high rainfall would have had a significant effect on livelihoods in the areas.

The periods of moderate winds and rainfall were observed by the respondents to be the most convenient and secure for fishing equipment. However, temperature variations were observed to have no effect on the fishing equipment in both locations.

Climatic Trends in Owena River Between 2008 and 2017: Wind Trends and Rainfall Pattern in Owena Osun State Between 2008 and 2017

The statistical records on wind and rainfall data were obtained from the Department of Meteorological/Climate Science Technology Department of the Federal University of Technology, Akure, Nigeria, as presented in this chapter. Figure 7 shows the monthly trend of wind data for Owena Osun (2008–2017); Fig. 8 shows annual rainfall pattern/data for Owena Osun State (2008–2017); and Fig. 9 shows

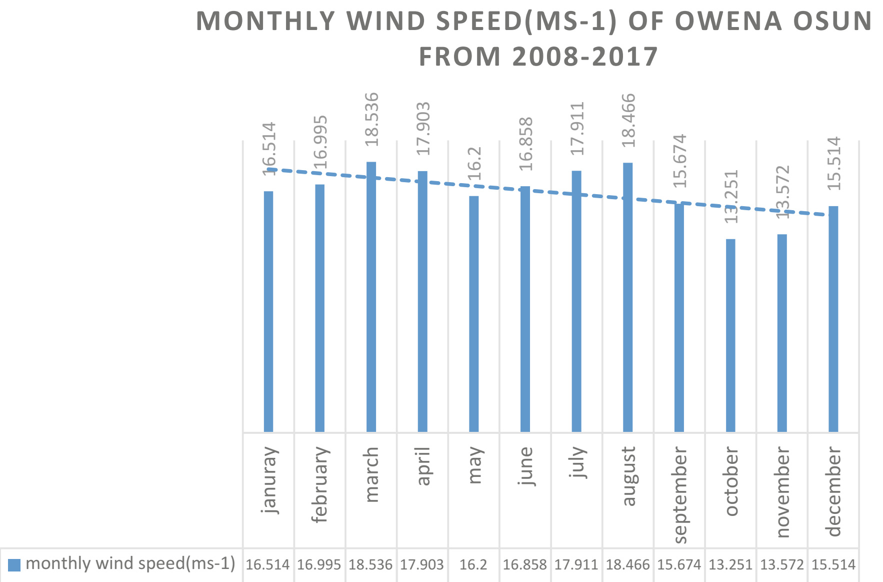

Fig. 7 Monthly trend of wind data for Owena: 2008–2017. (Source: Climate Records of Department of Meteorological/Climate Science Technology, The Federal University of Technology, Akure. Nigeria, 2018)

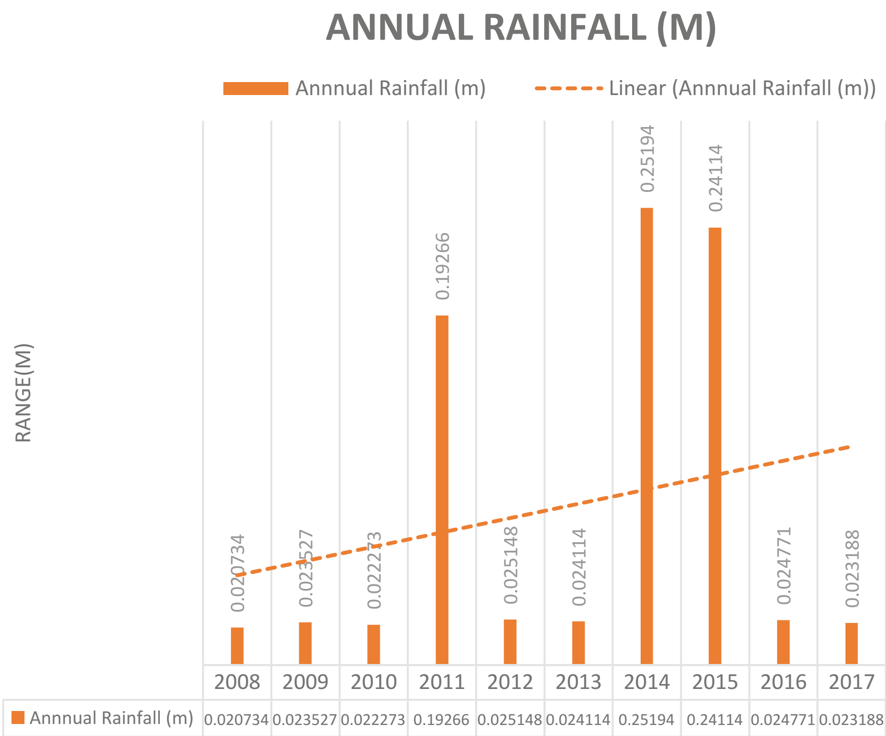

Fig. 8 Annual rainfall pattern/data for Owena Osun State: 2008–2017. (Source: Climate Records of Department of Meteorological/Climate Science Technology, The Federal University of Technology, Akure. Nigeria, 2018)

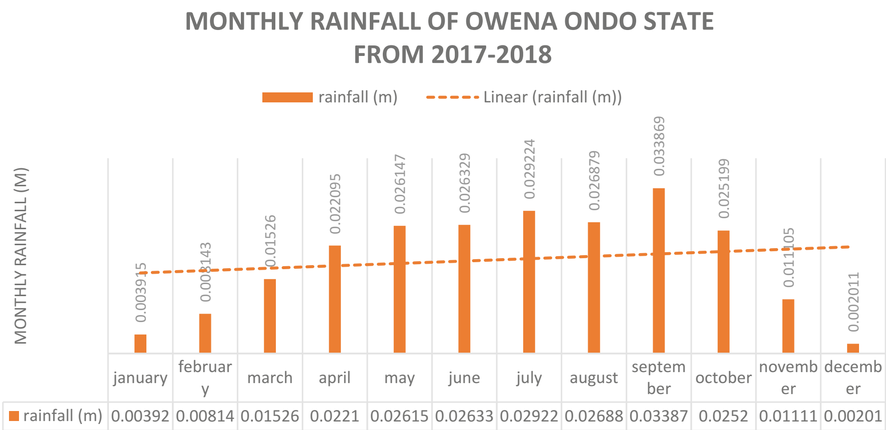

Fig. 9 Monthly rainfall pattern/data for Owena Osun State: 2008–2017. (Source: Climate Records of Department of Meteorological/Climate Science Technology, The Federal University of Technology, Akure. Nigeria, 2018)

monthly rainfall pattern/data for Owena Osun State: 2008–2017. The record reveals over the 10 years duration of the wind trends and rainfall pattern. For the 10 years under consideration (between 2008 and 2017), a decreased trend in the average wind speed across the months from September to December was observed. The highest wind speed was in the month of March and the lowest wind speed in the month of June.

Also, the recorded data on rainfall from 2008 to 2017 showed an increasing trend in annual rainfall. The irregularity in rainfall pattern from these records points a clear indication to weather and climate variability; some years like 2014, 2015, and 2011 have exceptionally high average rainfall. These trends certainly will affect fishing activities. More so, fluctuation in the pattern of rainfall will have both positive and negative impacts on fish catch in the inland Owena water. As opined by Adeleke and Fagbenro (2013), fluctuations in the climate variables will pose adverse effect on the fisher folks and fisheries activities in the coastal areas of Nigeria. In addition, strong winds according to Jallow et al. (1999) have adverse effects on fishing infrastructure as fishing vessels get destroyed, lost, or submerge

Conclusion

This chapter revealed that climate variability has affected fishing activities, fisheries resources, and structures in Owena Osun and Ondo State. The potential impacts of climate change range from impact on the fisher folk, some of which are loss and destruction of fishing equipment's, impact on health, alteration in fishing duration, alteration in fish catch, and change in fishing techniques and equipment. It was also observed that the success and optimum benefit derived from fishing is dependent on favorable climatic conditions. Fisher folk and fishermen that depend on fisheries resources as a source of livelihood will continue to be at risk if proper preventive strategies and measures against the adverse effect of climate and food insecurity are not set in place. This chapter, therefore, recommends the need for extension education and innovation on the various possible strategies, fishing techniques, equipment, and beneficial knowledge to help fisher folks to be able to counter or lessen the adverse effect of climate variability in order for fisher folks to attain maximum sustainable catch.

Abstract

Climate change impact on rainfall and temperature extreme indices in the Vea catchment was analyzed using observation and an ensemble mean of bias-corrected regional climate models datasets for Representative Concentration Pathway (RCP 4.5) scenario. Rainfall extreme indices such as annual total wet-day precipitation (PRCPTOT), extremely wet days (R99P), consecutive wet days (CWD), consecutive dry days (CDD), and temperature indices such as warmest day (TXx) and warmest night (TNx) from the Expert Team on Climate Change Detection Monitoring Indices (ETCCDMI) were computed for both the historical (1986–2016) and future (2020–2049) period using the RClimdex. The parametric ordinary least square (OLS) regression approach was used to detect trends in the time series of climate change and extreme indices. The results show an increase in mean annual temperature at the rate of 0.02 °C/year and a variability in rainfall at the catchment, under RCP 4.5 scenario. The warmest day and warmest night were projected to increase by 0.8 °C and 0.3 °C, respectively, in the future relative to the historical period. The intensity (e.g., R99p) and frequency (e.g., CDD) of extreme rainfall indices were projected to increase by 29 mm and 26 days, respectively, in the future. This is an indication of the vulnerability of the catchment to the risk of climate disasters (e.g., floods and drought). Adaptation strategies such as early warning systems, availability of climate information, and flood control measures are recommended to reduce the vulnerability of the people to the risk of the projected impact of climate extreme in the future.

Introduction

In the last century, global surface temperature has increased by 0.71 °C with significant warming observed in many regions (Trenberth et al. 2007). This increase in global surface temperature reveals more warming of land than the oceans and has diverse consequences on water resources and the livelihood of people. In view of this, much attention has been given to climate change and extremes over the past decades (New et al. 2006; Larbi et al. 2018; Adeyeri et al. 2019) due to its intense impact on natural and human systems. At the study region, the high variability in rainfall has also resulted in higher frequency of flood and drought events, putting the socioeconomic activities at risk (Awotwi et al. 2015).

The impact of climate change on climate extremes and other sectors require tools for its assessment, and the most common approach for the assessment is the use of climate model outputs. Though Global Circulation Models (GCMs) have been widely used for various climate change studies (Minville et al. 2009; Chen et al. 2012; Panday et al. 2015), it is not suitable for analyzing the projections on a regional or local scale due to its coarse resolution nature (Xu 1999; Maraun et al. 2010; Seager and Vecchi 2010). In West Africa regions, GCMs are unable to represent key features of the West African monsoon (WAM) such as the Africa Easterly Waves (AEWs), Africa Easterly Jets (AEJ), and Tropical Easterly Jets (TEJ) (Sylla et al. 2013). Regional climate models (RCMs) are therefore used in climate change studies because of its ability to accurately take into account orography, thus providing a better reproduction of regional climates (Sylla et al. 2013).

Extreme climatic events such as heat waves, floods, and droughts affect lives and livelihoods of people over varied regions (Alexander et al. 2006). Floods and droughts generate socioeconomic effects such as hunger, habitat, and infrastructure destruction. Over 40% of the populace has encountered hunger situations, that resulted from failure of one-third of crop produced when compared to 2010 data, leading to humanitarian appeals (Sarr 2012; FAO 2013). These and other ensuing impacts have necessitated the analysis of changes in future climate extremes necessary in reducing potential social, economic, and ecological consequences (Amuzu et al. 2018; Bohle et al. 2018). This need has necessitated studies in the analysis of past trends and the prediction of the occurrence of extreme climate events on rainfall and temperature using different approaches. Several studies have therefore achieved this by the use of RCMs. This model has been frequently used for climate change impact studies (Zhang et al. 2008) and future extreme climate projections analysis (Tomassini and Jacob 2009).

In West Africa, M'Po et al. (2017) assessed climate change impact on rainfall extremes over the Ouémé River Basin in Benin using RCM. The results showed a decrease in extremely heavy precipitation and annual total wet-day precipitation in most stations for the future 2015–2050. The Vea catchment in Ghana is seen as one of the vulnerable areas to climate change and is faced with issues of climate shocks such as flood and drought. This has devastating effects on various sectors of the economy particularly water resources and agriculture. However, information regarding climate change and climate extremes which are vital to improve societal awareness and preparedness is limited in the Vea catchment. To this end, understanding trends and variations of historical and future climatic variables is pertinent for the future development and sustainable water resources management in the catchment (Ogountundé et al. 2006). This chapter assesses the impact of climate change on rainfall and temperature extreme indices in the Vea catchment in the Upper East Region of Ghana. This is based on the Representative Concentration Pathways (RCP 4.5) scenario, which would recommend adaptation strategies required at the community level to reduce the vulnerability of the people to the risk of climate change and extreme events in the future.

Description of the Study Area and Methodology

This section describes the area where the study was conducted, the data used, and the methodology applied to achieve the aim of the study. The Vea catchment, one of the sub-catchments within the White Volta basin (WVB), is located between latitudes 10° 30′N–11° 08′N and longitudes 1° 15′W–0° 50′E (Fig. 1). It has an area of about 305 km^2 and covers mainly the Bongo and Bolgatanga districts in the Upper East Region of Ghana, with a small portion over the south-central part of Burkina Faso. The climate of the catchment is controlled by the movement of the Inter-tropical Discontinuity (ITD) over the land that dominates the climate of the entire West African region (Obuobie 2008). Located in a semiarid agroclimatic zone, the catchment covers three agroecological zones: the Savanna and Guinea Savanna zones in Ghana, and north Sudanian Savanna zone in Burkina Faso (Forkuor 2014). It is characterized by a unimodal rainfall regime from April/May to October with a mean annual rainfall of 957 mm which normally peaks in August (Larbi et al. 2018). The temperature is uniformly high with a mean value of 28.5 °C while potential evapotranspiration in the catchment exceed monthly rainfall for most part of the year, except the three wettest months of July, August, and September (Limantol et al. 2016). It is characterized by fairly low relief with elevation ranging between 89 m and 317 m (Fig. 1) and mainly dominated by cropland followed by grassland interspersed with shrubs and trees and woodland (closed/open).

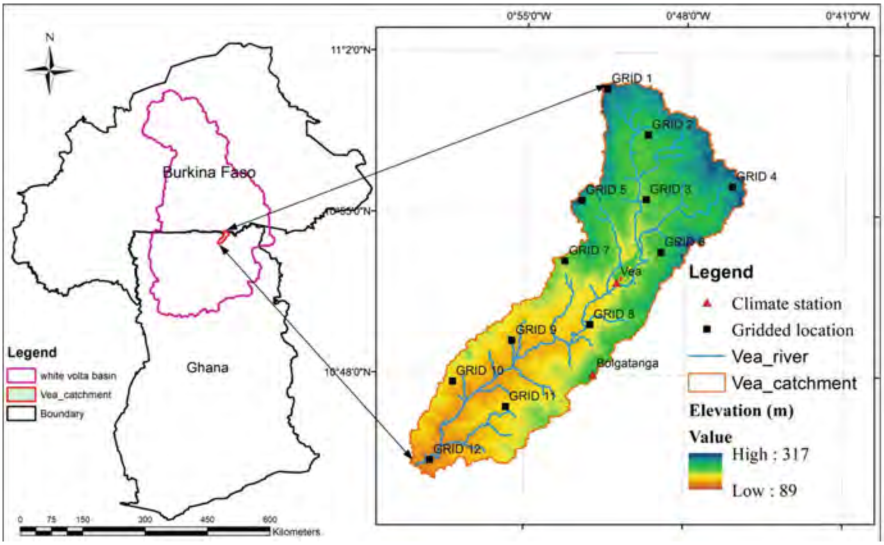

Fig. 1 Map of the Vea catchment showing the station and gridded precipitation locations within a 12 km grid

Observation and Climate Change Scenario Datasets

Observed daily rainfall, maximum and minimum temperature within the Vea catchment from 1986 to 2016 for two climate stations (Vea and Bolgatanga) were obtained from the West African Science Service Centre on Climate Change and Adapted Land Use (WASCAL) research center and Ghana Meteorological Agency. Additional 12 (Fig. 1) gridded daily precipitation data at 0.05° spatial resolution from Climate Hazards Group InfraRed Precipitation with Station data (CHIRPS) were also downloaded from http://chg.geog.ucsb.edu/data/chirps (Funk et al. 2015). CHIRPS incorporate satellite imagery with in-situ station data to create gridded rainfall time series. The performance of the CHIRPS data in reproducing the climatology of the Vea catchment has been evaluated in previous research (Larbi et al. 2018). According to Larbi et al. (2018), the CHIRPS data is able to reproduce well both the seasonal and annual rainfall pattern of the Vea catchment, and the validation resulted in a very high correlation coefficient (r = 0.99) and a Nash–Sutcliffe efficiency of 0.9.

Four RCMs datasets (Table 1) within the CORDEX-Africa experiment and Weather Research and Forecasting (WRF) models were obtained from both CORDEX-Africa website and WASCAL geoportal (Heinzeller et al. 2016), respectively. The CORDEX-Africa RCMs have been selected based on its ability to simulate the basic climatological features in West Africa (Kim et al. 2013). The WRF simulations were produced by the Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, Atmospheric Environmental Research (KIT/IMK-IFU), Germany, and the West African Science Service Centre on Climate Change and Adapted Land Use (WASCAL) regional climate simulations. The WRF (WRF-H and WRF-G) simulations were downscaled from two GCMs namely: the General Fluid Dynamics Laboratory Earth System Model (GFDL-ESM 2 M) and the Hadley Global Environment Model (HadGEM2-ES) using the Weather Research and Forecasting Model (WRFv3.5.1). A detailed technical description and parameterization of the WRF models have been reported by Heinzeller et al. (2017). The CORDEX-Africa RCMs (REMO2009 and KNMI-RACMO22T) and the WRF models were selected due to its remarkable skills in reproducing the climatology of the Vea catchment for the period 1981–2005 (Larbi et al. 2020). The WRF models skills have also demonstrated to do well in terms of rainfall distribution in a study conducted within West

Table 1 Description of the CORDEX-Africa and WRF models whose ensemble mean was used

GCMs	RCMs	Institution	Resolution
ICHEC-EC-EARTH	REMO2009	Max Planck Institute – Computational methods in systems and control theory (MPI-CSC), Germany	50 km
ICHEC-EC-EARTH	KNMI-RACMO22T	Koninklijk Nederlands Meteorologisch Instituut (KNMI)	50 km
HadGEM2-ES	WRF-H	WASCAL / KIT/IMK-IFU	12 km
GFDL-ESM2M	WRF-G	WASCAL / KIT IMK-IFU	12 km

Africa by Bessah et al. (2018). Details on the RCMs evaluation and bias-correction can be found in Larbi et al. (2020). The ensemble mean of the bias-corrected RCMs output used consist of daily rainfall and temperature for the future (2020–2049) under Representative Concentration Pathway (RCP4.5) climate change scenario.

Climate Extreme Indices Analysis

Several climate extreme indices have been developed by the Expert Team on Climate Change Detection Monitoring Indices (ETCCDMI) for understanding climate extremes and are widely used in several regions (Mouhamed et al. 2013; Soro et al. 2016; M'Po et al. 2017). Six of the indices were adopted. The selected rainfall and temperature extreme indices (Table 2) were computed for each climate location for both the historical (1986–2016) and future (2020–2049) period on the interface of R software using RClimdex. The historical extreme indices was computed using climate observation data while the future climate extreme indices were computed based on the ensemble mean of the RCMs data for the RCP 4.5 climate change scenario. The computed rainfall and temperature extremes indices at the annual scale were analyzed at spatial and temporal scale using the inverse distance weighting (IDW) technique (Feng-Wen and Chen-Wuing 2012). Trends in the climate extreme indices time series were computed based on the parametric linear regression approach (M'Po et al. 2017).

Presentation of Results and Discussion

Annual Rainfall and Temperature Projections and Trends

The results for the projections of mean annual rainfall and temperature in the Vea catchment by the ensemble mean of the RCMs under the RCP4.5 scenario is shown in Fig. 2 and Table 3. The ensemble mean of the RCMs shows an increase in mean annual rainfall and temperature by 22.6 mm (2.4%) and 1.3 °C, respectively, for the

Table 2 Climate extreme indices

Indices	Descriptive name	Definition	Units
PRCPTOT	Annual total wet-day precipitation	Annual total precipitation from days ≥1 mm	mm
R99p	Extremely wet days	Annual total precipitation on the days when daily PRCP >99th percentile	mm
CWD	Consecutive wet days	Maximum number of consecutive days with PRCP ≥1 mm	days
CDD	Consecutive dry days	Maximum number of consecutive days with PRCP<1 mm	days
TXx	Warmest day	Annual maximum value of the daily max temperature	°C
TNx	Warmest night	Annual maximum value of daily min temperature	°C

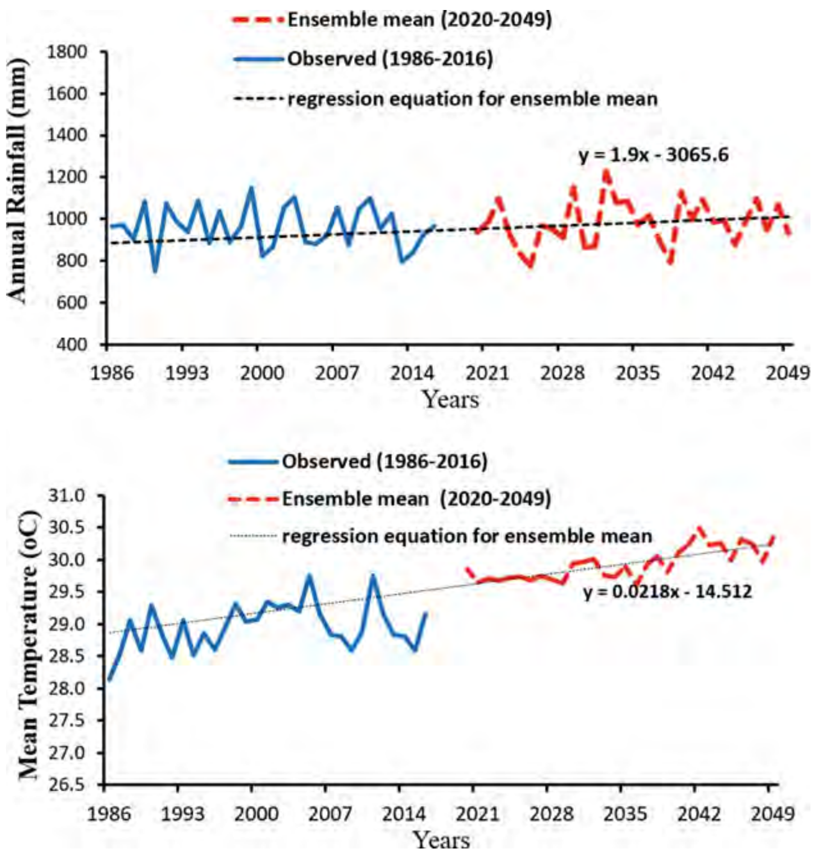

Fig. 2 Mean annual rainfall and temperature projection for the Vea catchment in the future (2020–2049) under RCP 4.5 scenario relative to the 1986–2016 period

period 2020–2049 relative to the baseline (1986–2016) period. An increasing trend in the future annual rainfall and temperature was found to be at the rate of 1.9 mm/year and 0.02 °C/year.

Trends and Projected Changes in Extreme Rainfall Indices

The results for the extreme rainfall indices (PRCPTOT, CWD, CDD, and R99p) projected by the ensemble mean of the RCMs under RCP4.5 scenario relative to the baseline (1986–2016) period are shown in Table 4 and Fig. 3. The annual total precipitation (PRCPTOT) is projected to increase from 951.9 mm to 952.1 mm (Table 4) at an annual rate of 2.2 mm/year (Fig. 3a). Extremely wet days (R99p) is projected to increase by 29.1 mm; however, a decreasing trend at a rate of 0.77 mm/year is projected in the future 2020–2049 (Fig. 3d). Unlike consecutive dry days

Table 3 Mean annual rainfall and temperature projections for the Vea catchment relative to the baseline period

Variables	Baseline (1986–2016)	RCP4.5 (2020–2049)	Change
Tmax (°C)	34.6	35.9	1.3
Tmin (°C)	22.6	24.0	1.4
Tmean(°C)	28.6	29.9	1.3
Rainfall (mm)	958.5	981.1	2.4%

Table 4 Projected changes in mean annual climate extreme indices at the Vea catchment

Climate extreme indices	Baseline (1986–2016)	RCP4.5 (2020–2049)	Change
PRCPTOT (mm)	951.9	952.1	0.2
R99p (mm)	46.6	75.7	29
CWD (days)	5	4	−1
CDD (days)	105	131	26
TXx (°C)	41.5	42.3	0.8
TNx (°C)	28.9	29.2	0.3

(CDD) which is projected to increase from 105 to 131 days, consecutive wet days (CWD) is projected to decrease by 1 day in the future 2020–2049 (Table 4). The spatial distribution of the extreme rainfall indices (Fig. 4) indicates a projected increase in CDD in most part of the catchment, with the exception of the center parts of the catchment that shows a decrease of 5 days (Fig. 4c). The PRCPTOT is projected to decrease in most parts of the catchment except the extreme north and south which shows an increase of 28.7 mm (Fig. 4f). R99p is projected to increase in all parts of the catchment especially in the northern and southern parts and will range from 27.7 to 35.7 mm (Fig. 4L). Unlike R99p, CWD is projected to decrease in the entire catchment in the range of −3.4 to −0.4 days (Fig. 4I).

Temperature Extreme Indices Projections and Trends

The time series of the projected extreme temperature indices (TXx and TNx) and its spatial distribution are shown in Figs. 5 and 6, respectively. As shown in Table 4, the warmest day (TXx) is projected to increase by 0.8 °C from 41.5 °C to 42.3 °C. The warmest night (TNx) is also projected to increase from 28.9 °C to 29.2 °C. The future trend analysis of the extreme temperature indices shows an increasing trend in both TXx and TNx at a rate of 0.04 and 0.01 °C/year, respectively. At spatial scale, TXx is projected to increase in the entire catchment for the period 2020–2049, with a higher increase in the southern part of the catchment in the range of 0.79 to 1.29 °C. The TNx is also projected to increase in the range of 0.0 °C to 0.48 °C in the greater part of the Vea catchment.

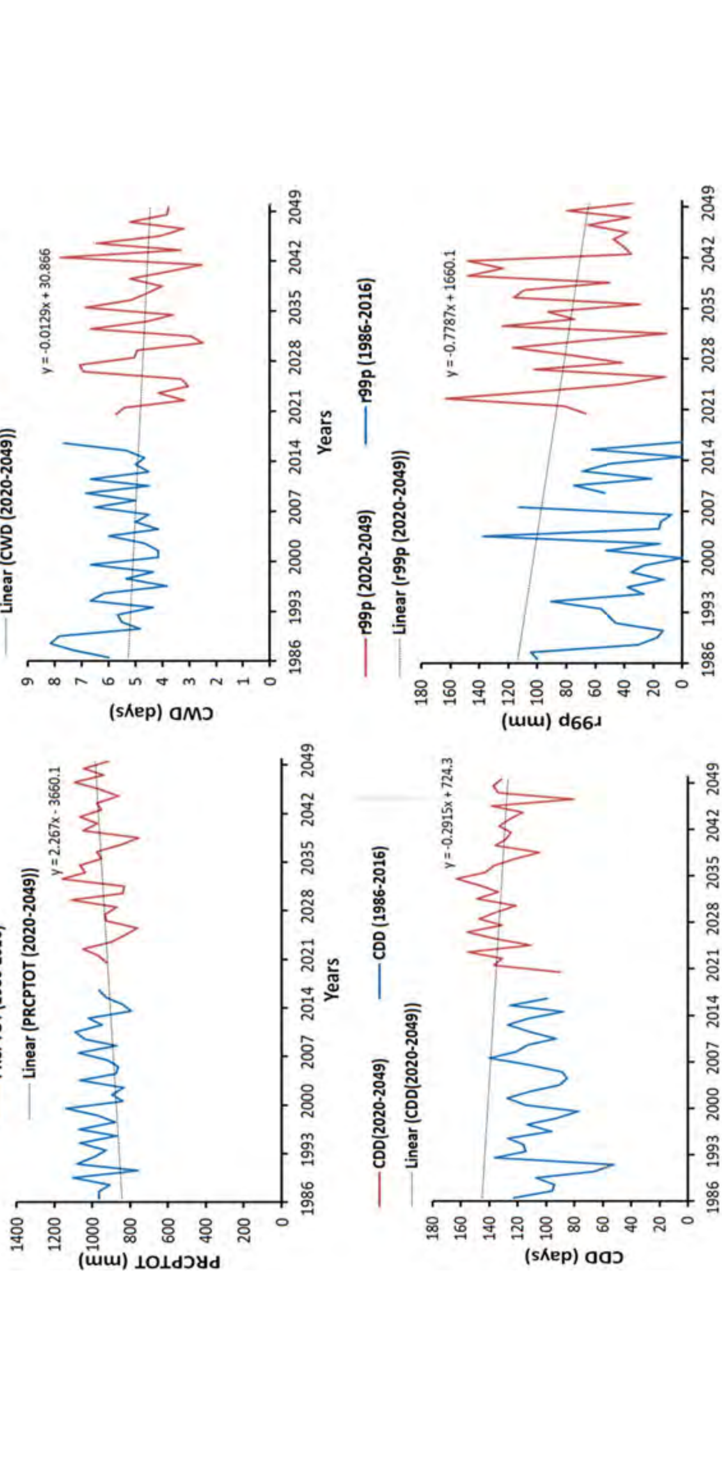

Fig. 3 Trend analysis of extreme rainfall indices: (**a**) PRCPTOT, (**b**) CWD, (**c**) CDD, and (**d**) r99p at the Vea catchment for the historical (1986–2016) and future (2020–2049) period

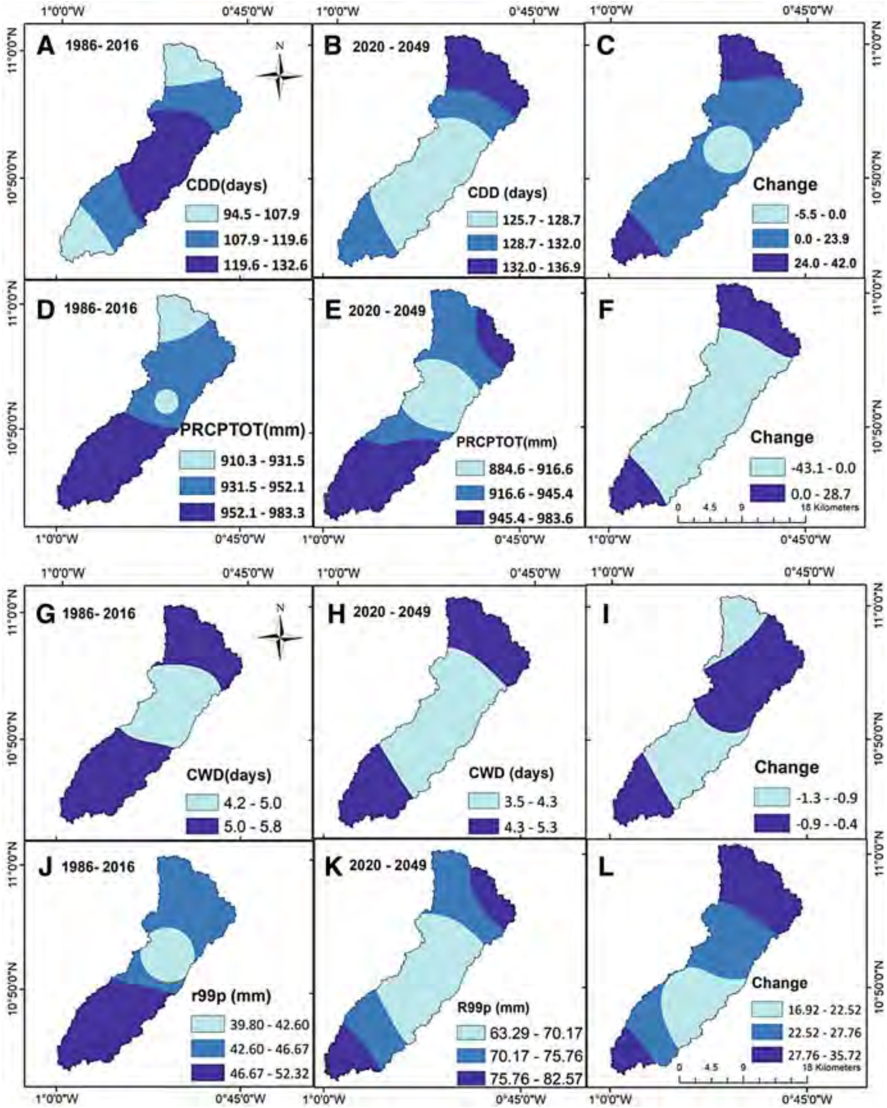

Fig. 4 Spatial distribution of the projected changes in the extreme rainfall indices: (**a**) CDD, (**b**) PRCPTOT, (**c**) CWD, and (**d**) r99p in the Vea catchment

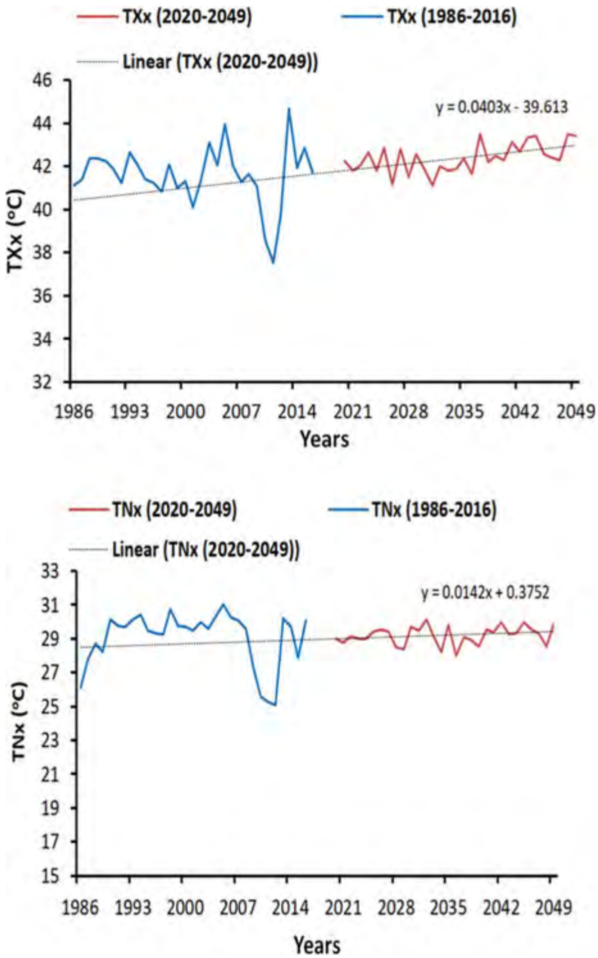
Climate Change and Climate Extreme Impacts at the Study Region

The agroclimatic zone of the Vea catchment is characterized as semiarid region in West Africa and can influence growth when managed efficiently. With the expected increase in precipitation and temperature, there is a likelihood of potential risk to

Fig. 5 Trend analysis of extreme temperature indices for TXx and TNx in the Vea catchment for the historical and future period



natural disasters and destruction of infrastructure which would have environmental, economic, and societal implications (Gobiet et al. 2014). The climate analysis performed on the daily rainfall and temperature series for the historical and future period provides evidence that the Vea catchment would be affected by climate change and warm extremes based on the indices analyzed with warming more pronounced during the day than the night. Although in Ghana climate change projections vary considerably among different models, there is a consensus on the evidence of increasing temperature across the country. The mean annual temperature at the Vea catchment is projected to increase by 1.3 °C for the period 2020–2049. This finding is in line with observations reported by other climate change studies (e. g., McSweeney et al. 2010a; De Pinto et al. 2012). Additionally, a study by De Pinto et al. (2012) reported a projected increase in the mean annual temperature of Ghana

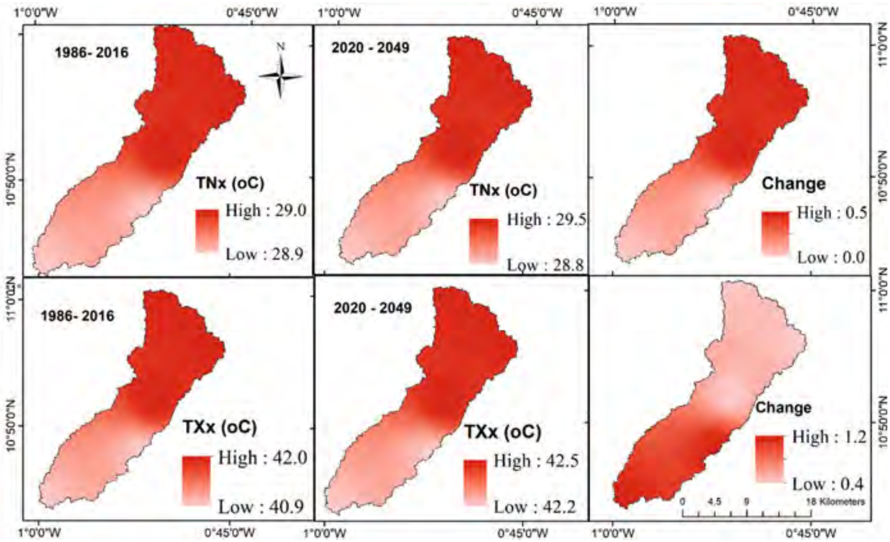


Fig. 6 Spatial distribution of the projected changes in the TNx and TXx temperature indices relative to the baseline (1986–2016) period

in the range of 1.0–3.0 °C by 2060 and by 1.5–5.2 ° C by 2090, with more rapid increases expected in the northern sector of the country. Similar increase in temperature of 0.6 °C, 2.0 °C, and 3.9 °C by the year 2020, 2050, and 2080, respectively, in Ghana has also be projected by the Ministry of Environment Science, Technology and Innovation of Ghana [MESTI] (2013). These projections in temperature are noticed to be across all regions in the country with a rapid increase in the northern sector (World Bank 2010). However, rainfall projections in Ghana are characterized with greater uncertainties with some models predicting an increase while others a decrease (McSweeney et al. 2010b).

In terms of climate extremes, the study region has witnessed periodic extreme climate shocks and disasters such as high temperature, highly variable and erratic rainfall, and long spells of droughts (Kanlisi and Arkum 2013). According to EPA (2007), such extreme weather events are expected to intensify in the region by 2080. The ensemble mean of the four climate models projected a nonsignificant increase in the mean annual rainfall; however, there exist spatial variations in the annual total rainfall (PRCPTOT), CWD, and CDD with some part of the Vea catchment indicating an increase while other parts indicate a decrease in the future period. These projections in climate change and extremes would have serious socioeconomic impacts on rural farmers in Ghana whose livelihoods depend largely on rainfall (Abeygunawardena et al. 2003; Fosu-Mensah et al. 2012). The changes in climate would affect agriculture and other sectors such as water resources, especially in the Upper East Region of Ghana where the Vea catchment is located (Gyasi et al. 2006). The projected warming trend at the Vea catchment lead to a higher evaporative demand from water bodies and irrigated crops in the future. Limantol et al. (2016)

indicated that temperature and evapotranspiration have been on the increase in the Vea catchment. And according to Ofori-Sarpong (2001), the increase in evapotranspiration could lead to soil moisture deficit and poor crop yield, particularly when there is no corresponding significant increase in rainfall. Also, evapotranspiration propelled by temperature will majorly affect agriculture through droughts and soil moisture deficits (Limantol et al. 2016).

Existing and Recommended Adaptation Strategies to Address Poverty and Ensure Sustainable Livelihoods in the Catchment

In sub-Saharan Africa, adapting to the impact of climate change on agriculture and other sectors of the economy has become a major concern to various stakeholders with special emphasis on improving adaptive capacity (Apata 2011). The projected climate change and extremes at the Vea catchment underscore the need to put in place appropriate adaptation measures to foster resilience to climate change in order to enhance water security and livelihood of the people within the area. In the Vea catchment, Limantol et al. (2016) examined farmers' perceptions and adaptation practices to climate change and variability, and noticed that farmers are aware of climate change and are adopting strategies to cope with the effects. At the catchment, some farmers use rain-fed practices to adjust to climate variability by varying crop types via rotation without fertilizer, while others employ irrigation practices to offset climate variability with a greater use of fertilizer application. According to Limantol et al. (2016), farmers identified irrigation development (access to water), followed by access to credit and health services as the most urgent needs for adaption to climatic change in the Vea catchment. Similarly, Kumasi et al. (2017) also reported that, the farmers in the Upper East Region of Ghana mostly practice crop selection, changes to planting dates and density, communal pooling (e.g., labor or income sharing across households), and traditional irrigation techniques as adaptation strategies to climate change. Additionally, Lawson et al. (2019) investigated the intersectional perceptions and adaptation strategies of women farmer in dealing with climate change in semiarid regions of Ghana. It was revealed that women farmers perceived the occurrence of climate change in the community and have incorporated some adaptation measures to counter its impacts. These adaptation strategies include changing planting dates, mixed farming, intercropping, planting early maturing varieties, composting, and seeking off-farm activities.

In Ghana, national climate change adaptation strategy has been developed and various adaptation programs and strategies have been outlined to combat climate change. Some of these strategies include: (i) increasing resilience to climate change impacts: identifying and enhancing early warning systems, and (ii) alternative livelihoods: minimizing impacts of climate change for the poor and vulnerable needs to be implemented at the study catchment to help reduce the vulnerability of the people to future climate change and extremes. Other adaptation strategies recommended for the Vea catchment include:

1. Implementation of water use efficiency system as part of effective management of water resources at the catchment. Due to the projected increased in temperature and the variability in rainfall, water use efficiency system such as drip irrigation needs to be promoted to ensure not only all year-round farming but also reduce demands from the three main water sectors: domestic supply, agriculture, and industry.
2. Enhance local capacity to adapt to climate change through improved land use management and agricultural diversification.
3. Awareness creation on the need to protect and effectively manage the Vea dam and streams within the Vea catchment through the creation of vegetation buffers to protect the water resources.
4. Developing early warning systems and farmers access to climate information so as to adequately inform policy makers and enhance farmers' resilience to extreme events as a result of climate change.

Conclusions

The changes in future climate and extremes indices in the Vea catchment was computed from the Expert Team on Climate Change Detection Monitoring Indices based on the observed climate and multi-model mean of four bias-corrected RCMs. The climate simulation under RCP4.5 scenario for the catchment show a warmer climate with 1.3 °C temperature increase in 2020–2049. The trend analysis of the rainfall and temperature extremes indices indicated a continuous extreme temperature rise as well as an increase in intensity of extreme rainfall events in 2020–2049 at the catchment. The projected increase in extreme temperature (TXx and TNx), intensity (R99p), and frequency (CDD) of extreme rainfall indicate the catchment vulnerability to the risk of climate disasters, hence the need for decision-makers to adapt and mitigate climate change over the area. The study also provided evidence that the daily maximum temperature (warmest day) would increase at a faster rate compared to the daily minimum temperature (warmest night), indicating more warming in the day compared to the night. Encouraging adaptation policies such as rainwater harvesting, availability climate information, flood control measures, and the development of early warning systems are necessary at the Vea catchment to mitigate the effects of future extreme climate events.

Contents

Abstract

A holistic response and adaptation to climatic vicissitudes and extreme conditions as well as their associated risks to human and ecological sustainability must adequately cater for energy needs and optimization. An interventional approach should, among other measures, seek to improve the resilience of existing and prospective energy systems to climate change. The structured and policy-driven

nature of adaptation measures require a bottom-up proactive approach that envisages the performance and efficiency of these systems, especially in terms of their sensitivity and vulnerability to changing climate conditions. Therefore, this chapter seeks to scrutinize various sources of energy concerning their resistance capabilities to climate change in the face of increasing global energy demands and consumption. Renewable and conventional energy sources are co-examined and compared vis-à-vis the current trends and predictions on climatic factors that are bearing on their principles of production, supply, and distribution. Findings from this chapter will serve as assessment tools for decision makers and corroborate other ongoing discourse on climate actions towards socioeconomic development and a sustainable environment.

Climate change · Extreme conditions · Energy resources · Sustainability · optimization

Introduction

Energy represents a fundamental requirement for wealth and job creation in many parts of the world. For many decades, humans have leveraged on the conversion of chemical energy in fossil fuels to other forms of energy. Unfortunately, these energy conversions are accompanied by the release of gases into the atmosphere and this has gradually engendered climate change; hence, the recent emphasis on energy policy alterations that factor sustainable energy supply and environment (Bang 2010). On a global scale, climate change poses increasingly severe risks on the ecosystem; the effect is particularly telling on human health, environmental safety, agriculture and economy. These changes are mostly as a result of the release of large amounts of greenhouse gases (GHG) into the atmosphere. These gases result from anthropological activities all over the world, such as burning fossil fuels for electricity and heat generation, as well as the use of internal combustion engines for transportation (EEA 2017). According to the 2019 report of the International Renewable Energy Agency (IRENA), despite the actions towards global energy transformation, carbon dioxide (CO_2) emissions that are related to the energy sector, have increased annually by over 1% on average from 2013 and 2018 (IRENA 2019). The European Environment Agency also submits that the energy sector, especially in relation to utilization of fossil fuels, lies at the heart of the challenges that are associated with climate change (EEA 2017). In fact, the utilization of energy by humans constitutes the largest contribution to the emission of greenhouse gases. The Energy Sector Management Assistance Program (ESMAP) presents the urgency of actions to control emissions and the necessity to adapt to unavoidable climate effects from the damage already induced in the biosphere due to anthropogenic GHG emissions. Energy generation and utilization do not only contribute to climate change due to greenhouse gas (GHG) emissions but are also directly influenced by its adverse effects (EUEIPDF 2017).

Environmental concerns will largely influence the generation, supply and utilization of energy in the near future; hence, the interest in alternative fuels and improvement in energy conversion technologies (Bauen 2006). In a broad sense, climate change affects energy supply and demand in terms of endowment, exploitation infrastructure and transportation. The effect of climate change on energy security ripples to other sectors such as socioeconomy, industry, and biodiversity (Ebinger and Vergara 2011). More specifically, in 2005, climate change resulted to over 10% variation in energy yield in developing countries (World Bank 2009). Changes in climatic parameters are evidential and can be observed in the lower atmospheric conditions, sea level and surface temperatures as well as topsoil wetness or dryness (Ebinger and Vergara 2011). Some predictions by the Intergovernmental Panel on Climate Change (IPCC) include an increase in global average temperature by close to 5 °C by the end of the century, fluctuating precipitation patterns and intensity, recurring extreme weather events and sea-level expansion (EUEIPDF 2017). Changes in ambient air temperature will affect the energy required for heating and cooling applications. Storms are notable for the destruction of electricity distribution infrastructure and this is being mitigated through underground cable networks. In relation to overcoming the adverse effects of climate change on clean energy generation, Bauen (2006) opined that there is great need for ingenuity, research, investment, and regulations.

Among other merits, renewable energy plays a crucial role in future low-carbon-emission plans aimed at mitigating global warming. When combined with improved energy efficiency, renewable energy is capable of achieving a 75% reduction in energy-related CO_2 emission (IRENA 2019). Bhuiyan et al. (2018) suggested that conservation of biodiversity and environmental sustainability require the exploitation of different renewable energy sources. However, the dependence of renewal energy exploration on and climatic conditions and susceptibility to climate change is a significant area of concern (Ebinger and Vergara 2011). This is in addition to their relatively high cost of generating electricity and uneven natural distribution cum availability. In principle, the adaptation of energy systems is primarily aimed at sustainable energy supply as well as balance between energy production and consumption under varying temporal and spatial conditions (IPCC 2007). However, in reality, climate variability and extremes represent the most significant threat to the entire energy supply chain. Some future projections reveal that the energy sector will become increasingly susceptible to climate change; hence, the need for effective adaptive measures (Ebinger and Vergara 2011).

Energy adaptation in the face of climate change requires reliable and sufficient weather and meteorological data, forecast models and modalities for the performance evaluation assessment of energy systems (Troccoli 2009). Climate change impacts are envisaged throughout the energy system; affecting both demand and supply. There are associated changes in demand patterns for heating and cooling due to rising temperatures. On the supply end, impacts include changes in wind direction and intensity, solar and hydropower resources, the available crops as raw materials for biomass energy production, costs and accessibility of fossil fuels in the face of frozen sea water and permafrost, the efficiency of Photovoltaic systems, thermoelectric power plants and cable systems due to increasing temperatures, as well as operational downtime due to the occurrence of extreme weather events (Cronin et al. 2018). In low income countries, energy supplies are unstable as a result of the relatively high dependence on hydroelectricity and biomass energy which are contingent on rainfall patterns and intensity (Ebinger and Vergara 2011).

Although there is an increased focus on investigating the impact of climate change on energy systems, the formal knowledge base appears to be limited (Wilbanks et al. 2007; Schaeffer et al. 2012). More importantly, studies are based on scenario analysis rather than predictions and are hindered by inherent uncertainties in modeling tools (Schaeffer et al. 2012). There are significant uncertainties that are associated with future climate projections and its effect on energy systems (Schaeffer et al. 2012). This chapter seeks to scrutinize various energy sources, especially concerning their resistance capabilities to climate change using existing research database on global and regional predictions on the vulnerability assessment of energy systems. Renewable (hydropower, wind, solar energy, biofuel etc.) and fossil energy (oil and natural gas) sources are co-examined and compared vis-à-vis the current trends and predictions on climatic factors that are bearing on their principles of production, supply and distribution.

Vulnerability Assessment of Various Energy Systems

Hydropower

Hydropower contributes significantly to total and per capita energy supply in many countries as a prominent renewable and primary energy source of electricity. The main requirement for the production of hydropower is runoff, which is largely dependent on rainfall (Hamududu and Killingtveit 2012). In view of the absolute dependence of hydropower on water resources, countries that depend largely on this source of energy experience a seasonal variation in the production of electricity (Teotónio et al. 2017; Rübbelke and Vögele 2012). Climate variability will definitely affect precipitation rate and regularity (Costa et al. 2012; Turner et al. 2017), which in turn affects hydroelectric power generation through changes in river flow, water storage, and downstream energy production (Tapiador et al. 2011; Teotónio et al. 2017). Apart from the direct effects, climate change can indirectly affect hydropower generation as a result of competitive demands and pressure on water resources by non-energy based economic sectors such as agriculture. Climate change can also engender contentions regarding water resource allocation and utilization between countries that jointly possess river catchments (Teotónio et al. 2017). Water reservoirs enhance the management of transient flow events and changes in river flow intensities (Lehner et al. 2005; Gaudard and Romerio 2014; Teotónio et al. 2017). Inter-seasonal water storages can also be adapted as resilience measures against the effect of climate change on hydropower. The effect of climate change on hydropower depends on the depths and surface areas of dams. The evaporation potential of shallow and wide dams makes them vulnerable to climate change as a result of the heat associated with global warming and the consequent increase in evaporation and drought intensity (Mukheibir 2013; Trenberth 2011; Teotónio et al. 2017).

Studies related to climate change impacts on hydropower can be done using different methods, with data that are assessed globally, regionally, or locally. Predictive impact assessments can also be carried out using modeling techniques. Although large scale analyses demonstrate inherent uncertainties based on modeling choices, they, however, provide tools for assessing global vulnerability hotspots. More impressive accuracies are achieved with models that are developed using data obtained from regions with similar climatic conditions (Turner et al. 2017). Some studies and projections found in literatures are reported as follows; Hamududu and Killingtveit (2012) used a group of simulated regional patterns of variations in runoff, which were generated from global circulation models (GCM), to estimate changes in global hydropower generation resulting from predicted changes in climate. The evaluation showed that significant impacts of climate change on hydropower generation, especially from existing power systems, is more probable on a country or regional level than a global scale. On the contrary, a recent study by van Vliet et al. (2015), using an integrated modeling and data framework on existing hydropower power plants, forecasted a decrease in usable output for more than half of the hydropower plants worldwide for a period of thirty (30) years starting from 2040. Unlike previous studies that adopted the coupled hydrological electricity modeling method on a small scale, van Vliet et al. (2015) utilized this model to establish the effect of climate change and varying water resources on global electricity supply in the twenty-first century. It is apparent that results of localized predictions of the effect of climate change on the generation of hydropower should be carefully interpreted and cannot be generalized. Furthermore, the generalization of parameters that have high spatial variation should be avoided (Schaefli 2015; Turner et al. 2017).

Turner et al. (2017) identified regions with projected significant losses in hydropower production using a coupled, global hydrological and dam operating model with three GCM projections for two emissions frameworks. The global vulnerability hotspots that were identified include; the countries of southern Europe that surround the Mediterranean Sea, as well as those within North Africa and the Middle East region. In a local study, Teotónio et al. (2017) employed an optimization model to predict the impact of climate variation on the availability of water resources and the electrical power generation in Portugal. Findings from the study showed that by 2050, hydropower generation may fall significantly and lead to higher costs of electricity in the study location as a result of climate. This result is corroborated by a similar analysis carried out by Carvajal et al. (2017) in Ecuador, which revealed that hydropower generation is relatively unstable and vulnerable to climate change since variations in throughput to hydropower stations would result in changes in the expected hydropower generation, given stable conditions.

While hydropower exploitation contributes to low carbon development initiatives, reduction in plant output due to drying climate conditions engenders the dependence on fossil fuels especially when other renewable energy sources are not competitive (Spalding-Fecher et al. 2017). The resistance of hydropower plants to climate change and its consequent effect on availability of freshwater resources can be enhanced through improvements in plant efficiency, cooling systems and fuel switches (van Vliet et al. 2015). Recently, the International Hydropower Association

(IHA), presented a six-phase approach to climate resilience for the hydropower sector which includes; comprehending what climate resilience means for the sector, a first phase of qualitative assessment of the project to climate risks, an initial or preliminary analysis, a climate stress test, risk management planning, and lastly the monitoring, evaluation and reporting of the outcomes of each of the phases (IHA 2019).

Solar Energy

Solar power ranks as the third most utilized renewable energy (after hydropower and biomass energy) and constitutes an increasingly essential component of the future low carbon-energy campaign across the globe (Panagea et al. 2014). Solar energy is mostly harnessed for both heating and electricity generation through active or passive energy systems which utilize solar collectors, photovoltaics, power towers, solar ponds, or ocean thermal collection. Through the Photoelectric effect, solar cells are utilized in the direct conversion of solar radiation to electricity; conversion efficiencies above 20% can be achieved through technologies that concentrate the incident light rays (Patt et al. 2013). The efficiency of Photovoltaic (PV) systems can be primarily influenced by geometry, ageing, ambient conditions, environmental pollution, as well as electrical, visual, and shade losses (Skoplaki and Palyvos 2009; Mani and Pillai 2010; Meral and Diner 2011; Panagea et al. 2014). The output of PV cells has a nearly linear inverse relationship with cell temperature and a directly proportional response total irradiance. Hailstorms can also affect the performance and most notably, the physical components of PV systems (the PV modules). Some of the existing solar energy technologies such as pump or circulation systems are used in environments with extreme freezing or overheating temperatures.

The impact of climate change on temperature and irradiance will significantly affect PV output (Crook et al. 2011). Climate change effects have a bearing on atmospheric transmissivity by changing atmospheric water vapor content, cloudiness (Cutforth and Judiesch 2007), and its aerosols content (Gaetani et al. 2014). Generally, the efficiency of PV modules drops by about 0.5% per degree Celsius rise in temperature (Patt et al. 2013). A study by Crook et al. (2011) utilized data obtained from coupled ocean-atmosphere climate models to indicate that PV output from 2010 to 2080 will change slightly in Algeria and Australia while it will probably rise or reduce in some parts of North America, Europe, and Asia. In another study conducted by Gaetani et al. (2014) using climate-aerosol modeling experiments, the results showed that by 2030, there will be varied effects of climate change on the production of photovoltaic energy in different parts of the world; this result is consistent with that of Crook et al. (2011). In Greece, there is an inverse relationship between the output of PV devices and the predicted rise in annual temperature, which is exceeded by the projected increase of total radiation resulting in a net increase in energy output (Panagea et al. 2014). Further location-specific studies are required for quantitative assessments of climate impacts on PV systems (Patt et al. 2013).

Wind

Wind energy is well explored for electricity generation, but it is not insulated from the influence of climatic vicissitudes since its energy density depends on global energy balance and the consequent atmospheric motion (Pryor and Barthelmie 2010; Schaeffer et al. 2012). The energy output from wind has a cubic relationship with the speed of the moving air mass, and it is proportional to air density (Manwell et al. 2002; Pryor and Barthelmie 2010). A differential change in wind speed will affect its potential for electricity production, timing, and the operational period of wind plant (Pasicko et al. 2012). According to Baker et al. (1990), a 10% change in the average wind speed could alter energy production by up to one-quarter of its initial capacity. Hence increase in wind speeds as a result of climate change should result in increased energy outputs and this could translate to an increased dependence on this energy source. Wind turbines are carefully structured to factor transient wind conditions such as the occurrence of extreme wind speeds, and other aerodynamics such as directional variations (DNV 2002). The reliability and safety of a wind power plant is determined by the maximum wind speed for which it is designed (Pasicko et al. 2012). Wind turbines should be kept nonoperational during conditions that exceed their reliability and safety indexes in other to avoid infrastructural damages.

Wind speed varies significantly with elevation from sea level as well as the spatial density of natural and artificial wind breakers (Ebinger and Vergara 2011). Several other variables can impact the vertical profile of a moving air mass, and the extrapolation of wind speeds at heights where they are not measured is quite convoluted. The logarithmic extrapolation method is popularly adopted in the estimation of wind speeds at hub heights of wind turbines that are above 50 m (Schaeffer et al. 2012). The consideration of the terrain roughness is characteristic of this method of estimation. With regards to wind energy, the roughness of a terrain is dependent on vegetative cover which can be significantly affected by climate changes and consequently impact the generation of wind power (Lucena et al. 2010; Schaeffer et al. 2012). As such, the development of wind energy production requires reliable information about the potential variations in wind energy availability as well as topographical parameters in a location of interest (Bloom et al. 2008).

Biofuel

Bioenergy (which is generated from crops are such as jatropha, sunflower, cotton, sugarcane, sorghum, and maize) is a vast and diverse energy source category since it consists of a wide range of organic fuels that can be adapted to various types of technologies to run engines, produce heat or generate electricity (Kirsten 2012). Perennials with suitable land cover are preferable as energy crops. Oilseeds are particularly used as pure plant oil and for biodiesel production while sugarcane and cereals are used in some parts of the world for the production of bioethanol as alternatives to gasoline for engines such as automobiles (Kirsten 2012), thereby portending significant contribution to the reduction of carbon footprint from transportation. The sustainability of biodiesel remains a debate as most studies come to a wide range of conclusions due to differences in approach, biomass input sources, land use and its associated change impacts, choice of system limits and functional units, as well as the methods that are adopted for allocation (Rouhany and Montgomery 2019). However, it is apparent that climate change has its toll on bioenergy production. For instance, liquid biofuels are indirectly susceptible to changes in temperature and rainfall patterns, as well as available CO_2 to crops which serve as feedstock for the production of transportation biofuels (Schaeffer et al. 2012). Average crop yields and arable land suitable for growing bioenergy crops are affected by rising temperatures and changing precipitation patterns (EUEIPDF 2017; Cronin et al. 2018). Some specific resulting adverse effects in this regard are land-area losses due to flood, salinity and dry-out influences of increased temperature (Mohammad 2013). For plants, CO_2 is an essential greenhouse gas because of its necessity for photosynthetic process. Haberl et al. (2011) explicitly examined mean cropland yield change under climate change in 2050 with and without CO_2 fertilization, and the findings indicated regional variation and increase as high as 28.22% in crop yield with full CO_2 fertilization and considerable loss (up to −16.02%) when this effect is controlled.

Oil and Natural Gas

The primary concerns regarding the utilization of fossil fuels are related to their depletion, future exhaustion, and carbon emission. Oil and gas conventional energy deposits are not likely to be affected by climate change due to their long-term formation process in geological traps (Ebinger and Vergara 2011). However, there could be indirect effects on the utilization of these resources especially with regards to the identification of natural reserves and accessibility to them (Schaeffer et al. 2012). Climate change events can affect oil and gas exploration, processing and transportation (Burkett 2011). Hurricanes and other extreme climatic events can hamper the production of these fossil fuels from off-shore facilities (Ebinger and Vergara 2011). Similarly, Burkett (2011) identifies that changes in climate variables such as sea and CO_2 levels, intensity of storms, wave regime, air and water temperature, rainfall patterns and ocean acidity also can affect oil and gas exploration in coastal regions (Schaeffer et al. 2012). There are also predictions that significant reduction in ice cover may increase the feasibility of exploration in areas of the Arctic (Harsem et al. 2011; Ebinger and Vergara 2011; Schaeffer et al. 2012), raising the prospect for oil and gas development in this region.

Thermal Power Plant

The impacts of climate change on thermal power plants are mainly related to generation cycle efficiency and water needed for cooling of power plants (Wilbanks et al. 2007; Ebinger and Vergara 2011). Some technologies that could be affected in this regard include coal, biomass residue, and geothermal power plants (Schaeffer et al. 2012). Generally, thermal plants operate with Rankine or Brayton thermodynamic cycles, require energy for heating and cooling processes, which depend on average ambient atmospheric conditions (Schaeffer et al. 2012). Increase in temperature is likely to reduce the thermal efficiency and output of power plant (Ibrahim et al. 2014; Linnerud et al. 2011; Cronin et al. 2018). Also, expected changes in water resource availability throughout the globe will have a direct influence on the use of water for cooling existing power plants and consequently, their output capacity (Wilbanks et al. 2007). Furthermore, reduction in water resources that is available for cooling may result to load-shedding or shutdown of power stations (Cronin et al. 2018). It has been projected that by 2040 capacity reductions of 12–19% in Europe and the US are possible due to rise in water temperatures and reduction in runoff (van Vliet et al. 2012; Sieber 2013). Generally, while it is expected that changes on power plants capacity will vary according to regions (for example, increase in India and Russia); generally, global annual thermal plant capacity is likely to shrink by 7–12% in the mid-century (van Vliet et al. 2015).

Conclusion

The global concern on climate change, extreme conditions and their associated footprints are in increasingly alarming degrees, especially in recent times. In spite of the preventive and adaptive measures that have been applied at local and international fronts, it is vivid that remedial actions must be taken to supplement the efforts against the adverse effects of climate change and this study shows that the energy sector is not left out of the need for intervention. The interaction between climate change and energy adaption is significant and should be taken seriously. This chapter makes a case of climate change-resistant energy utilization by examining the resilience of different energy sources to climate change, through a retrospective consideration of relevant findings from literatures on energy resources, needs and utilization as well as climatic factors, their current trends and future prediction. Consequently, it explicates the dire need for adaptive measures towards energy utilization in the face of climate changes and severe conditions. Climate change has direct and indirect effects on the exploitation of conventional and non-conventional energy resources. The effect of climate change on water resources and temperature seems to have the most significant effect on different energy sources and technologies. Extreme weather events such as hurricanes and hailstorms are detrimental to the energy systems with relatively fragile structures especially for renewable energy exploitation. This study reveals that there are temporal variations in the effect of climate change on energy systems in different parts of the world. Hence, local conditions must be considered in decision-making with regards to climate change and energy. It is hoped that this discussion provides an adequate injection of pooled examinations of different energy sources towards the sustainability and optimization of their utilization in response to climate change.

Uncertainties in Rainfall and Water Resources in Maghreb Countries Under Climate Change

97

Mohamed Meddi and Saeid Eslamian

Contents

Abstract

The vulnerability of the climate change in the South of the Mediterranean's south regions varies depending on the part of their climate which is sensitive to the economy. In Tunisia, agriculture represents 16% of the workforce and 12% of GDP in 2006. In Algeria, agriculture represents 20% of the workforce and 8% of GDP in 2009. In Morocco, agriculture accounts for 40% of the workforce and 17.7% of GDP in 2006. The agriculture is directly related to the availability of water which in turn is directly related to rainfall. The drought has affected all countries of the Maghreb. It is considered the most severe in the history of these

countries. The drought has forced the agricultural sector in Morocco to the limitation of annual crops which are not needed, the prohibition of any new tree planting and the ban on vegetable crops in dry years. During the years 1987, 1988, and 1989, Tunisia has experienced the most critical drought. It led to a water deficit of around 30%. For Morocco the rainfall shows a negative trend at national and regional scales, and spring rainfall has declined by over 40% since the 1960s. For Algeria, the western region has recorded a considerable reduction in rainfall. The winter rains have decreased between 40% and 70%. Contributions to dams have decreased between 30% and 50%. These changes had a negative influence on the water resource and crop yield. Many programs have been initiated since then to meet the growing demand.

Introduction

The issue of climate change settled permanently at the forefront of the news and concerns opinion's public. Confined for a long time to the scientific community and environmental groups, it has emerged in recent years at a government level with the signing of the Kyoto Protocol. But it is mostly the recent weather disturbances (repeated heat waves, devastating hurricanes). Meanwhile, advances in scientific knowledge have gradually transformed what was originally a simple hypothesis – a global warming caused by man – a virtual certainty, although there are still many unknowns about the accurate scope and the pace of the phenomenon.

According to the World Bank (2017), Tunisia, Algeria, and Morocco will become global hot spots by the end of the twenty-first century. Higher temperatures and reduced precipitation will increase the occurrence of droughts in this region (World Bank 2017).

Droogers et al. (2012) found that climatic changes will be responsible for 22% of water shortages by 2050 and 78% of water shortages will be the result of socioeconomic factors for North Africa. During the last century, Algeria has experienced several periods of drought, the most intense were felt in 1910 and 1940 and more persistent in the years from 1975 to 1990 and the beginning of the century. The last drought in the Maghreb countries since five past decades is particularly severe. The period 1950–1975 was wetter comparing to the long-term average, so that from 1977 there is an enough marked drought, unprecedented since the early observations. Algeria and especially the West region have experienced several major droughts in the last century, during the 1940s and 1970s until today (Meddi and Hubert 2003; Habibi et al. 2018; Merabti et al. 2018). The latest one was characterized by its spatial extent and its intensity. In Morocco, droughts continue to increase in both frequency and intensity and impact negatively water resources and agricultural production according to World Bank (2017). Droughts are recurrent and are becoming more frequent and more severe. Previous recorded droughts, which required government emergency plans, were recorded in 1992–1995, 1998–2001, 2005, 2007, and 2015–2016. The 1994–1995 droughts were particularly strong, resulting in an estimated GDP loss of 7.6% (World Bank Group 2017a). The 1999 drought cost about US$ 900 million and affected more than one million hectares of cultivated land (World Bank Group 2017a).

To the large spatial variability of precipitations correspond a clear regional difference in the potential of surface water. At the seasonal and interannual variability of rainfall, there is also a strong irregular hydrographical inflow with violent floods and low water periods that can last several months (Meddi and Hubert 2003).

Two-thirds of the territory of Tunisia is characterized by a semiarid climate to arid. This space is subject to drought may be common. The droughts are a common natural phenomenon in Tunisia. They become more and more frequent. The resulting consequences have increasingly serious social and economic impacts. The droughts date back to the last century and Tunisia experienced 31 dry years between 1907 and 2016. More recently, Tunisia experienced a drought during the years: 1982, 1987 to 1989, 1993, 1994, 1995, 1997, 2000, 2001, 2002, 2008, 2010, 2013, and 2016, and the worst drought since more than 50 years was recorded during the years from 1999 to 2002. These droughts cost about $ 54 million.

The agricultural sector is largely dependent on the availability of water resources, which is the most vulnerable to climate change (Farzaneh et al. 2014). In Algeria, the water consumption in the agricultural sector is about 7 billion m^3/year where it represents 70% of the total national consumption (http://www.mree.gov.dz). In Morocco, irrigation uses 80% of the country's mobilized resources, the rest being reserved for drinking water and industry (MDCE 2016). The used water in irrigation is about 12,038 million m^3 (Dahan 2017). In Tunisia, the volume of water intended for irrigation id about 80% of total water consumption (Chebil et al. 2019). These volumes of water used in irrigation to ensure food security and socioeconomic development in these countries demonstrate the importance of studies and the proposal of scenarios on the impact of climate change on water resources in order to be able to propose measures meet the growing demand in the medium and long term.

Climate projections confirm reduction of rainfall and rising of temperatures (Matari 2016), which will affect the availability of water resources in the medium and long term, hence the need to find ways to mobilize additional water resources (conventional and unconventional) to meet this ever increasing demand.

In this chapter, we will discuss the effects of climate change on water resources as well as adaptation measures in the three Maghreb countries.

Maghreb Countries, Water Resources, and Climate Change

The three Maghreb countries (Algeria, Tunisia, and Morocco) occupy an area of 3,254,000 km^2 (Fig. 1). The Maghreb is crossed from north to west by a mountain system called "Atlas." It is a barrier between the Mediterranean coast and the Sahara. It begins at the mouth of the Wadi Sous in southwestern Morocco to Cape Bon and

Fig. 1 Situation of Algeria, Tunisia, and Morocco (Zeroual et al. 2017)

the Gulf of Gabes in northeastern Tunisia. South of the Tell, there is the Saharan Atlas which separates the Algerian highlands from the Sahara. It continues its extension to the east by the Aurès and the Tunisian Dorsal. The Sahara occupies nearly 80 percent of the total area. The most fertile agricultural land is located on the coastal strip that separates the mountains from the sea and the highlands.

These three countries are characterized by considerable demographic growth. They are also facing the phenomenon of climate change which has led to a decrease in rainfall and an increase in temperatures. Rainfall in the Maghreb is already low, with average rainfall volumes of about 357 km^3/year, or 110 mm (Taabni and El Jihad 2015).

Tunisia is located between longitudes 7° and 12° east and 32° and 38° latitudes north. Humid to subhumid areas are in the north. The subhumid to semiarid regions are located in the northwest and the Cape Bon region. The semiarid to arid part is located in central Tunisia. The desert covers the south of Tunisia. In Tunisia, rainfall and temperatures vary considerably from north to south (humid coastal zone to desert conditions in the south) and from east to west. They are influenced by the Mediterranean Sea in the north and in the east and by the Sahara in the south and in the southwest. The rains fall mainly between the months of October and May. Temperatures in the arid and semiarid regions of the south and southwest of the country are generally high, while precipitation is much higher from November to April in the more northerly regions.

The northern part of Algeria is characterized by a Mediterranean climate with a relatively cold and rainy winter and a hot and dry summer. The annual rainfall reaches 400 mm in the west, 700 mm in the center, and 1000 mm in the east for the coast. This type of climate is also found in the Tellian Atlas chains where we record totals ranging from 800 to 1600 mm in the eastern summits, while the values are lowered in the center (700 to 1000 mm) and in the west (600 mm). In the plains of the Tellian Atlas, rainfall varies between 500 mm in the west, 450 mm in the center, and 700 mm in the east (Meddi and Hubert 2003).

In Morocco, rainfall follows a decreasing gradient from north to south and from west to east. Rainfall and temperatures are strongly influenced by the Atlantic Ocean to the west, the Mediterranean Sea to the north and the Sahara to the south and southeast. Most rainfall occurs between October and May like other Maghreb countries (World Bank Group 2017a). Morocco is characterized by spatial and temporal variability of rainfall. The northwest receives more rain than the rest of the country. The average annual rainfall varies considerably. It can reach more than 800 mm on the reliefs, while it hardly exceeds 300 mm on the adjacent plains (World Bank Group 2017).

The climate of Tunisia is strongly influenced by the Mediterranean Sea in the north and east and by the Sahara in the south and southwest. Like other Maghreb countries, rainfall occurs mainly between October and May. Rainfall varies considerably from a relatively wet coastal area to desert conditions in the south. Precipitation exceeds 400 mm/year in the north and reaches 1500 mm/year in the extreme northwest of Tunisia (TSNCUNFCCC 2013). In the central part of the country, precipitation varies between 150 and 300 mm/year (TSNCUNFCCC 2013). Rainfall is becoming scarce and less than 150 mm/year and at the extreme south, rains not exceed 50 mm/year. The average total annual rainfall varies from 1 year to another and is around 36 billion m^3/year (TSNCUNFCCC 2013).

The decrease in rainfall since mid-1970s has negatively impacted the renewal of groundwater and the dams filling. The scarcity of water resources has had a dramatic effect on the economy in general and agricultural production and agricultural development in these countries in particular. Agriculture is largely dependent on rainfall. In Morocco, irrigated agriculture contributes about 45% of agricultural added value, despite, irrigated agriculture, occupying only 15% of cultivated area. In Algeria, according to the Ministry of Water Resources, the water consumption in the agricultural sector is close to 7 billion m^3/year where it represents 70% of the total national consumption which is of the order of 10.6 billion m^3/year (http://www.mree.gov.dz). The rate for agriculture corresponds to the world water consumption in irrigation which is around 70%. In Morocco, irrigation uses 80% of the country's mobilized resources, mainly surface water, the rest being reserved for drinking water and industry (MDCE 2016). The used water in irrigation is about 12,038 million m^3 (Dahan 2017). In Tunisia, the volume of water intended for irrigation about 80% of total water consumption (Chebil et al. 2019). This volume was in 2004 of about 2130 million m^3 for an area of 375,000 ha and will be 2145 million m^3 in 2011 and 2035 million m^3 in 2030 for an area of 467,000 ha (www.environnement.gov.tn). In the future, rational pricing encourages farmers to use more and more water-saving technologies and varieties that consume less water.

The renewable water resources in the three Maghreb countries are estimated at 43 km^3, where surface water accounts for 73% (Taabni and El Jihad 2015). In 2010, the average per capita renewable water provision for the Maghreb countries was 548 m^3/person/year in 2010, and by 2030 it will be less than 290 m^3/person/year (Taabni and El Jihad 2015). These values are well below the standard set by the World Health Organization (WHO) of 1000 m^3/person/year.

All these statistics show the importance of the development of water resources management scenarios in the Maghreb countries to meet the increase of water demand for drinking water supply and especially for irrigation, so to increase the capacity of agricultural productivities, and sustainable production systems to reduce the problem of poverty and unemployment knowing that the agricultural sector is the main employer in the world with 40% of the world population.

The Maghreb countries are located in an arid to semiarid region. The climate is Saharian in the southern, oceanic in the western, and Mediterranean in the north. The population of Morocco, Algeria, and Tunisia was already 65 million in 2000 and attended more than 75 million in 2010. A population that is gathered for more than two-thirds on the shores of the northern Atlantic and Mediterranean region, the life of people in these countries is closely linked to climate and to these changes.

Climate data recorded in the Maghreb region during the twentieth century indicate a warming in this century estimated at more than 1 °C, despite its small share in global emission of greenhouse gases (GHGs) (www.anme.nat.tn). These data also show an increase in droughts and floods. Thus, we started a drought every 10 years at the beginning of the century to 5–6 years of drought in a decade now (Agoumi 2003).

The North African countries suffer from recurrent droughts, whose frequency has increased over the last 40 years. Increasing climate variability affects in particular the center and the north of these countries and the predictions of the Intergovernmental Panel on Climate Change (IPCC 2013) are worrying, even alarming. They indeed show a worsening trend for future decades (OSS 2009). The central Maghreb is characterized by a low average annual rainfall and strong fluctuations in rainfall. In recent decades, he suffered several episodes of drought and the latter tends to be more structural than cyclical. In years of drought, the scarcity of rainfall affects pluvial agriculture which occupies an important agricultural area in the region but also all other sectors dependent on water resources. Irrigated agriculture is also affected and measures of restrictions on water allocation are generally applied (OSS 2009).

Climate data recorded in the region during the twentieth century indicate a warming during this century estimated at more than 1 °C with an accentuated trend in the last 30 years (Fig. 2). These data also show a net increase in the frequency of droughts and floods. Thus, we started a drought every 10 years at the beginning of the century to 5–6 years of drought in a decade now. The general circulation models, even if they are not accurate enough for this region does not have a centered model converge to estimate a likely warming in the region of about 2° to 4° during the twenty-first century.

Trend analysis of rainfall variability in the Mediterranean region shows a significant decrease in rainfall from 1970 (Knippertz et al. 2003; New et al. 2001; Rodrigo and Trigo 2007; Khomsi et al. 2013). This downward trend is higher in winter (Jacobeit 2000; Giorgi 2002). In the Maghreb, Tramblay et al. (2013) observed a negative trend in precipitation intensity, in annual maximum precipitation, and in the 95th percentile of precipitation.

The vulnerability of the climate change in the Mediterranean's south regions varies depending on the part of their economy sensitive to climate (agriculture, tourism, infrastructures, energy, and ecosystem). In Tunisia, agriculture represents 16% of the workforce and 12% of GDP in 2006 (BCT 2007). After a decline of 7% in 2005 caused by drought, its rate of growth was 2.5% in 2006 and 2.1% in 2007.

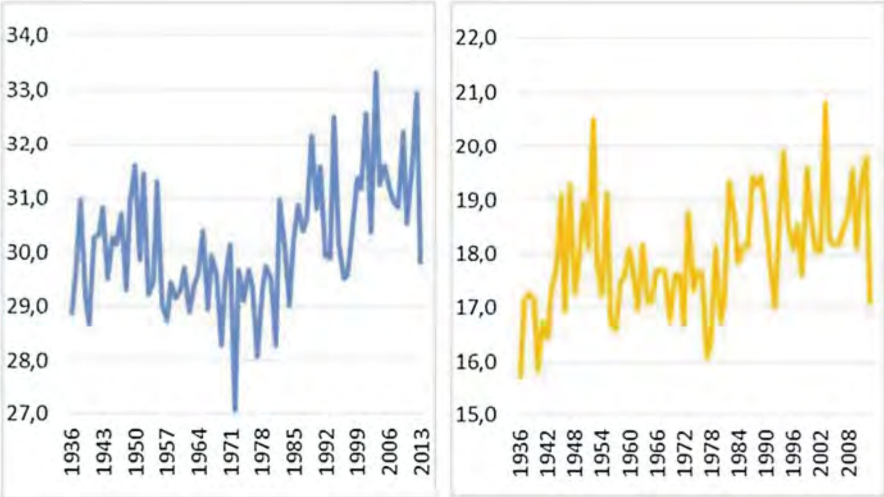

Fig. 2 Evolution of average maximum and minimum temperature in Algiers at Dar El Beida station 1936–2012 (Matari 2016)

For Algeria, agriculture represents 20% of the workforce and 8% of GDP in 2009. For Morocco, agriculture accounts for 40% of the workforce and 17.7% of GDP in 2006. This sector in these countries is directly related to the availability of water which in turn is directly related to rainfall.

Climate Change, Future Projection, and Adaptation

Algeria

Water Potential and Climate Change

Water potential of Algeria is estimated at 19.4 billion m^3/year according to the Ministry of Water Resources. The groundwater resources contained in the northern aquifers of the country (renewable resources) are estimated at 2 billion m^3/year and the surface water is estimated at 12 billion m^3/year. The water reserves of southern Algeria are very important and are of the order of 40,000 billion, this resource is not renewable according to the Ministry of Water Resources.

Water and its management represent a major problem in Algeria following specially in the South. It is amplified by the reduction of rainfall affecting the country since the 1970s. For example, the rainfall, in the northwest, decreases more than 20% (Figs. 2 and 3) and the temperature has increased as shown in Fig. 3. Droughts in rehearsing raise represent the most serious concerns for citizens and managers of the water sector. The climate scenarios and the availability of water are alarming and might have direct and indirect bad consequences on the potential of water resources (quantity and quality) and on their use in the Drinking Water Supply, in agriculture, and in industry.

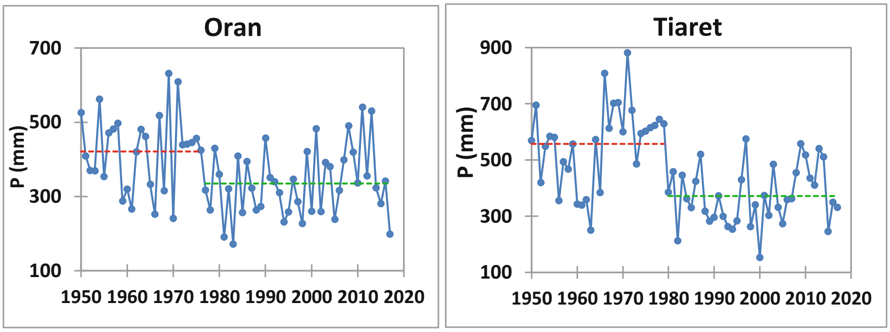

Fig. 3 Trend of annual rainfall variability at Oran and Tiaret stations

Water resources in Algeria are limited, vulnerable, and unevenly distributed in terms of geography. Many dams have been constructed to develop surface water storage capacity, whereas in 1962 there were only 13 dams capable of storing 450 million cubic meters of water, mainly used for irrigation of the plains in the west of the country (http://anbt-dz.com/). The storage capacity has multiplied several times and has reached eighty dams with a capacity of more than eight billion cubic meters in 2017.

According to the Ministry of Water Resources (http://www.mree.gov.dz), drinking water supply, after being confined in big cities, the network connection rate has increased from 78% in 1999 to 98% in 2017. The network is over 127,000 km in 2017. The increase in water availability per capita has increased from 123 l in 1999 to 180 l in 2017, but water distribution systems still lose about one-third of the water distributed due to leaks.

Immediate Water Needs

Water consumption in the agricultural sector is about 7 billion cubic meters per year, which is about 70% of the total volume of water consumed nationally. The drinking water consumption of the population is estimated at 2.5 billion cubic meters per year.

Future Water Needs

Climate change, strong urban and demographic growth, and the nature of water resource management will exacerbate water stress. The demand for drinking water can easily exceed 4 billion cubic meter per year over the next few decades.

In agriculture, we have two possible scenarios:

- **The First Scenario**:

  Represented by a slight change in the current management of water resources, an average increase in irrigated land and the maintenance of the current quality of agriculture, the demand for irrigation water will reach 15.4 billion m^3
- **The Second Scenario**:

  To improve the efficiency of water resources management, increase the irrigated area to 2,000,000 hectares and develop cereal and fodder crops, the demand for irrigation water will increase to 20 billion m^3.

In 1962, theoretical water availability per inhabitant per year was in the order of 1500 m^3, in 1990 was 720 m^3, 680 m^3 in 1995, 630 m^3 in 1998, 500 m^3 in 2009, and it will be only 430 m^3 in 2020.

Algeria is one of the countries where water availability per capita is below the threshold set by the World Bank (1000 m^3/hab/an). Water resources are estimated to 19 billion m^3 (corresponding to about 600 m^3/hab/an). The mobilization of water is facing the following problems:

- The spatial distribution of surface water resources requires substantial transfers to meet the needs of the less fitted regions; these facilities and operations of water mobilization are more and more expensive.
- The effectiveness of reservoir dams is reduced by the high evaporation affecting water bodies (reservoirs evaporate in Algeria from 1.3 to 2.2 m/year and the problem of siltation (32 million m^3/year for 52 dams whose initial capacity is about 5.2 billion m^3).
- The rate of loss in the networks of drinking water varies from 30% to 40%.

In Algeria, the observed climate change across the globe has resulted in:

- An increase in the average, minimum, and maximum temperature recorded on all stations in northern Algeria since the 1970s and that continues to these days.
- On other records, the impacts of climate change have caused our country endemic drought since 1970, resulting in a worsening desertification with a degradation of more than 8% of the forest, wind, and water erosion of soil.
- A trend in rainfall during the past 25 years had a negative impact on water resources by:
- A rainfall deficit of about 30%
- An impact on the level of filling of dams and groundwater recharge
- The impact on the socioeconomic structure
- An impact on the environment (desertification, urban pollution, industrial and agricultural, decline of groundwater levels and salinization of water result of the overexploitation of groundwater and drought)

Impact of Climate Change on Superficial and Underground Water Resources

Indeed, the 90 billion m^3, which precipitate in average each year, only 12 billion m^3 is surface water resources and two-thirds of this volume could be mobilized.

The decrease in rainfall creates a water deficit. It constitutes the most important factors to lead to reduce the flow of the seasons of winter and spring.

For example, lower liquid intake, on an annual scale, at the outlets of five basins in western Algeria (Fig. 7), varies from 16% (Basin of Sidi Ali Ben Youb) to 55% (chouly basins). At Bouhanifia dam, flows have registered a reduction of about 56% since 1979 date of change in the hydrological regime and 55% of reduction at Beni Bahdel dam since 1974 (Fig. 4).

At the level of the plain of Ghriss (west of Algeria) the exploited water varies from 72 to 88 hm^3 /year, while the natural recharge is about 64 hm^3/year (Fig. 5).

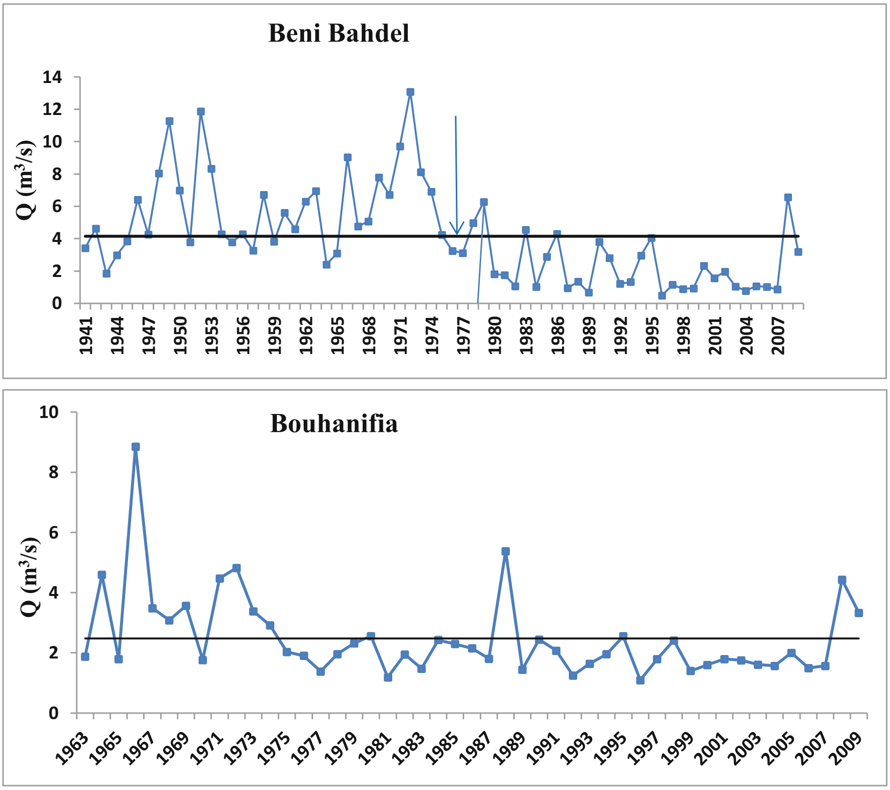

Fig. 4 Inflow to Beni Bahdel and Bouhanifia dams

This decrease is mainly due to the lower rainfall in recent decades. This imbalance has led to a lowering of the groundwater from 5 m to 40 m.

For the Chellif Basin, the total number of wells and drillings increased steadily from 5 in 1850 to 2080 in 2005. This increase in the number of wells and drillings resulted in a change in the amount of mobilized water. These volumes were 3.75 Mm^3 in 1970 and 110.7 Mm^3 in 2005 in the high and medium chellif (Meddi and Boucefiane 2009).

Future Projection

The study of the temporal and spatial evolution of surface and underground water resources is considered as a major decision-making tool for the socioeconomic development of the Maghreb countries.

Dams are filled mainly by the few floods recorded during the rainy season. The recharge of the aquifers is ensured by infiltrations which occur in winter and spring. This recharge has become insufficient since the mid-1970s following the decrease in rainfall (Meddi and Hubert 2003; Hallouz et al. 2013; Zeroual et al. 2017) and the

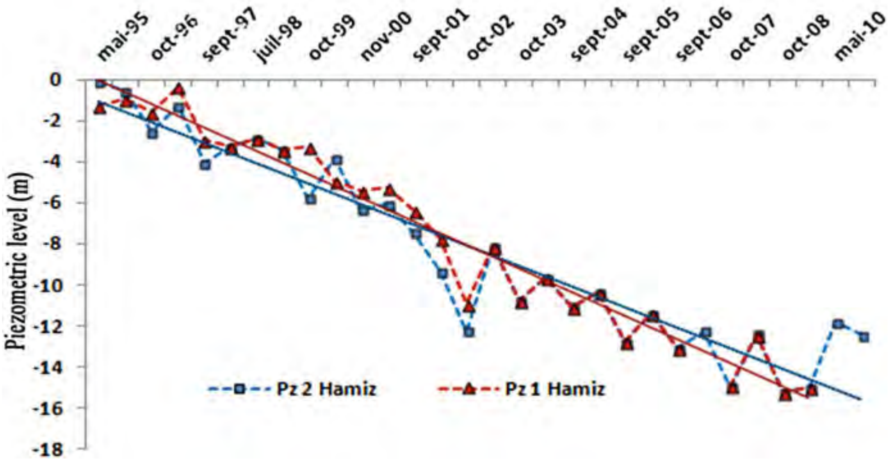

Fig. 5 Evolution of the piezometric level in Pz1 and Pz2 Hamiz, plain of Mitidja (1995 to 2011)

overexploitation of groundwater to meet irrigation water and drinking water needs. The drop in piezometric levels reached 40 m for the Mitidja Plain (Demmak 2008).

Climate projections will make it possible to establish scenarios for the availability of water resources at future horizons. Projections of the spatio-temporal variability of precipitation and temperature for the periods 2006–2060 and 2045–2100 performed by Zeroual (2017) using the RCA4 model (NorESM1-M), scenarios RCP4.5 and RCP8.5, for the periods 2006–2060 and 2045–2100 showed a stabilization of average rainfall compared to the period from 1951 to 2005 in eastern and southern Algeria and a decrease in the western part of Algeria (Figs. 6 and 7). This decrease will change from RCP4.5 to RCP8.5 and from 2006–2060 to 2045–2100. The climate models predict a decrease in precipitation and an increase in temperatures both on annual and monthly scales for the periods 2006–2060 and 2045–2100 (Zeroual 2017).

The impact on the flows will be very important as shown by Kahlerras et al. (2018) in a work on the Mazafran Basin (Fig. 8), in the center of Algeria. The Oued Mazafran, which drains a basin of 280 km^2, for the RC4.5 scenario, will record a decrease in flows will be of the order of 29% in 2033 to reach a volume of 134.01 Mm^3 compared to the reference period (1998–2014) which recorded an average volume of 189.85 Mm^3. For scenario RC8.5, a decrease will be of the order of 31.6% in 2028 with a volume of 129.8 Mm^3, by 2040, the volume will be of the order of 129.9 Mm^3. These 2 years will be the least rainy with 178.4 mm/year and 184.8 mm/year, respectively (Kahlerras et al. 2018).

Kahlerras et al. (2018) have shown that the demand for water for the Mazafran Basin, whose population is estimated at about 615,956 inhabitants in 1998 and will be of the order of 1,724,880 inhabitants by 2050, there will be a recovery of demand until 2040, the deficit after this date will be of the order of 3.44 Mm^3 in 2045 and will

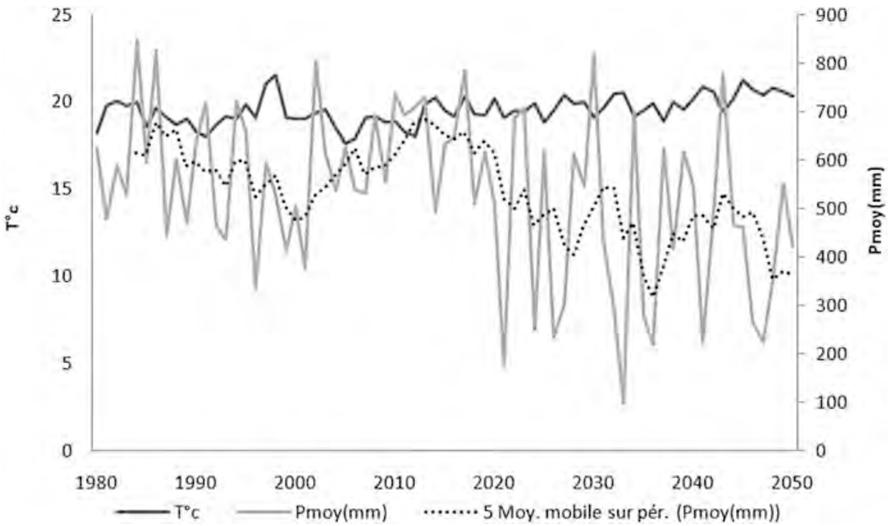

Fig. 6 Projected temperature and rainfall trend change at the time horizon of 2050 (scenario RC4.5) at the Mitidja plain (Kahlerras et al. 2018)

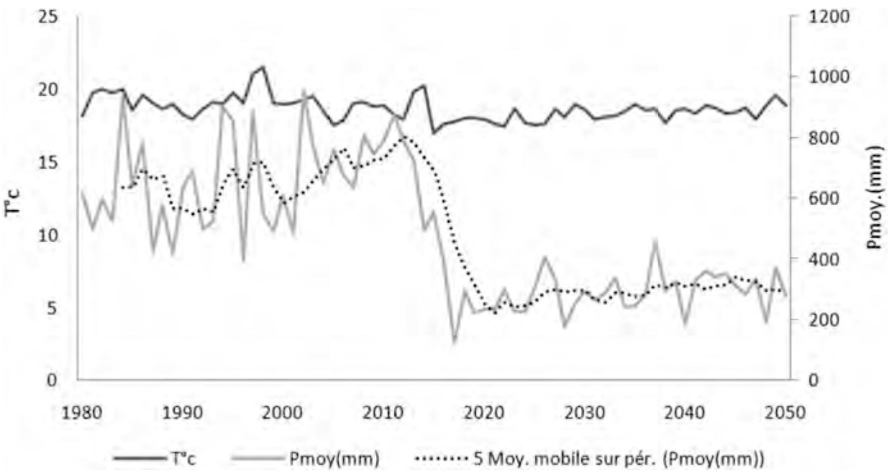

Fig. 7 Projected temperature and rainfall trend change at the time horizon of 2050 (scenario RC8.5) at the Mitidja plain (Kahlerras et al. 2018)

reach 95.3 Mm^3 in 2050 for scenario RC4.5 (Fig. 9). The situation will be more critical for the pessimistic scenario (RC8.5) where the rupture between supply and demand will be recorded as early as 2025. The deficit will be of the order of 56.65Mm^3 in 2030 and will reach 130.95 Mm^3 in 2050 (Fig. 10).

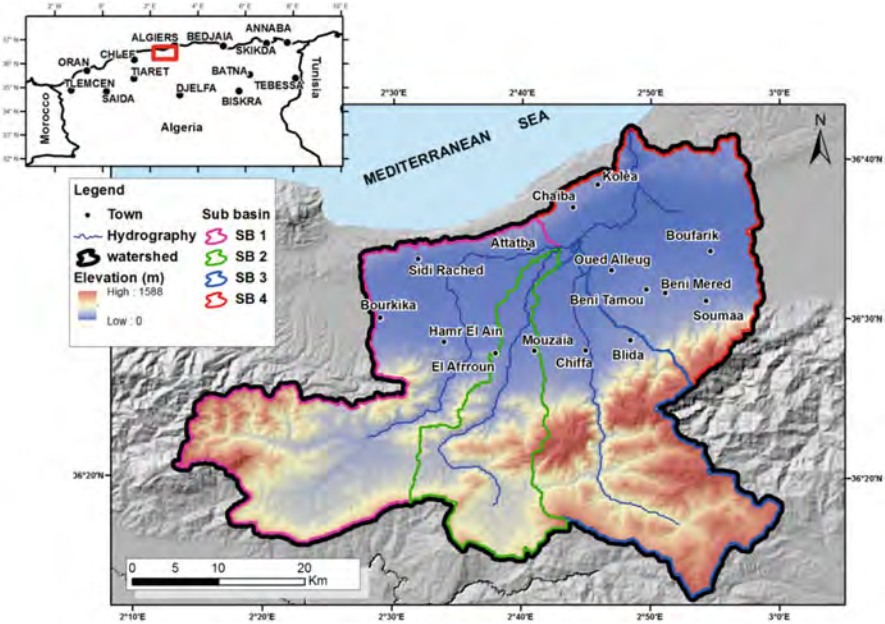

Fig. 8 Geographical situation of the Mazafran watershed (Kahlerras et al. 2018)

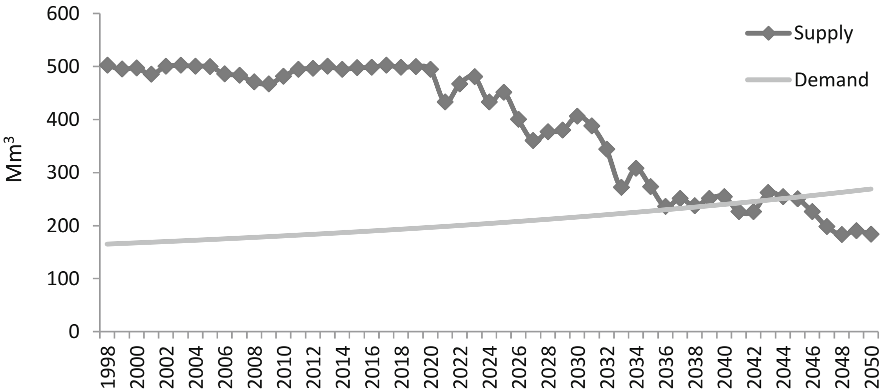

Fig. 9 Assessment of water resources management for the RC 4.5 scenario (Kahlerras et al. 2018)

For basins located in western Algeria, the region most affected by the reduction in rainfall by 25% (Meddi and Hubert 2003), winter flows will show a clear downward trend, mainly due to the decrease in rainfall and the increase in PET for the two scenarios RCP8.5 and RCP4.5. On the other hand, spring flows will increase according to RCP 8.5 and decrease according to RCP 4.5. In terms of observed differences, the RCP 8.5 scenario forecasts a decrease in winter flows of about 33% on average in all the studied basins by 2039, 31% by 2069, and 50% by the end of

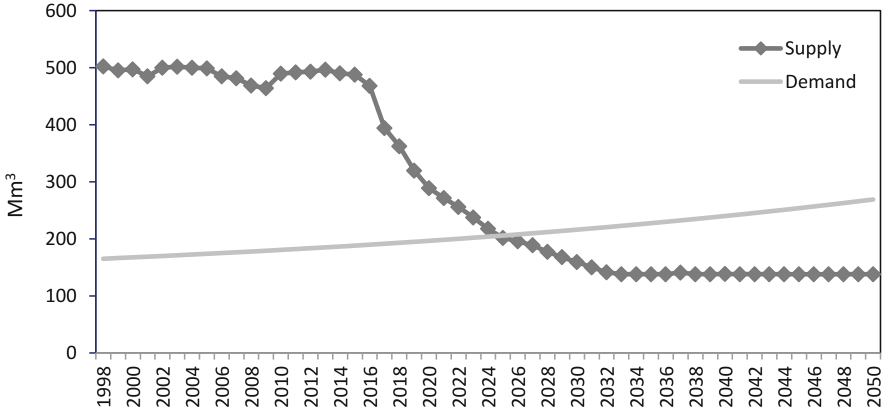

Fig. 10 Assessment of water resources management for the RC 8.5 scenario (Kahlerras et al. 2018)

the twenty-first century. The RCP4.5 scenario predicts a decrease of about 50 to 60% for all horizons. In addition, the decrease is estimated at 80% for spring flows according to the RCP4.5 scenario. In contrast, the RCP8.5 scenario forecasts a 25% increase for the same season (Haddour et al. 2019).

Palliative Measurements

To cope with the change in rainfall reduction, Algeria has undertaken a major program based on large transfers and the use of the non-convent water.

The state has made a considerable effort to increase the connection rate, mainly in rural areas. This rate increased from 44% for some rural regions to more than 60% (http://www.mre.gov.dz). The recent decision to use non-conventional water, desalination, will provide a substantial addition to alleviating the suffering of populations of large cities and rural areas. An emergency program was decided by the government for commissioning 21 desalination stations with a total capacity of 57,500 m^3/day (http://www.mre.gov.dz). For this project, the Government aims to strengthen the water supply of some urban areas situated in the coasts in the summer season. Water dams originally planned for these towns will be transferred to the interior cities. This procedure will develop these towns and villages that are in poverty and enable people to develop agriculture and prevent diseases inherent to the lack of water (http://www.mre.gov.dz).

During the warm season, the deficit is growing due to the increasing demand and declining reserves of conventional water (http://www.mre.gov.dz). However, these programs cannot alone solve the water problem in the long term. Rigorous management and increased storage capacities of surface and groundwater are essential to meet the demand. The reuse of wastewater, especially in aquifer recharge and irrigation, will increase, with no doubt, the water resource available in the medium and long term (http://www.mre.gov.dz).

There is a considerable waste in agriculture. To remedy to this, it is necessary to restructure the peasants in unions capable to organize the operation of irrigation and to modernize, as appropriate, irrigation techniques.

For a better management, decentralization of the management of water supply and sanitation in order to promote the emergence of effective management by elected authorities and representative committees of citizens. We must encourage and facilitate management by major river basins (basin agencies).

Once the impacts on water resources will be determined for the main socioeconomic activities, strategies to adapt to the negative impacts of these climate change scenarios for Algeria can be developed for the benefit of policy makers. They will be able to draw a proper water policy in the medium and long term.

Large Transfers

To cope with water shortages in certain parts of the country, the government has started the constructions of several large transfers across the country, we give as examples:

- Beni Haroun Development in the east of the country: 242 million m^3 will be used to supply drinking water for 4.62 million inhabitants of several department: Jijel, Mila, Oum El Bouaghi, Batna, Constantine, Ain M'lila, and Khenchela. Also, 262 million m^3 for irrigation of 30,000 hectares.
- Mobilization of water resources in Algiers: This project consists of projects set to ensure an annual volume of 595 million m^3. A total of 435 million m^3/year for drinking water supply for 7.95 million inhabitants and 160 million m^3 for the irrigation of about 30,000 ha.
- Mobilization of water resources in western Algeria: The development of the water production of Chellif-Kerrada called MAO provides 155 million m^3/year for the drinking water in the corridor Mostaganem-Arzew-Oran.

Desalination of Seawater

A very ambitious program was initiated to meet the water demand constantly increasing through desalination of sea water. This resource is inexhaustible and can be exhausted on a coast of 1200 km. In addition, the population and the industries that are large consumers of water are near the sea to defend this approach. The field of desalination of seawater has in recent years a remarkable technological step through the development of different processes. The program is composed of large monoblock stations and a desalination plant. For the first category, 21 stations with a total capacity of 57,500 m^3/day:

- 13,000 m^3/day for the western region.
- 22,500 m^3/day for the central region
- 7000 m^3/day for the east region

For the large stations, the regional distribution is made as follows: western region (1.29 million m^3/day), the central region (0.45 million m^3/day), and the eastern region (0.15 million m^3/day).

Recommendations

- Algeria will build more than 40 dams to reach 130 dams by 2030 to increase the mobilized water resources.
- Reduce leakage from urban and rural drinking water systems by 30% to 20% by 2030.
- Save between 20% and 25% of water intended for irrigation by 2030.
- Economy of 20% (1.4 billion m^3) in agriculture could provide drinking water to half of the Algerian population
- The used water treatment stations can process up to one billion m^3 in the future. This unconventional water resource is an excellent addition to irrigation and can easily cover more than 100,000 hectares.
- Integrated Water Resources Management (IWRM) is a good solution for smart and optimal management through the development of scenarios to counter the impacts of future climate change.
- Develop integrated management of water resources by basin.
- The development of research projects to be conducted by a consortium of farmers and research laboratories to develop optimized complete solutions for the reuse of treated water in irrigation.

Morocco

Water Potential and Climate Change

Morocco has a potential of water estimated at 22 billion m^3, 18 billion m^3 of surface water, and 4 billion m^3 of groundwater (Choukr-Allah 2011). Morocco counted 135 large dams with a total capacity of 17,500 million m^3 in 2009, as well as about 100 small dams with a capacity of 100 million m^3 for local needs in drinking water, irrigation, and livestock, and there are also 13 systems for transferring water between watersheds (https://water.fanack.com/morocco/water-infrastructure-in-morocco/). The national water strategy foresees the construction of about 60 large dams by 2030, with a total capacity of about 7 million m^3 plus 1000 small dams for local development (Alaoui 2013). The water resources reduce in particular because of overexploitation (Fig. 11). This depletion will increase with the advent of climate change. Similarly, the development of industrialization and intensification of agriculture water consumption would cause further degradation of groundwater.

In addition, water resources will be subject to further exploitation, the domestic and industrial wastewater will constitute a problem concern threatening the human health and the environment. Thus, the urban wastewater was about 600 Mm^3/year in 2015, it will increase to about 750 Mm^3/year in 2030 and 900 Mm^3/year by 2050 (World Bank Group 2017b).

The recorded rainfall shows a negative national trend (Fig. 12). The spring rains have fallen over 40% since the 1960s. The drought seems to become more persistent over time. The temperature has increased as shown by the Fig. 13. The dry maximum length is rising during the rainy season, significantly during the end of this season (February to April) where it increased 15 days since the 1960s. At the same time, the

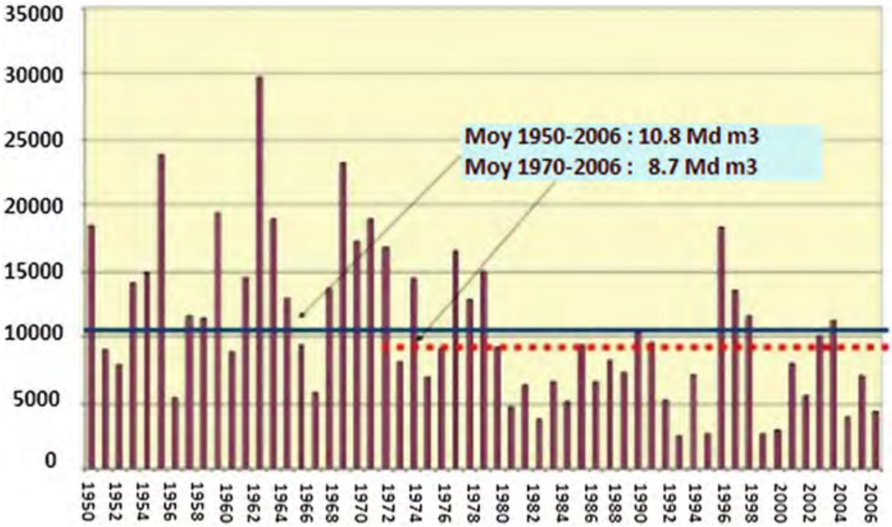

Fig. 11 Evolution of the water contributions in dams of Morocco (Ben Abdelfadel and Driouech 2008)

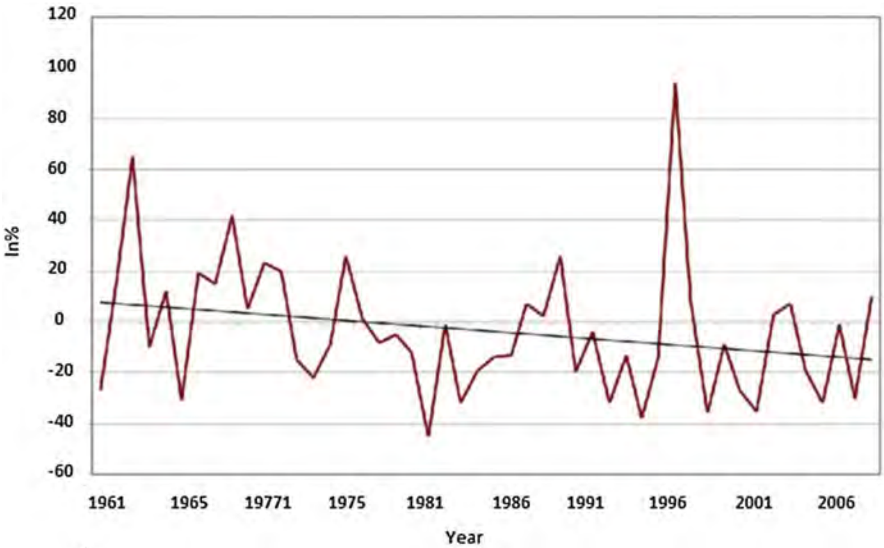

Fig. 12 National averages (%), defects of the cumulative rainfall totals annual, calculated on the 14 meteorological stations in Morocco (1961–2008), Driouech (2010)

total number of rainy days shows a negative trend and indicates an increase in the annual number of dry days. Many regions have become drier between 1961–1985 and 1986–2005 (Ben Abdelfadel and Driouech 2008).

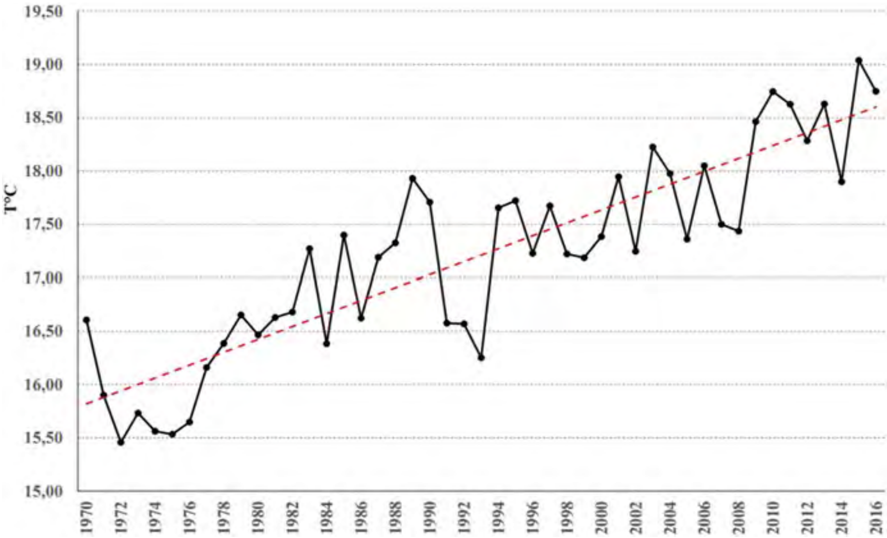

Fig. 13 Average annual temperatures at the Oujda station in Morocco (El Hafid et al. 2017)

The drought has led the agricultural sector in Morocco, for example, to limit the not needed annual crops, to the prohibition of any new tree planting and to the prohibition of vegetable crops in dry years from 1981 to 1982.

The potential of renewable water resources is estimated at 22 billion m^3 per year of which 18 billion m^3 of surface water. From the available potential two-thirds are currently mobilized and used up to 88% in irrigation and 12% in the drinking water.

Morocco's Third National Communication on Climate Change 2016 has shown that, according to observed climate trends and long-term projections, climate change is already underway based on the climate trends observed between 1960 and 2005 (MDCE 2016). Average annual temperatures have increased from 1.0 to over 1.8 °C (MDCE 2016). Precipitation has declined between 3% and 30% with a 26% decline in the northwestern region of Morocco (MDCE 2016). On average, warming varied between 1 and 3 °C depending on the region during the period 1998–2007 compared to 1971–1980 (MDCE 2016).

Surface Water

According to the second submission, river flows have recorded a 20% reduction since 1950 (SCNCCRM 2009). Knowing that the surface water resources on the whole territory are evaluated in average year to 18 billion m^3, varying, according to the years, from 5 to 50 billion m^3. More than 51% of the surface water resources are produced at the level of four hydrographic basins (Loukkos, Tangier, Mediterranean Coastal, and Sebou) (SCNCCRM 2009).

The last four decades have seen a marked decrease in stream flows and natural recharge of groundwater (Sinan and Belhouji 2016). The decreases in superficial

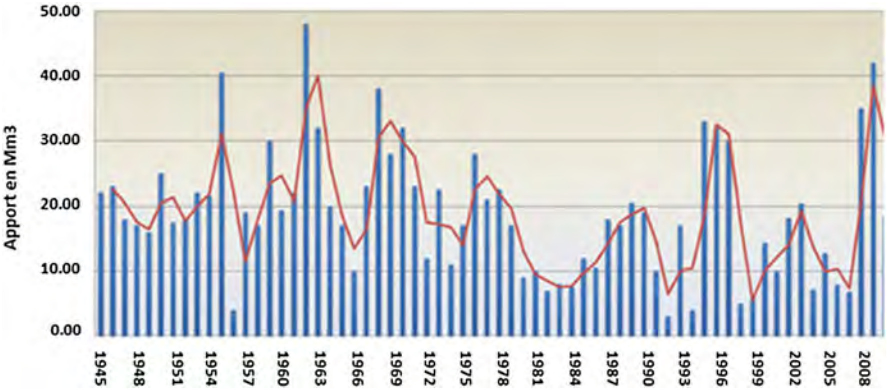

Fig. 14 History of surface water supplies in Morocco 1945–2010 (MDCE 2014 in Sinan and Belhouji 2016)

flows reached nearly 20% between 1970–2006 and 1950–2006 and exceed 70% in certain regions of Morocco (Sinan and Belhouji 2016), Fig. 14.

To show the probable effects of climate change on surface water resources, two basins feeding the dams of Hassan Addakhil (located on Wadi Ziz in the south-east) and Idris I (located on Wadi Innaouene, tributary of the oued Sebou, central Morocco) are considered. In Morocco, like other countries around the Mediterranean, surface water flows depend mainly on rainfall.

Figs. 15 and 16 present the history of water inflow in the Hassan Addakhil (by Wadi Ziz) and Idriss I (by Wadi Inaouene, Basin of Sebou) dams over the period 1950–2002 (Sinan et al. 2009; Sinan and Belhouji 2016; MDCE 2016). They show a clear downward trend in these inputs, especially since the beginning of the 1980s (more than 30 years ago), a clear consequence of the negative effects of climate change. The average water inflow during this period (1950–2002) was respectively 122 Mm^3/year and 516 Mm^3/year for the Hassan Addakhil and Idriss I dams (Sinan et al. 2009; Sinan and Belhouji 2016).

The water resources of the two basins will record decreases as below compared to the end of the twentieth century (Sinan and Belhouji 2016):

- 2020: −7.6% (optimistic scenario) and −8.6% (pessimistic scenario)
- 2050: −2.3% (optimistic scenario) and −12.8% (pessimistic scenario)
- 2080: −7.6% (optimistic scenario) and −40.6% (pessimistic scenario)

Groundwater

Groundwater represents about 20% of the potential of Morocco's water resources. These waters are of great importance for the socioeconomic development of the Kingdom. Morocco has 96 aquifers, 21 of which are deep and 75 shallow and cover a total area of 80,000 km^2. The level of these aquifers shows a continuous decrease due to drought, reduction of natural recharge, and overexploitation. This reduction in groundwater level is about 2 m each year. The volume of groundwater withdrawn

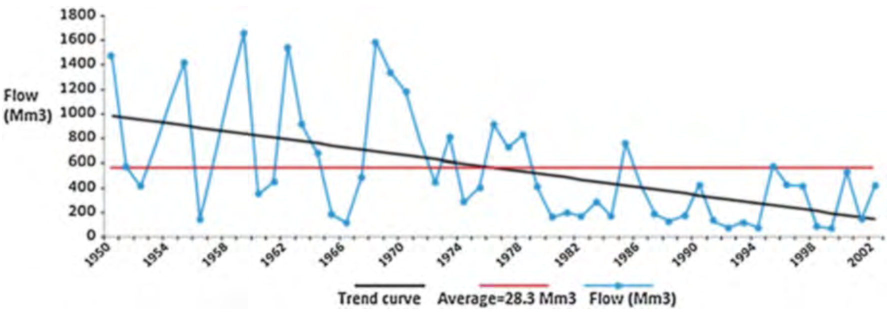

Fig. 15 Historical water inflow in Hassan Addakhil Dam by Wadi Ziz (Sinan et al. 2009)

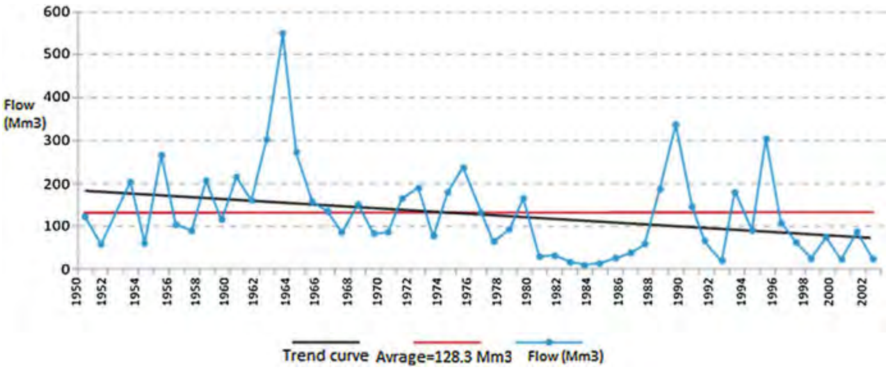

Fig. 16 History of water supplies in the Idriss I dam by the Inaouene wadi – Sebou basin (Sinan et al. 2009)

from the aquifers exceeds the renewable water resources. In fact, recent estimates estimate withdrawals at 5 billion m^3/year, which is a reflection of the nonrenewable potential of groundwater with an average volume of 1 billion m^3/year. This overexploitation has led to a general decline in groundwater levels sometimes exceeding 2 m/year in some aquifers (Sinan and Belhouji 2016).

The impact of reduced rainfall and consequently the groundwater recharge, as well as the overexploitation of groundwater has led to the lowering of the piezometric level. According to Amraoui (2019), between 1980 and 2017, the deep aquifer of Saiss plain at the level of the piezometer 290/22, controlling the region of Meknes, shows an average decrease of 3 m/year (Fig. 17). Groundwater exploitation in this area increased from 4 million m^3 in 2005 to almost 10 Mm in 2014 (Ameur 2017). For this aquifer, the Sebou Watershed Agency (ABHS) has identified more than 9000 water points exploiting the water table, most of which are not authorized (Amraoui 2019). This is the equivalent of 4 holes per Km^2 (Amraoui 2019). In terms of use, agriculture would take 225 million m^3 annually and 100 million m^3 of drinking water (Amraoui 2019).

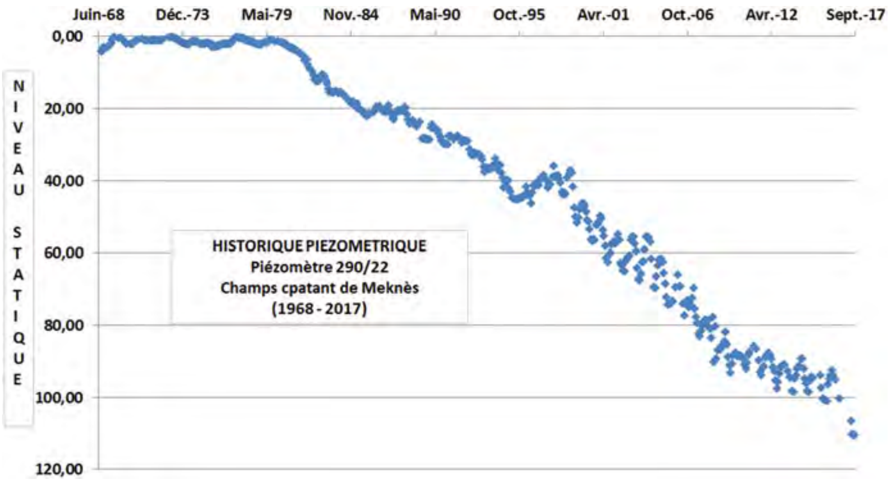

Fig. 17 Decrease of the level of aquifer of Siass plain, Morocco (Amraoui 2019)

The impact of climate change and reduction of water resources have led to:

- Worsening of water supply in rural areas
- Very important economic impact on the agricultural sector: drop in grain production, irrigation water deficit, increased unemployment in rural areas
- The impact on water quality

Future Projections

Projections of climate to future horizons indicate a negative trend of annual rainfall that varies between 10 and 20% to reach 30% in Saharan regions by 2100. The trend in annual average temperatures show an increase of 0.5 to 1 °C in 2020 and 1 to 1.5 °C in the 2050 and 2080 horizons across the country (MDCE 2016; Sinan and Belhouji 2016). The observed temperature has increased by 0.5 °C each decade since 1970. It is above the world average of about 0.15 °C (World Bank Group, 2017). The forecasts show that Morocco will reach 3 to 7 °C from here at 2100, with 4 to 7 °C for the summer months (June, July, and August). Annual rainfall is expected to decrease by 10 to 40%, especially by 10 to 30% during the rainy season from October to April and by 10 to 40% during the dry season from May to September (World Bank Group 2017a).

The water potential in Morocco is estimated at 22 billion cubic meters per year. With a forecast to 38 million inhabitants in 2030 and despite a considerable effort, in terms of construction of hydraulic structures and access to unconventional resources, this quantity of water could fall to 500 m^3 by 2030 under the pressure of climate change, population growth, and pollution increase in economic activity (INDC 2015). Over the next 20 years, Morocco will be more vulnerable to drought and other extreme weather events (World Bank Group 2017b).

These projections also show that the water/year/inhabitant capital would be significantly reduced by 2050 and 2080, thus creating a situation of water scarcity (water capital/year/inhabitant of less than 500 m^3/year/inhabitant) between the 2030 and 2050 horizons for all considered socioeconomic scenarios (Sinan and Belhouji 2016; MDCE 2016), Table 1 and Fig. 18.

Palliative Measurements

The adaptation is a process allowing improving, developing, and implementing strategies to mitigate the consequences of climatic events, to cope and to take advantage.

- Participatory approach: associate all communities and socio-professional categories capable to suffer the consequences of climate change
- Proactive approach: situations of crisis, so far as it is possible
- Optics of sustainable development
- Adaptation of infrastructure
- Use of nonconventional water resources

Currently, Morocco has 144 large dams and 13 others under construction. As part of a National Water Plan by 2030 and to meet the water needs of the population to avoid an imbalance between demand and supply by 2030, Morocco will realize close

Table 1 Projection of capita m^3/inhabitant/year (Sinan and Belhouji 2016)

Year	Optimistic scenario	Pessimistic scenario
1960	2560	2560
2000	775	775
2020	575	569
2050	518	464
2080	342	217

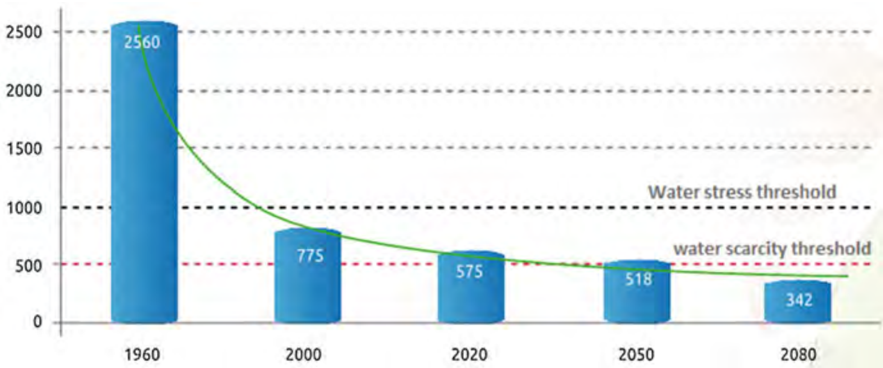

Fig. 18 Water capital projection (m^3/ inhabitant /year) optimistic scenario (Sinan and Belhouji 2016)

to 1000 small dams and dams in different regions of Morocco between 2019 and 2026 (Plan National de l'Eau, horizon 2030).

Nonconventional Water Resources

(a) **Reuse of Treated Wastewater**:

According to the national water plan for 2030, the potential of waters that can be reused by 2030 is around 325 million m^3/year. This volume constitutes the potential of the usable water. To achieve these objectives, Morocco plans to carry out 162 projects in the watersheds of: Loukkos, Moulouya, Sebou, Bou Regreg Chaouia, Oum Er Rabiî, Tensift, Souss Massa Drâa, Guir Ziz Rhéris, and Sakia El Amra Oued Eddahab.

(b) **Desalination**

Desalination of seawater is an alternative For Morocco. Morocco is using since 1990 the desalination of seawater including the establishment of a station in 1995. This unit has a production capacity of 7000 m^3/day of drinking water. In order to develop this sector, the government implements in Agadir another desalination station of 80,000 m^3/day, which should be operational in 2010. In addition, in view of saving water, the study suggests to "fight against failures in water networks and water distribution, to raise awareness on water scarcity and promote the use of plants resistant to water stress." Because, the study conducted by the High Commissioner for Planning shows that Morocco loses 1.3 billion per year including 1.1 billion m^3 in agriculture and 200 million m^3 in the drinking water and industrial sector.

A seawater desalination plant will be built in the Agadir region. It will be powered by solar energy, so it is a 100% ecological process in terms of renewable energy. Ultimately, it plans to produce about 275,000 cubic meters of water per day, of which 150,000 will be dedicated to human use and 125,000 to be used for irrigation of the 13,600 hectares of plantations in the southwest of the Kingdom, the maximum production capacity being 450,000 m^3 per day.

Recommendations

According to the national water plan for 2030 of Kingdom of Morocco and to ensure the balance between supply and demand, the following operations will be carried out:

- The increase to 80% of the national average of the efficiency of drinking water distribution networks by 2025.
- The maintenance of the same level until the year 2030 and the search and repair of leaks, which will reduce the demand for drinking water by about 120 million m^3 per year by 2025.
- Saving water in irrigation by transforming traditional irrigation systems to local irrigation system (drip system) at a rate of 50,000 ha per year and saving 4.1

billion m^3 by 2020, and as part of the Green Morocco plan, efforts will be made to save an additional 3.2 billion m^3 by 2030.

- The construction of fourteen dams in progress, a further 35 are planned, in addition to the use of non-traditional water resources, such as the desalination of seawater at a rate of 510 million m^3 and the reuse of 325 million m^3 of wastewater after purification (Plan national water supply by 2030)
- The World Bank (2017) indicates that 35% of potential water resources are wasted, which requires a new strategy to preserve this resource.
- The National Water Plan provides, to meet the demand for water by 2030, an investment of 220 billion DH by 2030, which will be used among others to the construction of 3 dams per year.
- Develop integrated management of water resources by basin.

Tunisia

Water Potential and Climate Change

Tunisia has about 4766 million m^3 of exploitable resources for the year 2017, the equivalent of 450m^3/year/inhabitant for all uses combined. The water mobilized in Tunisia is divided into surface waters (55%) 2630 Mm^3 and groundwater (45%) 2136 Mm^3. Also, it should be noted that 88% of groundwater has salinity greater than 3 g/liter (Lahacher and Pillet 2008). Water resources in Tunisia are distributed as follows: 80% for irrigation, 14% for water drinking, and 6% for industry and tourism (SIGMA 2017). Tunisia had 17 dams before 1990. It built 20 dams during the first ten-year plan between 1990 and 2000. Then, during the 2nd ten-year plan from 2001 to 2011, Tunisia made 10 dams. The current total capacity of the 33 dams is 1.8 Mm^3 in 2018 according to the Ministry of Agriculture. The 253 collinear dams have a total capacity of 266 Mm^3 (Ouasli 2015). The 893 collinear lakes have a total capacity of 93 Mm^3. Groundwater is produced by 138,000 shallow wells and 5400 deep wells (SIGMA 2017). The mobilization of water resources is about 95% of available water resources (Ouasli 2015).

By studying the evolution of the contributions to the main dams over the period from 1947 to 2004, two main conclusions can be distinguished (TSNCUNFCCC 2013):

- The contributions decrease by 27% during the period from 1976 to 2004 compared to the period 1947 to 1975.
- Contributions at the level of the northern dams during the period from 1976 to 2004, on the other hand, are 21% higher than the current average inputs.

Tunisia is located in the category of the least endowed countries with water resources in the Mediterranean. Indeed, for a population of 10 million inhabitants, the average allocation per capita per year is estimated at 450 m^3. This figure will decrease gradually to 350 m^3 per capita in 2030 for a population of 12 million inhabitants (Hamza 2007).

The surface water resources are highly variable in time and space. The average interannual surface water inflow is estimated at 2.7 billion m^3 per year (55.5%), 80% are from northern regions of Tunisia (Elloumi 2016). The groundwater resources are estimated, annual averages, about 2165 billion m^3 (45.5%) (Elloumi 2016). The volume of water mobilized in 2015 reached 4. 6 mm (98%) (Elloumi 2016).

The increase in temperatures would vary between 0.8 and 1.3 °C in 2020 and 2.1 °C in 2050 with the decrease of rainfall by 10 to 30%, the loss of 28% of conventional water resources, and 20% of arable land by 2030.

Nouaceur (2016) divided the rainfall trend for Tunisia into three periods:

- From 1970 to 1986, an absence of trend. This period is characterized by an important variation of the extreme years.
- The second period (1987–2003) is marked by a dry trend that lasts 16 years. The years of the dry and very dry class totaled 55% of the observations for all the stations.
- The third period (2003–2013) is described as wet. The wet and very humid years total almost 48% while the dry and very dry years 31.3%.

Climatic data show that average annual temperatures have increased by about 1.4 °C during the twentieth century, where the warmest temperatures have been recorded since the 1970s. Local warming rates may be higher, for example, in Tunis, temperatures rose by around 3 °C during the twentieth century (World Bank 2013). Annual totals of rainfall have decreased by 5 percent per decade in northern Tunisia since the 1950s (Fig. 19).

The study on the inflow to major dams during the period from 1947 to 2004 revealed two major conclusions: a decrease in discharge of the period 1976–2004 compared to the period 1947–1975 about 27% (Lahacher and Pillet 2008).

Deep and shallow aquifers exploitation increased by 333% and 228%, respectively, between 1968 and 2010. The largest increase occurred before the 1980s (Trabelsi 2016), Fig. 20.

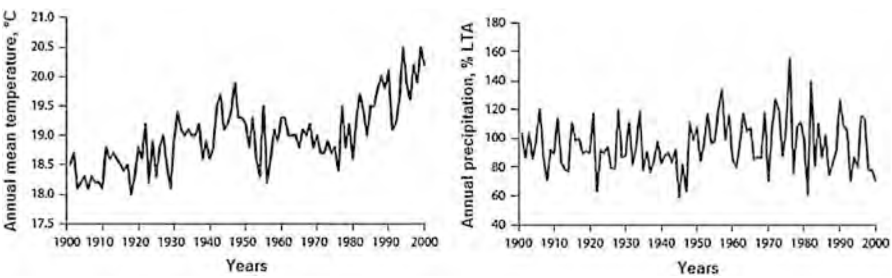

Fig. 19 Average temperatures of the twentieth century and precipitation in Tunisia (Mitchell et al. 2002)

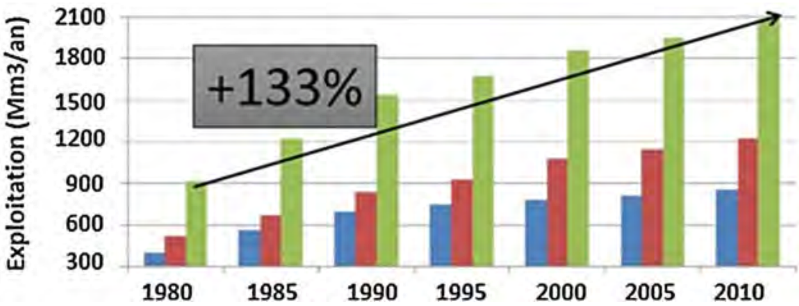

Fig. 20 Evolution of the groundwater exploitation in Tunisia in Mm^3/year (Trabelsi 2016)

The droughts will result from the intensive exploitation of groundwater. The simulation based on the historical evolution of the quality of groundwater resources has led to a decrease of the exploitable groundwater potential equal to 467 m^3 in 2030. This quantity corresponds to the volume of water currently overexploited. For deep waters, the reduction will be 517 million m^3. The exploitation of deep groundwater will require more energy to pump water (Lahacher and Pillet 2008).

The pressure on water resources will be major. Groundwater, coastal, non-renewable aquifers will decline from 28% in 2030, surface water will decrease by 5% on the same horizon, and the summer rainfall will increase the lack of soil moisture (Sarra 2009).

Future Projections

The projections from the HadCM3 model, according to the A2 scenario, show an increase in mean temperature of 1.1 °C by 2020 and 2.1 °C by 2050 compared to the 1961–1990 reference period. The largest increases will be in the South, with 1.3 °C by 2020 and 2.7 °C by 2050 (TSNCUNFCCC 2013). By 2100, projections of average monthly temperatures show a stronger upward trend over almost regions, the expected increase in temperature is above 2 °C (Fig. 21). The maximum is expected in the region of Gafsa in southern Tunisia with an increase of 3.91 °C (Ouasli 2015).

Dry years will become more frequent and intense by 2030, and extremely dry and wet seasons will vary from season to season (TSNCUNFCCC 2013).

The HadCM3 projections for the A2 scenario show a general decrease in average precipitation. This reduction is relatively moderate by 2020 but will become significant by 2050. In 2020, the decrease in annual rainfall varies between −5% in the north and −10% in the extreme south (TSNCUNFCCC 2013).

The decrease in rainfall varies between (−10%) in the northwest and (−30%) in the extreme south of Tunisia by 2050. Three regions can be distinguished: the extreme west of the country is characterized by a slight decrease in the order of (−10%), the south with a significant decrease of about (−29%) compared to the third

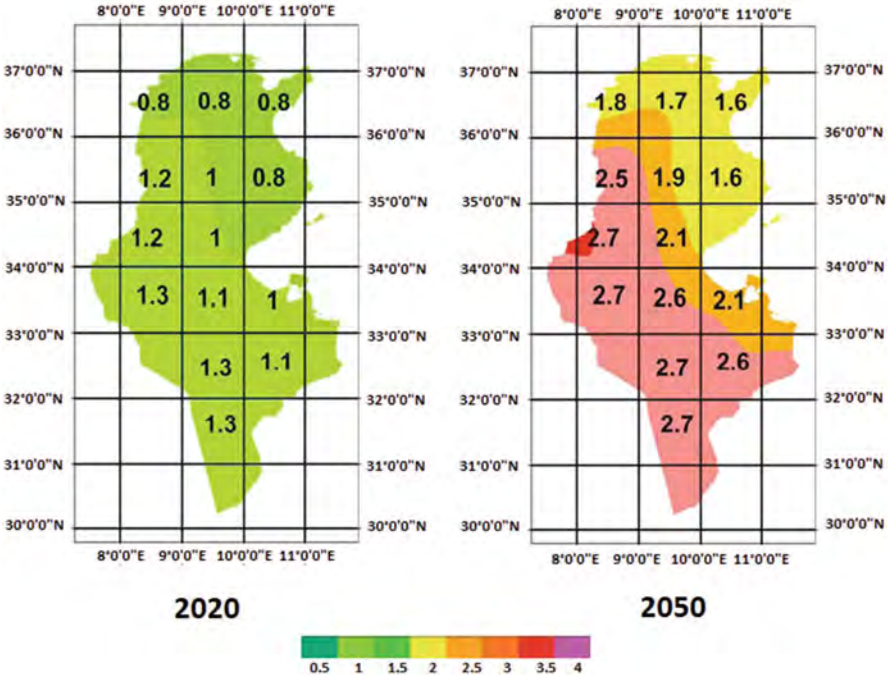

Fig. 21 Temperature (°C) average annual increases in the HadCM3 model (A2 scenario) compared to the reference period in 2020 and 2050 (MARH 2007)

region which includes the rest of the country where the reduction varies between −12% and −16% (TSNCUNFCCC 2013) (Fig. 22).

For seasonal changes by 2020, the lowest reduction in precipitation will be recorded in winter (0% to −7%). The largest drop from −8% to −40% will occupy the space from north to extreme south in summer (TSNCUNFCCC 2013).

The situation in autumn and spring is intermediate with rainfall decreasing from −6% to −12% in the extreme south. Seasonal changes are about the same by 2050 (TSNCUNFCCC 2013).

By 2100, future trends in monthly average rainfall are down for all Tunisia (Fig. 23). The maximum decrease is for the Sfax station, located in North East Tunisia, with a percentage of 78.23%. Projections show a strong gradient between trends in the north and those in the south (Ouasli 2015).

Climate projection models show that conventional water resources will decrease by about 28% by 2030. This decrease will mainly concern shallow groundwater with high salinity, coastal aquifers, and nonrenewable aquifers. In particular, the reduction of surface water reserves will be around 5% by 2030. The confrontation between the available water resources and the increasing demand for water shows that this demand will not be satisfied by 2030 (Fig. 24) without the implementation of more effective conservation and water saving strategies as well as water infrastructure development programs (MARH 2007). Projections of average monthly rainfall

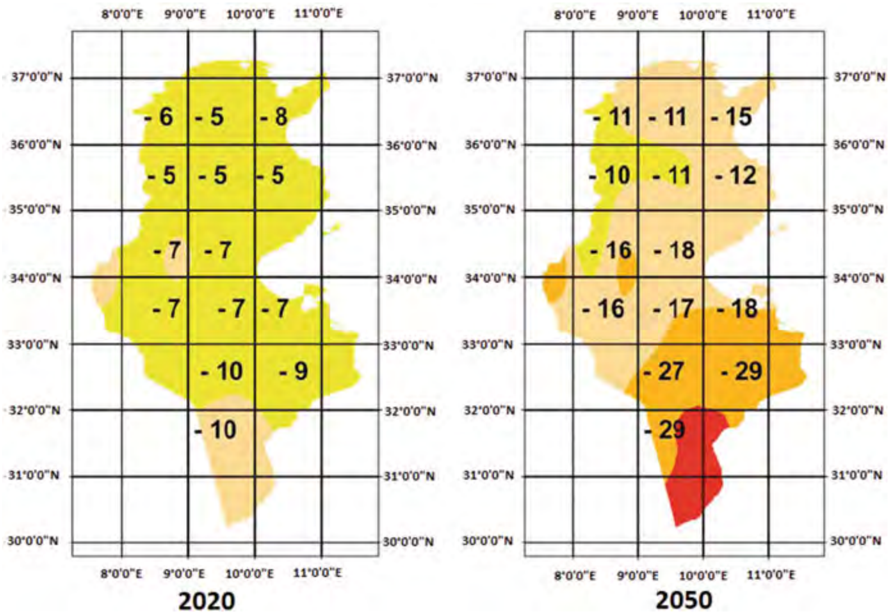

Fig. 22 Decreases of the average annual rainfall in % of the HadCM3 model (A2 scenario) compared to the reference period by 2020 and by 2050 (GTZ 2007)

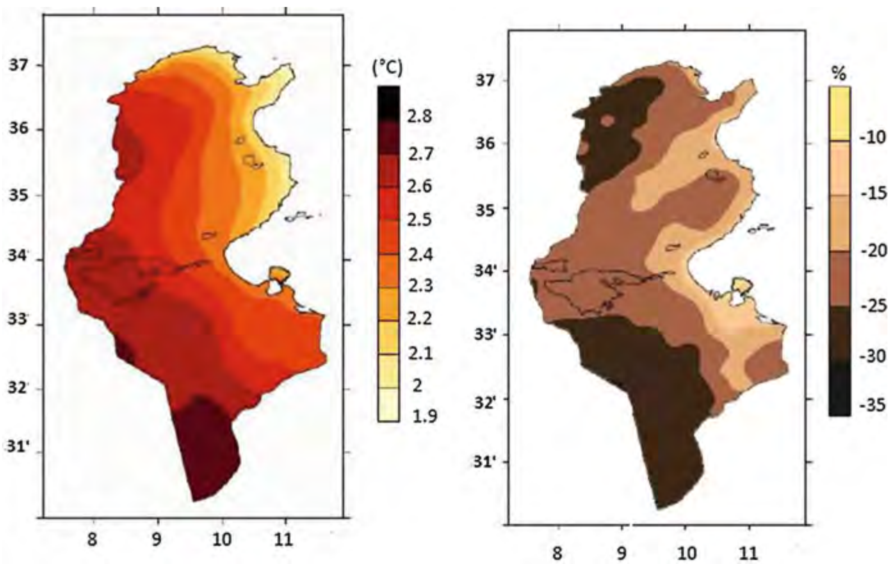

Fig. 23 Projection of temperature and rainfall by 2100 (INM in Ouasli 2015)

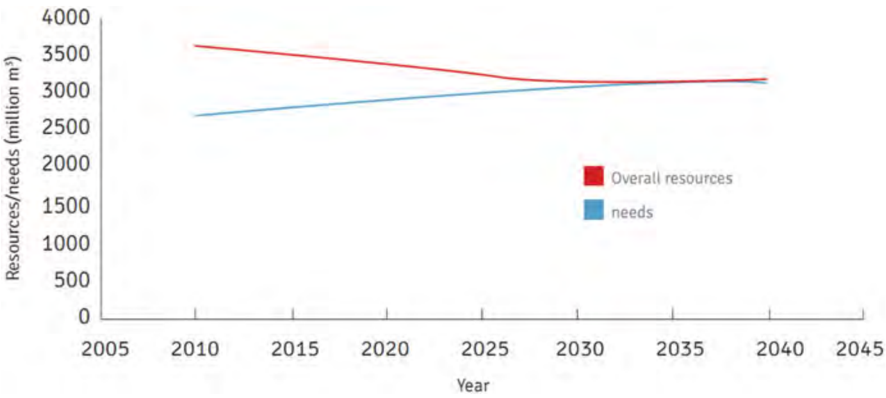

Fig. 24 Evolution (in million m^3) of overall water resources (in blue) and needs for water (in red) in Tunisia taking into account climate change impacts on water resources (MARH 2007)

over Tunisia show the future evolution of aridity and mark its trend to the north of Tunisia which shows the vulnerability of the south to water stress in the future (Ouasli 2015).

Recent climate projections confirm the reduction of piezometric levels of the aquifer in the Sfax region located in southeast of Tunisia by 2020 and 2050 for the following two scenarios (Boughariou et al. 2018): the first considers a constant and increasing consumption, the second integrates climate projections published by the Tunisian Ministry of Agriculture and Water Resources and the German Agency for International Cooperation (GIZ), using HadCM3 as a model for general circulation (Boughariou et al. 2018). Both scenarios also indicate the quantitative degradation of the groundwater by 2050 with an alarming marine intrusion (Boughariou et al. 2018).

The projection of water resources, on the basis of various hypotheses proposed, shows that the exploitable conventional water resources will be around 3,829 million m^3 in 2030, given that the water management program is carried out entirely (high hypothesis), of 3170 Mm^3 in the case where only a part of the program will be realized (average hypothesis) and 2718 Mm^3 and in the case where the program will not be realized (hypothesis low) (TSNCUNFCCC 2013).

The addition of unconventional water resources will strengthen the exploitable resources. This is the desalination of seawater (80 Mm^3 in the year 2030) and the reuse of treated wastewater (292 Mm^3) for agricultural needs. The total exploitable in Tunisia in 2030 will be around 4,201 Mm^3 (TSNCUNFCCC 2013).

Total water requirements by 2030 are projected at about 2911 Mm^3 in the case of the low assumption, 3,054 Mm^3 for the medium hypothesis and 3,743 Mm^3 for the high hypothesis. Needs-side assumptions are also defined based on the rate of achievement of the projected programs (TSNCUNFCCC 2013).

In the case where all programs for water mobilization are carried out, the projected needs can be met by 2030 (an excess of about 11% of the available amount is planned, Table 2). In the case where the planned programs are not all realized, a

Table 2 Evolutions of water resources considering climate change (in millions of m^3)

Source: Ministry of Agriculture and Water Resources (MARH 2007) lack of water is likely to appear from 2022 (and this, even if the low hypothesis of the needs side is retained) (TSNCUNFCCC 2013).

If water needs do not evolve as planned and programs to increase the availability of the resource are not realized (low hypothesis), the difference between needs and available water resources would be negative by 2015 (TSNCUNFCCC 2013).

.

The vulnerability of conventional water resources to climate change in Tunisia is characterized by (Ouasli 2015):

- A reduction of these resources by around 28% by 2030. The decrease will affect groundwater, coastal water, and nonrenewable groundwater.
- Increasing frequencies of extreme events: drought and flood.
- The reduction of water volumes in dams by around 5% by 2030.
- A deterioration of the quality of surface and underground waters.
- The succession of extreme events: floods and drought.
- The succession of periods of drought. These periods will have an impact on the natural recharge of groundwater. These aquifers will be exposed to over-exploitation to compensate the deficit in surface water for irrigation.

Adaptation

Water Saving Measures

The main threats to water resources are:

- The overuse of groundwater resources
- Pollution of water resources (rivers, groundwater, etc.). Discharges by solids or liquids into the environment, rivers, and vulnerable groundwater
- The silting of reservoirs
- The incidence of successive dry years that hinder the annual renewal of water resources
- Water wastage and losses
- The impact of climate change

It was recorded around 20 droughts during the twentieth century. During this period a severe drought is recorded every 6 years.

During the years 1987, 1988, and 1989, Tunisia has experienced the most critical drought. It led to a water deficit around 30%.

In case of drought, the agricultural sector, which currently consumes 81% of water resources, will suffer water shortages which will result in an increased use of groundwater and can have dramatic effects, since these resources contribute to maximum of 82% to the satisfaction of agricultural needs (Fig. 25).

To overcome the lack of water in the future, the below directions are to be followed:

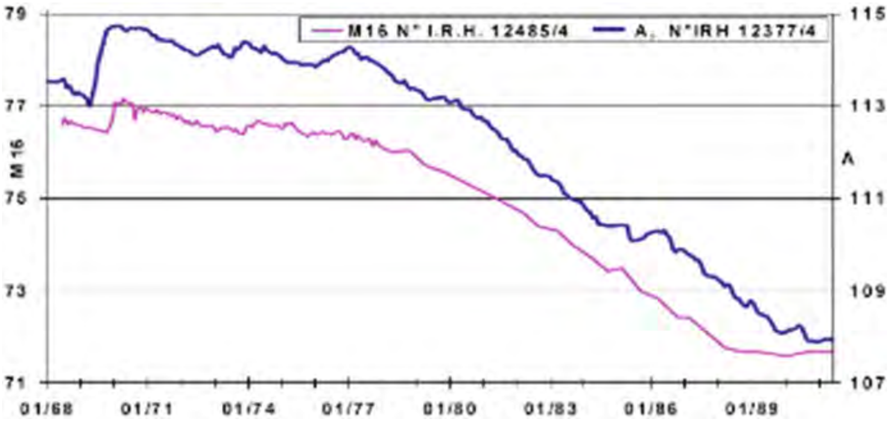

Fig. 25 Decrease of the level of aquifer Merguellil (central Tunisia)

- Complete the implementation of works to mobilize water resources to achieve a mobilization rate of 95%
- Integrated management of water resources by capitalizing excess of wet years in order to reduce the effects of drought
- The water conservation and demand management in all sectors
- The use of wastewater in agriculture
- The use of desalination water for drinking water
- The protection of water resources against pollution
- The protection of groundwater against overexploitation (Fig. 25)

The presidential program “Let us rise to the challenges 2009–2014” provides for an increase of 30% currently to 50% in 2014 the exploitation rate of treated wastewater in agriculture, industry, and tourism.

Large areas of around 8,500 ha of irrigated crops with treated wastewater will be built within this framework, in the Greater Tunis, Zaghouan, Beja, Sousse, Kairouan, Sfax, Gafsa, Kébili, Gabes, and Tataouine Medenine.

Meanwhile, the authorities will consider the study of potentialities for food, with unconventional resources, groundwater, notably those excessively exploited.

The desalination of water in the majority belongs to the SONEDE for a total capacity of 95,000 m^3 (Lahacher and Pillet 2008). Desalination of water is being expanded especially in the tourism sector. New desalination installations based on sea water are programmed by SONEDE in Djerba, Sfax, and Zarrat for a total potential of about 80 m^3 in 2030.

Recommendations

The following proposed measures may be the best way to cover future water demand (Ouasi 2015; Ben Nouna et al. 2018):

- Improve the consideration of ecosystems: necessary to ensure adequate recharge of aquifers for the production of good quality of water
- Improvement of water demand management and strengthening of the National Water Saving Program especially water saving for irrigation
- Develop a strategic policy regarding the prediction of extreme events, raising of dams to safeguard their capacity, encouraging the practice of less water-consuming crops
- Quantify the processes of water erosion and siltation rates of dams
- Control of energy consumption during the production of water (pumping, desalination) using clean energies (solar for example)
- Develop integrated management of water resources by basin
- Involve farmers so that they can participate in the future of their water resources
- Enhance knowledge and experience in the field of traditional hydraulic systems
- To further develop the artificial recharge of groundwater
- Development of scientific research related to the water sector

Conclusion

According to recent studies, the Maghreb countries will become hotspots by the end of the twenty-first century. Higher temperatures and reduced rainfall will increase the frequency of droughts in these countries. The drought observed in recent decades has tragic consequences. These effects are reflected by lower inflows to dams with more than 30% reduction in dam volumes and the lower level of groundwater sometimes with 40 m of drawdown in the plain of Mitidja in Algeria for example. This latter is the combined effect of drought and overexploitation of groundwater. This overexploitation is due to the decrease of the natural recharge and the increase of the water demand (Increasing demography and economic and social development).

The decrease in rainfall, as the lag time of rainy seasons, has penalized development projects particularly related to agriculture and affect the proper functioning of the carried out infrastructure.

To mitigate the impacts of climate change in the region, we recommend the integration of climate change in the programs and policies particularly in the context of sustainable development. It must also take into account the weather, and reinforce the measures of Weather assistance in the rural areas and to all users.

The undeniable effects of drought on reducing the level of production of cereals in particular require from planners to take into account the continuing risks associated with an arid climate and the risks of seasonal drought in all aspects of agricultural development. Thus the long dry season causes prolonged water stress to be taken into account in the selection of appropriate crops and varieties.

For the three countries, many projects and programs are developed and implemented to cope with the effects of climate change and Anthropic. These countries are also facing rapid population growth and sustained socioeconomic development. Agriculture is the cornerstone of this development, which will increase the demand for water. The water infrastructure programs must take into account this strategy which will ensure the food security of these three Maghreb countries.

In order to meet this ever increasing demand for water, especially for agriculture, it is necessary to set up special programs and develop irrigation techniques to reduce the consumption of water resources in agriculture. These programs should also make it possible to increase agricultural production to ensure food security in these three countries. Also, the reduction of water leakage from drinking water supply networks that are important in the order of 30 to 40%. The fight against water scourge makes it possible to create new irrigated perimeters and to effectively supply the population with drinking water.

Abstract

The impacts of climate change are already being felt, not only in terms of increase in temperature but also in respect of inadequate water availability. The Mkomazi River Basins (MRB) of the KwaZulu-Natal region, South Africa serves as major source of water and thus a mainstay of livelihood for millions of people living downstream. It is in this context that the study investigates water flows abstraction from headwaters to floodplains and how the water resources are been impacted by seasonal climate variability. Artificial Neural Network (ANN) pattern classifier was utilized for the seasonal classification and subsequence hydrological flow regime prediction between the upstream–downstream anomalies. The ANN input hydroclimatic data analysis results covering the period 2008–2015 provides a likelihood forecast of high, near-median, or low streamflow. The results show that monthly mean water yield range is 28.6–36.0 m^3/s over the Basin with a coefficient of correlation (CC) values of 0.75 at the validation stage. The yearly flow regime exhibits considerable changes with different magnitudes and patterns of increase and decrease in the climatic variables. No doubt, added activities and processes such as land-use change and managerial policies in upstream areas affect the spatial and temporal distribution of available water resources to downstream regions. The study has evolved an artificial neuron system thinking from conjunctive streamflow prediction toward sustainable water allocation planning for medium- and long-term purposes.

Seasonal classifier · Climate variability · Sustainable water allocation · Artificial neuron network · System thinking

Introduction

Background

The seasonal hydrological flow regime is of utmost importance in understanding potential water allocation schemes and subsequent environmental standards flow regulation. Streamflow is a fundamental component of the water cycle and a major source of freshwater availability for humans, animals, plants, and natural ecosystems. It is severely being impacted upon by human activities and climate change variability (Makkeasorn et al. 2008; Null et al. 2010).

Climate change variability has a profound impact on water resources, biophysical, and socioeconomic systems as they are highly interconnected in complex ways (Graham et al. 2011; Null and Prudencio 2016). A change in any one of these induces a change in another. The effects of climate indices on streamflow predictability are seasonal and region dependent (Katz et al. 2002). Although, there are different approaches to assess a basin response to climate variables change. Hydrologists have devised different approaches to investigate how water, the environment, and human activities are mutually dependent and interactive under various climatic conditions (Bayazit 2015). Most of the morphoclimatic challenge studies in any region are usually customized and basin specific. Though many studies have investigated the effects of changing temperature, precipitation, and evaporation as climate variables on water resources management (Katz 2013; Kundzewicz et al. 2008; Null and Prudencio 2016; Taylor et al. 2013), only few have examined seasonal fluctuations of water allocations in nonstationary climates and captured the hydrologic variability trend characterization based on different temporal scales on the whole catchment (Egüen et al. 2016; Gober 2018; Katz 2013; Poff 2018).

Topographic effects on rainfall vary seasonally due to the particular hydrologic process in the region which makes seasonal water allocation and varying environmental flow projection to be based on available meteorological past data for various design purposes (Jakob 2013). Seasonal fluctuations are commonly observed in quarterly or monthly hydrologic flow regime studies. As seasonality is a dominant feature in time series (Sultan and Janicot 2000), hydrologists have developed methodologies to routinely deseasonalized data for modelling and forecasting different annual conditions (Benkachcha et al. 2013). The common variation of inflow from one season to another mainly reflects the climatic variability which includes seasonality of rainfall and amount of evapotranspiration which is dependent on air temperature as well as precipitation in the basin (Ufoegbune et al. 2011). The understanding of these hydrological dynamics in a basin is crucial for sustainable water allocation planning and management. Different literature work reviews across the globe have found a nonlinear or linear relationship between station elevation and rainfall pattern, e.g., the Kruger National Park, South Africa and Mount Kenya, East Africa (Hawinkel et al. 2016; MacFadyen et al. 2018). Likewise, a linear pattern was found in a Spatio-temporal Island study in a European City (Arnds et al. 2017; Sohrabi et al. 2017) while a nonlinear relation exists in a central Asia Basin study (Dixon and Wilby 2019).

Rainfall heterogeneity obviously needs to be considered in a number of hydrological process studies in larger catchments area since it influences: infiltration dynamics, hydrograph regime, runoff volume, and peak flow (Bonaccorso et al. 2017; Fanelli et al. 2017; Gao et al. 2019; Tarasova et al. 2018). However, some hydrology studies still rely on small numbers of synoptic-scale rainfall measurements, and the problem of limited rainfall gauges is common in many watershed investigations, especially in developing countries (Birhanu et al. 2019; Liu et al. 2017; Moges et al. 2018). Therefore, prior to investigating the watershed functions and their contributions to the Mkomazi River flow, we examined the spatial attributes of rainfall in the area based on existing data. The past works conducted on the Basin includes Flügel et al.'s (2003) that had used a geographical information system (GIS) to regressed the local rainfall to the elevation, while Oyebode et al. (2014) has used genetic algorithm and ANN for the streamflow modelling at the upstream. Taylor et al. (2003) and Wotling et al. (2000) used rainfall intensity distribution and principal component analysis (PCA) to assess the complexity of the terrain in addition to the elevation. In general, differences in rainfall patterns may have involved a combination of two statistical outcomes: a shift in the mean and a change in the scale of the distribution functions. The gamma distribution is a popular choice for fitting probability distributions to rainfall totals because its shape is similar to that of the histogram of rainfall data (Kim et al. 2019; Svensson et al. 2017).

Similarly, Najafi and Kermani (2017) observed that in recent years, many researchers have used various empirical rainfall-runoff models to study the impacts of climatic change on basin hydrology. However, a good understanding of the future rainfall distribution across these zones is of vital importance if any meaningful development is to take place in the water resource management and agricultural sector which has been of utmost priority in recent times (Arnds et al. 2017). However, in order to address the foregoing issues, there is a need for the study of this nature. It will help in developing long-term strategic plans for climate change adaptation and mitigation measures and implementing effective policies for sustainable water resources and management of irrigation projects and reservoir operations for the overall sustenance of human well-being in the region (Al-Kalbani et al. 2014). This chapter utilizes regression analysis to investigate the upstream–downstream linkages under seasonal climate variability. Hydrological trend characterization was based on available morphoclimatic past data. Sen's slope (Pettitt's) abrupt change detection and the Mann-Kendall parametric trend analysis were used in detecting long-term variability in precipitation while ANN was used for seasonal classifiers and potential future streamflow quantification. Quintile regression was used to establish the relationship between climate indicators (historical rainfall and streamflow) and past catchment conditions to forecast future hydrological dynamics in the MRB. The main novelty in this study is that such a time-series representation is useful for considering the influence of projected shifts in environmental factors on the hydrologic budget, and subsequent coping strategies can be provided.

The Mkomazi catchment is located in the U Basin within the semiarid province of KwaZulu- Natal in South Africa as shown in Fig. 1. It is the third largest catchment in the province, draining an area of about 4400 km^2 with several large tributaries like Loteni, Nzinga, Mkomanzi, and Elands Rivers. The climatic condition of the study area varies with the seasonality of dry winters and wet summers (Flügel et al. 2003). Rainfall distribution is inconsistent along the catchment, ranging from nearly 1200 mm per annum at the headwaters to 1000 mm p.a. in the middle and 700 mm p.a. in the lower reaches of the catchment with highly intra- and interseasonal streamflows (Flügel and Märker 2003; Oyebode et al. 2014; Taylor et al. 2003). Prior water allocations were entirely based on "who got there first," which have become unstable and irrational with climate change. Thus, examining how climate-driven spatial and temporal changes to streamflows may reallocate water among the riparian users considering its seasonal variability is of immense importance. The Mkomazi River can be subdivided into five physiographic zones as shown in Fig. 2, namely:

(I) The coastal lowlands up to 620 m (mean annual sea level – m a.s.l.)
(II) The interior lowland area ("middle berg area") from 620 to 1079 m (m.a.s.l.)

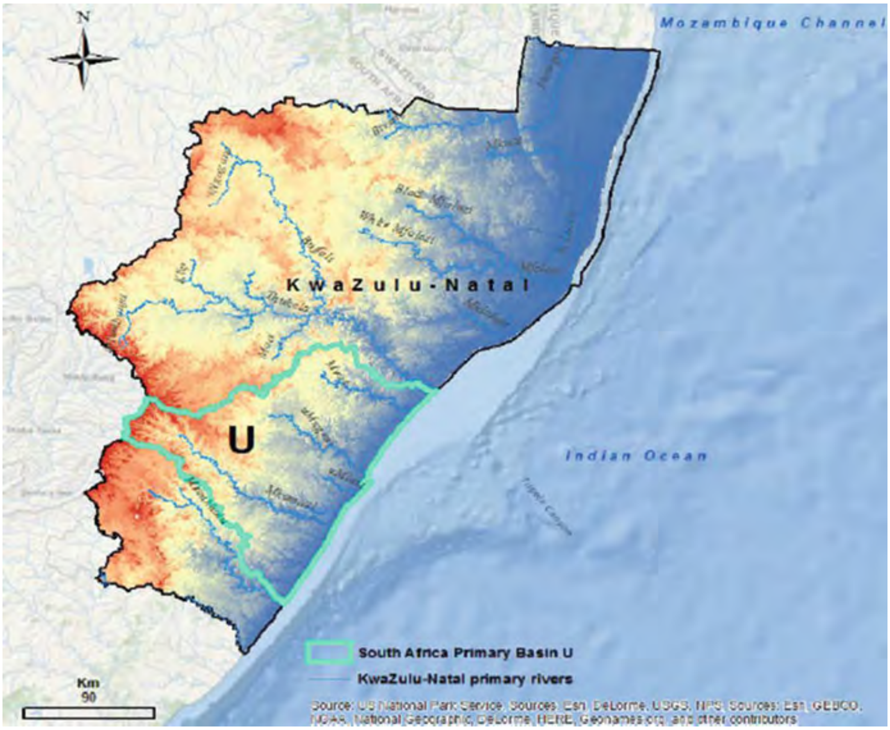

Fig. 1 The study area: Mkomazi River basin

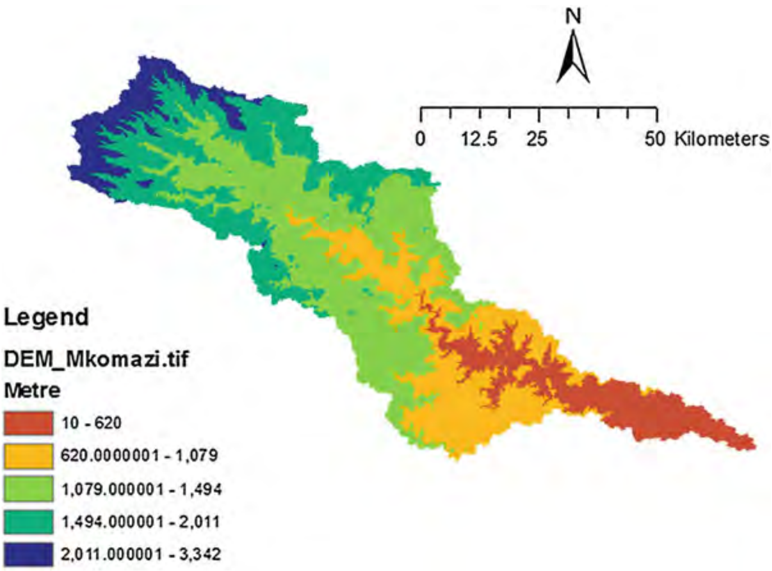

Fig. 2 Mkomazi Physiographic description with elevation zones

(III) Lowland area up to 1494 m (m.a.s.l.)
(IV) The mountain area up to 2011 m (m.a.s.l.)
(V) The highlands, with elevations up to 3342 m (m.a.s.l.)

Like other catchments in Southern Africa, the study area is characterized by high varying seasonality of dry winters and wet summer (Schulze and Pike 2004a). Many authors have suggested longer record lengths, approximately 20-year oscillations interval, in measuring the seasonal hydrological fluctuation (Abhishek et al. 2012; Schulze 1995; Tyson 1986). This variability was adjudged to be as a result of the influence of the currents in the Atlantic and the Indian Ocean that surround the country. The cold Benguela Current in the Atlantic Ocean (South West) brings not only cold air but also influences the pressure system (Haigh et al. 2010; King et al. 2000), while the warmer currents of the Indian Ocean influence the milder warmer sea temperatures and the humid air on the Northeastern Coastline in the country. These seasons are opposite to the seasons in the northern hemisphere (King et al. 2000). There are no clear-cut seasonal calendar based on phenology for the country; however, conventional seasonal variability run through summer (Dec–Feb), autumn (March–May), winter (June–August), and spring usually between September and November, to which the average temperature ranges from 20 to 30; 10 to 15, 7 to 10, and 15 to 20 °C respectively (De Coning 2006; Schulze and Pike 2004a, b).

Procedural Summary

The various stations source data from South Africa Weather Information System (SAWs), the Agricultural Research Council (ARC), and the Department of Water Affairs (DWA), South Africa, were processed and subjected to a rigorous scientific method to test their accuracy, reliability, homogeneity, consistency, and localization gaps. The detection of trends in a series of extreme values needs highly reliable data. Thus, only five stations met the above requirements and, as a result, corrected data sets were available for the hydrological years from 2008 to 2015 (for U10L 30530, U10J 30587, U10L 30813, U10 at Shelburn, and U10 at Giant Castle locations). Table 1 gives the statistical summary of the selected stations variables for (1985-2015) years.

Since the studied variables have different variances and units of measurements as shown in Table 1, the data set was standardized. This step was done by subtracting off the mean and dividing by the standard deviation (Ikudayisi and Adeyemo 2016). At the end of the standardization process, each variable in the dataset is converted into a new variable with zero mean and unit standard deviation. The original and standardized variables are displayed in Figs. 3 and 4, respectively. The standardized results are needed for minimization of bias and accumulation of predicted error from the observed data. These data were further subjected to various test/processing regarding homogeneity, consistency, and gaps closure before adaptation for model inputs. This helps to improve their predictive abilities and reduce uncertainty in data usage.

Table 1 Statistical summary of the selected stations year (1985–2015) variables

Variables	Unit	Minimum	Maximum	Mean	Std. Dev
MaxT	°C	14.400	33.170	24.408	3.442

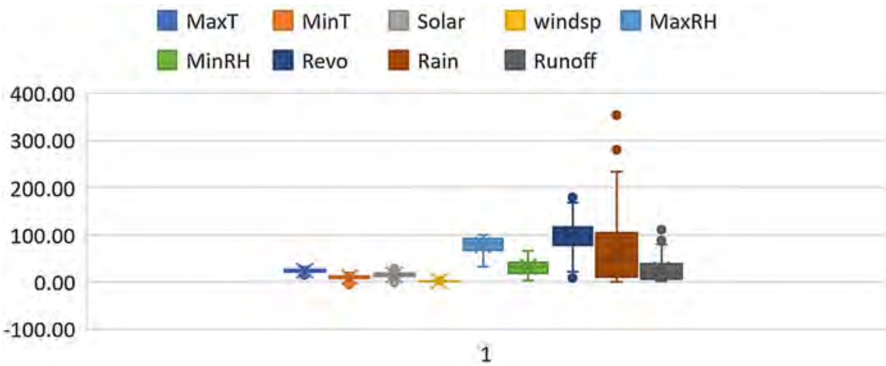

Fig. 3 Original data distribution of the climatic variables

Thus, the normalized data were used as input to the ANN classifier for seasonal forecasting and classification. Microsoft Statistical software XLSTAT by Addinsoft was used for Factor Analysis (FA) to explain the contribution of the unobserved common features in a target event from observed ones. FA as a choice of principal component analysis (PCA) was employed to reduce the variety of hydroclimatic data matrix to form a few selected derived component variables, which form a true representative of the original sets. The FA relates the trend, pattern, and fluctuations into wet or dry season in order to identify hydroclimatic variables responsible for streamflow characteristics as a basis for determining available water. This explains seasonal variation in water availability in the downstream environments. FA shows their level of influence and degree of different percentage contribution to the total streamflow volume (latent class). The regression relationships between the collected hydroclimatic data were developed as scatter plots and correlated to know their significance parameter sensitivity. Thereafter, the seasonal variability and trend detection were evaluated using Sen's method abrupt change detection and Mann-Kendall trend analysis in forecasting the hydrologic flow regime.

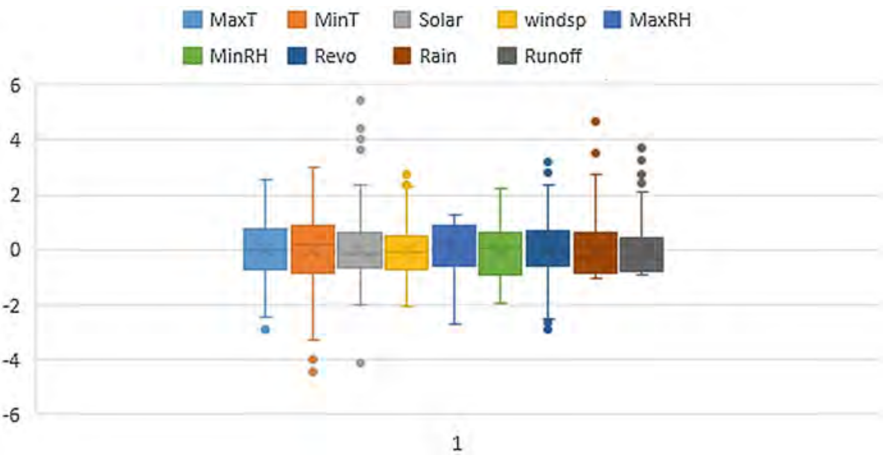

Fig. 4 Data standardization (normalization) of the climatic variables data

Key Findings

Seasonal Trend and Variability Changes among the Climatic Variables

A cursory run of the nonparametric and parametric approaches of Mann–Kendall and Sen's methods across the months (Dec–Nov) for the study duration (1985–2015) shows the discernible trend and variability changes among the climatic variables. The value of Sen's slope is given in Table 2 column 7. The closer it is to 0, the lesser the trend, while the sign of the slope indicates if the trend is increasing or decreasing. A Mann–Kendall test with a very high positive value of S (column 4) is an indication of an increasing trend while a very low negative value indicates a decreasing trend.

As shown in Table 2, decreasing trends are found generally among the variables across the months except for maximum temperature and solar radiation. This is understandable, as increased solar radiation brings about an increase in temperature. Increases in temperature and radiation forcing variables also alter the hydrological cycle. The resultant effect determines the amount of precipitation, its frequency, intensity duration, and the type of rainfall. In all, the hydro-meteorological variable shows a decreasing trend except for maximum temperature and evapotranspiration in the seasonal distribution pattern. The results show how changes in temperature and evapotranspiration could affect both the timing and total amounts of runoff, though the patterns of possible changes are both spatially and temporally complex. Future changes to allocation of water during seasonal water shortages is an important decision, which not only needs to be better coordinated within any given legal jurisdiction but needs to be better coordinated across any upstream and downstream uses and users.

Factor Analysis (FA) Findings

FA explores the dimensionality of a measurement instrument by finding the smallest number of interpretable factors needed to explain the correlations among the set of variables. This was particularly useful in the analysis of the meteorological parameters input for the ANN model. It places no structure on the linear relationships between the observed variables and the factors but only specifies the number of latent factors, determines the quality of the measurement instrument, identifies variables that are poor factor indicators, and are also poorly measured (Hu et al. 2014). The FA loading is shown in Table 3 to reduce the data into a smaller number of components which indicates what constructs underlies the data latent class. The bold squared cosine values depict the most significant variables that affect discharge flow.

The diagrammatical representation of the Factor Analysis as shown in Fig. 5 indicates each variable's level of significance on how they contribute to the total streamflow volume latent class. The table shows their proportionate percentage significance towards streamflow. All the meteorological data influence the streamflow except the wind speed presented in the statistical factor analysis biplot which stands alone thus depicting the least effect. This may suggest that air temperature is a more important climatic factor for water mass balance than precipitation.

ANN Pattern Classifier and Flow Regime Variation

Insights into the ANN configuration for the four seasons' classification are given in Fig. 6. The ANN internal algorithm using the gradient descent method for the hidden layer was able to classify them into the four prominent seasons based on collected data which were sorted on monthly basis and labeled inclusively with 1 - Summer, 2- Autumn, 3-Winter, and 4- Spring, respectively. The developed ANN model in the present study consisted of eight input layers that represent the input vectors of the hydro-meteorological parameters considered and four output layers representing

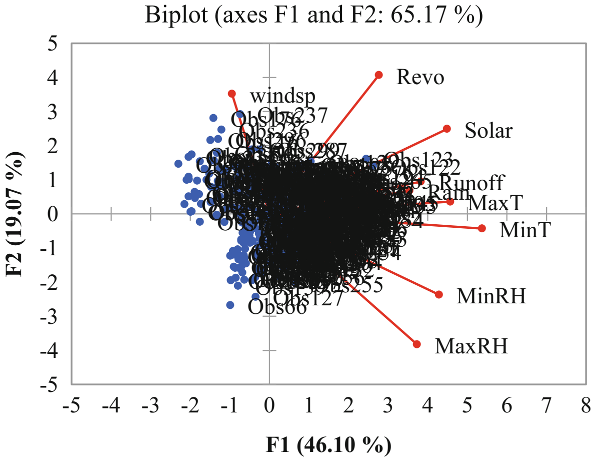

Fig. 5 The factor analysis based on their contributing factor of importance

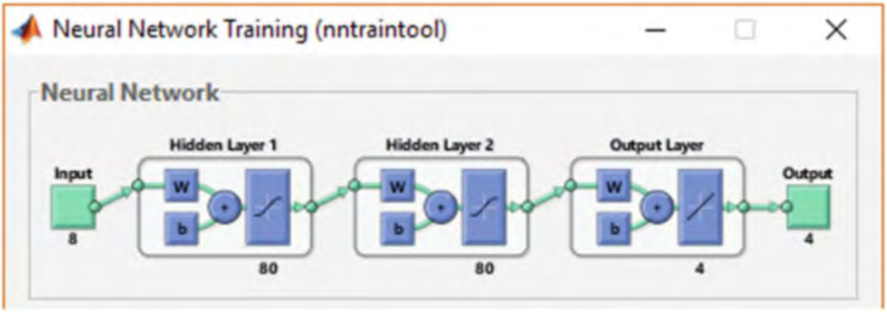

Fig. 6 MATLAB interphase for seasonal classification using hydro-meteorological data

the four seasons. The different monthly hydro-meteorological data of each of the six-catchment location serves as the raw data which was preprocessed to obtain the input vectors that was fed into the ANN. The MATLAB interface indicating the size of the input vector, a number of hidden layers, and neurons applied at the layers (which were experimentally determined) as well as the output layer is presented in Fig. 6, while Fig. 7 shows the confusion matrix obtained for the seasonal classification.

The confusion matrix indicating a 93.7% classification accuracy was achieved by the ANN classifier in cataloging the labeled data into the appropriate season. Given any unknown data set for the test, the developed model was able to distinguish it and classify it into the appropriate season. The corresponding number in the diagonal elements of the matrix indicates the number of instances that could be correctly classified for each of the seasons and how best the ANN classifier can recognize and distinguish data mined for each seasonal (summer, autumn, winter, and spring) classification respectively. The result of the optimal seasonal discharge forecast model is as presented in Fig. 8.

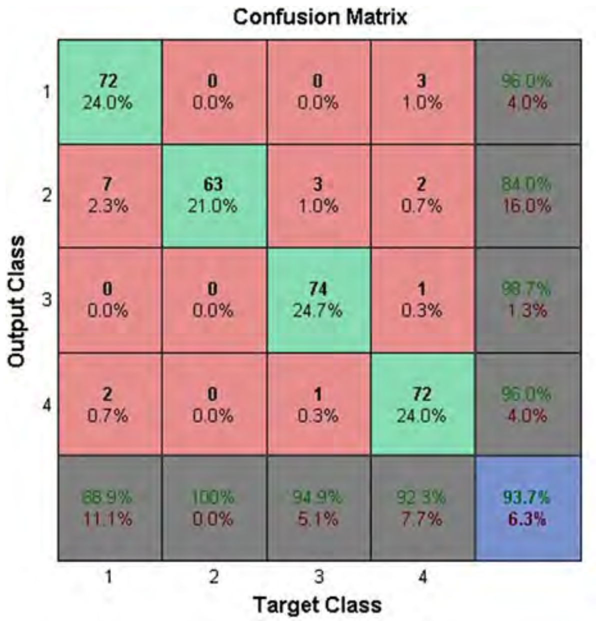

Fig. 7 Seasonal classification by ANN model

The ANN forecasted results provide the likelihood of high, near medium or low streamflow. The changes in the discharge regime were identified with the 5th, 10th, and 90th tercile streamflow magnitude curve as depicted in Fig. 9.

The streamflows in winter (wetter months) have increased slightly over the time period, whereas streamflows in summer (drier months) have decreased slightly. Figure 9 represents the estimated seasonal catchment yield of higher surface flow in winter with decreasing lower base flow across the seasons. Streamflow is observed to be at its lowest in the autumn period as the results further assert that climate change is real and have significance effects on the river flow regime (Archer et al. 2010; Schulze and Pike 2004a; Taylor et al. 2003; Viviroli et al. 2010). The coping strategy suggests sustainable use of any resource relies on the action of a number of regulatory mechanisms that prevent the user from reducing the ability of the system to provide services. “Polluter pays” principle was conceived as a way to proportionally allocate the effects of such alterations to those users that are responsible for them, thus producing a regulatory effect on the use of the resource. Also, the water allocation criteria include economic criteria with the aim of optimizing the economic value of the water resource.

Model Performance and Evaluation Measures

For improved accuracy, the root means square error (RMSE) and coefficient of correlation (CC) was used for performance evaluation measures during ANN

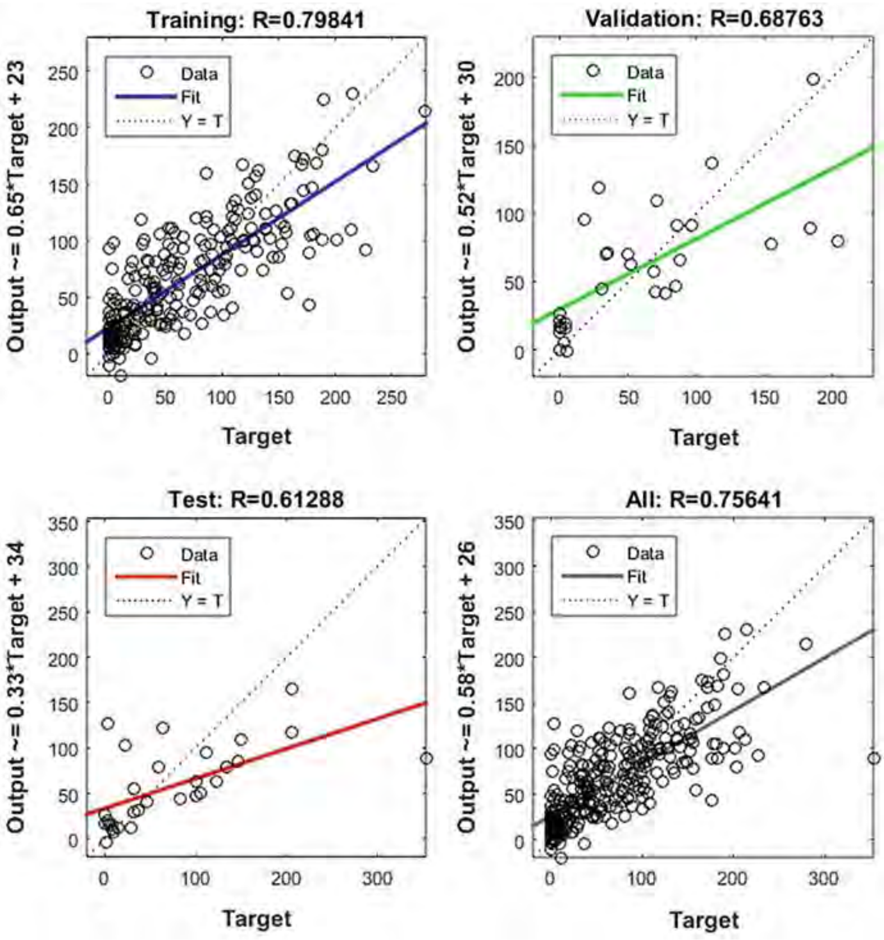

Fig. 8 Training output values for the optimal seasonal discharge model

training, testing, and validation procedures (Paswan and Begum 2014). They are defined as shown in Eqs. (1) and (2), respectively.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(Q_i - P_i)^2} \tag{1}$$

$$CC = \frac{\sum_{i=1}^{n}\left[\left(Q_i - \widehat{Q}_i\right).\left(P_i - \widehat{P}_i\right)\right]}{\sqrt{\sum_{i=1}^{n}\left(Q_i - \widehat{Q}_i\right)^2 . \sum_{i=1}^{n}\left(P_i - \widehat{P}_i\right)^2}} \tag{2}$$

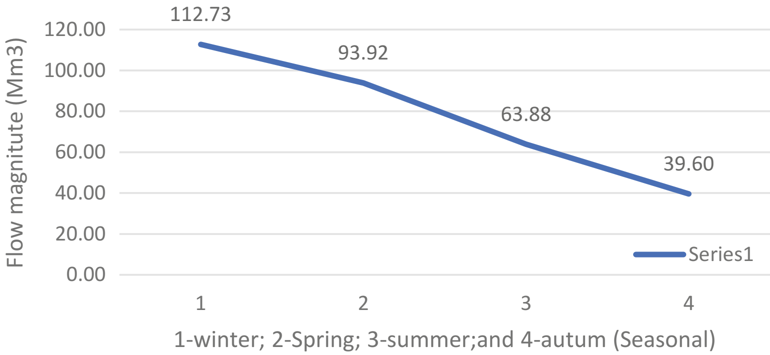

Fig. 9 Seasonal variability flow dynamic across the river

where Q_i is the observed value at time i, P_i is the simulated value at time i and $\bar{P}$ is the mean for the observed values. Observed runoff is used for model calibration and validation. Correlations are useful because they can indicate a predictive relationship that can be exploited in practice. The performance measures of RMSE and CC values obtained are 29% and 61% respectively during the calibration period. During the verification period, the RMSE and CC values are slightly improved as 18% and 75% were achieved respectively. Figure 10 shows the result of the training test as well as the optimum prediction performance of the network architecture.

Using FA as part of PCA has helped in screening the data and identifying the level of importance based on their contributing factor. The observed MRB runoff at (Mkomazi drift UIH009) station was used to compare with the ANN-model-simulated output in Shrestha (2016) Calibration Helper v1.0 Microsoft Excel Worksheet. The model performance was evaluated using statistical parameters and the result is represented in Fig. 11. Comparing ANN simulated value and observed runoff variables show a satisfactory ANN forecasting model for the seasons run.

The resulting data from the four seasons were detrended and deseasonalized (Wang et al. 2011) before forecasting the time series using neural networks. The results show that the neural networks with the right configurations give almost the same accuracy with or without decomposition of the time series. The streamflows in wetter months have increased slightly over the time period from 1985 to 2015, whereas streamflows in drier months have decreased slightly. These trends are also evident for the minimum and maximum temperature and relative humidity multiday events. The relationship between runoff and Mkomazi rainfall has been high and stable over the recording period. Other data analysis not presented shows a decreasing trend of precipitations. The summer rainfall variations are related more closely to maximum than minimum temperatures, with higher temperatures associated with lower rainfall. Lower rainfall in winter tends to be linked with higher maximum and lower minimum temperatures. These relationships were relatively stable over time. For this reason, there is a need to consider a range of possible future climate

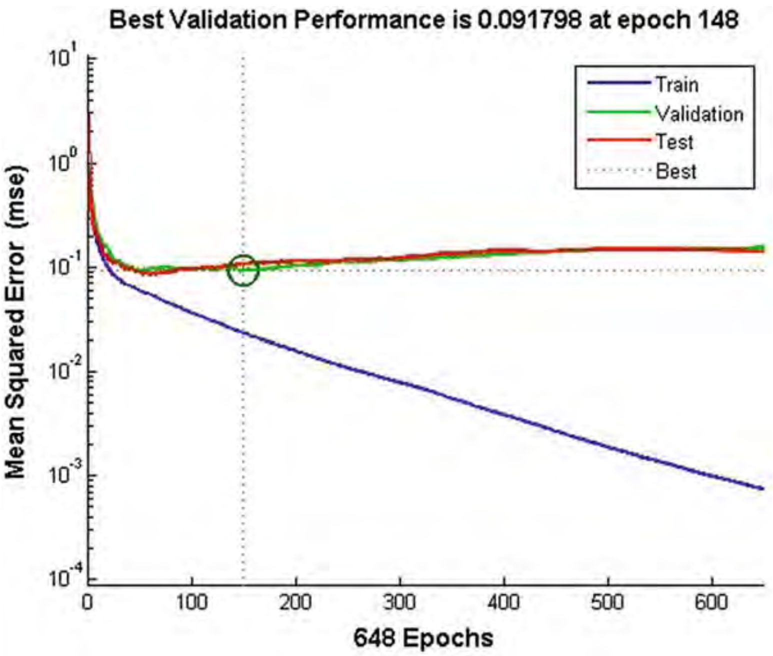

Fig. 10 Performance evaluation measures

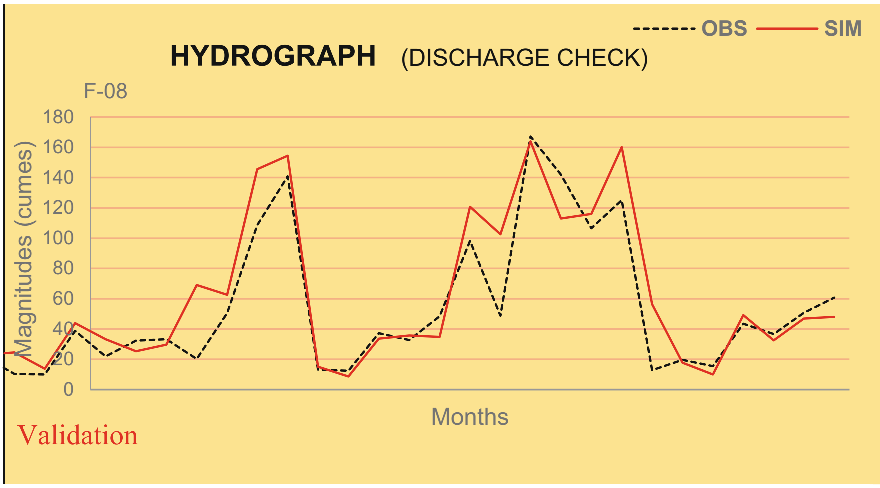
conditions in a region of increasing population, coupled with increasing demand for water resources for domestic, agricultural, and industrial activities and how these will affect water availability.

Limitations of the Study

Like all modeling studies, this research has assumptions and uncertainties which limit the findings. Many of the previous studies indicate that stationary climatic and streamflow data were used while we applied the historical probability that each water year type is based on the 2008 water year. This method assumes stationary climatic water year types. Future water year type frequencies varied somewhat with climate change (nonstationarity in data), although those changes are statistically insignificant. Also, decadal to multidecadal variability which includes the probability of extreme floods and droughts (Herrfahrdt-Pähle 2010) were not considered. Our findings likely underestimate water allocation impacts from extreme floods and droughts anticipated with climate change. In addition, for environmental flow allocations and streamflow, there is still substantial room for model misspecification through overfitting, thus the selection of optimal internal neural algorithms choice again raises the issue of robust neural network modeling.



Output statistics	Calibration	Validation

Seasonal Coping and Adaption Strategies to Climate Variability

Practical field investigation of views of stakeholders and their involvement should be simulated with model computer software in evolving solutions to water availability. Government political will and strategical alignment of various duplicating agencies in providing data for Sub-seasonal to Seasonal (S2S) Prediction should be harmonized toward a unified goal. Historically disadvantaged communities must be strongly supported and be encouraged to apply for water use licenses and the region must be in readiness to fast-track the processing of these water use license applications. Other available strategies to cope with climate variability include integrated water resources management by improving public water supply, regulating final users by facilitating the emergence of mediating agencies, the use of energy pricing and supply to manage agricultural water use overdraft, and better sensitization campaigns on rain water capture and recharge. The formalization of the water sector through the transfer of water rights and the more efficient use of water resources are among evolving strategies to achieve a sustainable water supply for the Mkomazi

River Basin. Turning all these adaption strategies into opportunity requires a need for both water technology innovation and water behavioral change to manage the scarcity of water resources in a sustainable manner. This chapter offers intuitive suggestions on how human being policies and cautious approaches can be used to manage and sustain the already depleted environment. Such intuitive agendum should be catalyzed through the institutionalization of proactive and capacity developmental platforms where climate change experts transfer knowledge, skills and expertise to upcoming researchers.

Conclusion

Understanding of climate change is continually improving, but the future climate remains uncertain (Yuan et al. 2016). For this purpose, a regression nonparametric approach consisting of the Mann–Kendall test and Sen's method and a parametric approach (ANN) based on factor analysis of extremes statistical theory have been applied. Owing to the seasonal character of the upstream–downstream variables linkages, the result concludes that all the variables considered the temperature as the most important factor in the estimation of streamflow. The results suggest a significant impact of input vector length, a few hidden nodes neurons, and the choice of activation function as ANN potentiality in characterizing the individual season and project maximum likelihood trend for the surface water patterns. Thus, careful assessment of the available water resources and reasonable needs of the basin/region in foreseeable future for various purposes must be based on reliable information concerning the meteorological variable trend which in turn impacts the peak flow to be expected after a rainstorm of a given probability of occurrence. The methods applied further confirms our assertion that these patterns are indeed unique across each month in the season. The water resources manager and agricultural water management sector would find optimal use in the developed ANN classifier model that links hydrologic variability on different temporal trend scales based on available past data and rainfall anomaly.

Abstract

Context appropriate adaptation interventions and strategies that respond directly to localized climate change stressors, hazards, and vulnerabilities are critical for the sustainable development of countries like Zambia. This chapter examines both localized and systemic climate change risk pathways and barriers to adaptation action in Zambia.

A three-staged methodology was applied, combining content analysis, focus group discussions, and expert interviews. Livelihood diversification was identified as the central adaptation option across Zambia, despite little empirical research detailing possible risks of diversification. The dominant adaptation discourse is focused specifically on diversifying within agriculture-based livelihoods. However, as all agricultural activities are impacted by climate change, diversification also needs to be explored in value-added or alternative sectors. With this, a weak policy framework and enabling environment are exacerbating cycles of poverty that underpin climate change vulnerability in Zambia. Moreover, maladaptation risks of existing diversification interventions are high as generic approaches often do not provide suitable options to complex and localized risk profiles.

To implement a sustainable transition toward climate resilient and compatible development in Zambia, the authors recommend that a systematic livelihood diversification strategy should be rolled out and future research programs designed to support this. Specifically, this necessitates a system-wide analysis of pre-identified livelihood diversification pathways that can be adapted to different scenarios given the current and future climate uncertainties at local scales. The approach should focus on harnessing the positive feedback loops for systematic change to build resilience, while minimizing the dominant risk pathways and eliminating persistent barriers that enable positive feedback loops driving vulnerability to climate change. Thorough stakeholder engagement and incremental development of diversification options, incentives, penalties, and other governance and/or policy mechanisms will be needed to support these processes.

Introduction

There is increasing evidence of the existing and potential impacts of climate change on ecosystems and society (Fischer 2019; Grüneis et al. 2018). These impacts are projected to increase in southern Africa due to projected increases in exposure and existing high levels of sensitivity and low levels of adaptive capacity (IPCC 2018). Climate change poses complex challenges to development planning and management at various scales (national, regional, and local) (Whitney and Ban 2019) through a multitude of risk pathways. Globally, enabling effective and efficient adaptation interventions has become a major policy goal over the last decade (Fischer 2019). Recent evidence suggests that adaptation strategies and policies are often developed using a top-down approach (Grüneis et al. 2018). However, there are increasingly urgent calls for locally appropriate adaptation strategies that respond to local scale climate hazards, stressors and vulnerabilities and take cognizance of localized socioeconomic and environmental conditions. Conventional public policy and sustainable development strategies do not effectively incorporate climate change impacts and projections (Whitney and Ban 2019) at a localized scale, often resulting in unintended negative consequences. Designing and implementing effective adaptation actions requires the active participation of local practitioners in order to make decisions on adaptation choices and activities that are locally relevant, credible, and contextually appropriate.

A variety of adaptation measures have been proposed across Africa. However, there is little empirical evidence of how adaptation decisions are contextually developed and to what degree local institutions participate and/or drive such processes. Local institutions understand local contexts and the various climate hazards within their regions and therefore need to be key decision-makers in the development of adaptation strategies and policies (Fischer 2019; Kupika et al. 2019). This is evidenced by extensive scholarship exploring the pervasiveness of maladaptation (e.g., Juhola et al. 2016; Magnan et al. 2016) and issues of scale and applicability of generic adaptation investments under deep uncertainty (Haasnoot et al. 2019; Hallegatte et al. 2012). This is of particular importance in developing adaptation responses to pursue sustainable development outcomes, taking into consideration ecological and social coping and adaptation capacities at multiple spatial scales.

Effective adaptation minimizes negative impacts and maximizes the potential benefits of climate change (Whitney and Ban 2019) given the resource constraints of a particular socio-ecological system. Thus, effective local strategies will, to a large extent, depend on the understanding and perceptions of local actors about opportunities to inform adaptation strategies (Whitney and Ban 2019). Thus, it is clear that pragmatic adaptation actions demand participation of all key local actors and institutions.

This chapter examines the risks from climate change that are currently being experienced and further explores current and future adaptation strategies and barriers to adaptation. Complex and cumulative climate change risk pathways and key barriers to adaptation and resilience building are explored through analyzing perceptions of local actors and institutions within the broader policy and environmental context of Zambia. The overarching objective of this research is to assess and recommend context appropriate and systemic adaptation interventions and strategies that respond directly to both national and localized climate change risks and vulnerabilities.

Climate Change in Southern Africa and Zambia

Southern Africa is one of the global climate change hotspots (IPCC 2018). Anthropogenically driven temperature rise is at approximately twice the average global rate of temperature increase (Weber et al. 2018). This is combined with the observed increased frequency and intensity of extreme events such as droughts, heavy rainfall events, heat waves, and floods over the past few decades (Paeth et al. 2010; Taylor et al. 2017). Climate projections for the region also indicate rises in temperatures, an increase in hot days, heat waves, and heat stress as well as continued increases in the frequency and magnitude of extreme events such as droughts and floods (Engelbrecht et al. 2015; Dosio 2017; Maúre et al. 2018).

The severity of these impacts will be magnified by low levels of adaptive capacity, stemming from a plethora of socioeconomic and environmental challenges facing the Southern African region. These factors include rapid population growth, natural resource-related poverty and inequality, regional migration, significant infrastructure deficits, low levels of access to clean water and sanitation, and inefficient food, and energy systems among others (Nhamo et al. 2018; Rawlins et al. 2018).

Zambia is no exception to these trends, with severe climate change impacts projected for the economy, local livelihoods, and the broader environment (Kaluba 2014; World Bank 2019). The country is particularly vulnerable to floods and droughts, which in the past 30 years have cost the country an estimated 13.8bn USD, equivalent to around 0.4% of GDP (Kaluba 2014). Zambia has also seen decreased rainfall by an average rate of 1.9 mm/month (2.3%) per decade since 1960, and the rainfall season has become shorter and more difficult to predict – with fewer, but more intense rainfall events (AfDB 2019; ZINDC 2015). Mean annual runoff is estimated to decrease by ~13%, under future climate change scenarios (Hamududu and Ngoma 2018). This, combined with increasing climate variability, is reducing water availability across the country. Moreover, vulnerability to climate extremes such as droughts and floods is also increasing, posing a significant threat to water security in the country.

Future scenarios for Zambia over the period 2070–2099 indicate that temperatures will increase by 2 °C and rainfall could decrease by 8–10% (Bwalya 2010) with an indication of heavy rainfall events becoming more frequent in the northern highlands (AfDB 2019). As stated above, the frequency of extreme events (droughts, seasonal floods and flash floods, extreme temperatures, and dry spells), along with their intensity and magnitude, has also increased, and is already having notable knock-on effects for local livelihoods.

Methodology

This chapter adopted a three-staged methodological approach, combining technical content analysis, focus group discussions, and semi-structured expert interviews. In the first stage, we conducted an extensive content analysis of key Zambian national policies that address adaptation to climate change and broader sustainable development in one way or another. This included the 2017 National Climate Change Policy, national sectoral policies (water, agriculture, and forestry), and national development plans (Seventh National Development plan and the Vision 2030). Analyzing these policies provided insights on policy direction at the national level and to what degree adaptation to climate change is addressed both implicitly and explicitly as well as the complex interrelations and interdependencies between adaptation and sustainable development objectives.

The second stage involved provincial workshops and a national stakeholder workshop (Lusaka, Zambia, August 2018). Provincial workshops were arranged by district sectoral leads. A total of three provincial level workshops were conducted in Western, Luapula and Northern provinces. These were useful in providing insights into key climate risks being experienced in the various districts of the provinces, and the possible adaptation interventions, which were prioritized by local participants. Participants were drawn from a variety of government departments, NGOs, private sector, and civil society organizations (CSOs). Provincial workshops had an average of 45 participants. We further conducted key informant interviews with provincial heads to understand how localized climate risks in each province related to national, provincial, and local policies and strategies for adaptation and sustainable development. These semi-structured interviews provided the necessary depth in understanding the drivers of and barriers to effective adaptation as well as how these different risks and barriers can interact and accumulate throughout socio-ecological systems. Lastly, we conducted a national workshop, which was attended by 60 experts drawn from across government departments (forestry, agriculture, environment, national development planning, and water), NGOs, and academics.

Finally, semi-structured expert interviews were carried out with experienced academics and practitioners working on a variety of climate change, natural resource, and sustainable development challenges in Zambia and Southern Africa at large. This multistaged approach has been widely used in related studies (e.g., Antwi-Agyei et al. 2018; England et al. 2018). The combination of content analysis, focus group discussions, workshops, and in-depth interviews was shown to be useful in identifying risks, barriers, and possible investments to help adapt to climate change. Specifically, the iterative development of the key findings of the analysis assisted the verification and validation of proposed systemic adaptation responses that will address both national and localized climate change risks in an integrated manner.

Climate Change Risk Pathways in Zambia

Zambia faces a multitude of climate change risks related to not only the direct effects of climate change but also to infrastructure, social and economic conditions, human health, agriculture, and the natural environment, among others. These risks manifest through a multitude of risk pathways with a variety of impacts over different time horizons that disproportionately impact the most vulnerable populations. Additionally, cumulative impacts of these risks regularly lead to positive feedback loops that serve to magnify localized climate change risks.

Infrastructure Risk

Heavy flooding frequently cuts road access to districts and their administrative centers. Some of the largest contributors to climate sensitivity and vulnerability in Zambia are low road density, the poor quality of many roads, the inability to traverse them for extended periods in the wet season, and the lack of maintenance and "climate proofing" of existing roads (Petrie et al. 2018).

An example of the impact of damage to infrastructure given by workshop participants was that, in remote districts, teachers may not be paid their monthly salaries for months at a time when floods cut road access. Left without an income, they must find the means to obtain food, which they may do by growing food crops themselves. This takes time that they would otherwise use for their teaching load (planning and administrative tasks), which affects the quality of education they deliver. Alternatively, teachers who find this situation difficult may not last more than 2 years in this employment and then leave, resulting in annual staff turnover as high as 30% (EPDC 2012).

Hydropower accounts for the vast majority of Zambia's energy supplies, with a number of systems currently in operation and a significant amount of planned future generation (e.g., the planned Batoka Gorge Hydropower Plant). The demand for energy is driving continued hydropower development in the region, despite the significant potential decline in hydropower output projected under a drying climate in the Zambezi Basin (Spalding-Fecher et al. 2017). The highly centralized nature and sheer size of the financial investments required to support hydropower infrastructure presents a significant fiscal risk to Zambia given these potential impacts of climate change.

Other examples of the direct and indirect impacts arising from vulnerable road infrastructure are reduced economic activity (trade cannot take place, as markets are inaccessible); and a seasonal lack of access to health and educational facilities. Finally, to compound these factors, authorities are unable to deliver aid when it is needed in times of disaster.

Socioeconomic Risk

Flooding destroys homes as well as crops and livestock and other household assets. This has an impact on public, household, and individual health and severely affects the access of households to social services. The poor road infrastructure restricts commercial enterprise, depressing local and regional economies and increasing the socioeconomic risks of the region.

A high population growth rate is a key underlying driver of vulnerability, with the rate often exceeding the ability of the economy to absorb job seekers. This highlights the potential future risks to local economies and threatens the ability of social services such as education and health facilities to cope with the situation. High levels of education give people more options in terms of diversified livelihoods and income generating activities, while poor access to schooling and poor education or low levels of education hinders adaptation. Without education, people are forced to fall back more strongly on traditional income generation practices. Moreover, risks from the impacts of climate change are exacerbated by the lack of income diversity and high levels of poverty in general.

Gender equality is low in rural areas of Zambia and gender-based violence is common (Samuels et al. 2015). For example, early marriages lead to increased vulnerability of the affected girls. Education levels are low especially for girls who drop out of school to get married. With limited skills, women are restricted in terms of both the value they can add to available natural resources, and the ability to utilize various economic opportunities that would increase the efficiency and productiveness of households to improve their adaptive capacities.

Human Health Risk

An unhealthy population (or one with a high burden of disease) has a lower resilience to climate change impacts that challenge human health (Smith et al. 2014). HIV/Aids, malaria, and tuberculosis are the most prevalent and therefore serious diseases in Zambia. In addition, the incidence of these diseases reduces the resilience of those individuals and communities affected by other health challenges (i.e., comorbidities).

Poor health infrastructure – inadequate resources, including too few health facilities and staff – is a significant source of vulnerability. This is exacerbated by the remoteness of many districts, and poor roads, meaning that some areas are periodically isolated from health facilities during the wet season, with its concomitant impacts of flooding. It is unclear at this stage how emerging global health risks such as the Corona Virus 2019 (COVID-19) will be influenced by climate change risks; however, it is clear that the potential knock-on effects of a national or global pandemic will further limit the available health infrastructure capacity.

Social issues that result from climate-induced stresses include impacts on mental health. Climate change can affect people directly through trauma, which is evident in climate hazards such as floods. It also affects mental health indirectly, through impacts on physical health and broader community well-being (Berry et al. 2010).

Heat waves and persistent high temperatures will not only alter disease vector habitat distribution (such as malaria and tsetse fly, see Caminade et al. (2014) and Terblanche et al. (2008)), but also pose direct threats to human health in the form of heat stroke, exhaustion, and death.

Agricultural Risk

Flooding is hazardous to crops across Zambia, though this risk profile varies from region to region. For example, in the higher, steeper areas of districts in Muchinga

Province, flooding is less of a risk because smaller areas of crops are exposed to the hazard. However, crops along the major rivers can be exposed to prolonged periods of heavy flooding, for example, those in Western Province or parts of Luapula and Northern provinces. With a substantial portion of their food resources for a season destroyed, people must seek alternative forms of income, including relocating for at least part of the agricultural year to other regions in order to generate an income, often by selling labor, charcoal manufacture, or fishing.

The impact of drought on crops and livelihoods varies between the provinces and their districts. In general, mean annual rainfalls are lower in the western and southern regions of Zambia, and droughts are more intense and longer than elsewhere. Droughts in this region have very significant impacts on crop yield. In the northern provinces, where mean annual rainfalls are significantly higher, drought is not a significant risk.

Temperature increases above certain thresholds substantially reduce the grain yield of maize, especially in soils which have a poor water holding capacity (see, e.g., Hatfield and Prueger 2015). This effect is more likely in the western and southern provinces than in the northern provinces, which are at higher altitudes, with higher rainfall and longer growing seasons.

Storm damage to crops – a result of high windspeed during intense events, or hail, is known as a relatively localized event. While devastating for the affected householders, these usually do not occur at district or provincial level. Climate change has shown to have negative effects on livestock leading to reduction in available fodder for animals due to droughts. Floods also affect livestock by reducing the grazing land available, further increasing pressure. Disease incidence for livestock also increased with corresponding increase in animal mortality.

Environmental Change Risk

Zambia has a burgeoning challenge in deforestation, which has been recognized for some time, in essence since the beginning of the last century (Holden 2001). There are three main causes – land clearing for "slash-and-burn" or *Chitimene* agriculture, charcoal making, and logging for high-value timber. The earlier land-use changes resulted from population growth and the *Chitimene* and *Fundikila* ("grass-mound") farming systems, which required migration and opening up of new areas, especially when cassava and maize-fertilizer systems were implemented in Northern Zambia. These entrenched practices have caused significant environmental changes across the Zambian landscape as well as increased dependence on unsustainable supplies of natural resources, both of which increase vulnerability to climate change.

Fisheries are a critical natural resource in Zambia, but are experiencing overexploitation and are under increasing pressure from external development activities that compromise river ecosystem services and functioning (Cowx et al. 2018). Although there is limited evidence directly linking the decline in inland fisheries in recent years to climate change, there are strong linkages to these declines with overfishing driven by human behavior change (Marshall 2012).

Deforestation and its relationship to climate sensitivity hinges on how changes in vegetation cover affect the physical and chemical components of the environment in ways that are likely to reduce resilience to change. Deforestation, followed by agricultural disturbance, results in loss of soil organic carbon and of soil fertility (Chidumayo and Kwibisa 2003). This effect is enhanced by grassland fires (in areas where grass has replaced lost tree cover), with repeated burns also reducing soil carbon. Soil carbon is also important for enhancing soil water retention, an obvious necessity for plant growth and for maintaining growth potential. Deforestation also leads to a decline in soil moisture, which then leads to more surface energy being converted into heat at the land surface. This results in a hotter environment, which at these latitudes is damaging to crop growth and alters pest and disease organism life cycles. Ultimately, deforestation often leads to lower climate resilience.

Cumulative Risks and Positive Feedback Loops

Infrastructure, socioeconomic, human health, agricultural, and environmental change risks of climate change are not independent of one another and more often than not serve to magnify each other (Mora et al. 2018). These positive feedback loops result in cumulative risk profiles across Zambia, that are deeply entrenched through the existing socio-ecological and economic systems.

Risks of climate change to infrastructure such as road closures and limited access to critical infrastructure serve to exacerbate human health risks because people cannot access hospitals and clinics. Poor health outcomes have knock-on impacts for socio-economic livelihood activities by reducing the capacity of individuals and households to generate income and/or support social activities within a household. Such risks are closely tied to agriculture as this is the dominant livelihood activity in Zambia; for example, if people cannot work due to poor health or are forced to travel far distances to seek medical care they are often not able to tend to their crops or livestock. This further magnifies the potential risks from climate change to agricultural activities and ultimately agricultural output. Deforestation and over-harvesting of valuable and limited natural resources such as inland fisheries often result from crop failure or livestock die offs, further increasing the risks related to environmental change.

Barriers to Adaptation and Resilience Building

There are a number of environmental, social, economic, and political barriers to effective climate change adaptation in Zambia. These barriers interact throughout complex socio-ecological systems to reduce adaptive capacities and compound the limits to adaptation throughout the country.

Poor Livelihood and Economic Diversification

Most rural livelihoods are dependent on natural resources and agriculture. In other words, Zambia has not seen the structural changes in its economy that would enable a permanent shift to one dependent on secondary or tertiary economic activities such as manufacturing and services, thus transforming from a natural resource-based economy. This is strongly aligned with broader development imperatives to shift employment from low- to high-productivity sectors.

Local markets and value chains for locally produced goods (especially agricultural products) are underdeveloped. Access to markets is low, primarily due to poor road infrastructure, impacted further by floods and extreme heat, which impact transport time and/or the modality of agricultural produce. Beneficiation processes related to output from key livelihood activities for economic development are highly underdeveloped. Thus, having livelihoods focused on a few highly vulnerable sectors and natural resources serves only to concentrate risks of climate change while simultaneously limiting the ability to adapt. Ultimately, this has resulted in low levels of livelihood and economic diversification both across primary, secondary, and tertiary economic activities as well as within primary production activities themselves.

High Rates of Land Degradation

Land degradation is primarily driven by unsustainable livelihood practices that are rooted in high levels of poverty and inequality. Harvesting trees for charcoal production and for trade (e.g., for export to China) is adding to already high levels of deforestation. Zambians are often not even the main beneficiaries of revenues from tree-based trade. *Mukula* (Rosewood), is heavily harvested for timber exports to China. Local cutters receive an average price of about US$23/cubic meter of timber harvested, while manufacturers in China pay around US$1,000/cubic meter to importers, before any further processing is done on the exported logs (Cerutti et al. 2018).

Populations are likely to continue to diversify their livelihoods through these and other activities, such as illegal poaching, until there is a proper incentive to secure their livelihoods more sustainably. Together with climate change impacts, these activities are resulting in widespread land degradation and loss of ecosystems, biodiversity, and services that are critical to human welfare and livelihoods, such as water, fisheries, and forests.

Low Levels of Technical and Technological Capacities

This aspect is evident in very low levels of adoption of new technologies, which range from alternative farming practices, such as conservation agriculture, to capacities to build new climate resilient infrastructure or to retrofit existing infrastructure to be climate resilient. The shift toward decentralization of governance in Zambia raises the challenge of meeting technical capacity needs across the levels of implementation. With this, districts across the studied provinces are limited by lack of the technical capacities needed to drive this implementation. There is thus an evolving trade-off between the necessity to decentralize decision-making power and governance structures with meeting the technical needs for livelihood and economic diversification at the local level to adapt to existing and future impacts of climate change.

Inadequate Infrastructure

Zambia's high levels of infrastructure deficits in transport, energy, Information and Communications Technology (ICT), and water and sanitation significantly impede adaptive capacities. Notably, business productivity is severely hampered by the infrastructure deficits. This reduces investments in commercial activities and limits expansion of smaller businesses, further limiting income diversification opportunities. Furthermore, 50% of the productivity gap in Zambia is attributed by firms to the state of the country's infrastructure (Foster and Dominguez 2011). Most of the productivity gap is attributed to power, followed by transport and ICT. As mentioned above, road infrastructure is insufficient and plays a pivotal role for all forms of infrastructure.

Entrenched Culturally and/or Policy-Driven Practices

Zambians are often forced to default to livelihoods and coping strategies that are supported by long-standing traditional beliefs, which are in some instances supported by well-entrenched policies. For example, high cultural value is placed on cattle ownership, to the extent that farmers often refuse to sell them off during extreme droughts, in the hopes they will survive and regain health, even though the farmers cannot feed and water them. Often the cattle do not survive.

Policies can also entrench practices not conducive to climate change. For example, policy-driven maize production has increased farmer dependence on a vulnerable livelihood and its status as the country's most desired food staple (Chapoto et al. 2010). Problematically, maize is not a drought-resilient crop and yields in Zambia are quite low, also partly due to the policy emphasis on production rather than productivity (Petrie et al. 2014). Consequently, farmers are not diversifying their risks by growing additional or alternate crops, which may be more drought resilient. Nor are they considering alternate livelihoods because the culturally and policy-driven practice of maize farming is so entrenched.

Weak Policy Implementation

Supportive policy frameworks that enable adaptation are relatively well established in Zambia. For example, the 2017 National Climate Change Policy details a broad approach to strengthen the implementation of adaptation measures to reduce vulnerability to climate change, which supports and builds on the objectives outlined in the 7th National Development Plan. However, these policies are generally not effectively applied or fully implemented due to a number of related barriers, such as breadth of technical capacity, conflicting discourse on development objectives, lack of financing opportunities, and weak institutional arrangements (Romdhani et al. 2018). This is particularly true in rural areas, where institutional arrangements and related enforcement mechanisms are relatively weak and government institutions are poorly capacitated; yet people in these areas are the most vulnerable to the impacts of climate change.

Persistent Inequalities

Gender inequality and gender-based violence persists despite transversal policy. Women lack access to land in comparison to men, under customary law that disadvantages women in terms of land allocation. This compromises agricultural productivity and food security, particularly in situations where women have the responsibility over daily household welfare without decision-making powers over land and land use, and in the face of little access to disposable income. With this, female farmers tend to have even lower access than men to agricultural inputs.

Even if there were greater opportunities for livelihoods and incomes beyond natural resource-based sectors, education, a key indicator of adaptive capacity, is low in the studied provinces. This limits people's access to opportunities, particularly affecting women. Inequalities are also highly evident in access to safe water, electricity, and public health services, which tends to be much lower in rural areas making people less able to adapt to the impacts of climate change. Ultimately, this reduces the adaptive capacity of these individuals and communities and reduces their opportunities to diversify.

Cumulative Barriers and Positive Feedback Loops

Similar to the cumulative nature of the climate change risk pathways, the above-mentioned barriers to adaptation can also create positive feedback loops that serve to reinforce these barriers and ultimately limit resilience building opportunities (Shackleton et al. 2015). A key example from the Zambian context relates to both weak policy implementation and the myopic culturally entrenched and policy-driven practices. Agriculture-based livelihoods being culturally entrenched and together driven by centralized blanket maize cultivation incentives create more significant barriers to effective adaptation when combined with poor implementation of climate change policies. Moreover, traditional livelihoods serve to reinforce the status quo around traditional gender roles and thus further entrench the persistent inequalities. Moreover, traditional livelihood practices and high levels of inequality and poverty drive unsustainable land-use practices and ultimately lead to degradation. This phenomenon is heightened due to the increasing nature of crop failures and livestock die offs due to the impacts of climate change.

Given that low population densities and high travel distances necessitate greater per capita investment for infrastructure construction (Chapman et al. 2013), the widespread nature of rural and subsistence-based livelihoods across the country compound the difficulty of infrastructure provision. The same logic applies to the adoption of novel technologies and livelihood practices as well as the opportunities to access alternative markets and economies.

Toward Improved Climate Change Adaptation

Climate change risk pathways and barriers to adaptation manifest through a complex network of social, economic, and environmental feedback loops, often resulting in positive feedback loops that intensify the initial perceived risk of a particular climate hazard or stressor. These potentially antagonistic relationships between different risk pathways and socioeconomic barriers to adaptation highlight the complexity of the interdependent nature of socio-ecological systems in Zambia. The benefits of developing adaptation responses that focus on individual climate change risk pathways or barriers will be abated due to the complex synergistic and antagonistic feedback loops that characterize these systems. Thus, these complex interactions highlight the need for systematic responses to minimize risks and overcome the barriers.

In Zambia, the complex and emergent properties of the socio-ecological systems, combined with their strong dependency on climate systems, elucidate the intrinsic and inextricable relationship between climate change and sustainable development. Thus, effective adaptation responses need to take a systematic approach that attempts to address the myriad of complex climate change risks concurrently with existing barriers to adaptation. Kim et al. (2018) show that community social and ecological climate change risk characteristics were reduced by higher levels of social capital combined with local proactive planning and policy measures focused on systematic responses to cumulative exposure. The notion of an integrated and systematic response to stressors and shocks on socio-ecological systems and related economic activities is widely considered effective, whether or not these external stressors and shocks are related to climate change or not (Cinner and Barnes 2019; Fedele et al. 2019; Hafezi et al. 2018).

Maladaptation Potential

Responding to a myriad of climate change threats across Zambia requires both increased resilience to short- to medium-term shocks (e.g., floods and droughts) combined with sustained and more gradual adaptation to climate change (temperature rise and seasonal rainfall changes) across systems and society. Moreover, this necessitates rigorous assessments of maladaptation potential for proposed interventions. Much of the onus for this falls on government institutions and the Zambian governance framework because the role of the developmental state is to balance social development with economic growth in a sustainable manner. However, maladaptation risks are high and generic approaches to diversifying livelihoods do not always provide the best options to complex risk profiles associated with poverty, climate change, and environmental degradation.

Maladaptive actions may lead to increased risks of adverse climate-related outcomes (IPCC 2018). Thus, understanding the potential for maladaptation is critical for planning and budgeting for adaptation interventions. Zambia faces enormous opportunities to improve livelihoods and living standards through adaptation; however, the significant scope of the opportunity raises the likelihood of maladaptive outcomes.

Improving road infrastructure, for example, has its own risks, despite the notable potential for positive sustainable development and climate change adaptation outcomes. In many parts of Zambia, such as Western Province, illegal tree harvesting of species such as Mzauli (African rosewood – *Guibourtia coleosperma*) is taking place, with the timber being exported through Namibia. This is leading to a decline in this species. Improved roads into these areas could facilitate increased penetration of illegal tree fellers.

Is Livelihood and Economic Diversification the Answer?

Livelihood and economic diversification are regularly identified as a key adaptation option given the current socioeconomic state of Zambian populations and communities and the current and projected impacts of climate change (Petrie et al. 2018). The dominant discourse around adaptation in Zambia is focused on agriculture-based livelihoods, which are facing the greatest risks from climate change. Currently, in response, adaptation interventions are focused on transitions to (and between) different forms of conservation agriculture, crop diversification, and a combination of farm and nonfarm activities such as seasonal fishing and charcoal production (Loison 2015; Romdhani et al. 2018).

Zambia's favorable agro-climatic conditions are suitable for producing a diverse variety of livestock and crops; however, legacy blanket policies promoting the cultivation and consumption of maize have limited these opportunities significantly. In 2015, ±98% of smallholder households were cultivating maize, while it is estimated that more than half of the land under crop production in Zambia is devoted to maize (CSO 2015). Moreover, Mofya-Mukuka and Hichaambwa (2018) found that government input subsidies and direct market support for maize have negatively affected crop diversification by rural households. Additionally, compared to neighboring countries in the region, Zambia's level of crop diversification is low (as measured by the Simpson Index of Diversification = ±0.37) (World Bank 2018). Despite this the potential for diversification has been shown to be good. Alfani et al. (2019) found in Zambia that general diversification actions such as livestock and income diversification and the adoption of agro-forestry as an alternative economic activity served to moderate the impact of a recent severe drought. Interestingly, it was also found that some agro-ecological practices such as minimum soil disturbance was not effective in moderating any yield and income effects of the drought. Additionally, Wineman and Crawford (2017) demonstrate that given the current set of available diversification options, autonomous on-farm adaptation will not be sufficient to offset the negative yield effects of climate change.

Combined with the notable vulnerability of maize production to projected climate change in Zambia (Wineman and Crawford 2017; Petrie et al. 2014), the rationale for diversification to improve income and/or food security is clear. However, the perceived benefits of diversification might not always materialize on the ground, as the enabling environment to support such diversification is weak. Loison (2015) emphasizes that it is only the relatively better-off smallholders with sufficient assets who achieve successful livelihood diversification; and thus, associated increases in income and wealth based on livelihood diversification are yet to show notable benefits for smallholder farmers that are implementing diversified livelihood activities. The same argument holds in relation to improving climate resilience through livelihood diversification. Climate change vulnerability in Zambia is largely a function of people's poor ability to adapt (i.e., adaptive capacity), which is driven by high levels of poverty and a lack of access to basic services and supporting infrastructure (Petrie et al. 2018).

Despite multiple proponents of diversification as a key strategy for climate-smart agriculture in Zambia (Arslan et al. 2018), there is little empirical research detailing the possible risks of diversification. Moreover, risks of promoting diversification are exacerbated by the weak enabling environment. For example, diversifying agricultural practices requires knowledge, skills, and inputs to grow multiple types of crops and/or rear multiple different types of livestock. Not only could this cost more in the short run; there is also a greater risk of making mistakes. Diversification can also lead to localized competition for markets, leading to possible conflicts. Importantly, promoting over-diversified livelihood activities might limit opportunities to upscale by taking advantage of economies of scale through access more well developed markets and value chains. These risks might exacerbate the cycles of poverty that underpin climate change vulnerability in Zambia.

It is clear that livelihood diversification presents significant opportunities and challenges, which means it should not be viewed as an adaptation panacea in low income settings. People will naturally adapt and diversify, where livelihood and/or income opportunities are better. Hence there is a clear need for dedicated policy and governance efforts to systematically target, support, and incentivize context-specific livelihood diversification opportunities that are harmonized across competing developmental objectives. Bhatta et al. (2015) highlight that livelihood and diversification strategies need to be tailored to both localized climatic and non-climatic resources alike to minimize risks and facilitate the lowest-cost (social and economic) transition to climate resilience.

Conclusions and Recommendations

The system- and society-wide impacts of climate change in Zambia require transformational change in sustainable development. Zambia's dependence, for example, on agriculture for its economy and for livelihoods, places the country and its populations at high risk to climate change. The related national policies, such as the incentivization of maize production, do not capture the localized livelihood contexts and climate risk profiles. The link between climate change and sustainable development in Zambia is inextricable, however, and thus these two concepts should not be viewed in isolation from one another.

Livelihood diversification was identified as the central adaptation option across Zambia, despite little empirical research detailing possible risks of diversification. The dominant adaptation discourse is focused specifically on diversifying within agriculture-based livelihoods. However, as all agricultural activities are impacted by climate change, diversification also needs to be explored in value added or alternative sectors. With this, a weak policy framework and enabling environment is exacerbating cycles of poverty that underpin climate change vulnerability in Zambia. Moreover, maladaptation risks of existing diversification interventions are high as generic approaches often do not provide suitable options to complex and localized risk profiles.

It is evident that there is a strong need to diversify both within and outside of the agriculture sector, but how this is done will be critical. Thus, the authors recommend the development of a detailed spatial assessment of the economic, environmental, and social complexities that contribute to differing levels of climate change vulnerability throughout Zambia and how these contribute to or detract from realizing national sustainable development objectives. Specifically, there is a need to focus on harnessing the positive feedback loops for systematic change to build resilience, while minimizing the dominant risk pathways and eliminating persistent barriers that enable positive feedback loops driving vulnerability to climate change.

First, this will necessitate a detailed examination of a selected range of pathways for alternate crops, livestock farming, fisheries exploitation, and secondary and tertiary services to understand key elements ranging from production to market economics across the various value chains. In this way it will be possible to establish which livelihoods are most appropriate for different areas, and how these might be influenced by projected changes in climate. It will also be important to ascertain how these can best be initiated and sustained from initial development onward in a way that aligns with national development objectives and policy priorities. Potential maladaptation risks of diversification can be addressed through continued stakeholder engagement and incremental development of diversification incentives, penalties, and other governance and/or policy support mechanisms.

To ensure a sustainable transition toward climate resilient and compatible development in Zambia, this systematic approach toward facilitating diversification throughout the economy should be supported by complementary approaches toward land-use and natural resources management, urban planning and infrastructure development. Future research endeavors in the region should focus on supporting this type of holistic approach by developing the evidence-base for change. Specifically, there is a need for a greater understanding of the complex interactions and emergent properties of socio-ecological systems in low-income settings that can inform policy direction at the local scale. This applies specifically to the derivation and classification of combined climate change and developmental risks, how these accumulate in a system and how best these can be addressed given existing resource constraints.

Additionally, future research should also focus on developing innovative densified development models in low-income settings, which can balance the need to simultaneously realize social, economic, and environmental development imperatives. Particular emphasis should be given to the potential role of nature-based solutions and the integration of ecological and traditional gray infrastructure. Ultimately, this approach toward evidence-led policy implementation will assist to minimize risks of upscaling livelihood and economic diversification actions, while continuing to facilitate an effective transition toward climate resilience through planned and incremental change.

Gendered Vulnerability to Climate Change Impacts in Selected Counties in Kenya

100

Daniel M. Nzengya and John Kibe Maguta

Contents

Abstract

Extreme climate change events such as frequent and prolonged droughts or floods associated with climate change can be very disruptive to peoples' livelihoods particularly in rural settings, where people rely on the immediate environment for livelihood. Shocks in the people's livelihoods can trigger diverse responses that include migration as a coping or adaption strategy. Migration takes many forms

depending on the context and resources availability. Very few studies in Kenya have used qualitative analysis to bring up women's voices in relation to gender, climate change, and migration, especially along hydrological gradient. This chapter presents results of qualitative research conducted from 58 participants in 2018 in three counties in Kenya, namely, Kiambu County, Machakos, and Makueni. The study sought to examine gender perceptions related to climate-induced migration, that is: whether climate change is perceived to be affecting women's livelihood differently from that of men; examine in what ways experiences of climate induced migration differed for men and women; explore perceptions on the county government efforts to cope with climate-induced migration; and examine perceptions of the role of nongovernmental agencies in helping citizens cope with climate change. From the results obtained on ways in which climate change affected women livelihoods more than men had four themes: (1) women exerted more strain in domestic chores, child/family care, and in the farm labor; (2) women also experienced more time demands. The sources of water and firewood were getting more scarce leading to women travel long distances in search to fetch water and firewood; (3) reduced farm yields, hence inadequate food supply; and (4) the effects of time and strain demands on women was a contributory factor to women poor health and domestic conflicts. Several measures that the county government could take to assist women to cope with climate change-induced migration had five themes which include the following: (1) developing climate change mitigations, and reducing deforestation; (2) increasing water harvesting and storage; (3) develop smart agriculture through the use of drought-resistant crops and drought mitigation education; (4) encourage diversification of livelihoods; and finally (5) providing humanitarian assistance to the most vulnerable populations such as orphans and the very poor. Thirdly, the measures mentioned that NGO's could take to assist rural communities to cope with climate change-induced migration did not vary significantly from those mentioned for county government, except probably for a new theme of *increasing* advocacy for climate adaption policies.

Keywords

Climate change-induced migration · Hydrological gradient · Gendered vulnerabilities · Rural livelihoods · Kenya

Introduction and Background

Climate change poses one of the greatest challenges to rural livelihoods in the Sub-Saharan Africa (SSA). Sub-Saharan Africa is among the regions of the world where majority of people still reside in the rural areas. Millions of households in the rural populations rely on rain-fed small-scale subsistence agriculture (Kalungu et al. 2013). Subsistence agriculture has continued to face many sustainability challenges in the last 10 years, namely, worsening land degradation, declining farm outputs due to declining parcel of land associated with continuing subdivision due to rising population, inaccessibility to farm drought resistance seed crops, extreme climate change events, particularly more frequent and prolonged droughts (Kalungu et al. 2013). Because rural population has risen during the last 15 years, increasing demands for farming and settlement has pushed communities to marginal and ecologically fragile lands, for instance, steep hill slopes, river banks, arid and semiarid areas (Ngugi et al. 2015). Poor land use practices have further exacerbated the continent' problem of soil erosion and desertification (Ngugi et al. 2015), further compounding population's vulnerability to extreme climate events such as droughts. It is estimated that climate change is partly responsible for the rural-urban migration in the SSA region, as people flee to towns and cities to pursue alternative livelihoods (Barrios et al. 2006; Hassan and Tularam 2018).

According to the Intergovernmental Panel on Climate Change, there is need to put in place mitigation and adaptation measures (Intergovernmental Panel on Climate Change 2018). It is because of climate change threats to human life that the United Nations took quick steps that resulted into holding conventions to mitigate climate change effects. According to the United Nations Framework Convention on Climate Change (UNFCCC) report developed from workshops held in 2006–2007 in Africa, Asia, and Latin America, all nations and people have a stake in reversing climatic changes (United Nations Framework Convention on Climate Change 2006). The UNFCCC paints a worrying report with claims that the developing countries are feeling the effects of climate change more than the developed ones. While developed countries have better and advanced coping mechanisms, the developing ones rely on crude means that leave them suffering the wrath of nature emanating from drought, excessive heat, and floods, and so on (Hurd and Smith 2004). There is need to put in place mitigation and adaptation measures as well as doing all that can be done to ensure the ecosystem remains balanced and conserved.

The objectives of this chapter are to: (1) examine if climate change was affecting women's livelihood differently from that of men; (2) in what ways climate-induced migration differed for men and women; and (3) to examine the measures county government and nongovernmental agencies were taking assist communities cope with climate-induced migration.

Overview of Global Perspectives of Climate-Induced Migration

Extreme climate change events interact with many factors to trigger human migration. For instance, the rising trends in climate related disasters, such as severe and prolonged droughts, floods, in different regions of the world have forced people to migrate for safety or for survival. Van der Land and Hummel (2013) has argued that there has been a tendency of low rainfall forcing man to degrade the land. When land is degraded, the environment is affected even more. Further, planning for people has become harder. It is hard to allocate resources to populations that keep moving from one region to another when threatened by the same weather the populations have contributed to make unfriendly. When populations migrate, they further strain the resources of their new areas of settlement. Kartiki (2011) has expressed concern that the ensuing migrations are likely to increase conflicts and political stability. This, the author argues, will result from the struggle over the scarce resources and probably reshaping of geographical boundaries. International conflicts are likely to increase when countries share boundaries.

Chindarkar (2012) has lamented that climate change though painful to all leaves the female gender suffering more in comparison to men. The author argues that women are disadvantaged in terms of property ownership and getting education making them poorer. Failure to give women good education and allow them access to natural resources leaves them with little options to deal with hazards of climate change among other outcomes that include poor health and forced migrations. There are reduced economic activities that are based on natural resources resulting in food insecurity among other things. Climate change induced displacements of people as well as migrations and relocation have continued to take place making the UN to take climate change as an agenda that calls for urgent action (United Nations 2016). Several agencies including the United Nations have called upon organizations and individual countries to have measures in place to address displacement and migration of people (United Nations 2016). However, despite the calls and efforts of the UN, migrations and displacements of people have been on the increase (Hassan and Tularam 2018).

Population movements occasioned by climate change are feared to adversely affect the poor and the vulnerable that have low coping mechanisms. Chindarkar (2012) has opined that since adaptation to and coping with climate change are gendered, women will continue to suffer as they have little income and access to natural resources in comparison to their male counterparts. Reduced access to food and water lays a bigger burden on women. As evidenced in the case of Chitwan Valley in Nepal, women are in most cases the primary collectors of the various provisions required by family members. Citing the case of Sonora in Mexico, the author states that the reduction of water affected the food processing industry forcing men to migrate to towns. The outcome was increase in the workload of women who were left with the burden of tending for families without the men who had migrated. In a similar trend, internal migrations have taken place quite to a large extent in the republics of Kiribati and Tuvalu as a result of induced climate change (Hassan and Tularam 2018). Majority of the people especially women in the Kiribati and Tuvalu rely almost entirely on agricultural-related activities.

The gender divide puts a heavier burden on women who are tasked with looking for water and much more often searching for food. The socially constructed gender differences heap the obligations and the burden of caregiving on women. Since the economic muscle needed to acquire food and water is in many cases lacking, as men monopolize this, women are left with no option but to trek long distances looking for the commodities. Kolmannskog (2009) in a study conducted in Somalia and Burundi has stated that women who are left behind by their husbands face another fear of being chased away by families or relatives of their husbands. When husbands migrate in search of better pastures for their animals, women and children are left behind with relatives.

This has been the trend in Mexico where apart from destroying plants and aquatic life, health has been affected through water pollution and sedimentation. Studies conducted in Bihar and Uttarakhand in India have confirmed that the people who have limited access to resources are more vulnerable and suffer more from climate change effects. Adding their voices to the debate on climate change-induced migrations, Waldinger and Fankhauser (2015) have opined that it increases incentives to migrate. Inability to cope with induced climate change has called for emergency relief and security for those affected (Serdeczny et al. 2017). The authors further argue that internal displacements have resulted in greater risks especially sexual and gender-based violence for women. The latter authors have claimed that when people have to move as a result of weather, the dressing code has compounded the problem like what happened to the Indian women during the Indian Ocean tsunami in 2004. The mode of dressing for Indian women is not suited for walking fast and covering long distances. Further, climate-induced migrations and displacements often lead to breaking of social networks and psychological impacts that are lasting. The authors here have argued that women feel the impact of climate change-induced migrations more deeply. In many cases, they are left with no choice but to think of themselves as well as their entire families. The situation becomes even worse for women as they are rarely allowed direct access to relief food and other emergencies due to cultural constrains. The scenario portrays a potential risk of women falling victims of sexual exploitation or even worse to be trafficked. In countries like Bangladesh and Philippines, due to their low education, women are subjected to low-working paying jobs with long working hours. They are employed as domestic house-helps who have to contend with mistreatments in order to earn bread. Climate-induced migration is not only dangerous but has also turned into a poverty trap (Rahman 2013).

Climate change has forced people to adapt into new cultures in order to survive. Chindarkar (2012) has cited the case of Bangladesh women who have migrated to India. For fear of detection and eventual deportation, many have adorned Hindu religious markers especially on their foreheads.

In Mali and Senegal both of which are in Africa, climatic changes have adversely affected subsistence farming and livestock rearing. Since this Sahel region of West Africa has majority of the people relying on the rains that have been declining, migration has become a common phenomenon (van der Land and Hummel 2013). With a good number being illiterate or semiliterate, farming has been the only way to as they cannot be absorbed in gainful employment that require skills. Waldinger and Fankhauser (2015) have claimed that people involved in the agricultural sector in developing countries will continue suffering climate shocks like droughts and flooding (also, see IPCC 2018). These are attributed to weak financial muscle and use of low technology.

Climate-Induced Migration in Kenya: Causes and Implications

Like the rest of the world, effects of climate change are being felt in Kenya. This is proved by the erratic and unpredictable weather patterns. Cuni-Sanchez et al. (2019) content that the amount of rainfall, fog, and temperature has witnessed serious variations in the last few decades. Rain seasons have changed making it hard to predict the weather and prepare land in good time for farmers. With the high reliance on rain-fed agriculture, variability of rains has threatened food security and complicated lives mainly in rural areas. Droughts and flooding are now a common thing with crops being destroyed. Desertification has increased making life even tougher especially for pastoralists whose livestock have faced grass shortages. Livelihoods have been destroyed with vulnerability increasing by the day. Migrations mainly to urban centers for wage employment especially by men have been taken as the option by some of the affected. Like in other countries, women have been left behind to cater for the families (IPCC 2018).

Climate variability in Kenya like the rest of the world has been blamed largely on human activities. As Sheikh (2017) has argued in a study of Dadaab area of North Eastern Kenya, human-related activities have led to stiff competition over resources which in turn has led to increased conflicts. The increased conflicts have compounded [the problem created the?] movement of people from one place to another. Further, the internally displaced persons in the country are exposed to other vices that include sexual and gender-based violence, dependency, instability, and living in fear as the future remains uncertain. With the scarce resources in the country, migrations emanating from climate change are a major threat to the well-being of all as one is either directly or indirectly affected. Sabbarwal (2017) has lamented on increasing temperatures in Turkana region with conflicts increasing as people compete over reducing pasture and water resources. The author claims that with the area drying up and with temperatures having gone up by approximately 2 °C between 1967 and 2012, raids and migrations have been common. With the rainy seasons becoming shorter and drier, women and girls who are charged with the duties of fetching water have no option but to trek long distances to get the diminishing resource. Water has to be extracted by digging dry wells and riverbeds. With the reduced pastures, animals have died or become famished.

Cuni-Sanchez et al. (2019) carried out a study in northern Kenya and noted a lot of climatic changes in Mt. Kulal, Mt. Nyiro, and Mt. Marsabit. Natural rivers had turned into seasonal rivers. Reliance on firewood and other non-timber products had been affected greatly by changing climate. The unreliability of rains that at times would come when not expected and in low quantities forced people to device different coping mechanisms which include migrations.

Climate-induced migrations have complicated life for those affected and created problems to the government (Corburn et al. 2020). Corburn and others (2020) recent work have pointed to Kenya's urban slums to a haven for COVID-19 infections. Some demographic projections estimate that over half of citizens in Kenya's capital, Nairobi reside in the slums (UN-Habitat n.d.). This has made it hard to share resources like water and housing. Both the national government and the county government have to struggle in provision of public goods and services to the slum population that is increasing by the day. Security has become an issue while environmental health has become an eyesore with dirt in the congested settlements becoming a nuisance.

Materials and Methods

This study employed use a qualitative cross-sectional survey design. Data were collected in 2018 from three counties using questionnaire with open-ended questions. The open-ended questions included: (1) if climate change was affecting women's livelihood differently from that of men; (2) ways in which climate change-induced migration of women differed from those of men; (3) the initiatives the county government should undertake to help people cope with climate change; and finally, (4) the participants' perceptions of the measures nongovernmental agencies should undertake to assist communities cope with climate change.

Study Setting

The research was conducted at three counties in Kenya which are Kiambu, Machakos, and Makueni counties. The Kiambu county is generally lies at a higher attitude, is generally cool with high amounts of rainfall, followed by Machakos, with Makueni being classified as arid and semiarid county. The Kiambu County is generally wet, and the average annual rainfall for the Kiambu is 1000 mm annually. Machakos County, on the other hand, receives average rainfall, with some parts of the county experiencing similar weather patterns as Kiambu County, and other parts being relatively dry. Makueni County is classified as an arid and semiarid region. The county receives low amount of annual rainfall of 600 mm. Makueni county experiences frequent and prolonged droughts triggering crop failures, and is among the list of counties in that receives relief food to mitigative starvation, malnutrition.

Data Analysis and Presentation of Results

This study used content analysis (Hsieh and Shannon 2005) and inductive coding (Strauss and Corbin 1998). Content analysis is a "technique for making inferences by objectively and systematically identifying specified characteristics of messages" (Holsti 1969, p. 14). Content analysis allows a blend of both quantitative and qualitative data analysis attributes to be combined. That is, the researchers can identify count data and compute frequencies/percentages for further analysis. In addition, these quantitative measures can be supported with themes/categories. This method was adopted due to the short nature of responses that was generated from the survey open-ended questions. There were two coding cycles. The first cycle enabled the researchers to describe the data. In the second coding cycle, the codes identified in the first cycle were compared, organized, and categorized (Tracy 2013). To increase credibility of the coding procedure, two people were involved, one of the researchers and a colleague who is familiar with the subject matter. The two researchers did both coding cycles together and where there was a disagreement, they discussed until they reached an agreement. Where possible thick descriptions were identified to support the themes/categories identified. In this study, the unit of analysis was the respondent and each of the four question were analyzed separately to identify themes.

Results and Discussions

Climate Change Affects Women's Livelihood Differently from That of Men: Empirical Evidence from the Study

Twenty two percent of the respondents did not think climate affects women's livelihoods differently than men. However, 88% of the respondents felt climate affected women's livelihoods differently from men. Table 1 summarizes the different themes emerged from the analysis of qualitative responses to the question "in what ways

Table 1 Ways in which climate change affected women livelihood differently from that of men

Themes	Subthemes	Explanation	No of mentions	%
More strain	Domestic chores	Women faced more strain as most of the household chores were assigned to them. For instance, collecting firewood and fetching water	4	6.45
	Child/family care	Women faced more strain from taking care of the young ones	5	8.06
	Farm labor	Women had more responsibilities in preparing the farm, cutting pasture for animals, and harvesting	6	9.68
Low income	Low yields and inadequate food supply	The farms yielded low yields, leading to inadequate food supply for the family and poor nutrition	8	12.90
	Women as bread earners	Women had to run small agro-related businesses/farming to supplement or basically provide for the family	10	16.13
Time demands	More time demands searching water and firewood	Women had to walk long distances searching for firewood and water	10	16.13
	More time demands searching food	Women had to walk long distances searching for food	3	4.83
Effects of time and strain demands	Poor health	Women were prone to sicknesses due to effects of harsh cold weather in the fields, and strain and experienced cold-related sicknesses such as colds, asthma, arthritis, among others	14	22.58
	Domestic conflicts	The strain and time pressures contributed to domestic conflicts between the women and their spouses	2	3.22

does climate change affect women's livelihoods differently from that of men." Four themes, namely, more strain, low income, time demands, and effects of time and strain demands. The theme "more strain" can be described as "exert extra effort in carrying out domestic and farm related chores." This theme was comprised of four themes described in Table 1, namely, domestic shores, child/family care, and farm labor. Women in the rural areas in many parts of the SSA, particularly in Kenya, bear disproportionate burden of household chores (Muasya and Martin 2016; Mokomane 2014). As men migrate to towns and cities to look for better income opportunities, this adds to the burden women bear as a consequence of climate change particularly prevalent and prolonged droughts. Majority of rural areas lack access to reliable and/or affordable water sources, and most households rely on surface water resources for household and domestic needs (Kelly et al. 2018). Most of these sources are seasonal rivers and water springs which run dry during dry spell, meaning women have to walk longer distances during drought seasons to look for the scarce commodity (Cherutich et al. 2015). As one of the participants A1 remarked:

> women are more burdened as they have to source for their families' necessities

while participant B1 had the same concerns:

> Women travel long distances searching for water for domestic use apart from caring for the family

Also, unlike urban areas where working class women hire house helps to assist with child care and other family chores (Muasya 2014), women in rural areas grapple with insufficient resources for survival, meaning they have to bear the burden of child and family care demands. Previous studies have shown that where husbands are present, they provide some support in these tasks reducing stress related to child/family care and work-balance conflicts (Muasya 2016). However, as men migrate to towns and cities, rural women have to bear the extra burden of attending to family chores while carrying children on their backs. As one participant B2 commented:

> Women are more affected as they have to fetch water and take care of the young ones

It is estimated that rural women provide over 80% of farm labor in the rural areas at the SSA region (Ogunlela and Mukhtar 2009). Majority of the rural households lack resources for mechanization, meaning they rely on rudimentary tools and approaches to accomplish most of the farm activities, from digging, land preparation, planting, weeding, harvesting, and postharvest tasks (FAO 2011). As men and young people migrate to towns and cities to run-away from difficulties precipitated by climate change in rural areas, which means women have to bear the burden of accomplishing all these tasks on their own as participant A5 alluded:

> Women are more into the farms harvesting crops and also its preparation

The theme "low income" implies that women earned low income due to declining yields. This theme comprised two subthemes, namely, low yields and inadequate food supply, and low income from agro-related businesses. Rural women rely on selling a variety of farm produce for financial sustenance, and also to provide support to diverse family needs, from purchasing food to educating their children, farm produce consists the main supply of food and nutrition to families. In a study of stressors and work family conflict among urban female teachers, Muasya (2020) found that low income was a stressor to teachers with low income which further made them seek extra sources of income exacerbating their work life balance challenges. In addition, severe and prolonged droughts associated with climate change have been prevalent in the study sites, particularly Makueni County in the last 5 years, resulting into massive crop failures and livestock deaths (Amwata et al. 2015). This led to massive starvation, malnutrition, especially where humanitarian interventions are rarely available (Amwata et al. 2015). This is worsened as most men migrating to towns and cities end up in low-income informal employment and lack extra income to sustain their rural families left behind in rural areas. As one participant C5 remarked:

> Yes. Most of women depend on small scale farming which due to climate change do not produce enough

This was echoed by participant C8,

> Low yields make women struggle very much to find food

The theme "time demands" implies "women spent more time in household chores, farming than men who migrate to towns for industrial jobs." This theme comprised of two subthemes, namely, more time demands searching water and firewood, and more time demands searching food. Although for households living in urban areas, both men and women participate in paying water bills, energy bills, and purchasing food, on the contrast, in the rural areas in most parts of SSA region, women are the ones responsible for collecting water, firewood for cooking, looking for food and the cooking as well (Tian 2017). The burden of the multiple task of looking for food and the time expended walking long distances to look for water particularly during droughts, collecting firewood causes real strain and stress upon rural women (Tian Tian 2017). The quotes by two survey participants below highlight the predicament rural women face out of the experiences during extreme climate change events, particularly droughts. As participants A5, B3, and C4 remarked, respectively:

> women spent a lot of time searching for clean water
> Yes. Women waste a lot of time walking far distances looking for water unlike men
> Women walk long distances searching for water hence wasting a lot of time

The last theme identified was on the effects of time and strain demands. The results of the survey identified two subthemes that had to do with how participants perceived climate change events to affect women, namely, poor health and domestic conflicts. Many participants attributed the vulnerability of women to women's prolonged hours in the farms, or walking to collect water and/or firewood to increase the prevalence of illnesses such colds, asthma, arthritis, among others. Given that women have to carry along their infants during most of these tasks, participants were concerned that their infants and children were by extension exposed to the negative health effects experienced by rural women due to climate change.

Besides poor health, women experienced domestic conflicts. Too much strain and time pressures led to strained marital relationships between the spouses. The women could not be in a position to be equally present at home to take care of children, prepare food in good time, or even offer conjugal rights to their spouses. Studies have shown women even in the formal sector with no adequate support for child care tend to quit their work (Muasya 2017). On the other hand, delegation of house chores and childcare chores can be a source of conflict as well, when these women fail to undertake these chores as socially expected. Moreover, as more household and farm tasks are carried out by women than their spouses, these women can perceive it that their spouses have neglected their duties and it can result to more domestic strife. Indeed, lack of work life balance and delegation of chores can be a source of domestic conflict (Muasya and Martin 2016).

Ways in Which Experiences of Climate Change-Induced Migration Differed for Men and Women

Majority of participants (90%) felt that that climate change-induced migration differed for men and women. Specifically, more men than women left home and migrated from rural areas to urban areas to look for alternative sources of income, search for pasture, or work in farms. Consequently, women were left with more responsibilities. The quotes below highlight participants perceptions on the different ways in which experiences of climate-induced migration differed for men and women as participant A10 narrated:

> men migrate to look for jobs while women engage in simple chores to cater to-day-today needs

and participant A12 remarked:

> most men migrate in search of alternative sources of livelihood while women remain behind to cope with the change

And participant B6 said:

> diverse climatic change makes most men travel to towns leaving families behind

Measures by County Governments to Assist Communities Cope with Climate Change-Induced Migration

Table 2 summarizes the different themes emerged from the analysis of qualitative responses to the question "measures by county governments to assist communities cope with climate change induced migration." Eight themes, namely, climate change

Table 2 Measures by county governments to assist communities cope with climate change-induced migration

Themes	Subthemes	Explanation	No of mentions	%
Climate change mitigation/ adaptation		Encourage reforestation, planting of trees, agroforestry, and reduce cutting of trees	7	6.31
Women empowerment		Women empowered to make financial decisions that can empower them	6	5.40
Strengthening water adaptive capacity	Increased water harvesting and storage	One way to curb drought is increased water harvesting storage through provision of water harvesting resources such as funds, materials, e.g., water tanks, involved in sinking boreholes, dam reservoirs	47	42.34
	Sensitization on water harvesting	Women farmers to be sensitized on the need of water harvesting and ways to harvest water	3	2.70
Soil and water conservation		The need to preserve soil and water through measures such as gabions, water friendly trees, curbing farming along rivers, etc.	8	7.21
Climate smart agriculture	Drought-resistant crops	Farmers to grow drought-resistant and fast-maturing crops with minimal irrigation	15	13.51
	Drought education	Sensitization and education on drought-tolerant crops and information on weather patterns, e.g., from meteorological department	8	7.21
Diversifying livelihoods		Women to be encouraged to explore other non-farm income-generating activities	6	5.40
Humanitarian assistance		The county and nongovernmental organizations to identify and support the most vulnerable groups to climate change such as orphans and the very poor	5	4.50
Individual and institutional capacity building		Enhancing the capacity of women and the local institutions on ways to harvest and conserve water	6	5.40

mitigation and adaptation through tree planting; women empowerment; strengthening households' water adaptative capacity; soil and water conservation (resilience capital); promoting climate smart agriculture; sharing meteorological information/data with rural households; promoting diversification of livelihoods; and targeted humanitarian assistance and strengthening individual and institutional capacity.

The theme on tree planting did not have many categories, and there was little variability of responses from sampled participants. Suggested items included "reforestation"; "sensitizing people to plant trees"; "educating residents on importance of planting trees"; "planting drives on water catchment"; "encouraging people to plant more trees"; "encourage people to avoid cutting down of trees"; and "encouraging tree nurseries." There are several ways in which these measures mentioned by participants can be linked to coping with climate change-induced migration. Planting trees becomes a source of income from the sales of animal fodder, firewood, fruits, thereby providing women with the need supplies to meet households and domestic needs. Some fruits planted in the study sites, particularly Machakos and Makueni Counties, include grafted mangoes that incidentally do well during seasons of crop failures, thereby acting as a buffer to household income and food supplies (Muema et al. 2018).

Women empowerment was another theme that emerged from the analysis of participants' responses regarding the open-ended question on what measures by county governments to assist communities to cope with climate change-induced migration. In most rural settings in the SSA region, patriarchal structures largely influenced decisions related to access to land for cultivation, farm inputs, harvest and postharvest, access to capital to support farm labor, access to capital for physical assets such as farm equipment, water harvesting, and improved cooking stoves (FAO 2011). Even where microfinance existed to support women's efforts, many women had to still seek consent from their spouses, even when the needs were pressing. Such patriarchal structures further limit or frustrates women's intention to build asset portfolio (social networks, human capital, natural capital, physical capital, and financial capital) necessary for climate resilience, and adaptation. The last decade or so has seen many countries including Kenya address women's marginalization particularly in relation to land inheritance, land ownership, and this has spillover benefits particularly reducing gendered vulnerabilities associated with climate change events such as droughts (FAO 2011).

The theme on strengthening households adaptative capacity has several subthemes, namely, increasing supply of materials for water harvesting/funds; supplying water tanks; drilling boreholes; digging dams and reservoirs; and sensitization of communities on water harvesting. Women and children, especially in the rural areas, suffer most problems associated with inaccessibility to reliable and affordable safe sources of water for household and domestic use (Graham et al. 2016). Consequently, improving water accessibility greatly improves the capacity of rural households to cope with climate induced migration, particularly when they are faced with limited human capital because men/husbands have migrated to towns and cities. Also, in pastoral communities, climate change-induced conflicts over diminishing water sources and pasture are quite common in the SSA (Witsenburg and Adano

2009). Consequently, measures such as digging boreholes, water harvesting structures such as dams help communities to better cope with induced migration as they have access to more options in terms of water sources to support their livestock (Witsenburg and Adano 2009).

Soil and water conservation was another theme that was identified, and three subthemes, namely, gabions, water friendly trees on catchment areas, and avoiding farming near rivers. Soil erosion and bad land use practices such cultivating along rivers backs undermine the resilience capital rural dwellers desperately require coping with climate change-induced migration.

Climate smart agriculture is further identified to be another theme that emerged in the analysis of qualitative responses related to county government measures to assist communities to cope with climate-induced migration. Three subthemes identified here included: drought-resistant or fast-maturing crops/seeds; irrigation; and sensitization and education of drought-tolerant crops. Other themes identified included: sharing meteorological information/data with rural households; diversifying livelihoods; timely and strategic humanitarian assistance; and strengthening rural institutions.

Measures by Nongovernmental Agencies to Assist Communities Cope with Climate Change-Induced Migration

Six themes emerged from the qualitative analysis of participants' responses in relation to measure nongovernmental agencies have taken to assist communities cope with climate change-induced migration. Four of the themes seemed to overlap with measures undertaken by county governments. However, two of these themes differed significantly from the measures participants suggested in relation to the role of the county government, namely, climate change advocacy and diverse range of humanitarian interventions. Statements implying climate change advocacy were most frequently mentioned measures by respondents.

The range of humanitarian interventions that NGOs were involved with to assist communities cope with climate change and consequences of climate-induced migration included: supporting children from very poor families; providing food to poor families; providing medical care, providing mobile clinics for health; child sponsorship; providing cheaper energy options for cooking; and providing seeds for planting (Table 3).

Lessons Learned, Study Limitations, and Recommendations for Future Research

Rural households in the study sites observed that climate change affects women's livelihoods differently from men. Specifically, climate change exerts more strain on women, lowers their agro-dependent income due to crop failures and reduced yields, increases time demands women have to spend on household chores such as looking

Table 3 Measures by nongovernmental agencies to assist communities cope with climate change-induced migration

Themes	Subthemes	Explanation	No of mentions	%
Adaptation through water harvesting	Providing water harvesting resources	This water harvesting can be achieved through provision of water harvesting resources and assistance in sinking boreholes and dams	7	8.33
	Water harvesting education and sensitization	Provide water harvesting education and sensitization to communities	2	2.38
Climate change advocacy		Engage the communities and government on policy change to change to new ways of farming technologies	21	25%
Support livelihood diversification			10	11.90
Support climate mitigation measures			13	15.48
Climate smart agriculture			16	19.05
Humanitarian intervention			15	17.86
				100

Source: Authors' survey results, 2020

for water as local water sources dry up, looking for firewood, and the effects of time and strain demands, and have negative impacts on women's, infants, and children's health. Rural communities felt that climate change-induced migration differed for men and women; specifically, more men than women left home and migrated from rural areas to urban areas to look for alternative sources of income, search for pasture, or work in farms. Consequently, women were left with more responsibilities. Regional/county governments' measures to assist communities cope with climate change-induced migration include: supporting climate change mitigation and adaptation through increased tree planting; women empowerment; strengthening households' water adaptative capacity; soil and water conservation (resilience capital); promoting climate smart agriculture; sharing meteorological information/ data with rural households; promoting diversification of livelihoods; targeted humanitarian assistance; and strengthening individual and institutional capacity. While nongovernmental agencies also participate in most of these measures, they seem to bring in strength in relation to climate change advocacy and a very diverse range of humanitarian interventions.

The study sample was limited the three counties in Kenya, and findings may not be generalizable in other parts of the SSA. The rural livelihoods communities studied are more-or-less sedentary, and future studies may need to focus on pastoral/nomadic communities. Also, the study investigated gendered vulnerabilities to climate change impacts and climate-induced migration largely among rural communities' settings. Future research will need to expand this work to urban settings and coastal communities.

The research design followed was cross-sectional survey, future studies are needed to include large sample, and probably use longitudinal designs to observe gendered vulnerabilities and climate-induced migration over a relatively longer study period.

In this study, trained research assistant participants filled responses to the open-ended questions according to participants answers. This limited the ability to capture participants emotions that can add perspective to the qualitative data collected. Future cross-sectional surveys would need to record participants narration, transcribe verbatim, the responses then analyze data.

Conclusion

Indeed, we can conclude that climate change does have negative effects on the livelihoods of rural women in a more disproportionate way compared to men. Thus, intervention whether through the county government or nongovernmental organizations may be required to factor in gender and socioeconomic factors in their policies and intervention programs. Failure to mitigate the negative effects of climate change in rural settings might worsen the livelihoods of women and children, undermining progress the sustainable development of reducing gender inequality, and also health for all citizens.

Abstract

Climate change has emerged as one of the greatest challenges faced by the world today. Adverse impacts of climate change are visible across sectors like agriculture and other natural resources due to increasing average temperature and changing weather patterns. Africa constitutes around 13% of the global population but contributes the least (around 2%) to greenhouse gas (GHG) emissions globally. Concerning the global climate vulnerability index, Africa is most impacted (around 21%) by climate change and its' population is most vulnerable to climate sensitivity and fragility of the continent's natural environment and increasingly erratic weather patterns, low adoption of climate-resilient technologies, and high dependence on environment-based livelihoods. Hence, Africa needs to adopt low carbon and climate-resilient development to address climate-related issues and to have sustainable development. In line with the low carbon/climate-resilient development agenda, 53 countries (except Libya) have submitted Nationally Determined Contribution (NDC) and have set ambitious targets under NDC and Sustainable Development Goals. A quick analysis of the NDCs and various studies indicates the enormity of the financing needs. According to Climate Invetsment Funds (CFI), Sub-Saharan Africa will require an estimated USD222 billion for climate resilience investments to reach its NDCs. One of the critical stakeholders to play a key role in meeting the financing needs of climate-smart agriculture (CSA) related targets is the private sector. There is around 98% gap in financing for CSA. Even though substantial climate finance potential exists in selected countries for the private sector, there are certain challenges and barriers like financial, policy, lack of awareness, and low provision for climate funding in the national budget.

Keywords

Climate-smart agriculture · Unlocking climate finance · Sub-Saharan Africa · Climate adaptation · Private sector

Introduction

An additional 2.4 billion people – representing a one-third increase in the global population – will occur between 2013 and 2050 (FAO 2013). Further, the Food and Agriculture Organization (FAO) approximates the additional population will translate into a 60% increase in demand for agricultural production. Undoubtedly, agriculture is well-positioned to be a reliable basis for economic growth and poverty reduction. Conversely, the ongoing global environmental concern of climate change has adverse impacts on agriculture that is also a contributing factor to the drastically changing weather and climatic patterns. Consequently, for agriculture to satisfactorily feed the growing population, the current agriculture practices need to spiral into more adaptive hence sustainable practices. A breakthrough hinged on climate-smart agriculture (CSA) approach that encompasses three perspectives: increasing productivity in a sustainable manner, enhancing adaptation/resilience, and mitigating the emission of greenhouse gases (GHGs) as emerged as a way to realize food security and achieve the developmental goals. Notably, 56% of Africa's population will reside in urban areas by 2025 and half of the projected population growth will be in Sub-Saharan Africa (UNDESA 2019 and 2014). This entails that agriculture, specifically in Africa, has to undergo a major transformation to fulfill the intertwined challenges of achieving food security, reducing poverty, and responding to climate change without depletion of the natural resource base. Despite the common consensus on the potential for climate-smart agriculture in Africa, there is a conspicuous paucity in wholesome quantifiable empirical evidence. To fill this gap, this chapter looks into the potential for climate-smart agriculture in 14 select countries in Sub-Saharan Africa (SSA) representing East, West, Central, and Southern Africa.

World Bank (2015) estimates that about 48% (approximately 450 million people) of Africa's population live in extreme poverty, i.e., less than US $1.25 in a day. Also, 63% of Africa's population lives in rural areas, wholly dependent on agriculture as a source of living (World Bank 2015). More than 60% of the African population works in the agricultural sector that accounts for about 25–34% of the continent's gross domestic production (GDP). Conceivably, agriculture looms large in the African economy. Unfortunately, a collective report by FAO, IFAD, and WFP (2014) revealed that agricultural production is low leading to high food insecurity. A reason attributed to sluggish income growth, high poverty rates, and dilapidated infrastructure in the rural areas that impair market access. A situation further exacerbated by weak policies, civil unrest, periodical disease outbreaks, overlapping rules, poor coordination, and inept collaboration among institutions within the climate-smart agriculture realm. One in four people remains malnourished in Africa with a high prevalence of stunted and underweight children due to poor dietary quality and diversity, mostly among the poor. Increasing agriculture's adaptive capacity will be necessary to prevent a slide back into poverty and hunger.

Growth in agriculture is the most viable and equitable strategy to spur economic growth in Africa by reducing poverty and enhancing food security in Africa. However, it has to overcome the climate change-related challenges. For instance, Barkhordarian et al. (2012), Radhouane (2013), and IPCC (2014) postulated that the annual rainfall in Sub-Saharan Africa will possibly decrease by about 4–47% resulting in droughts and increased salinity. It resonates with Intergovernmental Panel for Climate Change observations that crop and fodder growing periods in both western and southern Africa will likely shorten by an average of 20% by the year 2050. Resultantly, there will be a 40% decline in cereal yield and an additional reduction in cereal biomass for livestock (Lobell et al. 2011). According to Hoerling et al. (2006) western, central, and southern Africa will record a decline in the mean annual rainfall of 4%, 5%, and 5%, respectively. In the rest of Africa, drought conditions will not only be more frequent and intense but also more long-lasting leading to an increase in the arid and semiarid area approximately to about 5–8% by 2080 (Elrafy 2009). As a factor attributed to the sensitivity of the current farming systems to drought, the cumulative crop yield decline across the continent is forecasted at 50% by 2020. Thornton et al. (2008) contend that the net revenues from crops may likely fall by about 90% by 2100. Further, both agropastoral, pastoral, and mixed-crop livestock systems will potentially be affected by a constraint of animal feed and water in addition to advancing pest severity and disease distribution (Thornton et al. 2008). Against such a grim picture, there lies an excellent opportunity with CSA for transformation by collating agriculture, economic growth, and climate change under the umbrella of sustainable development. Four agroecological zones in SSA serves as case studies for underlying CSA investment potential.

To facilitate CSA adoption in developing countries, respective governments' have claimed their right to public grants with lesser regard to private financing (Pauw 2014). The latter predisposition of the developing countries is in line with the United Nations Framework Convention on Climate change (UFCC) principle of "the polluter pays." The approach implies that developed countries should play a greater role in providing climate adaptation finance for being major contributors of climate change. Bindingly, developed countries pledged US $100 billion every year from 2020 onwards (UFCC 2011). A target that Pauw et al. (2015) doubts if it will be met, actually UNEP FI (2009) postulates that public funding cannot sufficiently finance climate change adaptation costs. Pauw (2014) proposes that the private sector can supplement but not substitute public investment in climate finance. Observations by UFCC (2007) approximated the global private sector investment and financial flows at 86%. Further, SER (2011) cite that 90% of the population in emerging economies depends on the private sector as a source of income. Pauw and Pegels (2013) argues that the private sector can play a potentially significant role in adaptation engagement. As a result of the private sector potential, it was included as one of the finance sources. However, as put forward by Surminski (2013), the evidence base – reasonable activity, predictable returns and acceptable risk for private sector investment – is limited (Christiansen et al. 2012).

This chapter will contribute to the extant literature in twofolds. First is a pioneering academic exploration into quantifying the investment potential and the funding gap in climate-smart agriculture in Africa. This is unlike recent work of Tran et al. (2019) that focused on determinants for the adoption of CSA technologies in developing countries and Pauw and Pegels (2013) with a reflection on the role of the private sector in developing countries. This chapter also digresses from a study by Zougmoré et al. (2018) and Nciizah and Wakindiki (2015) that looked into the prospects and the achievements of CSA in Africa. Secondly, unlike past generalizations on the areas that need climate financing, this chapter will identify the financial, regulatory, and policy barriers hindering private sector investment into CSA projects in Sub-Saharan Africa. In general, this work will add to the ongoing research on the conceptual clarity of private sector engagement in climate adaptation in developing countries (Pauw and Pegels 2013; Pauw 2014).

Based on the selected sample, this work found out that the highest climate-smart agriculture finance potential (in USD billion) lay with Ethiopia at USD 26 billion, distantly followed by Nigeria at USD 17 billion, and further down is Kenya at USD 9 billion which is almost the same case for Madagascar at USD 8 billion. Interestingly, CSA was termed as more investor-friendly, receiving a cumulative investment of

USD 79 billion in the 14 countries. Notwithstanding the CSA potential, the sector faces several challenges including inadequate financing, weak policies, and knowledge gaps within the key institutions. Nonetheless, there is a 98% untapped climate-smart agriculture investment potential that the private sector can exploit through climate financing.

The remainder of this chapter proceeds as follows. The second section will provide an elaborate literature review while the following section will look into the methodology that was used to come up with the conclusions and recommendation. Finally, the chapter will conclude by presenting the conclusion and recommendations.

The Concept of Climate-Smart Agriculture

The approach to developing the technical capacity, accommodative policies and create an enabling environment for investment towards sustainable agriculture in the face of climate change was put forward by FAO (2013). CSA simultaneously addresses the global concerns of food security, ecosystem management, and climate change, therefore incorporating the three dimensions of sustainable development: economic, social, and environmental conditions. Nciizah and Wakindiki (2015) identifies three pillars of CSA as: (1) sustainably increasing agricultural productivity from crops, livestock, and fisheries without detrimental effects to the ecosystem, (2) reducing short-term farming shocks while enhancing their resilience by increasing farmers adaptability to long-term stresses, and (3) mitigating (GHG) emissions by either removing or reducing possible pollution instances. At the grassroots, CSA is intended to bolden the livelihoods through food security mostly among the small-scale farmers. This is by improving the management of natural resources and shifting to suitable technological approaches for the production, processing, and marketing farm produce. Relatedly, at the national level, CSA is tailored to prompt mainstreaming of policy, technical, and financial mechanisms that facilitate a base for operationalization of climate change adaptation within the agriculture sector. There is a vast array of CSA technologies that can be used singly or in combination in response to various environmental conditions (Teklewold et al. 2017). But mainly, the adoption of CSA technologies among farmers differs based on cultures, preferences, awareness, socioeconomic backgrounds, and resource availability (Maguza-Tembo et al. 2017). However, successful CSA requires an appropriate match between agricultural production technologies with social, economic, and environmental conditions.

The Potential for Climate-Smart Agriculture in Sub-Saharan Africa

In West Africa, there is a high and fast-growing population and increasing agricultural production intensification to meet the growing food demand is very limited. Buah et al. (2017), Jalloh et al. (2012), and Sanou et al. (2016) postulate that to enhance food security in West Africa there will be a need to have animals that have resilient genetic potential, drought-resistant crop varieties that are also hardly affected by insects and diseases. Besides, the management of soil carbon and fertility techniques will be handy for the region. Jalloh et al. (2012) also note that increasing capabilities among the smallholders and large-scale irrigated farms are likely to open up new opportunities for CSA through approaches such as crop-livestock interactions. CSA opportunities in Central Africa lie from an increasing but also a food-insecure population. In this case, sustainably increasing agricultural productivity will not only enhance food security but will also prevent deforestation. CSA aims at limiting the expansion of cultivated land into forests by seeking alternatives in better agricultural techniques that are productive hence restoring lost ecosystems.

Torquebiau (2015) contends that to enhance food security in East Africa, CSA practices need to put more emphasis on increasing livestock productivity, soil conservation, and management of water and natural resources at both landscape and small-scale levels, adaptive intensification of the cropping systems. Further, Partey et al. (2016) and Zougmoré et al. (2015) observed that CSA innovations in East Africa should expound into agroforestry, development of stress-tolerant crops and livestock, crop-livestock diversification, as well as combining conservation agriculture with integrated soil fertility management. For instance, research by Wambugu et al. (2011) in Western Kenya found out that short-term agroforestry fallows being used in some parts of Western Kenya increased the annual net income of farmers to between US $62 and 122. Such interventions need to be adopted across Africa although with regional-suited species.

According to Mapfumo et al. (2015), South Africa rainfall is expected to decrease and incidences of drought to increase just like other parts of Africa. Similarly, like East Africa, South Africa has to increase its agricultural productivity through intensification. The most crucial CSA approaches in South Africa will be integrated soil, water, nutrient, and organic manure management (Mapfumo et al. 2015). Additionally, soil carbon, salinity, and organic matter regulation will be critical gains for CSA in empowering the smallholder communities to overcome the food shortages and nutrient scarcity. Mbow et al. (2014) also advocated for the use of legume cereal rotational systems in South Africa that should be combined with inorganic fertilizers.

Majority of the Intended Nationally Determined Contributions (INDCs) have referenced agriculture as an adaptation priority, despite that in most cases, there are no cost estimates and adequate financial mechanisms (World Bank 2016). Of critical value in realizing the adaptation objectives is increasing the working and investment capital in climate-smart agriculture. In 2014, the total climate finance mobilized globally was US $391, and despite agriculture's vulnerability to climate change, only US $6–8 billion was committed to livestock, fisheries, and crops. Ironically, the total financing demand for smallholder farmers in Latin America, Asia, and Sub-Saharan Africa was estimated at $210 billion. Consequently, agriculture in developing countries has a challenge of access to sufficient and adequate finance due to high and perceived risks, low margins for financiers, and profitability. As a result, financiers limit their exposure, raise the interest rates, tighten the lending requirements, shorten lending durations, and others opt for other economic sectors with stable returns (World Bank 2016). Among the factors contributing to the funding gap are imbalanced risk-reward profiles, limited capacity to identify financial needs for adaptation, and insufficient evidence bases to identify suitable climate-smart practices and potential. Therefore, there is need to hypothesis that *there is a substantial climate-smart agriculture investment potential in African countries.*

Climate-Smart Agriculture Opportunities and Impeding Challenges in Sub-Saharan Africa

In June 2014, leaders from African Union member states endorsed the adoption of CSA in the New Partnership for Africa's Development (NEPAD). Further, the summit crafted the African Climate-Smart Agriculture Alliance whose aim was to partner with regional economic communities and nongovernmental organizations in enhancing NEPAD planning and coordination to impact on 25 million farm households by the year 2025. Progressively, ECOWAS (2015) and Zougmoré et al. (2015) note that Economic Community of West African States (ECOWAS) initiated the West Africa CSA Alliance to imbed climate-smart agriculture within the programs of ECOWAS Agricultural Policy (ECOWAP)/Comprehensive Africa Agricultural Development Program (CAADP). Respective heads of states that are signatory to NEPAD agreed to a collaboration between NEPAD Planning and Coordinating Agency (NPCA) and the nongovernmental organizations aimed at boosting agricultural productivity by boldening climate change adaptive capacity at the grassroots level. According to the African Union, the ensuing partnership was to avail technical aid to AU members to enhance CSA implementation. Similarly, the African Development Bank (ADB) together with partners were to support African countries on investing in CSA. Using FAO guidelines, several African countries have identified specific agriculture investment needs for the upscaling of CSA implementation (FAO 2012). More so, they have revised their National Agriculture Investment Plans.

On the analysis of the National Adaptation Plans of Action (NAPA) among the 47 least developed countries, about half (22) of the countries explicitly recognized the needed role from private sector (Pauw and Pegels 2013). According to the study, some of the countries broadly identified areas of engagement for the private sector. The countries view the private sector as a partner in the adaptation of sustainable sources of energy – specifically transition from wood and charcoal into solar and wind, agricultural practices, and water management. However, only one country (Mali) recognized the cofinancing role of the private sector (Pauw and Pegels 2013), showing low levels of awareness of the role of the private sector in climate adaptation. Alternatively, the failure to recognize the private sector in the NPAs may be intentional delusion to facilitate the scaling up of public funding. Altogether, 90% of the NPA recognized inadequate finance resources as a potential barrier to climate adaptation, and at the same time, only about 10% presented lack of private sector engagement as a barrier (Pauw and Pegels 2013).

Reportedly, national organizations have rapidly embraced CSA implementation. However, CSA is at its infancy due to a myriad of problems. Specifically, Barnard et al. (2015) present limited access to credit and finance as a major obstacle towards the adoption of CSA practices as they hinder access to farm tools and inputs. Further, Milder et al. (2011) argue initial investment into CSA is prohibitive especially for small farmers that according to Branca et al. (2012) constitute the largest share of agriculture investment in Africa. Mhlanga et al. (2010) reported that investment in agriculture by banks in Africa is barely 10% and attracts relatively high-interest rates. However, to unlock such potential, there is a need to carefully detail the barriers that may hold back CSA development in Africa.

Partey et al. (2016) noted that there is a limited understanding of the CSA concept and framework. All across Africa, farming practices and systems differ creating uncertainties into what technologies or activities constitute CSA. As the advocacy for CSA grows, essential stakeholders such as financial institutions fail to recognize their role in influencing the smart agriculture initiative hence failing to promote the scaling up investment. Williams et al. (2015) note that initially, there were policies, strategies, plans, and programs that were formulated without being informed by the concept of CSA. This has resulted in incompatibility challenges and at times leads to policy duplication. As an observation by Williams et al. (2015), the majority of the West African countries are yet to integrate climate change adaptation into their respective country's national agriculture programs. Additionally, there is limited investment in CSA due to a narrow number of technological packages and financial products (Partey et al. 2016). A factor that can be attributed to limited economic documentation of CSA implications that lead to a failed business case to attract investment (Sylla et al. 2012; Giller et al. 2009). Pauw and Pegels (2013) noted that attracting adaptation investment from the private sector may be challenging in developing countries due to constrained business environment, underdeveloped private sectors and lack of experience with adaptation engagement among the private sector. To help in the risk analysis necessary for private investment decision-making, there is need to hypothesize that there are *major challenges that hinder private sector investment in climate-smart agriculture in Africa.*

Countries Selection

This section describes the process of determining the country of focus for the assessment of the CSA financial potential as well as the barriers to CSA financing in Sub-Saharan Africa. The work carried out was conducted in 14 countries: 4 from East, West, and Southern Africa and an additional 2 countries from Central Africa. The countries are about 30% representative of the four different agroecological regions in Africa. Table 1, depicts the number of countries in each region and the number of those shortlisted.

Table 1 Number of shortlisted countries from each geographical region in Africa

S. No.	Sub-Saharan African region	Total number of countries	Number of countries shortlisted for climate finance study
1	Central Africa	7	2
2	East Africa	13	4
3	Southern Africa	14	4
4	West Africa	15	4

Sampling Selection Method

The shortlisted countries were based on five key indicators related to climate change. First, as the study relates to unlocking private capital, the *foreign direct investment* (FDI) inflows into each country was factored in. Secondly, a consideration was given to the *climate risk score* to enable the inclusion of the most vulnerable countries in detailed research. Thirdly, desktop research was undertaken to identify the *climate finance requirements* for each of the countries. Fourthly, it was a consideration of the *ease of doing business* to provide key insight into government initiatives. Lastly, the *GDP and its growth curve* were put into consideration to determine the demand for each country. In each indicator, countries were ranked from the highest to the lowest as shown in Table 2.

The data for each indicator was collected from credible sources such as the World Bank and the International Finance Corporation. The data on climate risk score was retrieved from the Global Climate Risk Index score released by Germanwatch. Nationally Determined Contributions that were submitted by each country as per the Paris Agreement were reviewed to determine the climate finance requirement. Data from the Germanwatch that monitors the impacts of weather-related loss events were used to develop the country ranks for climate risk index. Climate Risk Index data for 2017 was used as it was the most recent.

Situational Analysis of Priority Countries

After the indicator-based ranking, comprehensive desk research was carried out on climate vulnerabilities, climate change scenarios, national priorities, and policies related to climate change adaptation. Subsequently, a review of Nationally Determined Contributions and Sustainable Development Goals (SDGs) of the selected countries was conducted to identify climate adaptation investment potential.

Estimating Climate Investment Potential

To estimate the investment potential for climate-smart agriculture up to 2030, there was detailed desk research of documents like the National Adaptation Plan Actions, Climate-Smart Agriculture – country factsheets, Economic Cost of Adaptation,

Table 2 Ranking of countries based on the key indicators

Region/parameter	GDP (current USD Billion)	FDI inflow (USD Million)	Climate risk score	Climate finance requirement	Ease of doing business	GDP growth rate (%)
East Africa	1. Sudan 2. Ethiopia 3. Kenya 4. Tanzania	1. Ethiopia 2. Tanzania 3. Sudan 4. Uganda	1. Somalia 2. Kenya 3. Ethiopia 4. Sudan	1. Ethiopia 2. Tanzania 3. Kenya 4. Rwanda	1. Rwanda 2. Kenya 3. Seychelles 4. Uganda	1. Ethiopia 2. Tanzania 3. Rwanda 4. Seychelles
West Africa	1. Nigeria 2. Ghana 3. Cote d'Ivoire 4. Senegal 5. Mali	1. SierraLeone Nigeria 2. Ghana 3. Cote d'Ivoire 4. Guinea	1. Sierra Leone 2. Niger 3. Nigeria 4. Cote d'Ivoire 5. Ghana	1. Nigeria 2. Mali 3. Ghana 4. Senegal 5. Cote d'Ivoire	1. Ghana 2. Cape Verde 3. Mali	1. Guinea 2. Ghana 3. Cote d'Ivoire 4. Senegal Burkina Faso
Central Africa	1. DR Congo 2. Cameroon 3. Gabon	1. Gabon 2. DR Congo	1. DR Congo 2. Cameroon	1. DR Congo 2. Chad	1. Gabon 2. Cameroon 3. DR Congo	1. Central African Republic 2. DR Congo 3. Cameroon
Southern Africa	1. South Africa 2. Angola 3. Zambia 4. Zimbabwe	1. Mozambique 2. South Africa 3. Zambia 4. Namibia	1. Madagascar 2. South Africa 3. Mozambique 4. Malawi	1. South Africa 2. Zambia 3. Madagascar 4. Namibia	1. Mauritius 2. Botswana 3. South Africa 4. Zambia	1. Zimbabwe 2. Madagascar 3. Malawi 4. Sao Tome and Principe

NDCs, and other strategies, plans, and programs on the focus countries. More so, the approach for estimating CSA investment potential was with a consultation with a wide range of stakeholders to assess the status of climate finance sources and programs.

Experts were drawn from relevant government Ministries, stakeholders in the CSA sector, CSA technology providers, think tanks, civil society organizations (CSOs), Climate Bonds Initiative, and organizations like Africa Renewable Energy Initiative and other policy research institutions to take part in semi-structured face to face interviews. Further, national consultative and validation workshops were conducted with private and public sector players such as the UNFCCC, WB, AfDB, IFC, and other donors. To ensure a bottom-up approach, market players – early-stage, mid-stage, and matured companies – were consulted in developing priority actions for the implementation of CSA technologies. In every stakeholder consultation, a checklist was developed against which information was collected. The information collected was both qualitative and quantitative. To triangulate and complement the empirical findings, the results were further discussed with limited expert stakeholders to assess their opinions and thoughts.

CSA Financial Potential and Barriers Associated with CSA Financing

Financing Potential for Climate-Smart Agriculture in Sub-Saharan Africa

To assess climate smart potential, many adoption studies generally rely on the agricultural practices and opportunities that can be utilized by the private sector (Tesfaye et al. 2017; Pauw and Pegels 2013; Zougmoré et al. 2018; Atteridge and Dzebo 2015; Intellecap 2010; Pauw 2014; Pauw et al. 2015). The evidence generated is qualitative that is rather weak failing to constitute a strong business case to complement the adaptation finance gap in the context of developing countries. It is important to note that the failure to have an argument based on quantitative potential in pursuing private sector engagement in climate-smart agriculture contributes to the adaptation paradox. It is true there are insightful estimates on the business potential of climate-smart agriculture but that is mostly within high level and political contexts. However, agricultural vulnerability is essentially within the local contexts. To engage the local private sector and institutions in implementing the adaptation needs, there is an absolute urgency to create awareness on the underlying climate-smart agriculture potential, investment trends, and agricultural practices with the maximum returns.

Table 3 presents quantified climate investment potential among 14 countries in SSA. It can be observed that Ethiopia has the greatest climate-smart agriculture investment potential of USD 26.4 million. It is followed by Nigeria, Kenya, Madagascar, and Ghana at 17.0, 8.9, 8.4, and 5.5 million USD, respectively. The rest of the countries have a CSA investment potential between the range of 0.3 and 2 million

Table 3 Climate-smart agriculture investment potential

S. No.	Country	Climate-smart agriculture finance potential (USD millions)
1	Ethiopia	26, 400
2	Nigeria	17, 028
3	Kenya	8,910
4	Madagascar	8,360
5	Ghana	5,510
6	Rwanda	2,200
7	Senegal	2,092
8	Cameroon	1,800
9	Mozambique	1,760
10	Ivory Coast	1,656
11	Tanzania	1,500
12	Congo	1,563
13	Zambia	392
14	South Africa	NA
Total		**79,171**

up to the year 2030. In the views of the stakeholders, the cumulative investment potential of CSA is about 40%. Specifically, the private sector can tap into addressing climate change vulnerabilities that are tied to agriculture and water creating a win-win scenario for both the investors and farmers. The figures in Table 3 support the hypothesis that the CSA investment potential is quantifiable and varies across various countries in Africa. According to Quantum that ranks African countries based on Investment Index based on: economic growth, risk factor, business environment, demographic, social capital, and liquidity factor, South Africa, Kenya, and Ethiopia emerged among the top ten (Quantum Global 2018). Essentially, the private sector can single out these three countries on climate-smart sectors.

Climate financing comes from various sources, multilateral and bilateral, public and private, and possibly alternative sources such as remittances (Bendandi and Pauw 2016). According to the OECD (2018)), public climate finance from developed to developing countries in 2017 was at USD 56.7 billion that was a 17% increase from the previous year. Public finance can be used to unlock additional climate funding especially from the private sources that would generally increase the domestic revenue base through proportionate increase of agricultural finance. Despite the continued flow of public financing into developing countries to promote climate adaptation, its documentation as climate-smart agricultural potential for private sector exploration remains unclear.

Table 4 shows that the highest CSA investment is evenly spread among the top five highest receivers. Zambia has the highest investment at 29.4 followed by Madagascar with 28.1, Tanzania 23.4, Nigeria 19.8, and Rwanda 17.31. However, it should be noted that the inflow of multilateral funds in form of adaptation fund supply is 75% grant, 20% concessional loan, and 5% equity. Consequently,

Table 4 Investment trends in climate-smart agriculture in the shortlisted countries

S. No.	Country	Contributions to climate-smart agriculture per year in USD millions
1.	Zambia	29.40
2.	Madagascar	28.06
3.	Tanzania	23.42
4.	Nigeria	19.78
5.	Rwanda	17.31
6.	Ethiopia	17.26
7.	Mozambique	15.77
8.	Senegal	14.96
9.	Cote D'Ivore	13.32
10.	Cameroon	9.67
11.	South Africa	7.99
12	Ghana	7.06
13	Kenya	5.57
14	Congo	4.26
Total		**213.83**

classifying countries according to those with the highest grant inflows that are leaned to agriculture and water sectors, we have Tanzania, Zambia, Ethiopia, Madagascar, and Mozambique.

On average, there is a 98% funding gap in climate-smart agriculture. Out of which, 15–20% can be met by multilateral funds and investments from local governments, financial institutions, and private investors. Arguably, Sub-Saharan Africa will be the global destination for climate financing.

Table 5 identifies some key potential opportunities that could be explored by the private sector across Sub-Saharan Africa. In general, there are investment opportunities in integrated pest and disease control, soil fertility and water management, adoption of new agriculture technologies and practices in addition to farm diversification.

Barriers Hindering the Private Sector from Investing in CSA in Africa

According to the World Bank (2016) observations, investment alone will not be effective in promoting sustainable agriculture. The investments will be rendered ineffective by other existing barriers that are important to untangle. Neglecting uncertainties and failing to factor in nonfinancial and financial-related barriers while making financial decisions may result in wrong investment models that have detrimental effects on both the investor and farmers. Among the many difficulties experienced in trying to close in the financing gap, there is need to reflect on three of the most common barriers: financial, policy and regulatory, government and institutional barriers. Collectively, these barriers directly or indirectly result to income and liquidity variability mostly among the majority of the agriculture sector players – smallholder farmers.

Table 5 CSA implementation measures with the maximum potential for investment by the private sector

S. No.	Country	Climate-smart agriculture interventions with the maximum potential to attract private investment
1	Ethiopia	(a) Periodical application of biofertilizers (b) The precise application of fertilizer
2	Nigeria	(a) Agriculture-based research and development
3	Kenya	(a) Legume-based feeds for dairy cows (b) Organic manure composting and distribution (c) Crop rotation techniques
4	Madagascar	(a) Application of multi-hazard early warning systems and pest control (b) Integrated water resources management specifically in arid areas (c) Large-scale adoption of resilient agriculture
5	Ghana	(a) Agronomic-based support in soil and water conservation techniques (b) Enhancing agricultural productivity (c) Widespread better use of quality fertilizer among the smallholder farmers (d) Promoting agricultural diversification to boost income generation (e) Foster adoption of agriculture-based technologies in water management and small-scale irrigation
6	Rwanda	(a) Soil management in wetlands (b) Multiple mechanisms in pest and disease control (c) Adoption of green manure including crop biomass
7	Senegal	(a) Adoption of sustainable land management technologies (b) Enhancing the adoption of agriculture insurance policies (c) The wide reach of climate-based information (d) Trigger a market base for crop and forest products
8	Cameroon	N/A
9	Mozambique	(a) Adoption of drought-resistant crop varieties (b) Use of integrated pest control and organic manure (c) Management of crop-based biomass (d) Sustainable water management (e) Diversification of sources of livelihoods
10	Cote D'Ivore	(a) Improvement in agricultural production technologies (b) Introduction of agricultural produce storage facilities (c) Popularizing climate-resilient crop varieties
11	Tanzania	(a) Management of soil fertility and extension of agriculture services (b) Introduction of in situ water harvesting techniques and agriculture-based insurance policies (c) Adoption of high yields drought-resistant seed varieties and crop diversification (d) Use of inter alia CSA and widespread knowledge
12	Congo	N/A
13	Zambia	(a) Widespread adoption of drought-resistant crops and agroforestry. (b) Increased biomass capacity. (c) Encouraging fire management and adoption of integrated pest and disease control.
14	South Africa	(a) Adoption of conservation agriculture and better cropping practices. (b) Diversification of farm activities. (c) Livestock and pasture management .

Evidence by Africa Climate Week shows that over 65% of African countries have started their implementation of the Nationally Determined Contributions (Africa Climate Week 2019). Moreover, 80% of the surveyed firms have attained substantial mileage in the adoption and implementation of climate change adaptation measures. However, the survey also established that more than half of African countries face problems in mobilizing both national and international funds. Further on, the Africa Climate Week study found out that over 75% of the surveyed countries did not have an efficient financing strategy with an additional 67% lacking agriculture-based financial instruments. Conclusively, despite the investment potential associated with CSA in Sub-Saharan Africa, it is worthwhile to note that access to climate finance at scale presents a major setback. Divulging more information on financial factors that have large uncertainty along with other intertwining obstacles will be of high value for enhancing investment decisions and policy advocacy. Some of the challenges facing the continent when it comes to CSA financing includes:

(i) Overlapping policies on climate change that are weakly enforced.
(ii) Inadequate and unstructured provision for climate funding in the respective country's national budgets.
(iii) Insufficiency in terms of government capacity to satisfy the required standards and procedures needed in developing viable projects and bureaucratic funding processes.
(iv) Inadequate knowledge and awareness on the sources of climate finances among the stakeholders in addition to constrained private sector engagement.
(v) Lack of appreciation that climate change is both a developmental and environmental concern leading to a silo approach that impairs financing and problem-solving.

Looking more closely at the CSA barriers, most of the stakeholders agreed that financial-related barriers were the greatest hindrance towards unlocking the potential in climate-smart agriculture by the private sector. Secondly, about 80% of the stakeholders interviewed expressed that policy and regulatory setbacks were holding back the private sector from being involved in undertaking climate change interventions in Africa. Additionally, stakeholders highlighted that economic-, infrastructure-, and institutional-related constraints prevented the private sector interest in CSA. It was important to disaggregate the various financial, regulatory, and governance barriers.

Financing products and instruments for climate-smart projects financing from the local commercial banks do not only have high-interest rates and collateral pledges but also short lending tenures. Lending interest rates for the local banks across Africa is between 18% and 20% and in most cases require 100% collateral for one to acquire an agricultural loan. The local commercial banks view climate-smart projects as highly risky due to their limited experience in the newly emerged sector. Arguably, the inadequate data on risk-profile data for climate-smart projects contribute to the financier's views. Also, the target short-term payback period of between 1 and 3 years set for climate-smart projects does not fit with the loan tenors.

Unlike countries such as Bangladesh that experienced a large uptake of climate-smart approaches due to a huge number of microfinance institutions, in SSA, the microlending infrastructure is poorly developed. Microfinancing in the majority of the African countries is still at its infancy, and product sales targeting climate-smart agriculture is virtually nonexistent.

There are conspicuously limited national funds that have been mobilized and distributed at low costs to the private sector. National funds aimed at financing climate-smart agriculture could be of great help in invoking private sector participation with the high costs attracted by commercial bank alternations. However, in the majority of the African countries, national funds for smart agriculture are inactive or are lacking.

Under the current situation, CSA financing in Sub-Saharan African is based on donor funding which is mostly prohibitive due to high mainstreaming and upscaling costs. The import and export of capital in SSA countries are both bureaucratic-lengthy and costly. Climate-smart entrepreneurs and start-ups that are the engine behind innovation and efficient use of resources lack capital. Much of the funding into early-stage business models and start-ups is through private equity, venture capital, or angel investor community that lack the pool of resources necessary to satisfy all sectors. Innovators end up competing against each other dwindling each other's chances of survival. Measures such as promoting blended finance, introducing guarantee funds, encouraging fiscal incentives, establishing accessible local climate funds, and developing friendly investment policies will be key in overcoming the financial barriers and stimulating investor interest.

Key players in smart agriculture need policies that recognize and support the implementation of CSA practices. Investor-based services in smart agriculture like risk insurance and safety nets need considerable policy support. However, in the majority of the SSA countries, several CSA policy loopholes impair the actualization of the action plans. There is a problem with CSA coordination and mainstreaming into the general public. Therefore, the expenditure and planning systems are blurred both at the local, national, and regional levels. It will be critical to strengthening existing synergies to enhance food security programs. The absence of effective policies and regulations discourages lending and creates obstacles to the flow of cash to agriculture. For instance, lack of appreciation by the government of the agriculture economic and market potential lead to ignored subsidies that discourage the development of private sector-based solutions into enhancing climate adaptation.

Financial institutions have limited knowledge on climate-smart projects thereby hindering their investment interest. Both banks and microfinance lack the understanding of the operations of agriculture smart and continuously demonstrate an experience deficit. In such instances, the financial institutions need training on agriculture smart technologies to tailor-make suitable business models and financing options. Circulation of information will be necessary to get rid of the high-risk perception by the lending institutions. Key stakeholders, among them government ministries, nongovernmental organizations, and farmers cooperatives have a knowledge gap on CSA limiting its uptake. It is important for the government to be aware of the agriculture potential in order to promote the development of other sectors that are not necessarily related to agriculture but are indirectly vital for its development, such as the infrastructure and communication networks.

Conclusion

Modern day agriculture has to meet increased food demand due to burgeoning population and evolving diets amidst dwindling crop yield, diminishing natural resources, and constrained biodiversity. Worse is that the continuously warming climate is greatly undermining agricultural productivity with disastrous effects on land, crops, and farmers. Fortunately, adoption of climate-smart agriculture can be a significant part of solving the environmental crisis of climate change. Through sustainable agriculture, there is the capacity to increase agricultural productivity hence increasing incomes through built and adaptive farming resilience. However, this is not possible without substantial increase in the amount of climate-smart investment that will increase the access to finance. There exist huge financial gaps in CSA investment due to the perceptions of high risks and low profitability. Robust financial investment from the private sector can greatly accelerate the adoption of climate-smart agriculture leading to societal gains of poverty reduction by supporting the global food system. Through quantifiable evidence, this chapter has practically provided a translation of the investment potential into investor “language” with the sole objective of invoking private sector interest. The work carried out as the basis of this chapter has gone a step further to identify the maximum potential areas within the smart agriculture in respective countries with a conclusion of disaggregating the sector barriers.

Sub-Saharan Africa has a substantial climate finance investment potential for the private sector. Countries need to promote low carbon development, resource use efficiency, and resilience building in their development strategies and policies. International collaborations should seek to promote regional capacity building in accessing climate finance to promote sustainable development. Multilateral and national climate financing mechanisms should be based on a country’s commitment to climate change adaptation. There is a need to strengthen the regulatory environment by creating effective policies and subsidizing the private sector investment to spur adaptation action. SSA needs to foster regional and cross-border collaborations to enhance an integrated approach towards climate change-related issues. National governments need to harness the innovative capacity by raising capital for the private sector that is driving climate investments. Channels to facilitate climate finance into cities and urban areas where there is access to a greater number of people is necessary to greatly reduce the poverty levels.

The contribution of this work is on the conceptual clarifications of the CSA investment potential for the private sector. However, it fails to distinguish the opportunities as either for the domestic or/and international private sector. Again, the chapter outlines climate-smart agriculture potential at a national level. To greatly elicit the private sector, there is need to further breakdown the potential into local contexts. More so, future research can explore the financial potential of each of the identified agricultural practices either regionally or nationally. Further, to objectively attract private investment into climate financing in developing countries, there is need to clearly define the short- and long-term investment activities that can be key for the financial institutions decision-making. The identified limitations create inadequacies in precisely defining the role of the private sector in their increasing engagement on climate finance.

National governments in Sub-Saharan Africa are supporting low carbon and climate-resilient development through local budget allocations, commitments to international programs and strategies that alone cannot achieve the sustainable development goals. They can further enhance their adaptation action through partnering with the private sector to alleviate the funding gap as a result of broadening public debt crises and increasing climate finance needs. This is by creating an enabling environment both in terms of policy, regulations, and infrastructure.

Africa–European Union Climate Change Partnership 102

Oluwole Olutola

Contents

Abstract

The need to heighten climate action momentum is a key outcome of the Climate Action Summit organized by the United Nations (UN) in September, 2019. The same concern reverberated in most of the presentations and discussions at the twenty-fifth Conference of Parties (COP 25) – the annual climate summit under the United Nations Framework Convention on Climate Change (UNFCCC). This chapter seeks to investigate the relevance of the call for more climate action in terms of what further climate priorities and strategies are required in the context of the existing climate change partnership between Africa and the European Union (EU). It relies on liberal institutionalism as its theoretical framework and data from a range of purposely selected secondary sources as reference points. Beyond arguing the case for more climate action to further strengthening the Joint Africa-EU Strategy (JAES), particularly in the area of environmental partnership, this chapter emphasizes the need to align the required further climate action with the mitigation goals of the Paris Agreement and the UN transformative initiatives on

the global climate action. It concludes with an insight into some policy recommendations, including the need for a dedicated and regional-based approach in tackling Africa's climate change beyond the conventional worldwide UNFCCC (United Nations Convention on Climate Change) framework that has failed to deliver tangible results for some time past.

Climate change · Liberal institutionalism · COP25 · Joint Africa–EU Strategy · Paris Agreement

Introduction

Addressing climate change as an existential threat to this generation (UNCC 2019a) and the future generation given its transgenerational implications is more urgent than ever. In recognizing this growing climate concern, the United Nations (UN) convened a global climate action held in New York on 23 September 2019. The primary objective was aimed at mobilizing wide-range support for the multilateral climate change process. In the end, the summit emphasized the need to increase mitigation ambition as well as accelerate climate action involving a range of stakeholders – state and nonstate alike, including multilateral entities (UN 2019). Less than 3 months after, similar concern reverberated in most of the speeches and statements given at the twenty-fifth Conference of Parties (COP 25) – the annual climate summit under the United Nations Framework Convention on Climate Change (UNFCCC) – which took place in Madrid from 2 to 13 December 2019. Generally described as the launchpad for significantly more climate ambition, COP 25 also ended with a call for improved climate action (CarbonBrief 2019).

This separate but joint call for more climate ambition and action could not have happened at a better time, considering the mounting threats of climate change to the global system, regional and subregional entities. Besides, the call is consistent with the mitigation goals of the Paris Agreement that was decided at COP 21 in December 2015 as the first-ever universally agreed climate deal after more than two decades of unduly prolonged negotiations that characterized the previous COP meetings (Amusan and Olutola 2016). Under the Paris Agreement, state entities commit to ensure that the global average temperature is pegged to 2 °C above preindustrial levels and, if possible, further down to 1.5 °C still above preindustrial levels (UNFCCC 2015). However, the collective efforts to meet the set mitigation target are currently insufficient (Boyd et al. 2015; Schleussner et al. 2016). Recent finding shows that there must be a cut in carbon emissions to about 45% and net zero by 2030 and 2050, respectively, to save this century from the irreversible and catastrophic impacts of climate change (IPCC 2018).

From the outcomes of the aforementioned summits and the IPCC carbon cut projection, it is deduced that both the past and current efforts – at all levels – to combat climate change remain inadequate and far less than what should be the case. The significant attention drawn to the mounting dangers of climate change and the multistakeholder approach in dealing with the phenomenon as a common enemy and global emergency in particular points to establish the summits' acknowledgment of multilateral entities as important rallying points for the desired enhanced climate action.

This chapter presents the case of Africa and the European Union (EU) partnership focusing on climate change as one of the priorities in the relationship between the two continental partners. It seeks to examine the relevance or otherwise of the call for more climate ambition and action in this particular case, and what further climate priorities and strategies, if any, are required. The chapter is structured into five sections as follows: section one contains the above introduction; section two systematically examines the key constructs of liberal institutionalism as a theoretical basis for this study; section three gives an overview of the UN climate action summit and COP 25 in the context of the Paris Agreement; section four appraises Africa–EU climate change partnership in light of the call for more climate action; and section five closes with a conclusion including an insight into key policy recommendations.

Liberal Institutionalism

Liberal institutionalism represents one of the theoretical strands of the liberal school of thought. Generally, liberalism introduced new paradigm of debates to the body of international relations theories, as it underscores the relevance of nonmilitary (security) approach to handling issues and matters of common priority within the international system. Liberalists' main concern is to construct a model of international relations with capacity to mitigate the unchecked use of military force as a foreign policy instrument by state actors.

For most liberal institutionalists, cooperation between state and nonstate actors remains the most important and mutually beneficial ordering feature of the international system (Keohane 1984; Keohane and Martin 1995). This interstate cooperation is facilitated through international institutions and regimes, defined as a set of implicit or explicit principles, norms, rules, and decision-making procedures around which actors' expectations converge regarding any aspect of international relations (Krasner 1983: 2). The implication is that international institutions and regimes are conceived as the primary means of limiting the power of states at both domestic and international levels, thereby mitigating anarchy in the international system (Burchill 2005: 65).

Besides, liberal institutionalism places emphasis on international institutions which have the ability to help overcome selfish state behavior by bringing them together in a cooperative manner in pursuit of shared foreign policy objectives otherwise unattainable in isolation. In other words, international institutions serve as entities for mobilization networks, within which transgovernmental policy coordination and coalition building could take place (Keohane and Nye 1987: 738). In addition to providing multilateral platforms through which states deal with collective action problems that threaten stable patterns of cooperation, international institutions also perform such roles as coordination and monitoring which together make them to become "valuable foundation" for international cooperation (Martin 2007: 111).

Another key assumption of liberal institutionalism is the existence of multiple channels of contact through which states and societies are interconnected (Keohane and Nye 1987: 731). This brings to focus the term complex interdependence and the argument that the ranking of global issues as high and low politics is uncalled for, particularly in a world of multiple issues imperfectly linked and characterized by transnational and transgovernmental coalitions (Grieco 1988: 490).

However, liberal institutionalists agree that interstate cooperation is constrained by cheating and noncompliance with international agreements given the self-enforcing and anarchic nature of the international system. The situation is further worsened by the lack of guarantee to ensure that state individual tendencies to maximize the gains of cooperation at the expense of other participating actors are regulated in such a way that benefits are shared equally.

These shortcomings notwithstanding, liberal institutionalists strongly believe that cooperation between states is still possible even though it is something that happens gradually. In their analysis, cooperation would first be achieved in technical areas where it was mutually convenient and, if successful, could be extended to other functional areas of mutual benefits (Burchill 2005: 64). Indeed, the emphasis on international institutions as an important rallying point for interstate cooperation and, also, a potentially effective mechanism for containing global emergencies brings to relevance the focus on Africa and the EU.

While the Africa–EU climate change partnership is not a standalone multilateral institution in itself, it represents a key element and one of the important thematic priorities under the Joint Africa–European Union Strategy (JAES) adopted at the second EU–Africa summit in Lisbon in 2007. Section four of this chapter provides more explanations on the JAES. However, it is important to stress that Africa and Europe as two key multilateral partners depend on the instrumentality of the African Union and the EU to provide the needed institutional framework for the implementation of JAES and, more specifically, the partnership on climate change and other related climate activities being discussed in this chapter.

Paris Agreement, UN Climate Action Summit, and COP 25

As a special creation of the UN, the UNFCCC is responsible for the global negotiations in response to climate change. Since its establishment in 1992, the global climate change process under the UNFCCC framework has experienced a back-and-forth approach to climate negotiations and, so, action. But after nearly two and half decades of interrupted negotiations, the Paris Agreement was agreed as a globally accepted climate action plan in 2015. By the agreement, state entities commit to ensure that the global average temperature is pegged to 2 °C above preindustrial levels and, if possible, to 1.5 °C above preindustrial levels (UNFCCC 2015).

To attain this long-term mitigation ambition, each party to the UNFCCC is under an obligation to develop and commit to a nationally determined contribution (NDC), which should be communicated to the UNFCCC secretariat and progressively maintained. The provisions of the agreement include a ratchet-up mechanism to periodically review and update the NDCs every 5 years effectively from 2018 upward. While the unanimity exists in terms of perception of NDCs as a collective response towards achieving the Paris climate goals, the common understanding of what exactly constitute the NDCs is still lacking among the UNFCCC parties. Besides, efforts to ensure its transparency, particularly in the context of national climate framework and objectives, are still quite challenging.

Besides, the current emission reduction pledges captured in the NDCs for the period up until 2030 though represent progress compared with "business as usual," but insufficient to secure the achievement of the mitigation goal set by the Paris Agreement (Boyd et al. 2015; Schleussner et al. 2016; UN 2019). Nevertheless, it forms the basis of any serious global struggle against climate change, especially on the part of state actors. It also points to establish that collective efforts beyond the UNFCCC are, indeed, needed to effectively address climate change. Stabilizing the global climate at safe levels requires wider international cooperation to complement the global climate change process within the UNFCCC (Moncel and van Asselt 2012).

Unfortunately, not so much of the mitigation ambition proposed under the Paris Agreement has been achieved. The full implementation of the Paris Agreement is yet to be actualized, as efforts are still ongoing at the level of the annual Conference of Parties to finalize its operational guidelines. The latest in the series was COP25 held in 2019 as the Launchpad for significantly more climate ambition. It is important to note that the Trump-led US in mid-2017 formally disclosed the country's intention to withdraw from further participating in the Paris Agreement (Lawrence and Wong 2017). While there is no consensus in research yet as to whether the US withdrawal represents an opportunity or a setback for the Paris Agreement in particular and the global climate action in general, some scholars have raised concerns around the potential damage that could result from the US nonparticipation in raising finance to support global climate action (Olutola 2020; Urpelainen and van de Graaf 2018).

Yet, the worsening impacts of climate variation are becoming increasingly evident in some parts of the world. Recent cases include the Hurricane Dorian that struck the Bahamas and Cyclone Idai landfall in Mozambique with their attendant unprecedented catastrophes. Obviously worried by this growing severity of climate change impacts, the UN as a universal body gathered together wide-ranging stakeholders – state and nonstate – in what was dubbed the global climate action summit held in December 2019. The intention was to provide support for the Paris Agreement and the UN 2030 Agenda for sustainable development. In particular, it offered state participants a unique opportunity to discuss how best to enhance their respective NDCs by 2020 (short-term) in keeping faith with 2030 (mid-term) mitigation goal of 45% emission reduction as well as the 2050 (long-term) mitigation objective of net zero relative to GHG emissions.

The summit focused on nine key areas where urgent climate action is required. These include energy transition; climate finance and carbon pricing; resilience and adaptation; nature-based solutions; mitigation strategy; among others (UN 2019: 3). Buried under 12 themes, the summit's climate action objectives are expected to be achieved through transformative initiatives for which stakeholders would be held responsible. These transformative initiatives include: the need for improved climate finance as a key element for the transition to net-zero emissions and climate resilient economies; pledges to decarbonize investment portfolios and systematically include environmental impacts in investment decision-making; setting limits for the use of coal, or phase it out altogether, including the development of a collective support system to help provide developing countries with the option of exiting coal; plans to eliminate deforestation, preserving biodiversity, and restoration of natural ecosystems particularly through planting of trees; integration of climate risks and resilience initiatives in decision-making systems and national development frameworks across the continent, including climate resilient development pathways for least developed countries (LCDs); and provision of insurance for the most vulnerable and support to prevent climate-related disasters, among others. More importantly, the summit succeeded in establishing an all-encompassing steering committee to provide strategic guidance and oversight of its planned action and activities as well as two advisory groups – science and ambition – to provide technical expertise.

Aside from stressing the need for the urgency of climate action in the identified areas, the summit called attention to the strategic importance of renewed leadership at all levels and across the board including collaboration between relevant stakeholders. Its multistakeholder transformative initiatives with commitments from 70 and 75 countries – mostly small and developing countries responsible for far below 15% of aggregate carbon emissions worldwide – to work towards more aggressive NDCs and net-zero emissions by 2020 and 2050 respectively, are nevertheless remarkable. Granted that the agreed initiatives are no doubt consistent with the Paris mitigation objectives, it is of concern that the summit could not secure concrete and immediate mitigation pledges from the world's leading GHG emitters – mostly the G20 countries (including the full EU) which together produce close to 30 kilotons of CO2 annually, as of 2015, thereby responsible for about 81% of all global carbon emissions (Globalist 2018).

Unfortunately, the COP25 – which was to provide a critical platform for the operationalization of the Paris Agreement with the year 2020 set as the deadline – fell short of expectations. Despite the momentum ignited by the UN climate action summit, the once in a year climate meeting could not achieve much. The climate ambition aglliance (UNCC 2019b) presented during the meeting is chiefly a recapitulation of the multistakeholder pledges made at the UN climate action summit. No consensus was reached regarding the planned increase in mitigation commitments, while virtually all other outstanding issues emanating from the Paris Agreement were also left unresolved. These issues range from failure to secure: increased NDCs pledges, especially from the world's biggest emitters; the final decision on the rulebook, regarded as the operating manual for the implementation of the Paris climate deal; specific operating guidelines for loss and damage; and new and enhanced climate finance goals, among others.

This lack of progress is worrisome and, certainly, not a good complementarity of the UN transformative initiatives concerning the global climate action. Besides, it exacerbates the concern raised in the emissions gap report that the existing NDCs, even if met, would not be enough to deliver the Paris mitigation goal. Based on the report, emissions need to reduce to 2.7% each year from 2020 to 2030 and 7.6% each year on the average for the 2 °C and the 1.5 °C goals, respectively, to meet the Paris Agreement's mitigation target (UNEP 2019: 26). Hence, the urge for increased ambition pledges is critical to closing the gap between the emission targets captured in the NDCs currently and the mitigation goal set by the Paris Agreement.

Just as COP25 was winding up, the EU signaled its resolve to achieve net-zero emissions by 2050. Encapsulated in what is known as the European Green Deal, the EU seeks to commit about 25% of its long-term budget to climate-related objectives. As a deliberate strategy to boost the EU's NDC pledge for 2030, the deal contains a proposal to reduce the bloc's carbon emissions from its current target of 40% to a higher target of at least 50% and towards 55% compared with 1990 levels (Claeys et al. 2019; EC 2019). If this deal is actualized, coupled with the fact that other key emitters – most especially the USA – are showing no indication to seriously commit to any increased mitigation plan, the EU would have once again reestablished its pivotal role in providing leadership to the global action against climate change. This self-assumed responsibility brings to focus the climate change partnership between the EU and Africa (another continent that is at the center of any discussions on the global climate action because of its high exposure to climate change impacts and little or no capacity in terms of adaptation).

Africa–EU Climate Change Partnership: A Revisit

The partnership between Africa and the EU was launched in 2000 – two decades ago – at the maiden edition of the Africa–EU meeting in Cairo. Seven years after, the two partners at the second edition in Lisbon adopted a Joint Africa–EU Strategy (JAES). The JAES represents the guiding instrument for the overarching long-term and political framework of the collaboration between the two continental entities (EU 2007). It outlines the basic principles (ownership, partnership, and solidarity) and general objectives of the partnership. These include a resolution on the part of the two partners to formalize the strategic partnership by moving away from the usual donor and recipient – give and take – approach; treat Africa as one entity; enhance their partnership at all levels on the basis of jointly identified mutual and complementary interests; and take their multilateral engagement to a new strategic level with reinforced policy dialogues and action plans, among other objectives (Bach 2010; EU 2013–2019).

Interestingly, climate change (and the environment) made the list as one of the thematic priorities of common concern in the Africa–EU partnership. Others include peace and insecurity; democratic governance and human rights; regional economic integration, trade, and infrastructure; millennium development goals; energy; mitigation, mobility, and employment; and science, information society, and space. Africa–EU climate change partnership can be viewed from at least two perspectives: the collaborative efforts of the two partners towards the global climate change process within the UNFCCC and the willingness on the part of the two partners to work together to combat climate change as a common enemy. Even though the vision of a joint agenda/position on climate change could not be achieved as envisaged partly due to lack of clarity on their common interests and internal divisions, the JAES's climate change partnership perhaps succeeded in building a common understanding of various climate-related issues and of their respective positions in the UNFCCC multilateral negotiations (Tondel et al. 2015).

The partnership has produced some level of significant progress over the years, as manifested in the launch of several climate-linked initiatives and programs. These include TerrAfrica, the Great Green Wall for the Sahara and the Sahel Initiative (GGWSSI), and Climate for Development in Africa (ClimDev-Africa). While TerrAfrica was created in 2005 as a platform for better coordination of efforts geared towards the upscaling of finance and mainstreaming of effective and efficient country-driven sustainable land and water management (SLWM) across the continent (NEPAD 2019), the GGWSSI was launched in 2007 as a "bulwark against the encroaching desert" (Bilski 2018), thereby strengthening climate resilience in Africa. ClimDev-Africa was designed as a tripartite arrangement of the United Nations Economic Commission for Africa (UNECA), the African Union Commission (AUC), and the African Development Bank (AfDB) through ClimDev Special Fund in 2010. Essentially, it aims to provide a solid foundation for an appropriate regional climate change response (UNECA 2014).

In particular, TerrAfrica and GGWSSI contributed significantly to strengthening the collaboration between the two partners, especially in the areas of sustainable land management and fight against desert encroachment in sub-Saharan Africa, respectively. Similarly, the EU financial intervention of €8 million through the ClimDev-Africa initiative was instrumental to the establishment of the African Climate Policy Center (ACPC) in Addis Ababa in 2012 and, by extension, the development of climate-based knowledge in support of policy-making in Africa (EU 2014: 24–25). By 2013, a €28 million contribution to ClimDev-Africa was launched to provide support (financial and technical) to the African Union (AU) – as the continent's collective representative – and many of its member states to enhance their capacities to make climate-sensitive policies. In 2015, the EU introduced another funding package amounting to €80 million to build disaster resilience in sub-Saharan Africa (EC 2015). Since the rebirth of the Organization of African Unity (OAU) as AU in 2002, Africa has received climate-related EU aid amounting to €3.7 billion (Khadiagala 2018: 440).

Many poor African countries with relatively high vulnerability to climate change (Chad, Cape Verde, Democratic Republic of Congo, Djibouti, Mali, Mauritania, Mozambique, Sudan, and Uganda, among others) have particularly benefited one way or the other from the EU global ecological charity administered through the Global Climate Change Alliance (GCCA 2018). The GCCA was created in 2007 to support climate change projects and programs in the world's most climate-vulnerable countries of which many are found in Africa. It provides technical and financial support for national, multicountry, and regional climate change projects and programs using a set of eligibility criteria (Miola et al., 2015). The GCCA is focused on five priorities, namely: mainstreaming climate change into poverty reduction and development strategies; adaptation, building on the National Adaptation Programs of Action (NAPAs) and other national plans; disaster risk reduction (DRR); reducing emissions from deforestation and forest degradation (REDD); and enhancing participation in the Global Carbon Market and Clean Development Mechanism (CDM).

Despite the progress recorded, climate change remains a challenging thematic priority for the EU–Africa partnership. For the most part, the partnership has been plagued by some issues ranging from cumbersome institutional structure; inefficient policy processes; mistrust; capacity differentials; lack of clarity on shared purpose and priorities; a deficit of political support on both sides; and the Brexit anxiety, among others. To address these issues and achieve common objectives in the important area of climate change, Africa and the EU must work more closely and commit to more climate action in line with the UN transformative initiatives.

The call for more climate action is therefore a wake-up opportunity for Africa and the EU to take deliberate action towards deepening the existing climate change collaboration between the two partners. Africa and the EU share affinities in the important aspects of their historical connections, geographical closeness, political vision, and interests, including the great potential for a common future. Up until this period, the two partners have played a pivotal role in the global fight against climate change. It is high time to consolidate their joint efforts and continue to take the lead in the global climate change struggle. One way to achieve this is by bringing the current approach in terms of climate action and strategies within the Africa–EU partnership into alignment with the agreed transformative initiatives on the global climate action. More specifically, it is high time that the Africa–EU climate change partnership complements the efforts of the UN steering committee on the global climate action, especially in providing strategic guidance and oversight of the implementation of the global transformative initiatives as they affect Africa.

In addition, Africa and the EU need to commit to a common climate change agenda and joint implementation framework that not only support the components of the UN transformative initiatives, but also consistent with the mitigation goal set by the Paris Agreement. Achieving this may face with the challenge of difference in priorities. As a marginal contributor to the global carbon emissions and, ironically, a core victim of climate change adverse impacts, Africa over the years has been consistent in its advocacy of adaptation bailout. The AU as the continent's collective representative minced no words in stating this regional climate change position in its Agenda 2063 (AUC 2015). While the EU has no doubt demonstrated support for the continent's adaptation priority, its primary focus like other developed parties to the UNFCCC is geared towards addressing mitigation in the form of emissions' reduction. This priority gap needs to be addressed.

Narratives about Africa and Europe are changing in recent years. The African continent, for instance, have demonstrated remarkable progress in some aspects such as governance and democratic accountability, human development, and sustained domestic economic growth. A case in point regarding changes in Europe is no doubt the Brexit phenomenon. There is therefore the need to adjust the EU–Africa relations in the context of these new developments. Africa–EU climate change policies in particular should be driven by common interests and objectives, with clearly defined priorities and action plans that recognize differences regarding the strengths and weaknesses of individual partners. More desirable is a balanced Africa–EU climate change relation. While it is important that financial and technical supports should be provided to African countries to enable them fulfill their climate action pledges, Africa cannot continue to depend entirely on bailout in its efforts to cope and adapt to climate change under the excuse of extreme vulnerability. A truly multilateral partnership entails collective action and shared responsibility in all aspects. With no prejudice to the fact that many African countries are relatively poor and faced with daunting challenges of sustainable development, it is time for Africa to stop paying lip service to the mantra "African solutions to African problems."

Actions in terms of climate action and strategies within the Africa–EU partnership should not only be aligned with the transformation initiatives, but also and above all, be structured around a dedicated and regional approach. This should go beyond the conventional worldwide UNFCCC (United Nations Convention on Climate Change) framework that has failed to deliver tangible results for some time past. Incidentally, climate change is one of the few areas where a continental position has been agreed. Mobilizing African solidarity and unity on any issues has never been easy given the continent's diverse national interests and agendas.

Conclusion and Policy Recommendations

Climate change continues to threaten both the present and future generations. Its growing worsening impacts in recent years have drawn remarkable global attention. One of such was the 2019 UN Climate Action Summit that drew participant from across the world and ended with a call for more global climate action, particularly on the part of state-stakeholders. Though a yearly event but in recognizing the increasing dangers of climate change and the need for accelerated global intervention, the COP 25 held in December same year (2019) concluded with a resolution calling for more climate ambition and action in line with the mitigation goal of the Paris Agreement and the UN 2030 Agenda for sustainable development.

On its part, the UN climate action summit succeeded in introducing a set of transformative initiatives for which state and nonstate stakeholders are responsible. But, it failed to secure concrete and immediate mitigation pledges from the world's top greenhouse gas (GHG) emitters. In the case of COP25, not much progress was achieved beyond the presentation of the Climate Ambition Alliance (CAA). The CAA in its presentation succeeded in merely reemphasizing the multistakeholder pledges made at the UN climate action summit. This chapter argues that the lack of complementarity between the identified two summits is not only worrisome, but also exacerbates the concern raised in the emissions gap report that the existing mitigation pledges otherwise known as NDCs, even if met, would not be enough to deliver the Paris goal. The urge for increased ambition pledges and climate action is therefore critical to closing the gap between the current assemblage of NDCs and the mitigation goal set by the Paris Agreement.

Furthermore, it is argued that though the separate but joint call for more climate ambition and action is a global question, it provides Africa and the EU in particular a fresh opportunity to deepen their existing climate change partnership. This chapter not only underscores the strategic positions and relevance of these two longstanding partners to the global fight against climate change, but it also highlights that the EU through the unveiling of the European Green Deal already set the pace for increased mitigation pledges involving world's leading emitters. It is yet to be seen though how much of the proposed mitigation objectives would be realized ultimately.

Going forward, this chapter recommends that Africa–EU climate change policies be aligned with the UN transformative initiatives on the global climate action, particularly the African components. Besides, there is the need for a more assertive and balanced Africa–EU relation, particularly in the context of climate change. Such relation should be based on common climate agendas, with clearly defined priorities and action plans including a joint implementation framework that not only support the transformative initiatives but also consistent with the mitigation goal of the Paris Agreement. Africa–EU climate change partnership should be adjusted to complement the efforts of the UN steering committee on global climate action, especially in terms of providing strategic guidance and monitoring of the implementation of the global transformative initiatives in Africa. While the EU is encouraged to continue to provide both financial and technical supports to African countries to enable them fulfill their pledges relative to the global climate action, there is need for Africa to also look inward for solutions. More focus should be directed at unveiling regional-based solutions to the climate change challenges facing the African continent beyond the UNFCCC framework.

Lastly, as the mitigation ambition proposed in the framework of the Paris Agreement is far from being achieved and that the full implementation of the Paris Agreement has yet to be concretized, because efforts are always underway at the annual COP to finalize its operational guidelines; more plausible concepts such as a truly multilateral partnership which involve collective actions and shared responsibilities in all aspects should be considered to have a good Africa–EU partnership on climate change in light of the call for more climate action.

Abstract

Female- and male-headed rural households have unequal opportunities in climate change adaptation. Efforts in climate change adaptation in regions with deeply entrenched sociocultural norms should also account for the varied gender components of climate change. The broad objective of this study is to integrate gender issues into climate change adaptation thereby distilling lessons and evidence for policymakers on how to approach the necessary transformation of gender relations in climate change interventions. The study employed focus group discussions to uncover the structural factors undermining women's adaptive capacity, thereby making them vulnerable to climate change impacts. In addition to this, in-depth interviews were also conducted. For the in-depth interviews, 27 farmers were sampled using a snowballing method, while four focus groups were carried out differently for male and female farmers. Ten extension personnel and ten representations from the ministry of agriculture were also surveyed using in-depth interviews. Results from the study showed that female farmers in the region were more vulnerable to climate change as a result of the deeply rooted cultural systems and unwarranted assumptions about women. Findings also suggested that women with high adaptive capacity were less vulnerable to climate impacts. We conclude that gender-responsive climate change adaptation is important in achieving balanced relations that will ensure climate resilience in more equitable and nonhierarchical ways.

Introduction

Climate change is a global phenomenon undermining the efforts towards achieving the Sustainable Development Goals [SDGs]. The Intergovernmental Panel on Climate Change [IPCC] described climate change as the change in global climate patterns which can be identified by variabilities in climate properties over time (IPCC 2014). Climate change has become more threatening not only to environmental quality but also to the fight against poverty, disease, and hunger. This is due to its direct and indirect impacts on agricultural production. While efforts are being made in addressing the causes of climate change through mitigation, building adaptive capacity is particularly important as it will help tackle the current and future impacts of the phenomenon (IPCC 2007). The IPCC defines adaptation as the "adjustment in natural or human systems to a new or changing environment" (IPCC 2007). In other words, climate change adaptation deals with the ability of a system to cushion possible impacts from climate change and to cope with the outcomes. The impact of climate change in the developing nations, according to Chukwuemeka et al. (2018), is mostly felt by the smallholder farmers, farmers that are highly dependent on rainwater and other climate-sensitive input and resources.

The vulnerability of these sets of farmers is expected to be even more severe in Nigeria, where majority of women folk are involved in agriculture for household consumption, yet are highly marginalized and excluded in climate decisions which directly affect them (Osuafor and Nnorom 2014). Gender relations in Nigerian agricultural sector have systematically subordinated women, limiting their access to adaptation information and supports (Uchem 2011). Chavez et al. (2011) describes gender as a social construct that portrays the distinction in roles and opportunities associated with the male and female sexes and the social relations between them. Studies on climate change adaptation by farmers in Nigeria have shown that gender relations and women exclusion in climate decisions adversely affect climate change adaptation efforts, as women contribute 60–80% of food production in the country, mostly for family consumption (Apata 2011; Tersoo 2013; Otitoju and Enete 2016). However, the underlying institutional factors behind these gender issues in Nigeria have not yet been clarified in literature. This gap in literature is what this study intends to fill. Paying attention to these relations is at the core of framing adaptation strategy that will allow farm households build resilience to the impact of climate change in agriculture (MacGregor 2010).

In Africa, literature in climate change adaptation have shown how smallholder farmers suffer high level of vulnerability due to their low adaptive capacity (Okon et al. 2010; Ume 2017). According to FAO (2019), "climate change impact first affects food systems and livelihood groups with a higher level of vulnerability." The IPCC defined climate change vulnerability as the extent to systems, such as geophysical, socioeconomic, and biological systems, which are prone to and incapable of coping with adverse climate change impacts (IPCC 2007). Otitoju and Enete (2016) further noted that among the smallholder farmers in Nigeria, the female farmers are expected to have an even higher level of vulnerability compared to their male counterparts due to their lower adaptive capacities. This, according to them, is due to socioeconomic and institutional factors that undermine their adaptation efforts. According to Eakin and Wehbe (2009), gender transformation – a reassessment of the socioeconomic and institutional factors and relations – established over time, which determines the relationships between the men and women, is therefore imperative if meaningful adaptation effort is to be achieved.

Understanding the gender dimension of climate change adaptation and the underlying socioeconomic factors influencing gender-vulnerability relations among smallholder farmers in Nigeria presents a veritable approach in moving away from the usual incremental adaptation approach to transformational adaptation response. One key importance of transforming gender relations among smallholder farmers is that it is gender that determines the control and ownership of adaptation resources. As stated in FAO (2011), "If women had the same access to productive resources as men, they could increase yields on their farms by 20–30 percent." Gender analysis among smallholder farmers in Africa is necessary for unraveling how best to mainstream gender issues into climate change adaptation plans and policies.

The impact of gender relations on farmers' level of adaptation has been extensively reported in the literature. Findings from literature suggest that these gender issues vary from location to location according to levels of socioeconomic developments (Gafura 2017). As stated in Gafura (2017), these socioeconomic and institutional factors are still unsettled issues requiring further study in order to establish a coherent scholarship in the area.

As women make up the majority of the smallholder farm labor force in Africa, the available studies on climate change adaptation among smallholder farmers in Africa such as Komba and Muchapondwa (2015) have highlighted the need for studies that will link information and evidence of the underlying determinants of gender inequality from expert knowledge and farmer's perception, in order to better understand the factors that undermine efforts in coming up with formidable and gender-balanced adaptation policies. More so, the few available studies were based solely on quantitative analysis of household surveys without any qualitative component (Enete and Amusa 2010; Chukwuemeka et al. 2018; Onyeneke et al. 2018). The implication is that since most of the underlying determinants of gender relations cannot be quantified, the results will lack the deep and contextual information needed for the appropriate policy interventions. This perhaps explains why studies on the gender dimensions of climate change adaptation among smallholder farmers in Nigeria have not been able to sufficiently identify and address the gender relations issues impeding climate change adaptation efforts in the country.

Gender and Vulnerability

The etymology and usage of the word gender show that the concept and its meanings have evolved throughout history. The historical development dates to the late Middle English, when the word was first used to mean "sex of a human being" (Nancy 1989). Recently, it has been conceptualized as a social construct that appropriates certain characteristics such as behaviors, feelings, and attitudes to the male or female individuals in a society (Jrank 2018). What this means is, by knowing a person's gender, we place her or him in a separate social class, and somehow by doing that we judge her or his actions in accordance with our expectations of that social class. According to Jrank (2018), this categorization ultimately leads to the formation of a gendered society – a society with sociocultural expectations of actions deemed appropriate and inappropriate for females and males. This conceptualization led to the emerging theoretical framings on gender roles and stereotypes.

According to Caragliu et al. (2015), gender roles are socially and culturally defined prescriptions and beliefs about the behavior and emotions of men and women. Linda (2017) noted that it is common for different societies to have a set of belief, ideology, and orientation that shapes sociocultural stereotypes among individuals within that society. Caragliu et al. (2015) remarked that it is these gender roles and stereotypes that give rise to the issue of gender identity – a personal perception of oneself which influences her or his status and relationship with other persons in the wider society. Linda (2017) argues that gender roles and stereotypes are determined by institutional factors such as rules, norms, and routines, and this consequently affect household interactions so that expectations from members of a household will be based on gender. Therefore, whereas it is traditionally acceptable for the men to have multiple streams of income, in countries like Nigeria, women, who are traditionally perceived as homemakers or housewives, due to stereotype threats, will only make do with farm produce and resources within the homes. According to Linda (2017), this stereotype threat arises as a result of the women's awareness that they are likely to be judged based on an overgeneralized societal belief about her gender roles.

Literature dealing with the influence of gender on vulnerability to climate change impacts follows three mutually exclusive criteria based on IPCC (2007) analysis. These three elements are: exposure (extent of susceptibility), sensitivity (degree of impact), and adaptive capacity (ability to adjust) to climate change impacts. The World Health Organization (2015) noted that female farmers in developing nations are more exposed to climate variabilities mostly because they make up greater percentage of the world's poor and are mostly charged with the responsibility of gathering firewood for heating and cooking, fetching water for domestic chores, and other activities directly linked to the environment. In terms of sensitivity to climate impacts, Mgbenka and Mbah (2016) noted that 80% of women in many African countries engage in agriculture and are more reliant for their means of support on natural resources that are vulnerable to climate change impacts. Expounding on this fact, Haque et al. (2012) recounted that more than 90% of the fatalities at the 1991 cyclone in Bangladesh were women, and this was due to their social status, limited skills set, and limited mobility. Finally, in assessing adaptive capacity of female-headed households, the RIO+ center in partnership with Food, Agriculture, and Natural Resources Policy Analysis Network conducted a survey in five southern African countries. The results of the survey showed a strong correlation between gender and adaptation level, with women more likely to have low levels of adaptation (Boko 2007). Further analysis showed that women and men in developing nations do not have equal access to climate change adaptation tools in agriculture, with men more likely to have higher access (Onwutuebe 2019). Other studies in various regions in Africa recorded similar results (MacGregor 2010; Ume 2018). Onwutuebe (2019) attributed these gender inequalities to the existing sociocultural norms and institutional factors that limit women's rights and control of resources such as land and financial services. However, none of such studies exploring the role of institutional factors in causing as well as transforming these gender differences have been conducted in Nigeria.

In Africa, studies have also shown that women are highly sidelined in climate decision-making processes, and this in turn affects their access to adaptation information and support in the country (Enete and Amusa 2010; Ume 2018). Enete and Amusa (2010) reviewed journal articles on the influence of socioeconomic characteristics on access to adaptation support in Nigeria in order to ascertain its impact on the agricultural sector of the economy and the implications for economic growth.

They noted, in line with RIO+ survey, that gender strongly influences access to support for climate change adaptation in agriculture in the country. Their work demonstrated the fact that although agriculture employs over 80% of the rural populace, Nigeria is the world's third most vulnerable country in terms of the impact of climate change in agriculture. Their main conclusion from the reviewed literature was that the adaptation differential between women and men undermines the capacity of the agricultural sector to absorb climate change multiple stressors and to maintain function in the face of climate change impacts. Similarly, Rammohan (2016) noted that women's lack of adequate access to adaptation support prevents the agricultural sector from evolving into more desirable configurations that build resilience.

Theoretical Framework

Gender Schema Theory

Gender schema theory as a perceptive theory attempts to explain the process involved in maintaining and transmitting gender-linked qualities from one generation to another, thereby creating gendered individuals in a community (Kendra 2020). Introduced by Sandra Bem in 1981, the theory shows that sex-linked information is mainly transmitted from one generation to another through "schemata," which is a systematic way of allowing some gender-associated information to be more imbibed by individuals within a society. This information consequently shapes the perception the society has about a particular gender in relation to the other gender, which eventually leads to gender stereotyping. The theory argues that the degree to which individuals become gender-stereotyped is influenced heavily by institutional factors and cultural transmissions such as norms, media, school, home training, etc. By institutional factors, the theory refers to configurations in the society that steers people's behavior (norms, routines, and rules). This means that changing any negative stereotype will involve a transformation of existing norms, rules, and routines.

Institutional Theory

The institutional theory attempts to explain the process by which societal configurations or social structures (schemas, rules, norms, and routines) become enshrined as authoritative standards guiding social behavior in society (Dobbin and Vican 2015). The theory attempts to unravel how these structures are formed, accepted, and transmitted over time. Dobbin and Vican (2015) argued that these elements of a social structure (norms, rules, and routines) are perceptive and normative elements, that are enforced and endorsed by individuals and organizations which he referred to as "actors" and transmitted by relational systems at different scales and levels. Since they are imposed and upheld by people, they can be altered by affecting changes in the social structures (Dobbin and Vican 2015). The theory suggests that through socialization, better and appropriate institutional elements in the form of cognitive orientation can be passed on to individuals and organizations, and when it is adopted, it becomes a new pattern or normal behavior. Over time, these new behaviors become resilient and sediment such that individuals begin to act autonomously without recognizing that they are being controlled by the institution.

Context of the Study

Study Area

The study area is Enugu State, Nigeria, that is located in the southeast geopolitical zone of Nigeria. The state was purposively selected because (a) the state is regarded as the capital and policy-making seat of the southeast geopolitical zone, (b) majority of the rural dwellers in this state engaged in small-scale farming, and (c) the state is reported to have experienced marginalization of women in climate change adaptation decision-making (Chukwuemeka et al. 2018). In the national census of 2006, the state has a population of about 3,267,837 (National Bureau of Statistics 2020). Based on the similarities in soil characteristics and by extension meteorological properties, Enugu State is divided into three agricultural zones [AZs]. The zones include Enugu zone, Nsukka zone, and Awgu zone (Fig. 1). The state is in a tropical rain forest zone, with a mean daily temperature of 27 °C and monthly rainfall of 18 mm to uncover the structural factors undermining women adaptive capacity, thereby making them vulnerable to climate change impacts.

Data Analysis

Two sets of qualitative data were generated using in-depth interviews and focus groups. Vulnerability analysis technique was employed to analyze the data generated from the interviews, while content analysis was employed to analyze the data generated from the focus groups.

Following Enete and Amusa (2010), we employed the adaptive capacity approach of the vulnerability index analysis to estimate and compare the vulnerability differential between male- and female-headed households in Enugu State, Nigeria. The justification for adopting this approach is based on the assumption that an increasing adaptive capacity (potential adaptation) will lead to a reduction in vulnerability (Enete and Amusa 2010). The measurement of the adaptive capacity of farm households was determined using sets of variables (vulnerability indicators). Results of this analysis are presented in Fig. 2. The variables that formed the adaptive capacity indicators include:

- Income level (farm income)
- Number of extension visit in the last cropping season

Fig. 1 Map of Enugu State showing the three agricultural zones. (Sources: Chukwuemeka et al. (2018))

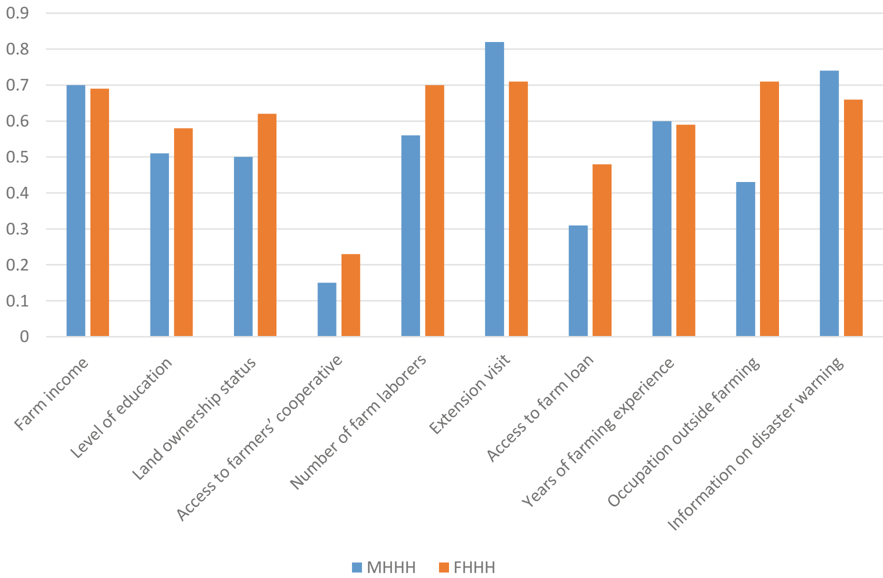

Fig. 2 Gender-vulnerability differential among smallholder farmers in Nigeria

- Educational level
- Land ownership status
- Years of farming experience
- Membership of cooperative societies
- Number of employees in the farm
- Access to farm loan
- Off-farm activities
- Access to mass media and information on disaster warning

To determine the final index, each of the indicators was normalized so that they will be free from their respective units and lie between min = 0 and max = 1. Equal weightage values were assigned to each variable and the average was taken as the value for the vulnerability index. We adopted the United Nations Development Programme method of normalizing life expectancy variables in the Human Development Index calculation (UNDP 2007). The normalization was carried out following Hahn et al. (2009) and Tewari and Bhowmick (2014) using the formula:

$$NSv = \frac{Sv - S\min}{S\max - S\min}$$

where:

S_v = value of the component
NS_v = normalized value for the component
S_{max} and S_{min} = the maximum and the minimum possible values, respectively

By calculating the simple mean of all the variables, the vulnerability index (VI) of all the respondents for the female-headed and male-headed households was determined. To determine the vulnerability index for each gender, we went forward to calculate the mean of the VI for the female-headed households and the male-headed households separately.

The underlining explanation of the gender dimensions in climate change adaptation in Africa can be explained by considering two important theories: gender schema theory and the institutional theory.

Gender-Vulnerability Differential Among Smallholder Farmers in Nigeria

Using years of farming experience as an indicator of adaptive capacity, the average vulnerability index showed that male-headed households (0.60) are more vulnerable compared to female-headed households (0.59). A discussion with the women in the communities showed that women are inducted into the farming occupation quite at an early age compared to their male counterparts. More farming experience suggests that women are better suited to acquire on-farm experience that will enable them autonomously adapt to climate change impacts. For instance, unlike the male farmers, most of the female farmers engaged with could identify several changes in weather patterns they have noticed over the years and how they were able to overcome them. For instance, one of the women stated: “When I was still a youth, working on my mother’s farm, we hardly water out maize farms, but now, in other to get a good harvest and fresh grains we do water two or three times in a planting season.”

Turning now to off-farm income, female-headed households were found to have a higher vulnerability score. This means that more of the female-headed households rely only on farming for income. We observed that more than half of male-headed households (60%) in the study area reported some off-farming activities such as carpentry, palm wine tapping, and material recycling. The high agriculture dependency index of female-headed households (0.71) suggests that the female-headed households might be very sensitive to climate change impacts, as agriculture, being a very volatile and unpredictable enterprise, is subject to total loss once there is a climate event such as flooding, heatwave, or even disease outbreak. Encouraging the women to engage in off-farm activities, therefore, presents a very good way of reducing their vulnerability.

Both the female- and male-headed households had almost the same VI when information on disasters warning is used as an adaptive indicator (Fig. 2). Information gathered from the Agricultural Development Program (ADP) agents indicated that most of the information on disaster warning is normally conveyed through radio stations. Therefore, only women farmers who have radio sets and are close to radio stations, which are mostly located at Enugu zone, can receive information on disaster warnings and weather forecasts.

In general, when all the vulnerability scores were averaged, findings from the analysis, using the adaptive capacity approach, showed that female-headed households in Enugu State, Nigeria, has lower adaptive capacity than their male-headed households. This finding was in line with previous studies such as Amusa (2010). However, we observed a relatively lower vulnerability gap between female- and male-headed households compared to studies such as Amusa (2010). Studies such as Amusa (2010) used the same variables and adaptive capacity indicators employed in this study and reported (female-headed households = 0.73 and male-headed households = 0.43); however, in this study, we estimated a vulnerability index for the female-headed households = 0.61 and male-headed households = 0.55. However, the variation in result reported can be as a result of variation in study area and time when the studies were conducted. The next section attempts to uncover the institutional factors that influence this gender-vulnerability differential.

Institutional Factors Undermining Climate Change Adaptation Among Female-Headed Households

Most policies and norms that are structured to tackle women’s adaptation needs do not address the bigger gender issues. Consistent with the institutional theory, beliefs within the societies have become enshrined as authoritative standards underpinning social justice behavior in the society, irrespective of the negative consequences it carries with it. Some of the cultural practices that need to be transformed are discussed below.

Land Tenure System

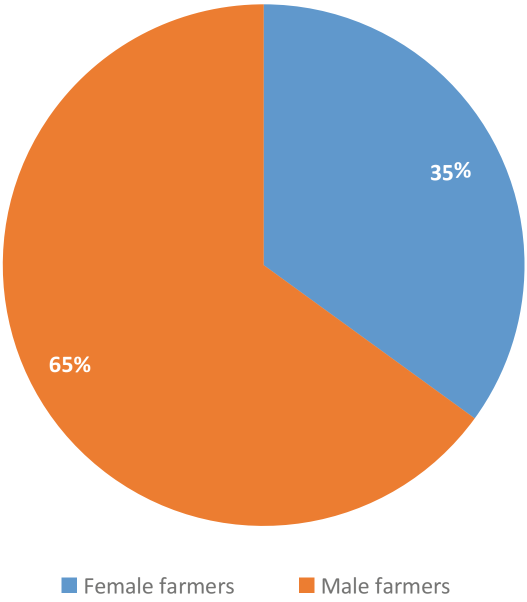
This includes the issues of land ownership and transference. From our focus group discussions with the farmers, it was observed that the people hold the belief that if a man dies and he has female and male children, that only the males have the right, by tradition, to possess the family lands. As one of the female farmers stated: "*this 3-story building you are seeing belongs to my brother and the well here for irrigation is also his, these are what he built from his 'Nsukka pepper' farm which is five times the size of mine, and I must pay rent for my own little piece of land.*" This is because the culture does not permit women to inherit land, they will resort to renting or saving huge some to purchase their own lands. Scholars in the domain of land reform claim that the main obstacle to climate change adaptation in terms of climate-smart agricultural practices like land rotation, fallowing, etc. is shortage of land and population pressure. However, evidence from our study so far showed that it is not really the shortage of land alone, which affects the adoption of adaptation measures but the structure of land tenure.

Greater population of the farmers in the rural areas are females, but the lack of proper land ownership shifts land title and hence access to the male. Female farmers with both structural and relational access to land have better control and decision on how to put the land to best use. This is predominantly the major problem particularly in most sub-Saharan African countries including Nigeria. The issue of land tenure system, land rights, and climate change adaptation, therefore, presents a very important area that needs to be transformed for better adaptation. Although a strategic gender-responsive and socially inclusive approach can foster a balanced representation of men and women in adaptation initiatives, climate change gender dimensions, and priority to include and empower women and men equally (e.g., by giving them a voice in structural and relations access to land) remain low. Climate change adaptation efforts rest critically on the aspirations and support of those who depend on land-based livelihoods – whose rights and access to land must be protected and promoted for climate change adaptation efforts and initiatives to be sustainable.

Education and Awareness

Similarly, it was observed that it is normal for parents to send their male children to school instead of their female children. The male farmers interviewed were of the opinion that "the females are 'liabilities' but the males are 'assets'". According to one of the male farmers, "*training my female child in school only for her to get married to another man doesn't benefit me.*" This shows the level of unjustified assumption about women. Some of these are the assumptions that women farmers

Fig. 3 Channel of extension visits to households



are less informed or intelligent; that some activities are not supposed to be taken up by women; and that women farmers have low self-confidence in taking certain farming decisions. Consistent with the gender-schema theory, these assumptions have been transmitted from one generation to another and have shaped the perception the society has about the female farmers. For instance, it was gathered that extension agents prefer explaining techniques to the male farmers, as they feel they are smarter than their wives, so they can pass the information to their wives. Even the females who oversee the family farms will always project their husband as the household heads, to be better positioned to receive extension services and government aids more easily.

Our study investigated the number of time extension agents visit the female farmers, or gave direct demonstrations to the female farmers, given that extension visits and service delivery helps encourage adaptation. We found that majority of the times (65%), most of the contacts were to the male household heads, though the actual farmers are the wives (Fig. 3).

Several studies (Amusa 2010; Apata 2011; Emeana et al. 2018) have shown the positive influence of direct contact in adoption of climate-smart agricultural practices such as zero tillage (Emeana et al. 2018), organic farming (Apata 2011), and increased soil water conservation practices (Amusa 2010).

Access to Credit and Loan

The result of our analysis revealed that women who have access to credit and loan facilities had a higher possibility of adaptation to climate change. This is in line with the general literature on credit and small-scale farming in the developing nations. According to Otitoju and Enete (2016), access to credits increases farmers coping capacities and access to more adaptation technologies. Similarly, farm size is as important as capital, and the coefficient of farm size was found to be a statistically significant positive determinant of adaptation. This means that females with larger farm sizes have a higher possibility of adapting (Amusa 2010; Enete and Amusa 2010; Chukwuemeka et al. 2018). This also corroborates the economic constraint paradigm which argues that economic constraints and resource endowments are the key determinants of adoption decision such that lack of access to capital or land could significantly constrain both adoption decisions and extent of adoption (Raihan et al. 2009; Zetterlund 2013).

Literature on micro-financing for smallholder farmers shows that microcredit facilities play a huge role in increasing the level of adoption of climate change adaptation technologies and sustainable land-use practices. Emerging theme from our focus groups shows that there exist functional credit schemes, known as "*Akawo Scheme"* in the area that supports the farmers with soft loans. Majority of the farmers explained that the scheme offered them loans from which they were able to support themselves in times of crop failures and even to purchase inputs that they will require in their farms. However, we observed that most of the individuals who did not have access to such networks were females. The female farmers explained that because their husbands are members, they are not allowed to take part as well. Most times, the males are not the farmers, so the loans they get are used for other things but aiding their wives on the farm.

Overcoming the Barriers

We observed two main manners to counter the gender barriers that we illustrated above. First is to improve gender competence and gender training. This means the ability to recognize the social construction and reproduction of gender roles and transform the discriminatory structures and processes. Understanding the gender identities and relations in society will help see the framework conditions provided for women and men, only then can we easily change the perspectives.

Climate change adaptation professionals might be aware of the assessment tools and adaptation strategies; however, they also need to be aware of how they can integrate gender into these strategies and tools in other to acquire gender competence. These can be done in two ways: first is to ensure training on gender and for women. Professionals should be taught on the impact of gender negligence on projects and policy outcomes. Awareness should be raised on how adaptation policies affect men and women differently, making professionals aware of these will have both immediate and long-term impacts. The second is to involve gender experts and specialists that can develop gender-sensitive political measures. They will be able to dictate gender lapses in advance and suggest which areas to pay closer attention to.

The second way is to ensure a bottom-top approach to climate change and gender mainstreaming. One important observation is that the women have indigenous adaptation strategies and are in tune with their environment. They adopt autonomously and can provide strategies that are very beneficial for them. However, adaptation policies are often designed through top-down and bureaucratic models. This has two adverse consequences. The first consequence is that the strategies offered to appear as an imposition of external views and knowledge, and thus appear as unnecessary burden to the female farmers, who are supposed to benefit from them. If the females are engaged in policymaking and are allowed to contribute their knowledge, it would certainly lessen the skepticism and opposition toward adaptation. This will make the policies to focus more on inciting and convincing individuals to autonomously integrate climate impacts prevision in their everyday business. The second consequence of the top-bottom approach is that the male counterparts find it easier to receive the knowledge and adaptation technologies when it eventually drops down to the bottom. If the role of adaptation policy is to reduce vulnerability to climate change through the present modification of the behavior of affected actors so that they integrate and anticipate future impacts of climate change, then it is far from an easy task when the women are engaged actively and at all level in conceiving, planning, and executing climate change adaptation policies.

Conclusion and Recommendation

A gendered perspective on climate change adaptation efforts among smallholder farmers is crucial to sustainable development. This study has added more evidence to the literature on gender and climate change adaptation. Although there appears to be a narrowing of the gender vulnerability gap among smallholder farmers in the area, evidence from this study shows that much work still needs to be done in addressing gender issues in climate change adaptation in Africa, including Nigeria. By taking a gender-sensitive approach, this study highlighted the determinants of adaptation among female-headed households in Nigeria and factors that influence their adaptation to climate change impacts. Furthermore, by incorporating context-specific evidence from the rural farmers, the underlying gender relations and cultural orientations undermining the adaptive capacity of female-headed households were explored. Transforming these gender relations and cultures must form the bedrock for building resilience among farm households in the area. The result of this study shows that cultural systems, policies and practices, and unwarranted assumptions about women are gender relations issues that undermine efforts in building climate change resilience among female-headed households.

Based on the findings from this study, shelving of the identified belief systems that hamper the adaptive capacities of females in the area should be encouraged. It has become obvious that with such societal configurations on the ground, adaptation efforts might be jeopardized. In line with the interactionist theory of gender, since gender relations issues are produced by people through interaction, through a deliberate effort by the people, the unwarranted assumption about women and the enshrined belief systems can also be changed.

104 Local Institutions, Collective Action, and Divergent Adaptation: Case from Agro-Pastoral Niger

Julie Snorek

Contents

Abstract

Adaptation is a highly contextual process, framed by institutions. When one group's adaptation to climate hazards reduces another's adaptive capacity, this is called divergent adaptation. The nuances of divergent adaptation are revealed in how institutions influence divergent adaptation outcomes, either to exacerbate conflict or to bring about greater peace and cooperation. By examining the sometimes conflicting adaptations of pastoralists and agro-pastoralists in Niger,

this chapter describes the process of divergent adaptation through an institutional analysis from multiple scales. At the national scale, climate change adaptation policies and perspectives are entrenched in sedentarization politics vis-à-vis pastoral livelihoods. At the local scale, pastoralists take a defensive position as an adaptation pathway, to ensure secure passage with their livestock to water and pasture. However, in localities where local institutional actors have enhanced collective action arenas in which pastoral and agro-pastoral groups are represented, conflict dynamics are abated. Climate adaptation is not without conflict; however, local and sub-national institutions are critical to providing opportunities for collective action, cooperation, and peace in the context of divergent adaptation. Based on these findings, it is recommended that conflict and adaptation management and planning be integrated at multiple scales.

Introduction

Institutions, Adaptive Capacity, and Divergent Adaptation

Climate change impacts are contributing to human insecurity of complex, social ecological systems (SES) (Adger et al. 2014). These complex systems are sometimes able to enhance their resilience through adaptation (Gunderson and Holling 2002; Lebel et al. 2006; Adger et al. 2007). However, in other cases, adaptation devolves into maladaptation (Barnett and O'Neill 2010; Magnan et al. 2016) and/or divergent adaptation (Snorek et al. 2014a). Divergent adaptation is the process by which one group's adaptation to climate hazards reduces another's adaptive capacity and may result in coupled conflict-cooperation dynamics or exacerbate inequities (Hoque et al. 2018; Sovacool et al. 2015; Snorek et al. 2017; Sovacool 2018). Building adaptive capacity for *all* and avoiding divergent adaptation are related to institutions, which have been shown to have a direct influence on adaptive capacity (Olsson and Folke 2004; Adger et al. 2006; Hill 2013; Gupta et al. 2010; Berman and Paavola 2012). Institutions are the informal and formal rules, values, norms, and cognitive processes that constrain individual and collective behavior as well as access to resources and information (Dennett 2013).

Adaptive capacity is dependent upon the inherent and prescribed elements that make up institutions, including those that empower social actors to respond to short- and long-term impacts either through planned measures or through allowing and encouraging creative responses from society both ex ante and ex post a hazard event (Gupta et al. 2010). By enabling or denying a user or groups' ability to obtain entitlements, access resources, and garner information necessary to their adaptive capacity, institutions, thus, create the conditions for or *frame* divergent adaptation

(Snorek et al. 2017; Adger and Kelly 1999; Berman and Paavola 2012). While some paradigms for adaptation and disaster risk management are dominated by top-down hierarchical approaches (Allen et al. 2010), the institutions that empower stakeholders to participate and make decisions to support adaptation demonstrate bottom-up, equitable, and democratic processes (Cleaver 2002; Olsson and Folke 2004; Ostrom 1999; Engle and Lemos 2010; Eriksen et al. 2011). Understanding how institutions foster cooperation through divergent adaptations has implications for the development of institutions (Gupta et al. 2010; Adger 2001; Ostrom 2005). In light of increasing human insecurities and the prevalence of divergent adaptation (Snorek et al. 2014, 2017), it has become critical to understand *how* institutions are shaping adaptive capacity, *for whom* (Adger et al. 2014; Magnan et al. 2016; Eriksen et al. 2011; Ruiz-Mallén et al. 2015), and with *what consequences* (Snorek et al. 2014a, 2017).

This chapter highlights these questions by examining farmer (agro-pastoral – sedentary pastoralism mixed with cultivation) and herder (pastoral) conflict in Niger (Snorek et al. 2014a). Pastoral and agro-pastoral societies typically live in marginal lands, which are vulnerable to the impacts of climate change such as rainfall variability (Adger et al. 2014; Snorek et al. 2012; Herrero et al. 2016) and also have been shown to be highly adaptable. It has been found (Snorek et al. 2014a) that when pastoralists and farmers engage in conflict, these are not caused by drought conditions and resulting adaptations directly, but rather by the institutional and structural conditions shaping adaptation. As Sovacool et al. (2015; 2018) and Snorek et al. (2017) highlight, the conditions leading to divergent adaptation include land tenure shifts from common to private property regimes or enclosures, the marginalization and exclusion of "the other" (defined here as the individual or communities not involved in the said adaptation efforts), encroachments from actors or groups that imperil the healthy functioning of a commonly shared resource (e.g., visiting herders not aware of grazing practices prompting degraded pastures), or the entrenchment of an institutional system in which social inequalities are permitted to pervade (e.g., laws that support agro-pastoralism and usurp pastoral livelihood needs). In turn, these institutional dynamics shape divergent adaptation and lead to conflict dynamics including land alienation, access refusals or exclusion, political marginalization, and violent instability (Snorek et al. 2014a; Alemu 2018).

Niger's rainfall (average 150–500 mm per annum) and climatic conditions (Bruggeman et al. 2010) are highly suited for dryland-adapted, pastoral, and agro-pastoral livelihoods (Mortimore 1989; Niamir-Fuller 1998). Reflecting this, more than 20% of Niger's export earnings are generated by livestock, produced upon rangelands and through transhumant pastoralism (Zakara and Abarchi 2007). Farming or agro-pastoralism is considered to be the principal rural activity (Lund 1998). The country's population grows at rates of 4% per annum (World Bank Data 2016), for which the majority subsists on rain-fed agro-pastoral activities. There is a high level of confidence that Niger's Tahoua Region will experience an increase in temperature by 2 °C by 2050 and a slightly less confident prediction of an overall increase in annual rainfall (+7%) with decreasing rainfall during the typical rainy season (−4 and − 6%, respectively) (Bruggeman et al. 2010). These data, along with other reports on rainfall projections for the Sahel (Biasutti et al. 2008; Shanahan 2009), point to increasing rainfall variability as a result of climate change, which has consequences for institutions relevant to divergent adaptation (Snorek et al. 2014a).

The country's adaptive capacity, which is among the lowest in the world (Vincent 2007), is exacerbated by chronic poverty (55% of rural population), widespread illiteracy (84% of those older than 15), and frequent droughts that devastate the rural economy (IFAD 2016). High levels of rainfall variability coupled with overgrazing, poor soil management, the enclosure of land and water resources (Snorek et al. 2017), precarious pasture spatial and temporal availability (Bode 2011), and decreasing agricultural production yields (Snorek et al. 2014a) result in degradation feedback loops, which further impact the local-scale climate system.

Understanding how divergent adaptation, pastoral-agro-pastoral conflict, and institutional processes play out in Niger is important to developing adaptation policies that reduce the prevalence of divergent adaptation. Institutions governing adaptation must seek out the ways that they are producing divergent adaptations, understand which actors in a social ecological system are the "winners," and create systems to lessen the consequences for the "losers." The following chapter highlights how these processes take place through a case study. The aims of this chapter is to specifically examine how more adaptive and inclusive institutional models relate to divergent adaptation processes and if they might bring about more sustainable, peaceful modes of adaptation (Magnan et al. 2016; Eriksen et al. 2011) for groups facing livelihood insecurities, social and climate vulnerability, and marginalization.

Niger's Institutions Relevant to Divergent Adaptation

National legislation relevant to climate change and adaptation provides an overarching framework for how adaptation functions as a process. In the Nigerien context, the implementation of national legislation is filtered through multiple layers of decentralization. For the most part, very few lower-tier institutions in Niger understood specific elements of the Rural Code (Lund 1998; Benjaminsen et al. 2009; Snorek et al. 2011). At the sub-national scale, it is the members of the commissions foncières (COFOs) or land commissions, court officials, administrators, and experts from governmental and nongovernmental associations that support processes of implementation of this legislation through multiple methods and means. While documentation of infractions is scarce, *Procès Verbaux* (PVs) represent the main legal documents filed for litigation related to land and water access and use and cattle theft at the time of data collection (2011). A thorough review of PVs provides deep insight into how legislation is being implemented and what conflicts are occurring.

The sparseness of documentation in Niger, however, translates to only a fragmented understanding of conflict resolution mechanisms. In turn, most conflict is resolved outside of the formal system through the canton and group (customary) leadership. These institutions reside at the local scale, where they have perhaps a strong influence on the adaptive capacity of pastoralist and agro-pastoralists in the country (Kpadonou et al. 2012). Customary chiefs represent both the traditionally pastoral (Fulani and KelGeres and Ouilimiden Tuareg) and traditionally agricultural (Hausa) groups. The pastoral counterparts of these local-scale institutional actors (group chiefs) are often on the move to visit their mobile constituents, scattered across the region. Often, group chiefs travel to places where they might influence decision-making processes in the village sites, along pastoral corridors, and in the camps of more affluent pastoralists.

In the water-stressed, administrative region of Tahoua, Niger, one finds large transhumant livestock herds migrating along the North-South axis between Nigeria and Niger's pastoral zone (Fig. 1), villages and nomadic camps empty of young male residents during the dry season due to high rural-to-urban migration, and a chronic dependence on drought relief due to frequent dry spells. In Tahoua, conflict breaks out most often along in vulnerable areas where pastoral corridors snake through croplands. As a result, local agriculturalists plant in pastoral resting areas to "herd" livestock elsewhere and away from croplands. Security in this region is tenuous not only due to a lack of infrastructure and policing but also due to the growing presence of clandestine and sometimes jihadist activities.

Tahoua, in turn, represents a North-South, low to high rainfall gradient that consists of the northern pastoral zone, the southern agro-pastoral zone, and the high cash crop production areas (Fig. 1). Residents in Locale P are majority pastoral households, a region receiving 187 mm rainfall per annum and possessing common

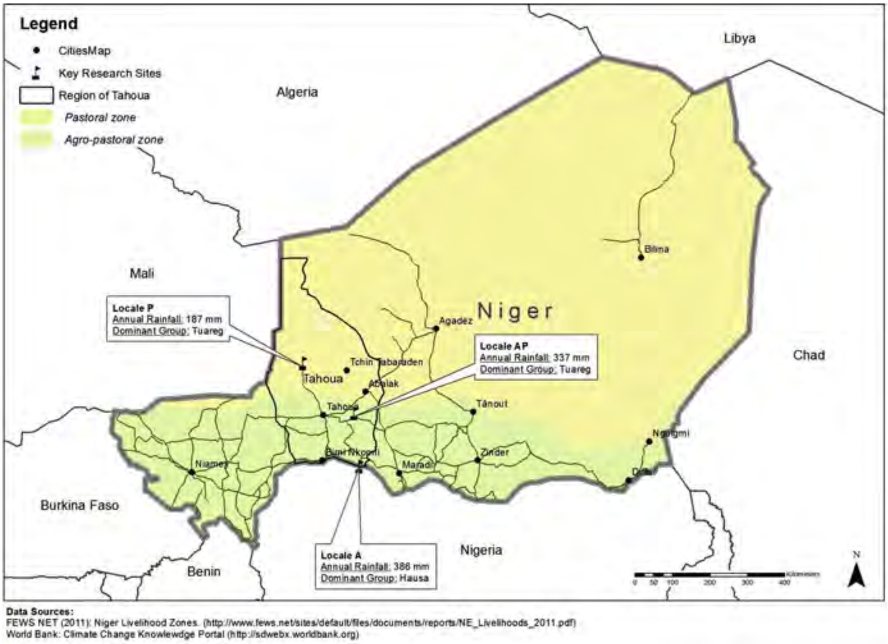

Fig. 1 Map depicting the Tahoua Region – a thin, black outline – and the three locales (Locale P or pastoral, Locale AP or agro-pastoral, and Locale A or agricultural)

pastoral areas, governed by local customs. Locale AP is populated by a majority of agro-pastoral households and receives 337 mm per annum. In Locale A, the majority takes part in multiple agricultural activities including dry and irrigated cultivation and also some localized and mobile livestock production, receiving 386 mm of rainfall per annum (Fig. 1).

There is high institutional diversity across the different scales and localities, resulting in variable levels of adaptive capacities between users. Cultural groups include both traditional sedentary and nomadic groups from the Hausa, Fulani, KelGeres Tuareg, and Ouillimiden Tuareg at both the local and sub-national scales. Users were aggregated by their activities and status as a local (strong place connection) or nonlocal to the zone – local pastoralists (seminomadic, livestock as their primary capital), local agro-pastoralists (sedentary, land and livestock as capital), and nonlocal, visiting pastoralists (mobile, sometimes serving as shepherds).

According to 43 pastoral and 34 sedentary households as well as customary, administrative, and technical leaders, there are three key conflict-triggering events in this region of Niger: the spreading of cultivated fields (also an adaptation), crop damage (a response to adaptation), and livestock theft (a response to adaptation). Conflict is related to hydro-climate hazards, the ways in which groups control access to resources like water, pasture, croplands, the mode of common pool resource management, and historical institutional arrangements such as placing boundary markers for a pastoral corridor or declaring a certain plateau for pastoral purposes. These multiple dynamics are key to understanding the relationship between institutions and divergent adaptations.

Adaptation Without Mobility

In 2011, a group of multiple experts on pastoralism and agro-pastoralism in Niger came to a consensus that in light of future scenarios of climate change for the country, mobile pastoralists would eventually cede to a sedentary, agro-pastoral livelihood. The main element contributing to this determination was the rapid transition of pastoral commons to semiprivatized, cultivated land, even within the northern, official pastoral zone (Snorek et al. 2017). What fuels this transition are an utter lack of political will to support pastoral livelihoods and multiple institutional arrangements supportive of sedentarization (Snorek et al. 2012). An unwritten but widely shared de facto policy that "land belongs to the cultivator" originated in the Former President Kuncé's post-drought radio address to the nation and was meant as a way to life up the peasant and give him/her land rights and food security. This movement shifting a pastoral nation to a sedentary farming landbase has roots in the precolonial and colonial frameworks, which shaped the modern national and sub-national institutions in Niger and, in turn, have framed how entitlements to common land and water are distributed at the local scale. These policies, while not specifically titled "adaptation policies" in word, were enacted in response to the key climate change impact on the Sahel – drought.

In 1961, as Nigeriens watched the high rainfall periods of the 1950s fall in a downward spiral of rainfall deficit years, the fledgling Nigerian government established Law N°61–05, which effectively divided the country into two sections. Supporting the burgeoning southern populations with new land tenure, the far northerly edge of the Sahara was designated for pastoralism, while new parts of his “new” South were earmarked for cultivation (Fig. 1). This was heralded as an effort to strengthen the pastoral system; however, this demarcation served, rather, to enclose the pastoral population and restrict their mobility while concurrently expanding cultivation. Concurrently, due to disputes about the exact location of this zone, cultivation continues to creep northward with impunity.

In the years following the two great Sahelian droughts, a 1987 decree designated the South as a semi-commons, affirming the rights of agro-pastoralists to forbid livestock from grazing within cultivated areas during the growing and harvest periods and collect sanctions from offending pastoralists. While this political move strengthened political support of newly decentralized governments by providing greater land tenure security, it was stated in the aftermath of Kountché’s remarks to “clear the fields” and cultivate to gain land tenure, a statement made in direct consequence to the famine stemming from the great droughts. What occurred on the ground as a result of the 1987 decree is that the southern zone shifts seasonally to a full pastoral space after department officials declare the *liberation des champs* or “freeing of the fields.” The date is determined by a department-scale committee made up of individuals from the government administration and customary authorities as well as the technical representatives from the ministries of livestock and agriculture. Prior to the *libération des champs*, livestock are only permitted to graze in designated pastureland (Niger Decree N° 87-077 1987). This also established the very lucrative framework, which then permitted agro-pastoralists (cultivators) to collect compensation if crops or residues are damaged prior to the liberation, at a rate determined by local and sub-national institutions (Table 1). These two legislative acts alone were sufficient to provide several alternative sources of income to rain-fed agriculture, in the case of a drought. In turn, these policies stripped pastoralists of their rights to mobility, effectively limiting their greatest drought adaptation mechanism.

In 1993, the Rural Code established formal rules to land and water access and tenure. The ensuing privatization of territory culminated a national development plan to enhance the rural sphere for agribusiness opportunities, including large-scale irrigation, livestock fattening, and agroforestry. Land began to be more formally appropriated via a process that began with permission from customary authorities (canton chiefs handle all land claims in southern Tahoua) and moved into the realm of newly established land commissions. It was relatively easy for sedentary populations to garner land claims based on verbal reference from two separate individuals. Many pastoral communal areas, thus, were cultivated. Protecting commons required a more complex and costly collective action process, engaging multiple administrative actors including land commissions (Fig. 2) and customary authorities in the South; thus, pastoral territories have been often ignored (Touré 2015).

The 2010 Pastoral Code seemed to provide the possibility of reinforcing mobility to disenfranchised pastoralists. The Code’s aim was to fill the gaps, define, and specify the rules and principles concerning pastoralism and what the 1993 Rural Code had previously established (Snorek et al. 2011). The Pastoral Code mandates

Table 1 Description of Niger's pastoral and agro-pastoral legislation. (Adapted from a similar table in Snorek et al. 2014a)

Legislation relevant to divergent adaptation in Tahoua		
Name	Description	Relevance to divergent adaptation
Law N°61-05, 1961	Sets the geographical limits to cultivation (with the exception of small gardens)	Pastoralists lost territory to cultivation, as the limit moves northward annually
Decree N°87-077, 1987	Permits pastoralists to graze in southern agricultural zone after harvest or in designated areas	Concurrently permits the sanctioning of pastoralists by land-holding agro-pastoralists
Ordinance N°93-15, "Rural Code," 1993	Recognition that natural resources are shared by all equally, supported creation of livestock corridors and pasture areas	Organizes rural sphere (commons and semi-commons), yet many administrators have no understanding of its content
Law N°93-14, 1993	Private and public water sources (ponds, wells, boreholes) must be accessible to pastoralists, provided the load capacity of the infrastructure allows for this	This has not been implemented in the South, resulting in exclusion of pastoralists from water points
Decree N°97-007/PRN/MAG/EL, 1997	Establishes home territories (*terroir d'attache)* in which pastoralists have priority rights over natural resources, but cannot limit others' access	Home territories remain an enigma due to the legislation's vague treatment of this important historical pastoral territorial tenure practice
Decree N°97-008/PRN/MAG/EL, 1997	Sets the organization, attribution, and functioning of institutions implementing the principles of the Rural Code	Established weak land commissions (*commission foncières* (COFOs)) without decision-making power, resulting in corruption
Decree N°97-368/PRN/MHE, 1997	Sets attributes and modalities for COFOs of communes, villages, and indigenous groups	Poorly implemented village COFOs with few pastoral representatives
Law N°2001-23, 2001	Established democratic, decentralized administrative constituencies and local authorities	Land tenure decisions devolved from customary authority to multiple authorities, "democracy" to blame for land tenure disputes
Ordinance n° 2010-029, "Pastoral Code," 2010	Codifies a pastoralist's right to mobility	Protects pastoral territories and enhanced open-access property regimes void of local institutional norms
Ordinance n° 2010-09, "Water Code," 2010	Management of Niger's water resources	Established open-access property regimes on northern pastoral territories, permitting pay-for-use, private wells

livestock safety of passage and access to water points and areas of pasture in the zone of cultivation. It creates a legal framework for interaction between people whose livelihood is based on animal husbandry and other groups such as agriculturalists, mining companies, or commercial livestock production on ranches (ibid.). While these developments were heralded as important advances in the recognition of

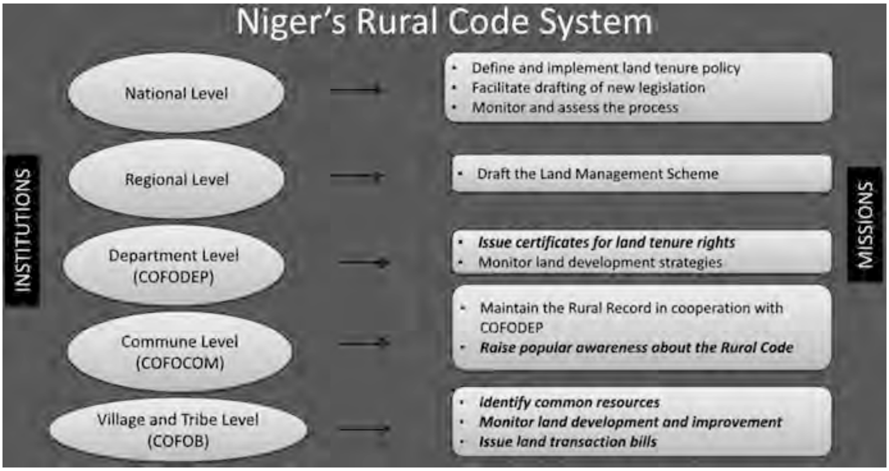

Fig. 2 Niger's Rural Code System presents a decentralized manner to disseminate, communicate, and implement rural legislation (bold text more relevant to conflict dynamics). COFO = *commission foncière* or land commission. (Snorek et al. 2014b)

pastoralists' rights, the Code further erodes customary control, which was considered to be a messy form of pastoral governance (Oxby 2011).

Multiple Sub-National Governance Arrangements

The reality for pastoralists, however, is that their main advocates were customary pastoral leaders. Under the colonial regime, the sub-national sphere was arranged into sedentary (farming) communities and mobile (pastoral) communities. *Cantons* (Fig. 3), headed by sedentary chiefs, are defined by territories that were arranged based on colonial interests, whereas the *groupements* (groups headed by pastoral chiefs) were based on ethnic groups linked to pastoralist actors (Fulani and Tuareg) and do not control territory. To encourage acceptance of these conditions, pastoralists were told that their territory was essentially "everywhere," but these chiefs were only permitted de jure jurisdiction over individuals, remnants of which have had broader implications in the protection of pastoral lands in modern day. Despite that the colonial period ended in 1960 with the election of Hamani Diori, the system of cantons and groups (generally referred to as customary authorities) remains in place (Fig. 3).

Beginning in 2002, the power of customary authorities began to erode through a process of state or administrative decentralization, which established municipal administrative units (commune mayors, departmental *préfets*, and regional governors, Fig. 3). Decentralization has contributed to a gradual shift of jurisdiction over land holdings from customary chiefs to democratically elected leaders, which have included land formalization processes (Hammel 2005). Perspectives on

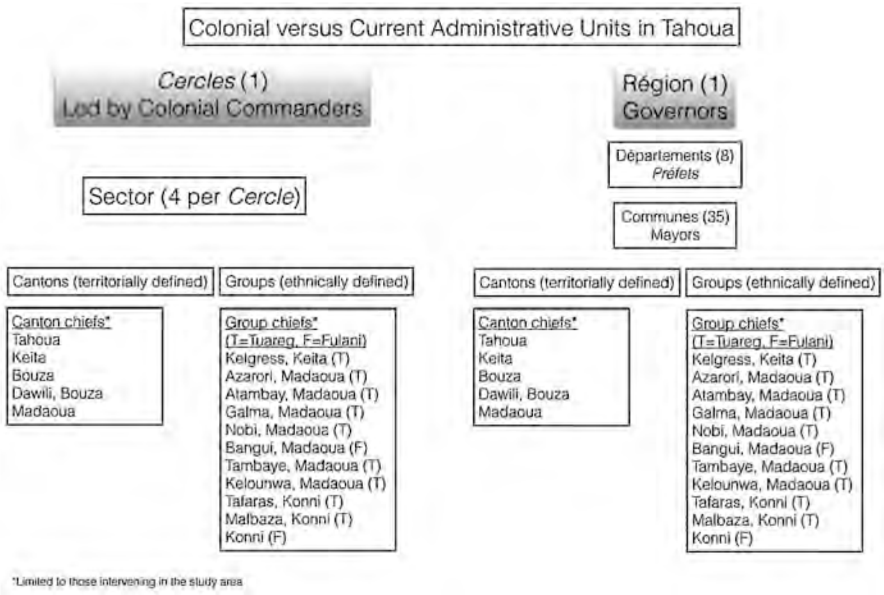

Fig. 3 Colonial remnants (left) and decentralized (right) regional administrative units in Tahoua, arranged hierarchically. Democratically elected governors, *préfets*, and mayors replaced the upper scales of regional governance, leaving in place the colonial institutions at the local scale. These colonial structures include *cercles* (now called "regions"), managed by commanders; *sectors* (now departments and communes), managed by military lieutenants; and *canton* and *groupement* (maintained same name), managed by local chiefs appointed by colonial administrators. *Chef du canton/groupement* or canton/group chief is the unit of rural leadership serving as the administration, justice, and police for rural peoples. (Source: author)

decentralization are highly variable and have been explained in more details in other texts (Mohamadou 2009; Olivier de Sardan 2011), though two viewpoints contextualize the responses from expert and household interviews. Firstly, state officials argue that customary officials are not democratically elected and thus become more easily corrupt and entrenched in the past. Contrariwise, the fragmentation of knowledge of short-term elected leaders is not favorable to the build continuity in relation to land arrangements and decisions, due especially to poor documentation and corruption. At the local scale, perspectives on decentralization are largely conflated with what people call "democratization." The results of democratization to local-scale users include local problems such as confusing land-holding arrangements, political alliances linked to campaigns and parties, and significant political bargaining related to land tenure.

While group chiefs have strong commitment to maintaining pastoral rights to pasture and water, they must interact effectively with other governance actors (*préfets* and mayors) to enforce pastoral rights, due especially to colonial legacies that established pastoralists as mobile and landless. Pastoral territories are mostly lost to cultivation, due to beliefs that the land belongs to those who cultivate it. Moreover, group chief distribution across administrative departments is not equal; Keita has only one group chief, whereas Madaoua possesses seven (Fig. 3). Despite the established procedures under decentralization, we found that in situ, land tenure is managed informally by group and canton chiefs and hand-written records (*Procès Verbal* (PV)) were often lost or unavailable (Table 2). The most common complaints are related to heritage claims, crop damage, and disputes over the location of pastoral commons. When actors were dissatisfied with a customary chief's decision, they turn to elected officials to find different outcomes. For example, a case that had been dealt with by a Fulani chef du *groupement* whom we were interviewing was usurped by a newly elected official 1 year later, causing the issuance of a land title for what had been declared the year prior as a pastoral area. Implementation often proves to be much more complex due to uncoordinated, multiple layers of governance.

The national and sub-national institutions presented here frame the outcomes from divergent adaptation in the local sphere in multiple ways. The next section describes how the institutional arrangements translate in the divergent adaptation arena in two case studies, one in the northern agro-pastoral zone (Keita) and one in the southern cultivation zone (Madaoua). Both of these cases are characterized by the dominance of agro-pastoral livelihoods, but the southern semiprivate property regime has a greater number of irrigated, enclosed gardens due to better water and soil conditions. Paradoxically, higher levels of natural resource-based conflicts were prevalent in the northern, more sparsely populated agro-pastoral zone compared to the highly concentrated, southern irrigated gardening and agricultural zone of Tahoua, contradicting neo-Malthusian assessments of scarcity and farmer-herder conflict in the Sahel (Bruggeman et al. 2010; Homer-Dixon 1999).

Conflict in the North: The Agro-Pastoral Keita Department

The agro-pastoral department of Keita (Fig. 1, Locale AP) sits in a precarious location with its northern border on the shifting and disputed edge of the pastoral zone and arid mountains and humid valleys to the South. The Keita Valley, which currently receives on average 337 mm of rainfall per annum (Fig. 1), unites four watersheds in the region of Tahoua, the Adouna, Tarka, Jangay, and Jaboyé valleys, and is surrounded by mountains and plateaus. Because of its potential for water management, the French colonial authorities built a dike in Keita in 1952, forming a large lake suitable for fishing, irrigation for wheat production, and bird-watching. Prior to this time, Keita was primarily inhabited by the Wodaabe (a subgroup of Fulani people) pastoralists and their cattle. The colonial investment brought migrant farmers, established two canton chiefs in Keita and Tamaske, and established wheat cultivation, developments which essentially pushed the Wodaabe northward in search of sufficient pasture. The KelGeres, a subgroup of the Tuareg, also had one group chief near the Akawal Plateau (Image 2), whose people migrated between Agadez and Keita up until the drought in 1974. This chief vehemently defends the Tuareg's historical land occupation of Keita and complains about how it has been overtaken by Hausa farmers, many of which he and his predecessors granted land

Table 2 Percentages of qualitative responses about specific social dynamics relevant to divergent adaptation. Codes for similar responses are listed on the left, and the percentage responses disaggregated by actor group are displayed

	Locale AP – Keita		Locale A – Madaoua	
Social and institutional dynamics	# of agro-pastoralists (N = 22)	# of pastoralists (N = 16)	# of agro-pastoralists (N = 9)	# of pastoralists (N = 10)
Conflict				
Existence of arms	9% (2)	13% (2)	0	10% (1)
Presence of livestock theft	41% (9)	38% (6)	22% (2)	30% (3)
Conflict on water access	5% (1)	13% (2)	0	30% (3)
Damaging crops	68% (15)	38% (6)	44% (4)	10% (1)
Violence	55% (12)	0	44% (4)	0
Rules, sanctions, enforcement				
Livestock corridors not protected	0	31% (5)	0	100% (10)
Locally derived enforcement	23% (5)	0	33% (3)	10% (1)
Payment for damaging crops	27% (6)	44% (7)	44% (4)	50% (5)
No payment for crop damage	27% (6)	6% (1)	11% (1)	0
Governance				
Trust in gendarmes	36% (8)	6% (1)	0	0
Trust in customary officials	18% (4)	6% (1)	44% (4)	30% (3)
No trust in elected officials	14% (3)	25% (4)	22% (2)	60% (6)
No trust in customary officials	4% (1)	12% (2)	11% (1)	10% (1)
All officials are corrupt	41% (9)	13% (2)	0	10% (1)
Elected officials favor cultivators	9% (2)	56% (9)	11% (1)	50% (5)
Social capital between groups				
Marriage of "other"	5% (1)	6% (1)	0	20% (2)
Other group as problem	55% (12)	63% (10)	22% (2)	50% (5)
Transactions between groups	14% (3)	4% (1)	66% (6)	20% (2)
Cooperation and acts of kindness	5% (1)	6% (1)	0	50% (5)

tenure. He is the only customary chief in Keita representing pastoral interests, and he was approximately 100 years old at the time of our visit.

In the 1950s, Keita's wetlands were abundant, nourishing low-lying areas with nearly year-round cultivation of millet, several strains of sorghum, and some vegetables; however, according to Keita's canton chief, when the dike of Keita broke for the first time in 1964, the valley became eroded and the water table lowered, leaving behind many dry wells and sediment-filled waterways. The loss of this infrastructure was followed by two periods of drought in 1974 and 1984, during which a burgeoning farming population cultivated much of the territory, removing trees and causing vast deforestation in the zone, promoting erosion, soil degradation, landslides, and property loss. Concurrently, soil loss and desiccation promoted that water run off the hillsides and across the valleys to lower ground, which formed into a lake in an adjacent commune, called Tabalak. Today, due to water shortages, a woman's dowry must consist of at least a donkey, to enable her to travel a sufficient distance in search of water (Image 1).

After the disastrous drought of 1984, the Italian-funded Ader Doutchi Majiya Project began a massive reforestation effort and concurrently built many water-retaining infrastructures throughout the department to increase food security in the region (Rossi 2002). More than $88 million was invested in forest and soil regeneration in the region over the course of 25 years. Concurrently, Italian initiatives attracted migrants from around the region to Keita, due to promises of plots of land by the project, which prompted an expansion of cultivation and further displaced transhumant pastoralists (Image 2). Keita thus shifted from a sparsely populated pastoral zone to a burgeoning agro-pastoral livelihood zone in the span of 50 years.

Every year, transhumant pastoralists descend into Keita as the seasonal lakes dry in the Northern pastoral zone, typically in October and December. The official declaration of the *libération des champs* typically occurs in Keita during November or December. Pastoralists descending earlier than this typically remain on designated corridors and in pasture areas, when available. If the pastoral zone received less rain, this departure is earlier, often before the *libération des champs.* Pastoral infrastructure including transhumant routes, pastoral wells strategically located along these corridors, and pasture "rest" areas (*aires de pâturage*) have been installed throughout

Image 1 (Left) Denuded hillside shows extreme erosion of Keita, Niger (author). (Right) Women travel by donkey in search of water (author)

Image 2 Image of a pastoral well surrounded by recently planted fields (Keita, Niger, author)

Keita as part and parcel of the Ader Doutchi Majiya project's efforts to support pastoral and agro-pastoral development. During our field visit, a primary transhumant corridor was not being used due to water access problems, curtailing the southern transhumance through farmer's fields (Table 2). Also, upon inspection, many pastoral wells identified by respondents had been or were in the process of being enclosed by cultivated fields (Image 2).

Drought policies established in the 1990s promoted agro-pastoralism or animal husbandry in farming households as a form of investment in light of the vulnerability of rain-fed agriculture to rainfall variability. While policies were effective in bringing foreign aid and development programs supporting "animal fattening" for sedentary households, farming households in Tahoua complained about the lack of fodder for fattening. As a result, the governor promoted the cutting and stocking of farming residues, which before had been left in the fields to decay or be consumed by any of the livestock passing through after the *libération des champs.* This lengthened the timing of agro-pastoral work, as field residues must be fully dried in the field prior to stocking, and thus delays the date of the *libération des champs*. Such residues sometimes bring in more revenue than grain due to drought, though their removal has reduced soil fertility and increased agricultural vulnerability to climate hazards. Concurrently, these policies break the territorial continuity for pastoralists, greatly impacting their fodder source through commodification of fodder as well as broadening the range of what is considered "crop damage."

Thus, the divergent adaptations expressed in Keita include the commodification of farming residues and water due to the animal fattening project, the enclosure of pastoral wells and corridors via field expansion, and the sale of water from village wells when pastoral wells are not accessible or viable. Relative to these divergent adaptations, pastoralists expressed a great deal of fear about passing through the Keita department, due to the outcomes of divergent adaptation and also due to their limited representation in the department by pastoral institutions or even other officials in the elected administration. The interactions and outcomes are described below.

"Trapping" Livestock in Keita's Divergent Adaptation Arena

Agro-pastoralists in Keita see the need to expand their agricultural fields from the valleys to the traditionally pastoral plateaus, as this is the only way to "catch" spatially and temporally variable rainfall. Their legal ability to expand their land tenure has been established by multiple legal codes and verbal precedent. While the expanse of cultivation alone tends to increase agro-pastoralists' adaptive capacity in the face of drought, the Decree N°87-077, 1987 (Table 1), allows the sanctioning of the owner of any livestock wandering into one's field. These sanctions can be costly, charged by the head and type of animal. Payments to release livestock cost on average 8 USD for large and 5 USD for small ruminants per head, which adds up to a hefty sum for a herd of 20 cattle. As income from millet and sorghum production has become less reliable, crop damage payments extracted from pastoralists have proven to enhance livelihood security for those experiencing damages. Thus, expansion is a lucrative "trap" for rainfall and for livestock. As stated by an agro-pastoralist from Konni, "Each one who damages [crops], the Hausa [farmers] make him pay money. But [before] there was pasture and the camels could go where they wanted, but now there are people everywhere. And there are fields of onions everywhere." Some villagers sleep in their fields to protect them from harm and also to "trap" pastoralists. To divert pastoralists, village residents living near pastoral corridors remove official markers and plant to claim the space.

Fear of "the other" shapes this conflict, which at times turns violent (Table 2). But leadership in Keita tends to be sympathetic toward agro-pastoralists while perceived that pastoralists damage crops with impunity. "[They believe] that if their cows spend 3 months grazing in that valley, they can withstand a drought," said a Keita area vice mayor in reference to a sorghum-filled valley. Elected officials and customary canton chiefs have turned to enforcement officers to help manage the conflict. As cell service becomes more available in the zone, a pastoralist "descent" warning system has been established. Upon seeing the first pastoralists descending from the North, village chiefs immediately phone the *gendarmerie* (military police) to request their assistance. These gendarmes stay in villages to both prevent conflict and also (with the same motivation for payment) "catch" any livestock wandering into fields and damaging the harvest. Gendarmes were observed packing several sheep into the back of a government vehicle during the research team's passage. These were the payment for the gendarme's protection of a villager's field from crop damage (Image 3).

The presence of gendarmes has not been welcomed by all. Agro-pastoralist respondents prefer localized forms of compensation and conflict resolution

Image 3 Gendarme vehicle with confiscated sheep (Keita, Niger, author)

(Table 2). When gendarmes profit from crop losses, this lessens the compensation paid to farmers. Moreover, this enforcement disrupts the long-standing cooperative system of negotiation between both groups. “Before, when the Fulani pastoralists put their livestock in our fields, we’d intervene ourselves to chase them away, but we noticed that when the gendarmes are here, it is us farmers who are punished for intervening, so since then, we do not intervene anymore ” (pastoralist in Keita).

Pastoralists, realizing that safe transhumance is dependent upon land tenure, have settled in several makeshift villages and begun cultivating to establish a resting area for their kin traveling along the transhumant routes. Yet for those pastoralists who depend upon mobility as their adaptation to climate variability, they often lack an alternative to entering cultivated fields. So, to avoid conflict, pastoralists in Keita travel through fields under the cover of night, escaping to the mountains before they can be detected, and their livestock confiscated as collateral.

As a form of solidarity to pastoralists, some Keita cultivators cleared their fields early when the pastoralists began to descend. These also preferred negotiating a token amount convivially for crop damage. Despite these examples of cooperation, pastoralists have resorted to protect themselves and their safe passage by shooting arrows at farmers and gendarmes. This has resulted in several severe injuries among local agro-pastoralists and enhances the fear and distrust between both groups. In Keita, when the problem cannot be resolved at the local level, violence replaces the endemic systems of livelihood protection including cooperation, negotiation, and discussion to maintain pastoral mobility in this department.

Despite the gendarme’s involvement in Keita, very few cases of crop damage are recorded in Keita. Only eight cases were registered between 1997 and 2011. No earlier records were available. The *Procès Verbals* (PVs) averaged payments of 172 USD, and half included cases of violence. Three of the crop damage cases were handled by the gendarmes, and one was negotiated by the land commissions (COFO). Only one litigation was relevant to protection of pastoral space (see Table 2), and it was resolved in favor of pastoral rights.

Cooperation and Customary Chiefs: The Heavily Cultivated Madaoua Department

To the South, Madaoua is a mixed use zone with a high prevalence of irrigated (winter) cultivation and a series of livestock routes passing to the higher-value markets of Nigeria. One central exodus point is the commune capital of Bangui, where nearly four million FCFA (8,000 USD) in export taxes were collected in October and November 2011. Along with livestock exports, the region produces onions by the truckloads. Rainfall in Madaoua is slightly greater than Keita (386 mm, Fig. 1) which is evidenced by the many seasonal lakes in the department as well as a higher water table. Contrary to the rocky hillsides and deep valleys evidenced in Keita, Madaoua is a broad plain, met by a large dry riverbed along what is now the southern border of Niger.

The average farmer cultivates rain-fed crops like millet, sorghum, and cowpea in the summer (May–October), and those who have been lucky to obtain a coveted valley plot cultivate and sell onions or other vegetables in the winter (October–January/February). Irrigated cultivation is typically reserved for the valleys and low-lying areas where it is possible to dig a shallow well, and irrigation is derived by hand or with a diesel-powered pump. In Madaoua, these irrigated crops are often *not* protected by fencing, so that herding requires careful observation and guarding of livestock even after the *libération des champs*, to avoid the heavy fees charged to damage to this high-value irrigated agriculture. Every space appeared to be cultivated across this zone, saving a few pastoral corridors and pastoral rest areas.

In the precolonial period, Madaoua was occupied by Fulani herders and Hausa farmers, both of which used Sokoto, Nigeria, as their commercial and political capital. The Fulani herdsmen who dominated the zone called the place Bangui after a large cow by that name that died in the location. Due to the abundance of water, residents cultivated rice in the valleys. Farmers tended to plant in the paths of their pastoral neighbors putting seeds in soil fertilized by the livestock. The reciprocity of this practice shifted with population growth, and land was organized into farming and livestock areas. The Fulani pastoralists considered that they had more rights "before the moment of democracy," because "the customary chiefs [of today] have no protocol [for protection.]" "During the time of Ibrahim [a Fulani chief], there were never any problems. He would get on his horse, come, and say, 'here it is the pastoral are,' stating to pastoralists, 'if the people plant this, just come and graze it anyway." Upon his death in 1999, cultivators overtook these zones.

Increasing temporal and spatial variability of rainfall as well as demographic growth shifted the patterns of cultivation and livestock rearing in this department. To adapt to rainfall variability, agriculturalists become agro-pastoralists, holding livestock as "drought insurance" and cutting the crop residues from their fields for fodder. Concurrently, many residents in Madaoua, to increase their chances of receiving rainfall, purchase fields in other villages, hoping to increase their chances of the rain falling on their crops. Bangui is located along an international livestock corridor established in 1968 and stretching for 90 kilometers from Nigeria to Keita (Image 4). However, as villages have grown, their populations have enclosed pastoral resources.

Image 4 (Left) A village on the border of Nigeria (Bangui) has grown around the pastoral well on the international livestock corridor and (right), a disputed seasonal lake in northern Madaoua is forbidden to pastoralists by the village leaders. (Madaoua, Niger, author)

Near Bangui in Locale A, the valleys are moist nearly all year. As a result, the villagers grow high-value crops such as cowpea, sorghum, and some squashes. The residues are sold to livestock owners. On the dune behind the valley, the villagers grow millet in nutrient-poor soil, for which some pastoralists are contracted to "sit" in farmers' fields with their livestock. These informal contracts are paid at a rate of approximately one sack of millet per month. Valleys are rarely penetrated by livestock, despite that they grow a desired food. Farmers bring field residues to the livestock sitting in fields, as another form of exchange. Livestock rarely damage crops, despite the fact that there is only one small route to water. Pastoralists pay higher rates to consume the cowpea vines; they are especially interested in fattening their animals to sell in Nigeria.

If there was a conflict, Madaoua has multiple customary chiefs – one canton and six group (five Tuareg, one Fulani) chiefs living in the commune (Fig. 3). They meet frequently, sometimes traveling long distances or hosting events or gatherings at their own expense or with the assistance of government and pastoral associations (see *Association pour la Redynamisation de l'Elevage au Niger* [AREN]) in order to meet with their constituents before, after, or during the biannual transhumance. During these face-to-face discussions, pastoralists are able to raise concerns about the route and access to water. Their efforts to control the territory have sometimes resulted in cooperation between sedentary and pastoral groups, yet dialogues also fail and devolve to nonviolent conflict. Based on the *Procès Verbal* (PV) from Madaoua, six cases of land and water conflicts were recorded from 1999 to 2010. Of these, three were handled and recorded by village chiefs, two for crop damage, and one related to the protection of a livestock corridor. The other litigation was managed by the canton chiefs (2), the group chief (1), and the Court of Appeals (1). Three of the recorded conflicts enforced the protection of pastoral commons.

Communication Promotes Collective Action in Madaoua's Divergent Adaptation Arena

Despite large tax income from livestock, institutions do not do a sufficient job of protecting pastoral space. Respondents often blamed democracy or decentralization.

"[N]ow with the democratization, [protection of pasture] has become a problem. Even if you see someone planting in the *aire du pâturage*, they [the customary chiefs] will say that they are coming, but they never arrive." Despite pastoralists' complaints, elected officials do little to manage common pastoral spaces due to a desire to garner favor (votes) among the more populous Hausa people, who typically have large families and thus need land tenure for their children's inheritance. All of the pastoralists in this area complained of the lack of safe corridors for their passage due to encroachment (Table 2). Cultivators often dispute ownership of pastoral space, declaring that it was cultivated by their ancestors. During one such dispute, the Fulani chief and Hausa cultivator argued about historical rights to the land without resolution (Image 5).

Average payment for crop damage is higher than in Keita. This forces pastoralists to be more vigilant. In turn, crop damage costs are frequently negotiated face-to-face between parties, with the support of customary officials. For rain-fed crop damage, the average cost per head for a large ruminant is 14 USD, and for a small ruminant, it is 6 USD. For garden damage, costs are higher, typically 215 USD. Some of the agro-pastoralists we interviewed tended to forgive crop damage, even for those pastoralists who were foreigners to the zone, but this practice of forgiveness was not common (Table 2). Other villagers in Locale A thought that damage was the fault of the field owner for not guarding his field properly (Table 2).

Along with the high-cost sanctions, these normative responses are also due to administrative support of peaceful resolution. Administrators, group, and canton chiefs in Madaoua (Fig. 3, Image 5) prefer face-to-face discussions to prevent conflict. At the beginning of the descent, Fulani and Tuareg chiefs from five groups travel with administrators to every commune in Tahoua to discuss conflict resolution measures including places to safely "rest" their livestock and how to manage conflict. When these visits are finished, the chiefs return to villages in Madaoua, some of which are along the pastoral corridors. Locale A is very strict about pastoralists entering the village, even along the international livestock corridor, which is just south of the moist valley. When the harvest is complete, village chiefs grant pastoralists entry, and if these rules are not followed, higher-level customary chiefs are quickly called in to negotiate. When describing one such occasion,

Image 5 Agro-pastoralist discussing crop encroachment into pasture area with Fulani group chief, during our community mapping of Bangui (author)

pastoralists may wait in already-harvested fields, which may concurrently serve as a "contract" for fertilization services.

Thus, crop damage is solved without violence and through conflict prevention. Locale A's chief explained the first resort, to negotiate with offending pastoralists, and second resort, to call upon the administrators and customary chiefs in the commune capital Bangui (20 kilometers away). There was never a need to take any further action. Locale A experiences few violent conflicts (Table 2) but communicates frequently with both pastoralists and local and regional institutions. If local chiefs need assistance with a conflict, local officials engage both parties in face-to-face conversation about the problem, evoking discussion among multiple parties. When asked how they manage to maintain peace despite the descent of pastoralists into the village, an agro-pastoralist replied: "The pastoralists need to talk with the farmers. Otherwise, we don't have many ideas. Calling the administrators is the best solution.. .. Yes, [sometimes the customary chiefs have discussions with the population], and it is valuable" (Madaoua pastoralist).

"Democracy as Problem"?

What some agro-pastoralists and pastoralists termed "democratization," referring to the decentralization process in Niger, has created overlapping layers of governance (customary/elected official/COFO). In turn, this has produced a resounding accusation that "democracy is the problem," referring to patterns of corruption that have been supporting the marginalization of pastoralists. Pastoral commons, which have in the past been identified and protected by group chiefs, have declared the property of sedentary groups as a way of garnering their votes in the democratic system. This outcome is synchronous with rent-seeking behaviors across these new layers of governance.

In the context of this nascent democratic system, the creation and distribution of entitlements are related to elite capture processes that subjugate the rural pastoral more than agro-pastoral systems. This is a key institutional factor contributing to divergent adaptations such as the expansion of cultivation into pastoral space and the commercialization of field residues. In Keita, multiple scales of institutional actors (gendarmes, local chiefs, administrators, etc.) induce an atmosphere of fear resulting from heavy enforcement of crop damages and rent-seeking from both rural actors (pastoralists and agro-pastoralists). The *gendarmerie* engages in sanctioning pastoralists, in some cases confiscating pastoral property with impunity. Thus, there are high perceptions of corruption in the zone and low levels of social capital between user groups (Table 2). Gendarmes, in turn, reinforce these biased accounts of the codes by failing to protect pastoral commons. These conditions have been found in similar case studies of farmer-herder conflict (Benjaminsen et al. 2012) and result in these groups seeking other means to defend their livelihood, including violence (Snorek et al. 2014a).

In Madaoua, actors in Locale A mentioned fewer conflict dynamics and more locally derived systems of collective action and enforcement (Table 2). Moreover, the behaviors mentioned during conversations with individuals at the local scale exemplify that actors are informed of how to seek help from leadership, are empowered to solve their own problems (through dialogue with the chief), and understand planned measures and support systems (a step process of seeking support from local and external sources), which are elements that are reflected also in polycentric, adaptive institutions (Gupta et al. 2010; Ostrom 1999; Berman et al. 2012; Allen et al. 2010). Due to high levels of marginalization of pastoral actors, having a higher number of group chiefs living in Madaoua has helped to enhance opportunities for collective action due to the greater representation through these chiefs. Villagers in Locale A stated that they would ask the help of outside administrators or customary officials for the purpose of preventing conflict. Administrators and customary officials from sub-national scales participate in deliberation processes and negotiate solutions through face-to-face dialogues with multiple actors.

Neo-Malthusian concepts of scarcity induced by concentrated land use and demographic growth would state that Madaoua is a more likely case for scarcity-induced conflict. Yet despite the divergent adaptations, coupled with factors of exclusion (due to expanding cultivation) and marginalization (represented by ignorance of the need to protect pastoral spaces) present in both case study areas, Keita faces greater conflict. Crop damage is present in Madaoua, and sanctions are justifiable means of reducing crop damage. Yet unlike in Keita, sanctions are not used for elite capture, nor do they serve as a means of marginalizing pastoral actors. Rather, face-to-face conversation (Ostrom 1999) is a means to support collective action over common pool resources. As a result, both actor groups perceive communication as essential to the annual transhumance and shifting of land tenure regimes through the *liberation des champs.* Furthermore, social innovations such as “livestock waiting areas” in agro-pastoral villages enhance agency and provide spaces for social learning to take place in safety and security. This local mechanism for preventing both damage and conflict is possible both because of the history of communication between actors, the presence of physical pastoral enclaves or waiting areas, and the open and transparent sharing of information in Locale A, Madaoua.

To overcome marginalization and spatial exclusion, institutional actors at the local scale need to have more support from government officials including access to land, fodder, and water to support pastoralists during their passage. While some efforts to maintain pastoral water access remain entrenched in age-old systems that profess that pastoral commons cannot be enforced (Hardin 1968), there is a greater concentration and historical presence of charismatic leadership among pastoral customary leaders in Madaoua to negotiate and overcome these challenges (Ostrom 1999; Gupta 2010). This emphasizes the importance of representation by customary officials who, in turn, interact closely with their constituents and speak on their behalf to defend livelihood access rights and support other complex and uncertain livelihood trials stemming from divergent adaptations.

Conclusion

This chapter illustrates how institutions, especially those at the local scale, shape divergent adaptation. Analyzing responses from pastoralists, agro-pastoralists, and multiple customary and administrative officials in Niger identified two divergent adaptations prevalent in the case study areas: (1) the closing of pastoral spaces by cultivation, which is related to crop damage payments, and (2) limited water and fodder access and availability due to agro-pastoralism and cutting of field residues. For both of these, the adaptive capacity of pastoralists is reduced. Yet, despite the similar typology of the divergent adaptations, the in situ institutions produced different outcomes in each locale.

The violence experienced between pastoralists and agro-pastoralists in Keita, exemplified by the presence of arms, livestock theft, and land and water access, was in contradistinction to the way that conflict was experienced in Madaoua, where informants did not negate the presence of conflict, but identified more preventative and cooperative behaviors including transparent information and itinerary sharing, availability and support from multiple institutional scales, transactions such as farmer-herder "contracts," expressions of cooperation and kindness to the other group, and trust of local, customary officials. These outcomes contradict neo-Malthusian logic that posits that increased human concentrations lead to scarcity dynamics (Homer-Dixon 1999) and support the idea that conflict is relevant to how institutions frame adaptation (Snorek et al. 2014a). Reflecting these and other findings (Kpadonou et al. 2012), local-scale, collective action institutions are more capable of promoting trust, cooperation, and reciprocity through face-to-face discussion of rule and expectations (Gupta et al. 2010; Ostrom 1999).

Integrating adaptation planning and institutional capacity building across administrative jurisdictions is essential to sustainable, peaceful adaptation outcomes in Niger. The adaptation needs of mobile pastoralists demand uninterrupted and well-stocked pastoral corridors and resting areas. Yet when their needs are not met, suppression of conflict equates to greater conflict. As other research has shown (Snorek et al. 2014a, 2017), institutions that encourage expressions of conflict by direct confrontations, dialogue, and discussion may better promote sustainable adaptation than the top-down, conflict-suppressing institutions exemplified in Keita, as the latter tend to reinforce unequal power relations and promote marginalization. By enhancing institutional models that provide space and time for collective action, multiple users can express and discuss their adaptive capacity needs, which have greater potential to bring about more sustainable, peaceful adaptation (Eriksen et al. 2011), especially for groups facing livelihood insecurities, social and climate vulnerability, and marginalization. Furthermore, as was demonstrated in the cases and in other research (Niamir-Fuller 1998), flexibility in resting points and enclaves as well as more transparent information about timing and spatial constraints related to the clearing of fields is essential to peaceful adaptation and will require more locally mediated and managed models of governance.

This chapter shows that local institutions that support engagement of multiple groups in collective action processes tend to lessen the tensions relevant to divergent adaptation. This research further elaborates (Snorek et al. 2014a, 2017) how divergent adaptation is a process that can change institutions *through* conflict or cooperation dynamic and should be applied to other social, ecological, and political contexts, to further examine how to bring about more peaceful and sustainable adaptation.

Acknowledgments The research was funded as part of the 3-year European Commission Seventh Framework Program CLICO (Climate Change, Hydro-Conflict, and Human Security), devoted to the study of climate change.

W. Leal Filho et al. (eds.), *African Handbook of Climate Change Adaptation*,
https://doi.org/10.1007/978-3-030-45106-6_191

Abstract

Adequate and proper adaptation strategies to climate change depend largely on activities in the rural sector, which drives national economy through exploitation of natural resources. Consequently, actions in rural areas are essential to successful climate change adaptation. Rural communities are highly dependent upon natural resources that are affected by climate change, thus affecting their food security, livelihoods, health, and physical infrastructure. Women and their livelihood practices are thereby affected negatively, leading to increased poverty level and low income, because they find it difficult to respond adequately to climate change effects. This study examines the past and existing interventions on climate change adaptation strategies in two rural communities in Oyo State, introduces climatepreneurship strategy, and assesses its effectiveness. This is an explorative study, employing qualitative approach to gather information through in-depth interview (IDIs) from 50 farmers, before and after the interventions. Data collected were analyzed using Atlas ti. This is a powerful workbench for qualitative data analysis using coding and annotating activities to generate different thematic issues for discussions and interpretations with networks. Study revealed that communities had previously experienced some interventions. Such had no impact on livelihood practices because steps to successful intervention were not followed. Socio-cultural practices hinder women development. The newly introduced climatepreneurship strategy improved livelihood practices. Study outcomes will expectedly be integrated into policy framework for sustainable rural women entrepreneurship development and also replicated in other rural areas in Nigeria.

Keywords

Climatepreneurship · Adaptation strategies · Climate change · Rural women · Entrepreneurship development · Nigeria

Introduction

In recent years, the terms viable adaptation strategies and climate resilience have become important concepts for both scholars and practitioners working on climate change. This progress reflects a growing interest from various disciplines in a holistic understanding of complex systems, including how societies interact with their environment and adapt to the increasing effects of climate change. This new lens offers an opportunity to focus on communities' ability to prepare for and adapt to the challenges posed by natural hazards and the mechanisms/strategies that have been developed to cope and adapt to threats. This is important because repeated stresses and shocks still cause serious damages to communities across the world, despite efforts to better prepare for disasters. This is especially relevant to the rural communities that are highly dependent upon natural resources which are affected by climate change, thereby affecting their economic activities, food security, livelihoods, health, and physical infrastructure.

Women in particular and their livelihood practices have become highly vulnerable. They face various challenges from effects of climate change such as drought, delayed rainfall pattern, heat wave, flood, etc. According to Howden et al. (2007), agriculture as a major economic, social, and cultural activity of most women, particularly in the rural areas, provides a wide range of ecosystem services. The sector is saddled with the responsibility of meeting the projected growth in human population and per capita food demand. Unfortunately, this sector remains highly sensitive to and affected by climate variations. The economic activities are therefore affected negatively, leading to increased poverty level and low income, because the rural women find it difficult to respond adequately to climate change effects.

Many studies have argued that climate change and its effects are clear, escalating and will continue to be a contending issue around the world, because enormous quantities of greenhouse gases (GHGs) have been released into the atmosphere over the past decades through anthropogenic activities (UNDP 2010; Adesina and Odekunle 2011; IPCC 2014, 2015; Salami 2010). According to Dube and Phiri (2013), climate change is now a well-accepted reality with emerging evidence that climate change poses a massive threat for development especially in poor countries. Also, Sadashivam (2010) reported that climate change is a global and regional environmental problem faced by humanity and livelihoods with strong implications for rural populations, particularly women. Kumar and Sharma (2013) analyzed the impact of climate change on agricultural productivity and submitted that variation in climate affects food grain and non-food grain productivity and other livelihood practices. This is due to the fact that climate change often alters the physical geography of an area leading to a disappearance or reduction of natural habitats that constitute the livelihoods of the women. Declining precipitation and rising temperatures are making farming increasingly more difficult with declining productivity, and thus aggravating food insecurity.

In Nigeria, Nwokeoma et al. (2017), Ikehi et al. (2014), Akinbami et al. (2015, 2019), and Ali (2011), have reported on the effects and social consequences of climate change on the farming families, livelihood practices, farmlands, economic activities, food security, health, and physical infrastructure in various communities in the country. These studies reveal that global warming which is as a result of climate change has serious impacts on the communities and their livelihood practices, and these effects will spiral out of control, if the current trend of increasing greenhouse gas emissions is not curbed. This will bring about more natural disasters, increased declining livelihood practices, worsened global food supply, and also threaten the existence of millions of people, with a disproportionately high impact on the impoverished and indigenous populations, particularly, the women. Therefore, there is a need to continue to pursue climate change mitigation and adaptation strategies with vigor (IPCC 2014).

Climate Adaptation Strategies Among Rural Women in Nigeria

Some studies have documented various adaptation strategies geared toward economic development of women in Nigeria (Ikehi et al. 2014; Abid et al. 2015; Etim and Etim 2019) such as planting date adjustment, crop diversification, conservation agriculture, and crop and livestock integration. However, according to Yilmaz (2014) and Etim and Etim (2019), many interventions have failed due to low awareness level and lack of proper involvement of stakeholders, inappropriate non-local technologies to the areas affected, and improper communication of interventions and implementation as the top-down approach was adopted, without the participation of community members. Howden et al. (2007) also alluded that there are many potential adaptation options available with substantial benefits only under moderate climate change for some cropping systems and are therefore not very effective under more severe climate change. In addition, most interventions lack long-term plan for monitoring and sustainability.

In order to build the resilience and sustainable development of women across the whole disaster cycle, involvement of communities in identifying problems (community communication) and involving them in addressing the identified problems become key factors to be considered in determining information-based adaptation strategies that are borne out of earlier sensitization programs. This is more of a bottom-up rather than top-down approach. It is believed that this approach will reduce the impacts of climate change as well as disaster-related losses and lead to faster recovery and the ability to "build back better" (Cutter et al. 2008).

Joo et al. (2011) further expatiated on steps that will aid sustainable development through implementation of interventions as (a) identifying key performance measure for the intervention by creating a plan to know the community to have an idea of their problem, attitude, and behavior; (b) measuring own's internal performance level by how you have to be knowledgeable about the identified intervention and able to gather a team of experts to handle the identified problem and work on the actual and appropriate intervention; (c) identifying intervention advantages and disadvantages, process, and training models and materials; and (d) implementing intervention to close a performance gap by holding meetings and executing all the planning that have been done and importantly, follow through to achieve successful implementation which is monitored thereafter.

Therefore, in responding to the need of implementing appropriate measures to address the severity of climate-related hazards among Nigerian rural women, adequate and effective adaptation strategies are necessary to handle the effects of climate change. Such strategies will integrate the findings of climate change risk assessments into planning processes for disaster risk reduction and management and embrace methods that are climate smart and able to turn climate change challenges to entrepreneurship opportunities, thereby reducing poverty among the rural women, in particular, hence, the introduction of climatepreneurship.

Climatepreneurship and Other Smart Strategies

In literature, scholars had conducted studies on smart strategies and termed differently, such as agri-preneurship, ecopreneurship, etc. Agri-preneurship, according to Ashe (2019), is a new measure taken by developing economies utilizing various forms of technological tools and methods to tackle farm yield, which is sometimes referred to as smart farming. Pai, Shah, and Bohara (2020) also stated that, as the effects of climate change and population growth resulted in high food demand, smart farming is now being adopted. Agri-preneurship comprises of some farming methods such as geo-mapping, greenhouse farming, hydroponics, nutrient cycling, and soil analysis that could address the issue of low farm yield in developing economies (Ariani et al. 2018).

Ecopreneurship was seen as an answer to market breakdown in dealing with negative environmental impacts caused by the industries by focusing on underlying green values and solving the problems in the society caused by these businesses (Kirkwood and Walton 2010). That is, business activities should be geared toward providing values across three dimensions: economic, social, and environmental. Priority is given to addressing the effect of the negative externalities of firms' economic activities on these firms' immediate surroundings (Doman'ska et al. 2018). The goal is, therefore, to build a business model that is sustainable in the long run which ecopreneurship contributes to achieving this goal by seeking simultaneously for both profit and environmental sustainability (Rekik and Bergeron 2017). The concept of ecopreneurship is based on three pillars: innovation, caring for the environment, and long-term sustainability (Hultman et al. 2016).

Climatepreneurship is an adaptation strategy to climate change effects which consists of activities that are climate smart and make use of locally available resources for economic empowerment and enhancement of the social status of rural women. It also helps to turn climate change challenges into opportunities, and thereby emphasizes livelihoods' diversification. This concept entails climate change, adaptation strategies, and entrepreneurship, while according to Omodanisi et al. (2020), smart agri-preneurship entails smart agribusiness, smart technology, and entrepreneurship. Entrepreneurship in agri-preneurship is defined as the means to create and develop a profitable agribusiness, while in climatepreneurship, it is a means of turning climate change challenges into business ventures in all livelihood practices, as well as developing profitable agribusiness by adopting adaptation strategies. That is, agri-preneurship deals with ways of increasing farm yield, while climatepreneurship deals with climate-related issues as they affect the livelihood practices and more importantly, turning the challenges of climate change to various business ventures. On the other hand, ecopreneurship deals with the means of carrying out entrepreneurial activities in order not to affect the environment negatively.

Though, the concepts are geared toward achieving sustainable development and reducing starvation among the populace, climatepreneurship goes a step higher by introducing livelihood diversification, exposure to the use of natural resources in the local environment, and turning climate change-related challenges into business opportunities as a major adaptation strategy (Rehman and Shaikh 2014; FAO 2011). Agri-preneurship can therefore be seen as a subset of climatepreneurship aimed at increasing farm yield and enhancing food security in an eco-friendly manner (FAO 2018; Lin et al. 2015; Omodanisi et al. 2020; Ponisio and Ehrlich 2018; Adebiyi et al. 2018). Succinctly put, climatepreneurship is an adaptation strategy to climate change effects which consists of activities that are climate smart, eco-friendly process, and making use of locally available resources for economic empowerment and enhancement of the social status of rural women. It also helps to turn climate change challenges into opportunities.

Thus, climatepreneurship can be regarded as a viable and significant option to safeguard rural livelihoods and ensure rural sustainable development. Hence, this study on climatepreneurship, which presents viable adaptation strategy for addressing climate change, impacts women entrepreneurship development in Nigeria. It aims to examine the past and existing interventions and assess the effectiveness of implemented climatepreneurship strategy introduced by this study among rural women in selected communities in Oyo State.

Theoretical and Conceptual Framework

Theoretical Framework

This study is anchored on socio-ecological system approach which sees a community as a coherent system of biophysical and social factors that regularly interact in a resilient, sustained manner and are linked systems of people and nature, emphasizing that humans must be seen as a part of, not apart from, nature (Berkes and Folke 1998; Redman et al. 2004). The socio-ecological model (SEM), therefore, provides the framework for understanding the interactions between the multiple levels of a social system and how behavior and attitude are thereby affected. The multiple levels according to SEM are individual, interpersonal, community, organizational, and enabling environment (Fig. 1). The main tenant of this theory is based on

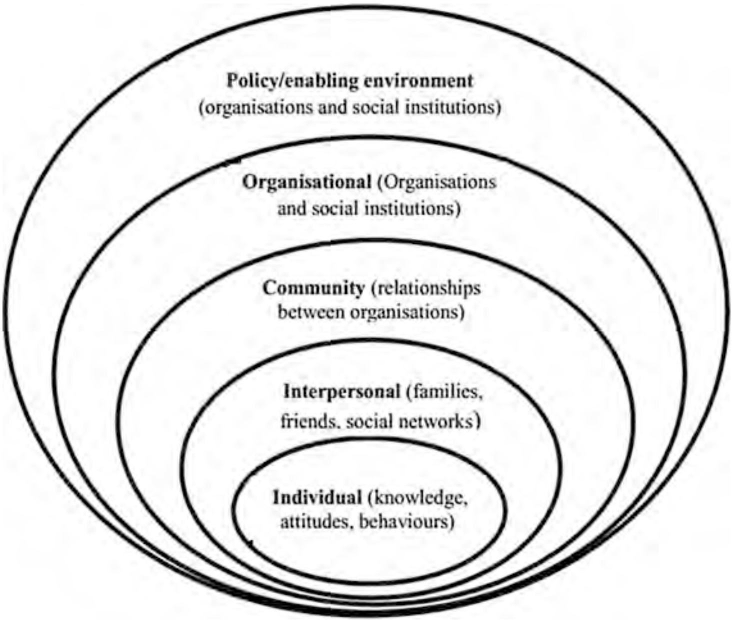

Fig. 1 Socio-ecological theory. (Adapted from Bronfenbrenner (1989))

cooperation between individuals and environment within the system with emphasis on the model of communication for development (C4D), how to incorporate social norms and needs into program planning and partnerships to finally achieve capacity strengthening (CDC 2014).

Consequently, in this regard, adaptation strategies have been acknowledged as useful measurement to understand to what extent the intervention measures address the needs of people as end-users, to what conditions people are still vulnerable, whether the potential outcomes are expected or unwanted (MOVE D.5 2011; Yilmaz 2014). In this sense, it is important to monitor the effects of implemented strategies, especially in terms of observing how the affected communities adapt economically and socially.

Conceptual Framework

The conceptual framework (Fig. 2) further explains the operationalization of the concepts in order to achieve positive results in the rural areas. The individual (rural woman) is the victim of climate change impacts, norms, and socio-cultural activities, and with low livelihood practice, who equally needs to change her own personal attitudes and beliefs toward climate change. Though, aware of the effects of climate change on her livelihoods but yet helpless because of the major and drastic changes

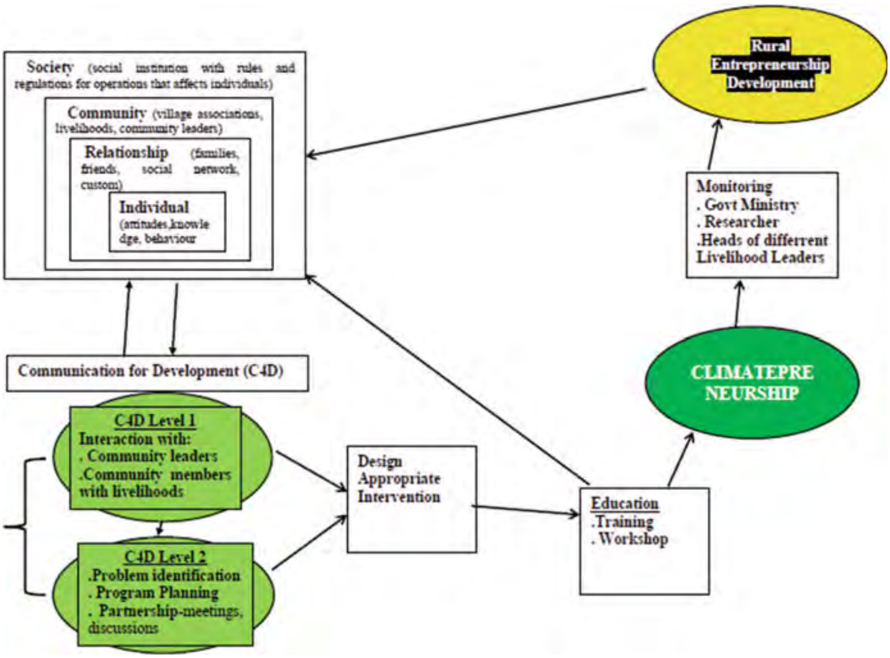

Fig. 2 Conceptual framework. (Source: Author)

in weather being experienced and leading to low farm yields and sales. Even though currently taking steps of engaging in moderate activities in order not to be idle, the poverty level is still on the increase. Having awaited help from government circle for so long, and now frustrated, the victim of the climate change impacts seeks for solution to the economic challenges. The community houses the relationships among institutions and informational networks within defined boundaries, which comprises of the total environment (social, economic, norms, and various association groups) as they affect the individuals reflecting gender specifics. The society at large dictates the enabling environment at the local, state, and national levels including policies that affect and regulate the choices the individual makes.

This framework underscores communication as a vital instrument for development, with the argument that livelihoods have been left to suffer as a result of non-involvement of the community members (i.e., partnership) in most of the interventions/programs that have at various times been designed for rural development. Consequently, the approach to the implementation of such programs had been top-bottom approach, and this has led to the failure of most of the interventions. If interactions through stakeholders meetings take place in order to identify actual problem and gain better understanding before planning a program, clarify limiting socio-cultural issues, designing appropriate training on handling and management of intervention, and establishing a monitoring team (as part of the monitoring and evaluation mechanism), then the designed program will definitely be successful, and the livelihoods of individuals will improve with poverty level reduced and eventually leading to sustainable development in the rural areas.

In essence, in order to reduce disaster and build resilient communities, the socio-ecological model should be an effective learning and assessment tool for the development of rural livelihoods. As the increasing new information and training on how to improve livelihood practices amidst impacts of climate change are gained, the employment of both bottom-top approach and partnership method will stir up a strong will among the rural dwellers to follow through with the new intervention (s) designed. The society and communities will directly be affected positively since both are collections of individuals.

Methodology

This study was carried out to determine the extent to which adopted adaptation strategies to climate change have impacted on the rural women entrepreneurship development in Nigeria. An assessment study (Akinbami 2015) had been carried out to determine the impact of climate change on the livelihood practices of women in the rural areas of some southwest States of Nigeria. Due to limited fund available for the interventions in this study, Oyo State and some of the communities in the State were purposively chosen based on the assessment report on vegetation zone and availability of needed resources (Akinbami 2015) to pilot the implementation of the climatepreneurship strategy. This is an explorative study, employing qualitative approach to gather information through in-depth interview (IDIs) and questionnaire administration from 50 farmers, both male and female, before and after the interventions. This study adopted descriptive research design to examine the past and existing interventions in the last few years before the introduction of climatepreneurship strategy. The study area is in Oyo State which is in the southwest region of Nigeria.

The study was carried out in two purposively selected communities – Araromi Idowu and Abokede Communities at Ido LGA, Ibadan, Oyo State, Nigeria (Fig. 3). The communities are made up of men and women whose different livelihood practices have been affected negatively by climate change. The target populations for this study are mostly women and few men involved in crop farming activities (cassava, maize, oil palm) and who were able to supply land space for planting. Pre-intervention interview was conducted only to participants who were able to supply up to an acre of land each. This was to capture necessary immediate situational experiences of the women and be able to compare with post-intervention interview.

Some men were also added for them not to view the project as just solely pro-women activity and a means of empowering the women against the men. This became useful in order to address the existing socio-cultural issues. The instrument for primary data collection was structured interview questions developed from literature reviewed for the study with inputs from the pre-intervention stakeholders meetings. The use of in-depth interview was to harvest the views and experiences of the respondents on the nature of perceived climate change impacts on their livelihood practices and previous interventions in their communities. The IDIs targeted participants who could provide up to an acre of land to accommodate intervention varieties, more for the purpose of monitoring and evaluation while the questionnaire was distributed among the other participants who showed interest in the intervention.

The project targeted 50 participants who had portions of land available and who were interested in participating.

The employed methodology involved some activities, such as:

- Community visitation and sensitization program.
- Meetings with different stakeholders in the communities to identify challenges.
- Distribution of improved drought-tolerant maize varieties and beta-carotene fortified cassava for planting.
- Distribution of hybrid oil palm trees (those who were able to supply up to an acre of land each) for planting,
- Training of women on entrepreneurship businesses in the oil palm tree products.
- Meetings with government parastatals saddled with women affairs, climate change, and agriculture in the State to intimate them with the objectives of the study and solicit their partnership and collaboration for its success.
- Facts finding workshop for all stakeholders involved in the study.
- Agricultural extension officers from the State Government were also part of the training exercise and workshop for effective monitoring of the intervention.

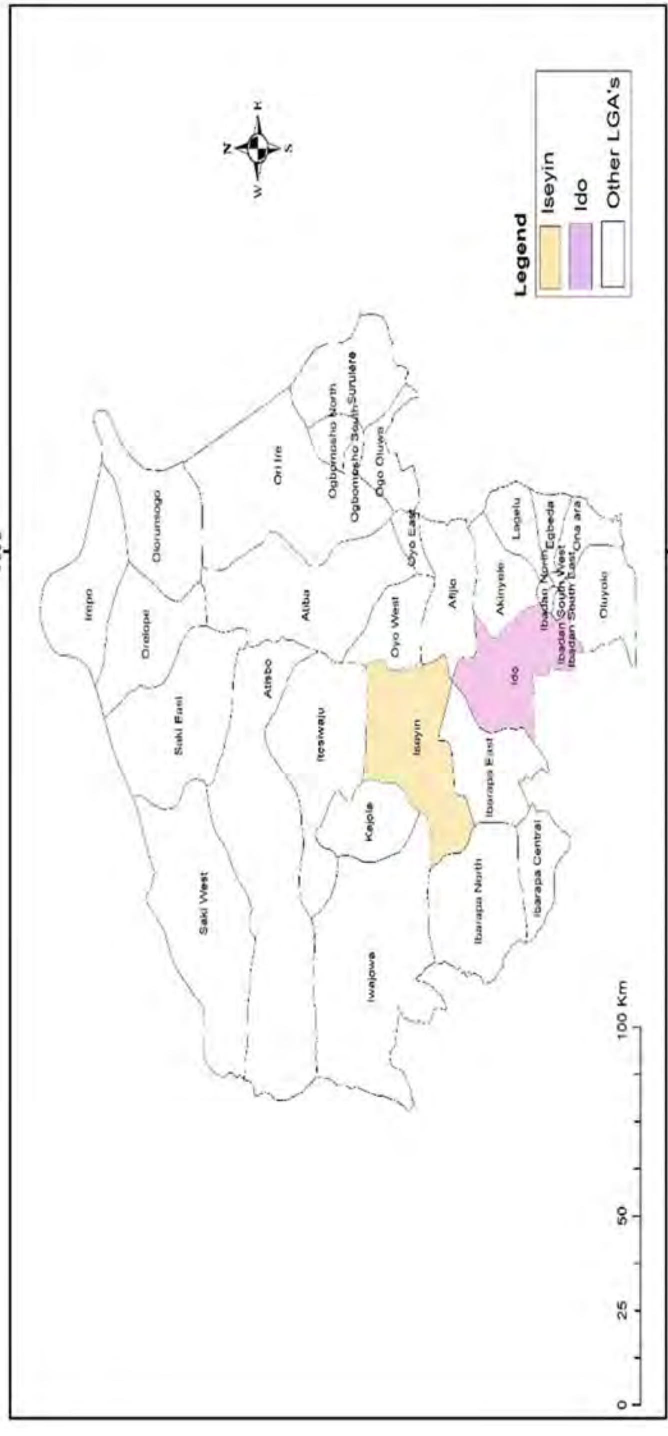

Fig. 3 Map of Oyo State showing the Ido Local Government Area where the study areas are located

Data Analysis

Data collected were analyzed using Atlas ti. This is a powerful workbench for qualitative data analysis using coding and annotating activities to generate different thematic issues for discussions and interpretations with networks.

Result and Discussion

Socio-Demographic Characteristics of Respondents

This section provides descriptive summary of the characteristics of the rural women and men entrepreneurs (18) gathered during IDIs, who were able to supply up to an acre of land each for the intervention in Table 1. However, the other 32 participants who showed interest in the exercise and with less than an acre of land were also accommodated by the intervention. The 18 participants reported in Table 1 were given drought-resistant maize, vitamin A-enhanced cassava, and hybrid oil palm trees. In addition, the intervention provided drought-resistant maize and vitamin A-enhanced cassava to the 32 participants (those with less than 1 acre of land) for planting on their farming space.

All the 18 participants were in the age range of 40–65 years (Table 1). Participants were mainly into crop farming involving planting of maize grains, cassava, and palm tree. All of the women were found to be involved in another occupation, such as food processing of garri (cassava-based Nigerian staple food); cassava and palm oil ventures; and sales of cloths, beverages, and other food items. While all the men had crop farming as their major economic activity, about 67% were not involved in any other economic activity. The table further revealed that about 20% of the men were into additional occupation of commercial transportation using their motor cycles, and it was observed that these are of the younger generation. About 10% of the men were involved in food processing as an additional economic activity.

Table 1 also showed their educational status; about 72% of the participants were not with formal education, 22% had only primary school education, and 6% were with secondary school education. About 96% of the participants had spent more than 15 years in crop farming business.

The age range of the other 32 participants is between 38 and 65 years, with 80% being women involved mostly in food processing, while the men (20%) were mainly into crop farming. It was observed that the educational status, awareness of climate change, and involvement in other occupational activities are the same as those respondents in IDI. The opinions of the respondents in both instruments are presented in the analysis.

Awareness of Climate Change and Impacts on the Business Activities

All the respondents (from IDIs and questionnaire) reported that they are aware of the changes in the weather recently. The participants stated that the changes had been

Table 1 Socio-demographic factors of participants during IDIs

Respondent	Age	Sex	Educational status	Occupation	Community	Years of farming engagement	Second occupation
Respondent 1	40	Female	Secondary	Crop farming	Abokede	5	Sales of provision
Respondent 2	60	Female	No formal education	Crop farming	Abokede	30	Sales of cloth
Respondent 3	50	Female	No formal education	Crop farming	Abokede	25+	Food processing (palm oil)
Respondent 4	40	Female	No formal education	Crop farming	Abokede	20	Food processing (palm oil, cassava)
Respondent 5	65	Female	No formal education	Crop farming	Abokede	30+	Food processing (palm oil)
Respondent 6	50	Female	Primary education	Crop farming	Abokede	20+	Sales of yam flour
Respondent 7	40	Male	Primary education	Crop farming	Araromi-Idowu	15	Commercial motor cycling
Respondent 8	52	Male	Primary education	Crop farming	Abokede	30+	None
Respondent 9	60+	Male	No formal education	Crop farming	Abokede	30+	None
Respondent 10	62	Male	No formal education	Crop farming	Abokede	30+	None
Respondent 11	55	Female	No formal education	Crop farming	Abokede	20	Food processing (palm oil)
Respondent 12	62	Female	No formal education	Crop farming	Araromi-Idowu	30+	Food processing (palm oil)
Respondent 13	42	Male	No formal education	Crop farming	Araromi-Idowu	30+	Commercial motor cycling
Respondent 14	57	Male	No formal education	Crop farming	Abokede	30+	None
Respondent 15	60	Female	No formal education	Crop farming	Araromi-Idowu	30+	Sales of dry maize
Respondent 16	50	Male	No formal education	Crop farming	Abokede	30+	None
Respondent 17	56	Male	No formal education	Crop farming	Abokede	30+	Food processing (palm oil)
Respondent 18	48	Male	Primary education	Crop farming	Araromi-Idowu	30+	None

Source: Study Survey

observed through personal experiences and comments from colleagues as far back as 30 years' ago, and this has been confirmed by information from the radio programs they listened to on climate change. Their awareness cut across the elements of weather vagaries such as distortion of rainfall pattern, drought, sea level rise, temperature rise, and increase in humidity. They reported "as farmers, we have experienced hard times as a result of the changes, which ranges from delayed rainfall to increase in temperature and drought." Consequently, the communities have suffered some economic hardship and social consequences from impacts of climate change. Some of the responses of the respondents are:

> There is too much heat, as a result, our crops, vegetables and other things planted do not do well. Sometimes, the farm products harvested are both too few in quantity and small in size that we do not have good quality crops to sell. This has increased poverty level in this community, especially among the women. **Female Participant, Abokede Community, 40 years old**
>
> The weather has become so unfriendly, we as farmers do not have rains as at when due, the sun is too much, our crops therefore produce low yield. Ultimately, we have little to sell and are having poverty increasing in this community. **Male Participant, Araromi-Idowu Community, 42 years old**

This study outcome supports the work of Suleiman (2014) which stated that farmers had crops uprooted prematurely and destroyed due to harsh weather condition; as such, crops could not be taken to the market. They lost money that should have been gained.

This could be the reason why the younger-generation men in this study subscribed to another business (commercial transportation) because the pangs of impacts of climate change were being felt. The income generated from only farming activity was no longer enough to cater for their needs. These impacts had led to the increase of poverty level in the communities and particularly, among the women. It has further shown the relationship between climate change, livelihood practices, and community empowerment.

Also, due to the low level of education of the rural communities, participants could not process the information received into finding out the causes of climate change and what adjustments are needed to be made to improve the livelihood practices. Participants knew nothing about crop diversification strategy which could have helped to improve the livelihood practices. This study revealed the communication gap that exists between the rural areas and research outcomes. This submission is in line with FMENV (2010) which stated that programs, policies, and activities of the Ministry on climate change do not seem to have specifically targeted and involved farmers. Consequently, the farmers are exposed to hardship. In affirmation, participants from both communities stated:

> We are hoping that help will come one day. Our community leaders know about our plight since we are in it together, unfortunately, they don't know what to do. **Female Participant, Araromi-Idowu Community, 62 years old**
>
> We don't even know the cause of the change nor do we know the solution. **Male Participant, Abokede Community, 57 years old**

Participants could not produce any observed weather pattern based on the reported climate change, to help them know when and what to plant, that is, adjusting the planting calendar in order to adapt to the change in rainfall pattern, as stated by Ikehi et al. (2014) that "planting date adjustment" is one of the strategies that can be employed by the rural communities to cope with impacts of climate change. The study is also of the opinion that the low level of education of the participants may be a major factor responsible for this inability.

Participants declared that they have been coping through prayers. They perceived climate change as an act of God and not induced by the activities of man. They also said God has decided to punish man as a result of sin which is on the increase daily. This has affected their readiness and preparedness for mitigation and adaptation strategies. A participant said:

> Sacrifices were done by our forefathers with animals and now are being done with human beings, so, why will God not be angry. **Male Participant, Araromi-Idowu Community, 62 years old**

The participants' lack of understanding therefore calls for urgent and proper training at the rural areas by the agriculture extension officers, so that rural dwellers especially will not continue waiting for the government to handle what they can quickly put right by themselves. This study sees this step as important because an enlightened community will be able to contribute to the process of developing adequate adaptation strategies which the community will own and preserve. Consequently, intensive and extensive sensitization and education programs mounted by both public and private sectors including the faith and community-based organizations as well as climate-based NGOs are essential since effective adaptation requires a holistic approach that incorporates both policy, people, and investment issues into the planning and decision-making processes. This is of great importance as no one solution will adequately address effective adaptation in all communities (UNDP 2010). Effective adaptation will require long-term planning approaches at the national, regional, and also, local level, which is responsible for the national food supply. However, at all the levels, their associated impacts in the rural communities may not succeed if the end users are not carried along due to the lack of understanding of subject matter.

Experiences of Participants and Their Livelihood Practices on the Effects of Climate Change

The study revealed some of the experiences of participants from the effects of climate change as it affects their livelihood practices. According to the participants, the climatic change ranges from delayed rainfall, strong wind, increase in temperature, and heavy rainfall leading to flooding, thereby affecting the roads and also resulting in overflown rivers. It was observed that participants from the two communities have similar experiences as they commented on the effects of different aspects of climate change. It was reported that there has been delayed occurrence of rainfall, and when it occurs, the intensity was unusually heavy and had an adverse effect on their farm products. This was reported by participants during the in-depth interview sessions and questionnaire administration conducted in the two communities. The reported effects of climate change on the participants' crop farming business are presented in Fig. 4. According to Akinbami et al. (2019) and Slater et al. (2007), these negative impacts have implications on food security of the nation. As a nation, researchers, civil society, and policy makers should be in quest for innovative approaches to food security and not depleting the available quantity, especially with population increase which may expose people to the risk of hunger and its associated social vices.

Previous Intervention in the Two Communities

According to some of the participants from Araromi-Idowu and Abokede communities, it was reported that they have never been part of any intervention either from the government, NGO, or a researcher. The community leader at Araromi-Idowu reported that there has not been specific intervention from the government except for a borehole that was dug for the community about 3 years ago. The borehole has ceased functioning due to lack of electricity to pump constantly. However, he further stated that some researchers in the last 2 years had visited the communities with some interventions. He retorted:

> About two different times, some people (researchers) visited our community and distributed cassava stem (they said it is fortified with vitamin A) and maize grains to few male farmers. We were not taught the importance of the seedling and grains. As a result, most of us did not plant them. I kept the grains in my house and l know that my colleagues did same. **Youth Community Leader. Araromi-Idowu Community**

From the submission of the respondents, it was observed that interventions did not succeed because the measures that lead to successful implementation of interventions were not taken into consideration. Measures such as communication and partnership with the communities' members, as well as monitoring, were missing (Joo et al. 2011; CDC 2014; Yilmaz 2014; Etim and Etim 2019). Apart from the ineffectiveness of the previous interventions, the women reported special challenge they are facing as a result of socio-cultural practices which are still very strong in the rural areas.

> About three years ago, some people came to train us women on how to manage our businesses, the men did not allow us to participate fully. They felt threatened and it is also against the rules/practices of this community to gather only the women. The cause of their anxiety is that they thought we would be exposed to things that will make us rebel against them, especially, when we are financially liberated. **General response from women in the two communities**

This study is of the opinion that these unattended to changes in weather patterns through various appropriate and effective adaptation and mitigation measures will

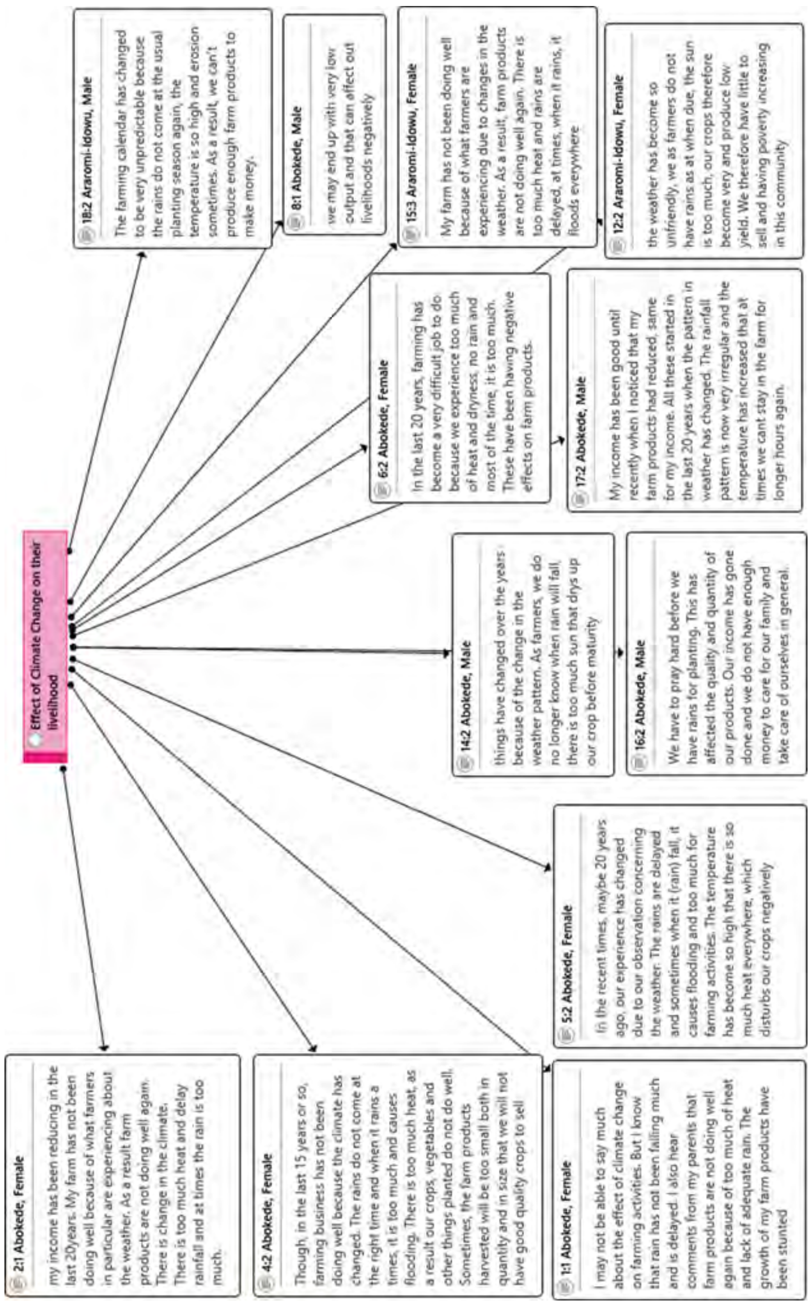

Fig. 4 Effects of climate change on participants' livelihood

result in increasing series of devastating natural disasters and low economic activities and poverty level in the rural areas. Consequently, more people will continue to abandon rural areas that are strongly affected by climate change and migrate to cities. Furthermore, extreme weather events such as floods and heat waves can also pose significant health threats such as diarrheal disease, dehydration, or cardiac complications, and mean temperature changes can alter the range and transmission potential of diseases such as malaria (Akinbami and Momodu 2013, GIZ and MoEF 2009).

Coping Strategies from Communities

During the interview conducted, participants revealed that they have employed some strategies such as diversifying into other business line, use of fertilizer, and wetting of plants from nearby river. It was observed that all of the women and just a few of the men were involved in business diversification. This finding agrees with WEDO (2007) that stated that women have developed specific adaptive strategies to cope with climate change-induced problems in livelihood, health, shelter, energy sectors, etc. in some countries. This suggests that women, if exposed to the right training, can employ their initiatives to develop strategies that will help handle immediate and long-term strategies that will gradually reduce the impacts of climate change in the rural areas. Figure 5 presents various coping strategies the women and some men in the communities visited adopted to alleviate the sufferings associated with effects of climate change. The figure depicts the readiness and willingness of the rural women.

However, the women reported that the socio-cultural climate of their communities hinders their ability to cope. Firstly, the practice around land tenure which prevents women from owning land hinders their ability to diversify. This was well experienced in Araromi-Idowu where the community missed out of oil palm intervention due to lack of land and strong existence of patriarchal system in place.

Climatepreneurship Intervention

The climatepreneurship intervention provided a template which would improve the coping strategies of the participants. Climatepreneurship intervention also exposed participants to the use of natural resources in their community that can be turned to various business activities, such as clay work. This became necessary, in order to create avenues to increase their income generation activities. Also, they were trained on entrepreneurship businesses in the oil palm tree products, such as basket weaving. This was with the aim of introducing them to business diversification concepts.

In order to strengthen participants' coping strategies through proper monitoring, the researcher held series of meetings with the government parastatals in charge of women, community development, and extension officers. This was to enable them get proper understanding of climatepreneurship concept and see to the success and continuity of the intervention through its replication in other communities.

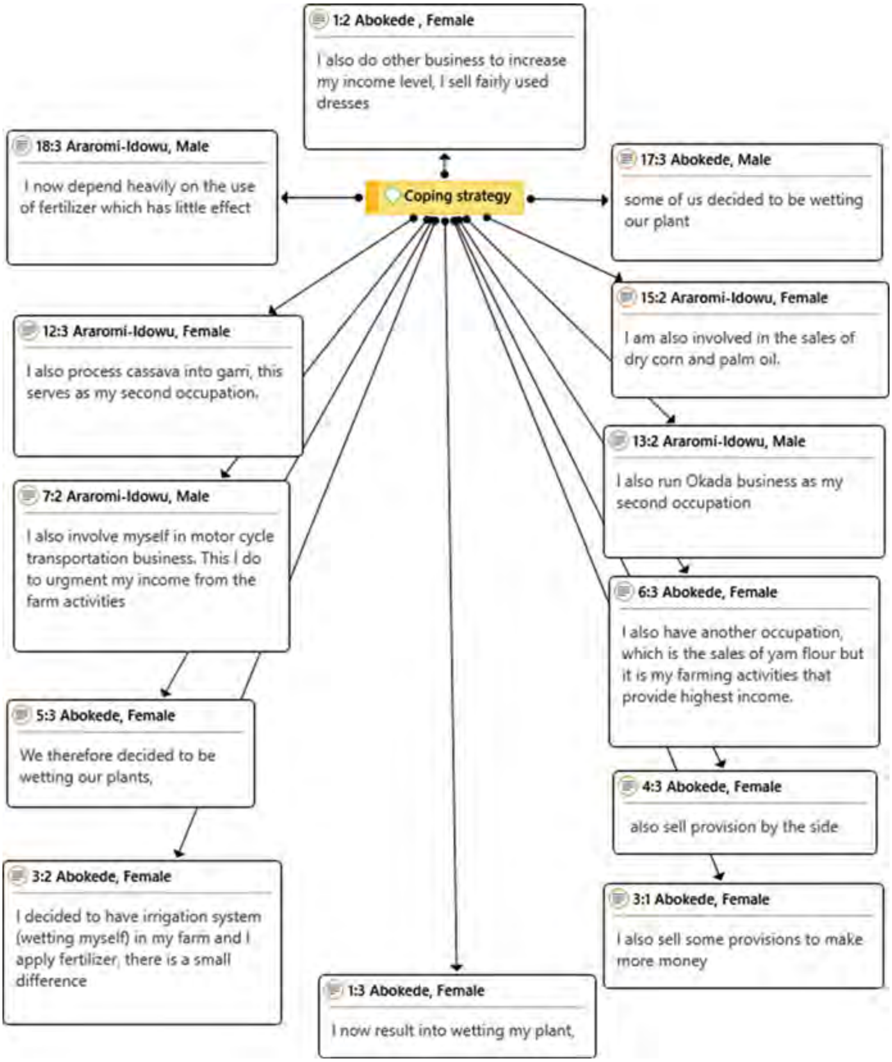

Fig. 5 Coping strategies employed by participants in both Araromi-Idowu and Abokede communities

Effectiveness of Climatepreneurship Intervention

Climatepreneurship was designed by the researcher as an adaptation strategy intervention by employing the opportunities that climate change present to enhance entrepreneurship growth and development for the economic empowerment of the rural men and women. It provided some climate smart grains and seedlings to participants of Araromi-Idowu and Abokede communities in order to empower the women in the communities by helping them to have their livelihood practices improved. This intervention employed some methods that led to its success. Some outcomes were observed as a result of the activities employed by climatepreneurship intervention to demonstrate community communication, partnerships, and bottom-up approach, in order to strengthen their economic capacity and increase entrepreneurship development. These outcomes include:

- The actual needs of participants were known such as lack of monitoring from agricultural extension officers.
- Actual impacts of climate change on their livelihood were stated.
- The drought-resistant maize grains, hybrid oil palm seedlings, and vitamin A-enhanced cassava stems were identified to improve their livelihood practices, thereby enhancing entrepreneurship development and economic empowerment.

The basic and fundamental step was to enlist their interest that led to the acceptance of intervention by community leaders and members. Training sessions were organized in the two communities to educate participants on the handling and management of grains and seedlings. Thereafter, drought-tolerant maize grain varieties, beta-carotene fortified cassava stems, and hybrid oil palm seedlings were distributed to participants and were planted as revealed in Fig. 6. Monitoring tool was employed via periodic visitation to communities and the involvement of the government parastatal attached to agriculture services in the state.

Participants retorted that they have never planted such improved and enhanced seedling varieties before climatepreneurship intervention, though, most of the participants claimed that they have heard of their existence through friends and neighboring communities.

Post-intervention interview was conducted when the drought-tolerant maize grain varieties and beta-carotene cassava stems planted were matured for harvesting, and the participants were able to express their experiences. All the farmers attested to the effectiveness of this intervention over the local maize grains they were used to. Some of the participants from the two communities reported their experiences with climatepreneurship as evidence to its effectiveness and said:

> We have not seen this before. It seems we are going back to those days when farming was rewarding. The maize harvested is quite different from the local grains we normally planted. This one got matured before it was normal 3 months, which means we farmers will have more to sell and thereby have more money to cater for ourselves. It is also sweeter in taste than the one we were used to. What really gladdens my heart is that we will have more trips to the market from the look of things. I will distribute the grains to other people in this community, so that we can all have access to this new grain. **Male Participant, Araromi-Idowu Community, 48 years old**
>
> I never knew the outcome will be this fantastic. We were mocked by some of our colleagues in this community because there was not enough rains. They were so sure that we were wasting our time, despite the training we had before the grains were handed over to us. Maybe, if the researcher had handed the grains over to us without staying on the farm with us to plant every grain, l would have just gone to keep the grains also. But now, l thank God that l participated. Our people that mocked us then are now asking for the grains. I am preparing for good sales this season. **Female Participant, Abokede Community, 50 years old**

Fig. 6 Participants with climate-smart grains and seedlings

> The cassava stem planted yielded so well. Apart from the fact that the tubers are big, l now have cassava that can also improve our health. In this community, we eat a lot of cassava and we process it to fufu (staple food made from cassava) which we take to the city to sell. So apart from having more quantities to sell for money, we are also contributing to the well being of people. I know that we will always have this in this community now by replanting the stem. **Female Participant, Araromi-Idowu Community, 62 years old**

From Fig. 7, it is evident that the rural areas are ready for innovative adaptation strategies, if the right investment is made.

To further enhance the effectiveness of this intervention and strengthen the capacity of participants, it was observed during the pre-intervention activities that

Fig. 7 Post-intervention measure pictures showing harvested maize and cassava in the two communities

Fig. 8 A dug well for improved economic activities by the intervention

the communities lack good clean water supply for the processing of the harvested cassava into fufu (a Nigerian staple food), a well was also dug in the communities to improve their economic activities and their health status because this well water will be used for drinking purposes as well by the communities (see Fig. 8). Unlike the previous intervention of a borehole that was dug by the government which ceased functioning due to the lack of electricity to pump water constantly, the well was made people-friendly which even a young boy or girl would constantly be able to operate manually at any time.

However, in spite of the success of the various aspects of the climatepreneurship intervention measures, the hybrid oil palm aspect was not as successful as others. This is mainly due to the existing land tenure and strong patriarchal system in place in the communities. Since the condition for eligibility for the hybrid oil palm was access to at least 1 acre of land so that the quantity to be harvested would have a positive impact on economic status of the women, most of the women jointly contributed land to be eligible. Also, unfortunately, the community experienced clash between herdsmen and farmers. It was later observed in between the periodical monitoring of the project that cattle rearers had led cattle to the oil palm farm, which was not close to farmers' dwelling places and devastated some of the seedling planted, thereby defeating the objective of this part of the project.

Conclusion

Adapting to climate change represents a new challenge particularly in the rural areas. Already, linkages exist between business-as-usual development strategies and adaptation to climate change impacts. Therefore, development strategies that will generate benefits for managing climate change risks are highly essential. Such will result in poverty reduction, improved nutrition, enhanced education, expanded infrastructure, and improved health which will also reduce vulnerability to climate change and enhance wellness.

This study presented available adaptation strategies suggested by various authors for testing of conformity with rural farmers, following the view that environmental knowledge and resilience to climate change lay within societies and cultures. Farmers in these communities of study have experienced hard times as a result of climate change effects ranging from delayed rainfall, heavy rainfall which lead to flooding, increase in temperature, and drought. Consequently, the communities have suffered some economic hardship and social consequences from impacts of climate change. This necessitates the rural dwellers diversification and integration of other livelihood practices in addition to crop farming. Observations made in the communities of study agreed with previous studies such as Suleiman (2014) and Yusuf et al. (2017).

Due to the low level of education of the rural communities, participants could not process the information received into finding out the causes of climate change and what steps to take to abate the climate change impacts and improve their livelihood practices. It is therefore essential that intensive and extensive sensitization and comprehensive education programs mounted by both public and private sectors including the faith and community-based organizations as well as climate-based NGOs be incorporated into the development intervention strategies in the rural communities in their various local languages for effective and benefitting communication. For example, such sensitization and education programs may include the production of facts sheet and radio interactive programs specifically tailored to address rural farmers' challenges.

Innovative adaptation strategies such as climatepreneurship which consists of activities that are climate smart and make use of locally available resources for economic empowerment and enhancement of the social status of rural women and also help to turn climate change challenges into opportunities have been assessed as effective intervention measures in rural communities. It therefore reveals that successful climatepreneurship intervention measure entails a bottom-up approach that requires a situational report of rural communities for a good understanding of the peculiarities of their climate and environmental assessment based on vegetation zones in each geopolitical zone in the country, as well as locally available raw materials that can be turned to sustainable economic empowerment ventures. These will help to forestall the increasing rural-urban migration with its attendant food insecurity and social vices and further help in developing the rural dwellers especially the womenfolk through sustainable economic empowerment and also enhancing their socio-political status in the society. Ultimately, many more micro-, small-, and medium-sized enterprises (MSME) can begin springing up and thereby enhancing environmentally sustainable industrial rural development and increasing economic value additions to both sub-national and national economic growth and development.

The paper concludes that the purpose of undertaking adaptation strategy is to effectively manage potential climate risks over the coming decades as the effects of climate change continue to increase because such can help inform decisions by farmers (both women and men), agribusiness owners, policy makers, and development partners of implications over a range of timeframes from short-term tactical to long-term strategic options. This is because inadequate consideration of and in-appropriate actions to adaptation options could result in increased vulnerability to climate change generally in the rural areas and particularly by women and children, and thereby giving rise to more severe mitigation targets and costs.

Abstract

It is a widely accepted notion that climate change affects men and women within agrarian populations differently; consequently, their adaptation strategies are gendered. Besides climate change, women's vulnerability and their corresponding adaptation strategies are embedded within a complex web of social identities/status, agroecological location, gender norm/roles and power struggles within the plurality of normative orders governing land (property rights). This chapter focuses on Cameroon and seeks to analyze how the interactions between various normative orders governing access to land, co-dependent upon the multiple gendered identities (intersectionality), impact climate change adaptation strategies of female farmers. The results show that the degree of vulnerability and adaptation strategies of women are context specific and gendered across the five distinct agroecological zones of Cameroon. Furthermore, secured access to and ownership over land is crucial in determining the adaptation choices and options available to female farmers. A complex mix of state and non-state norms govern property rights in Cameroon, within which women have to constantly negotiate their land claims. These negotiations are influenced by marital status, ethnicity, educational level, and community/social relations, such that the outcome translates differently for women within the Muslim, Anglophone, and Francophone communities. The chapter concludes with context-specific recommendations to strengthen the adaptive capacity of agrarian women across Cameroon.

Women · Property rights · Intersectionality · Climate change · Adaptation · Cameroon

Introduction

Climate change and its adverse effects on the livelihoods of agrarian communities in the global south have gained visibility within global development debates. Although these adverse effects are diverse and context specific, they are projected to hit developing countries in the global south the hardest due to technological, resource, and institutional constraints to adaptation, as well as their over dependence on natural resources as a livelihood base (Ngondjeb 2013; Pumenta 2014). Furthermore, issues of gender and climate change adaptation are increasingly being raised as women are looked upon as a marginalized vulnerable group relying on agriculture and natural resource related activities for sustenance (Denton 2002; Arora-Jonsson 2011; Kaijser and Kronsell 2013). Gender roles/norms, unequal power relations, differential access and entitlements to land entails differences in the level of vulnerability, and effects of climate change on agrarian men and women, as well as their adaptive capacity. Thus, it is a widely accepted notion that climate change affects men and women within agrarian populations differently;

consequently, their adaptation strategies are gendered (Denton 2002; Arora-Jonsson 2011). However, most studies focus on the binary construction of gender (men vs. women) thereby overlooking the influence of other factors such as geographical location, social relations, power, social/societal norms, social identities, etc. on the adaptive strategies of farmers, especially women (Kaijser and Kronsell 2013; Osborne 2013; Carr and Thompson 2014; Kings 2017). Recent intersectionality approaches to gender analysis have, however, demonstrated that the gender binary needs to be interconnected with other markers of identity and social position (Kaijser and Kronsell 2013; Osborne 2013; Van Aelst and Holvoet 2016; Boltana 2017; Elum et al. 2017).

In an agrarian economy like Cameroon with five distinct agro-ecological zones where subsistence agriculture is the mainstay for about 80% of the country's population (Molua 2011; Pumenta 2014), the effects of climate change are multiple and diverse, with negative consequences dominating. With most smallholder farmers highly dependent on rain-fed agriculture, climate variability and changes are detrimental to their livelihood base and as such the agricultural sector is among the most vulnerable to the risks and impacts of climate change (Tingem and Rivington 2009; Pumenta 2014). Although agriculture is the livelihood base for most Cameroonians, women are the backbone of smallholder agriculture and food crop production, bearing most of the responsibility of household sustenance. Women constitute 51% of the entire Cameroonian population, 51.3% of whom rely exclusively on livelihood activities that are directly linked to the natural environment (Molua 2011; UICN-PC 2015; Beckline et al. 2017). Women are thus highly vulnerable to the impacts of climate change. Besides climate change, the agrarian livelihood base of these women is further complicated by a dual land tenure system within which women (based on their social identity/status and related gender norms) are constantly negotiating land access and rights, trying to mobilize the appropriate gender and customary norms that can be used to enforce their land claims (Faith 2019). Thus, women's vulnerability to climate change and their corresponding adaptation strategies are embedded within a complex web of social identities, gender roles, and power struggles over land within the various agroecological zones. Hence, the need to look at an intersectional perspective of factors that influence climate change adaptation strategies of agrarian women in Cameroon.

This chapter therefore seeks to analyze how the interactions between various normative orders governing access to land, co-dependent upon the multiple gendered identities (intersectionality), impact climate change adaptation strategies of female farmers in Cameroon. It reviews how climate change affects agrarian populations and how they generally adapt, both at the household and community level. Specific attention will then be given to women's access to farmland within the plurality of normative orders governing land and how land rights, social identities, and socioeconomic factors jointly influence their adaptation strategies (intersectionality).

This chapter is an exploratory desk study based on general literature review and discourse analysis of peer-reviewed journal articles, government policy documents, reports, and other unpublished texts about gender/women, climate change vulnerability and adaption strategies, intersectionality, and land governance. A keyword search was used to identify and isolate relevant texts, using gender/women, climate change adaptation, climate change vulnerability, intersectionality, smallholder farmers, and land tenure as keywords. Approximately 50 documents were obtained from the keyword search. In order to understand the current/recent dynamics relating women and intersectionality to land tenure, climate change vulnerability and adaptation in Cameroon, the focus was on literature (journal articles, policy documents, reports, etc.) produced within the last 10 years (2009–2019), except one document on land tenure issues in Cameroon which dates back to 1996. This document was retained because no other recent/current document was found. Thus, based on their relevance to the study, a quick scan through the 50 documents obtained led to the elimination of 15 documents. In summary, this chapter exploits literature from 35 documents on the following thematic areas:

– Gender, climate change vulnerability and adaptation strategies
– Land rights, smallholder agriculture, intersectionality, and climate change adaptation

Conceptual Framework: Intersectionality

This study adopts the concept of intersectionality that emerged as a critique of the universalism of women's oppression portrayed by initial Western feminist movements. The concept of intersectionality was first used by black feminist (specifically by Kimberlé Crenshaw) to elucidate the triple oppression and discrimination of women of color resulting from an interplay of race, gender, and class. Although the concept emanates from black feminist movements, it has evolved over the years into multiple disciplines of feminist research to illuminate the interconnectedness of power and multiple axes of irreducible social categories (beyond race, gender, and class), and their effect on the identity and lived experiences of women (Davis 2008; Cho et al. 2013; Kaijser and Kronsell 2013; Kings 2017). However, even within feminist research, intersectionality has been defined, interpreted, and used in various ways (an analytical tool, a research paradigm, a buzzword, etc.). Given the ambiguity and open-endedness of the concept, we define intersectionality as "*the interaction between gender, race and other categories of difference in individual lives, social practices, institutional arrangements, and cultural ideologies and the outcomes of these interactions in terms of power*" (Davis 2008, p. 68). This definition highlights the fact that intersectionality is inextricably linked to power analysis between an infinite combination of overlapping social identities and categories that culminates to inequalities, discrimination, and oppression within a broader societal context. Put simply, intersectionality acknowledges that oppression is the outcome of interactions of multiple simultaneously linked identities, power relations, and lived experiences. Thus, the concept of intersectionality has been applied in myriad ways within critical feminist studies to highlight the historical "situatedness," social relations, and power structures that results into the irreducible, layered and co-constitutive identities of women within in a given context (Cho et al. 2013; Osborne 2013; Hankivsky 2014).

Within the context of climate change, "*[t]he responsibility, vulnerability, and decision-making power of individuals and groups in relation to climate change can be attributed to social structures based on characteristics such as gender, socio-economic status, ethnicity, nationality, [. . .] and place*" (Kaijser and Kronsell 2013, p. 420). Consequently, the impacts and corresponding adaptations strategies of individuals and groups may reinforce or alternatively change these social structures and categories. Thus, the degree of climate change vulnerability, impacts, and adaptation strategies of smallholder farmers (especially women) is influenced by multiple intersecting social identities embedded in power structures (Arora-Jonsson 2011; Kaijser and Kronsell 2013; Osborne 2013; Carr and Thompson 2014; Hankivsky 2014; Kings 2017). Hence adopting the lens of intersectionality moves beyond "women as a homogenous analytical category" to unravel the dynamics of the interconnectedness of power, social relations, socioeconomic status and their various co-constitutive and mutually enforcing identities of women in relation to climate change vulnerability, impacts, and adaptations. This permits an informed and constructive understanding of gender and the multiple normative orders that determine the lived experiences and "true" effects of climate change on women within agrarian communities in Cameroon. An intersectional approach will therefore incorporate the concepts of gender, land tenure, and socio-economic status so as to gain critical and constructive insights on the vulnerability, impacts, and adaptation strategies of over 50% of women in Cameroon reliant on agriculture and other natural resource base activities for sustenance in different agroecological zones.

Climate Change Vulnerability and Effects Across the Different Agro-ecological Zones

In an agrarian economy like Cameroon, where a majority of the population rely on rain-fed agriculture and natural resource exploitation (especially forestry and non-timber forest products–NTFPs) for sustenance, climate change impinges on the climate-sensitive livelihood activities of most Cameroonians. Cameroon currently faces increased annual average temperatures and seasonal rainfall fluctuations with accompanying hazards such droughts, floods, heat waves, mudslides, etc. which are experienced differently across the country's agro-ecological zones, with diverse effects and impacts on the farmers. Located between West and Central Africa, Cameroon has five distinct agro-ecological zones with distinct topographic and climatic diversity which can be assumed to account for the variations in the degree of vulnerability and corresponding effects on agricultural activities within each zone (Yengoh et al. 2010; Pumenta 2014; MINEPDED 2015). Figure 1 presents five agroecological zones and their distribution across the national territory.

The Sudano-Sahelian Zone

Covering the North and Far North Regions, it is the driest part of the country with a semiarid climate. Annual temperatures here range between 17 °C and 34 °C over

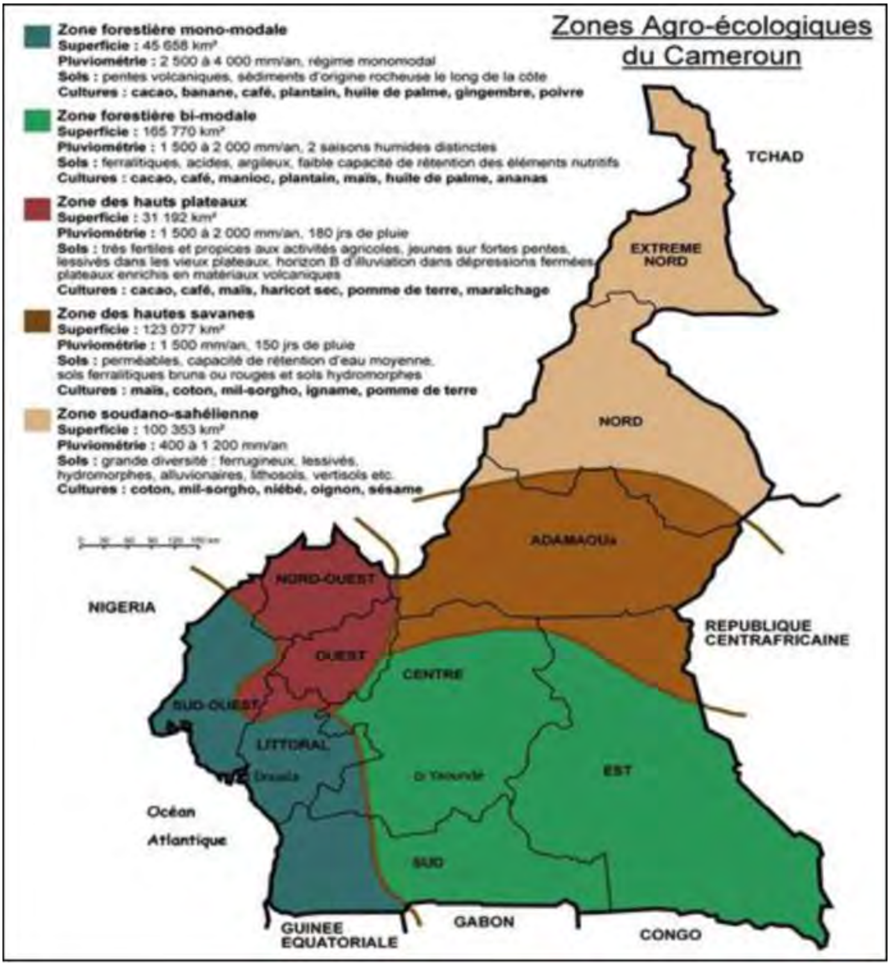

Fig. 1 Agro-ecological zones of Cameroon. (Source: MINEPDED 2015, p. 24)

long periods of the year making it highly vulnerable to droughts, heat waves, and dry spells. Despite its low rainfall distribution (between 400 mm and 1200 mm), extreme interannual variability often with strong torrential showers are common, making the regions periodically vulnerable to floods (with high incidence of waterborne diseases). It is the most vulnerable zone in Cameroon with serious repercussions on the agricultural sector. Some of the consequences of climatic variations include: drop in crop yields (resulting from poor germination, crop drying), decreased fodder coverage, increased proliferation of animal pest (especially tsetse fly) and livestock mortality, drying up of water bodies (lakes and ponds), drop in fish production, and exhaustion of fish stocks. The abovementioned consequences translate to famine and food insecurity, increased conflicts over arable land, and population migration to other regions (Yengoh et al. 2010; Pumenta 2014; MINEPDED 2015).

The Guinean Savannah Zone

It covers the Adamawa region and is a transition zone between the moist equatorial southern regions and the drier Sahelian northern regions. It is characterized by average temperatures of 22 °C and annual rainfall ranging between 700 mm and 1500 mm making it suitable for production of a variety of crops and livestock. This zone is considered the "breadbasket" of the country but with increasing temperatures, decreasing precipitation together with erratic rainfall patterns, the region is vulnerable to droughts, dry spells, and heat waves. The effects and impacts of climate variations in this zone are similar to those of the Sudano-Sahelian zone presented in the previous section, although more moderate (Yengoh et al. 2010; Pumenta 2014; MINEPDED 2015).

The Western Highlands Zone

It covers the West and North-West Regions of the country. Although it has a savannah vegetation, its mountainous topography with high plateaus (over 800 m tall) influences its climate. Influenced by this orographic effect, its annual rainfall ranges between 1500 mm and 2000 mm with an average temperature of 20 °C giving it a cold equatorial climate with the possibility of off-season rains. This region experiences the highest seasonal fluctuations of rainfall and temperature patterns. Climate variations here results in drop in crop yields (crop decay during flooding, soil leaching, and erosion), increase proliferation of animal pest (especially tsetse fly), and livestock mortality. These translate to increased competition over arable land and farmer-grazer conflicts. However, erratic rainfall patterns provide the opportunity of off-season farming and thus stabilizing crop production in this zone (Molua 2009; Yengoh et al. 2010; MINEPDED 2015; Innocent et al. 2016).

Coastal Lowlands or Mono-modal Forest Zone

It covers the Littoral and South-West mountainous regions characterized by a rainy, hot, and humid equatorial climate. It registers the highest rainfall in the country ranging between 2500 mm and 4000 mm throughout the year with mean temperatures of 28 °C. The population practice artisanal fishing and fish farming, and its rich volcanic soils, moisture-laden tropical maritime climate, and sea access makes it suitable for roots, tubers, and plantation agriculture. However, with increasing temperatures and intense rainfall, this zone is vulnerable to sea level rise, storm surges, floods, and mass movements such as landslides, mudslides, and falling rocks with negative effects on the population. Variations in climatic parameters results in increased proliferation of pest (malaria parasites), saline water intrusion and destruction of salt-intolerant crops, destruction of mangrove habitats, and increased waterborne diseases. However, increased sea temperatures also lead to improved fish habitat and changes in fish species diversity, hence a beneficial effect of climate change (Yengoh et al. 2010; Bele et al. 2013; MINEPDED 2015; Beckline et al. 2017).

The Bimodal Forest Zone

Covering the Center, South, and East Regions of the country, this zone harbors the country's dense evergreen tropical forest vegetation, with an average temperature of 23 °C and annual rainfall between 1,500 and 3,000 m. Exploitation of forest resources (including NTFPs and hunting), agriculture (mostly cocoa production and poultry farming), and artisanal fishing remain the principal activities of most households. Increased temperatures and decreased rainfall results in nonavailability of NTFP, increase in animal species mortality, and decrease in crop yields. However, occasional drying up of swamps and marshlands provides an opportunity for vegetable cultivation, which is a beneficial effect of climate change (Sonwa et al. 2012; Bele et al. 2013; MINEPDED 2015).

Farmers Household and Community Adaptation Strategies

Cameroon has a National Adaptation Plan of Action (NAPA), which mentions gender issues in reference to the need to incorporate and prioritize women (as a homogenous group) in all sectoral adaptation initiatives at all levels in the different agro-ecological zones. Although the NAPA has clearly defined adaptation initiatives developed by state institutions at national level, its effective implementation at regional and local levels is often limited by structural (poor-coordination within and across ministries), financial, and technological (outdated research and climatological stations) constraints. Thus, farmers and rural households do not rely solely on state assistance for adaptation options. Over the years, they have developed various individual and collective strategies (both on-farm and off-farm) to cope with, and lessen the adverse effects of climate change based on their local knowledge, perception, experience, and interpretation of natural phenomena. Although there is a variability among the adaptation practices of male and female farmers, in general, smallholder farmers (both male and female) adopt a combination of on-farm agricultural practices among the following (Molua 2009, 2011; Tingem and Rivington 2009; Innocent et al. 2016; Beckline et al. 2017):

– Use of improved seed varieties (drought-tolerant and early maturing varieties)
– Seasonal alterations of farm size and/or location
– Adjusting sowing/planting time (early planting in mono-modal and bimodal forest zones, late planting in Sudano-Sahelian and Guinean-Savannah zones) and sequencing (plant spacing, row orientation, terracing)
– Mixed farming, crop rotation, and agroforestry
– Manual irrigation of crops using boreholes, watering cans, and hand buckets
– Installation of sprinkler irrigation systems

- Adjusting level and timing of fertilizer and pesticide application
- Gardening on dried marshlands and swampy areas (in the bimodal forest zones)
- Implementing soil–water conservation techniques (minimum tillage, mulching, use of compost/manure)
- Decreasing herd size, increasing livestock diversity, and switching to heat- and drought-tolerant animal species
- Seasonal animal migration to river banks (transhumance)
- Increase collection and marketing of NTFPs for food and income, respectively

In addition to these agricultural practices, farmers are increasingly engaged in various off-farm income-generating activities to cushion farm income shocks such as petty trading and migration (to seek employment). Distress sale of household assets and reduction in nonfood expenditures are also observed as more detrimental coping mechanisms. Although these individual adaptive measures are successful, there is a limit to its overall contribution in a broader community resilience. Collective action is therefore needed to build community resilience against climatic shocks. Hence, the aforementioned individual adaptation strategies are complemented by other community actions which include: community rotational saving schemes ("*tontines*" or "*njangis*") with lending possibility, group collection and marketing of NTFP, cultivation of fodder crops for livestock, creation of community fodder banks, creation of community firebreaks (protecting against wild fires), family/community information sharing meetings, and community regulation of common-pool resources (land, water, and forest) (Molua 2011; Bele et al. 2013; Innocent et al. 2016).

The array of on-farm and off-farm adaptation strategies used by farmers in Cameroon vary across the agro-ecological zones and is influenced by an intersection of other factors such as gender, property rights, educational level, income (including credit access), access to technical assistance and extension services (including climate-related research and information) (Molua 2009; Innocent et al. 2016). This highlights the importance of intersectionality in climate change vulnerability and adaptation as will be discussed later.

Women and Land Tenure in Cameroon

Land governance/tenure in Cameroon is characterized by a plurality of normative orders, wherein the effective "rules-in-use" and daily management practices are determined by the interaction between colonial and post-independence state "law" (state normative order) on one hand, and the existing social/cultural norms of the people on the other hand (Belaunde et al. 2010; Pumenta 2014). A series of gender-neutral laws, decrees, ordinances, and their corresponding implementing institutions define the state normative order. Shaped by its colonial history, the state normative order, which is applicable to the entire national territory, is based on the notion of "private ownership" and land registration documented by formal instruments (title deeds) as a basis for securing property rights and economic development. Resource access and subsequent rights are therefore determined by the ability to pay (Van den Berg 1996; Fonjong 2012; Fonjong et al. 2013; Pumenta 2014; Njoh et al. 2017). This provides equal opportunity for all irrespective of gender, ethnicity, or religious background to have unchallenged rights over land. However, various financial and socio-cultural factors shape the gender-differentiated access to land.

The religious and social/cultural norms (non-state normative order) governing land are based on communal ownership, with slight differences across the country especially concerning women's land claims, as these engulf gender norms and roles embedded within unequal and changing power relations (Faith 2019). Cameroon is made of over 250 different ethnic groups spread across the ten regions of the country with diverse gender ideologies, norms and roles in relation to land, natural resource management, and agricultural production (Njoh et al. 2017; Faith 2019). Thus, as Van den Berg (1996) opines, "*ideas about breadwinnership, the division of labour and responsibilities within the household largely influence women's access to land*" (p. 18). However, these 250 ethnic groups can be regrouped under three main communities based on their religious (Christian or Muslim), linguistic (Arabic, French, or English), and colonial history, namely (Van den Berg 1996; Ahidjo 2012; Njoh et al. 2017; Faith 2019):

– Muslim community: made of the French- and Arabic-speaking Adamawa, North and Far North Regions of Cameroon, colonized by the Arabs, Germans, and French.
– Anglophone community: predominantly Christians and comprised of the English-speaking North-West and South-West Regions of Cameroon, colonized by the Germans and British.
– Francophone communities: predominantly Christians and comprised of the French-speaking South, East, West, Littoral, and Center Regions of Cameroon, colonized by the Germans and French.

Within these communities, a woman's access to and rights over land is determined by a mix of colonial, state, and non-state normative orders, influenced by other social determinants such as gender norms, ethnicity, and socio-economic status. The following sections highlights daily struggles female farmers encounter to access arable land across the different communities.

Muslim Communities

Within the Muslim communities, an important determinant of a female farmers' intra-household access to land is her marital status, as wives primarily rely on their husbands to gain access to farmland. However, access to farmland is not automatic upon marriage but earned through years of marital compliance, successful reproduction, and labor provision on the family field/farm. Wives are granted permissive use rights on degraded marginal or fallow lands for food crop cultivation, while their husbands still hold control and transfer rights over the land. With divorce or widowhood, divorcees lose access and rights over family land while widows with minor children may be granted usufruct and "limited" control rights over land held in trust of their son (the heir to the land). Nevertheless, wives, divorcees, and widows have devised alternative means to temporarily obtain farmland in their community within the appropriate socio-cultural norms used to enforce their land claims, such as renting and sharecropping. Inheritance and purchasing land could be a viable option of obtaining secured property rights but land ownership by "women" is stereotyped as a threat to family unity (decrease of sibling/son's inheritance or signs of marital discord), thus land purchase by women is almost inexistent within the Muslim communities. Furthermore, daughters and widows can only inherit land in the complete absence of a male relation (which is never the case) (Van den Berg 1996; Ahidjo 2012; Faith 2019). The insecure and temporary nature of these land tenure arrangements often limits the amount of investment Muslim women can and are willing to make on the farmland. With the advent of climate change, their adaptation strategies are therefore constrained.

Anglophone Communities

Within the household, Anglophone women also acquire land through male relations (fathers, husbands, and sons). However, differences exist in the rights and degree of control Anglophone women hold over land. Daughters are granted "permanent" use rights on family land and could inherit the land provided she remains unmarried even though sons are prioritized in relation to land inheritance. Upon marriage, wives are automatically granted usufruct rights on family land by her husband or his kinsmen, to ensure their principal duty of household food production (unlike Muslim wives who earn their access to farmland). At the discretion of the kinsmen, widows may keep their farmland as trustees for their sons (patrilineal inheritance) or nephews (matrilineal inheritance) with a greater degree for control and management rights. Divorced women are dispossessed of any rights they held over the husband's family land and return to their natal family for land or seek alternative strategies of acquiring farmland. However, although men in this community "own" the land, women hold the decision-making power and controls what is cultivated on the land, how her labor is allocated, and how the farm proceeds are used (Van den Berg 1996; Pumenta 2017; Faith 2019).

Besides relying almost exclusively on male relations for farmland, in the community sphere, Anglophone women (daughters, wives, mothers, widows, or divorcees) have also been known to "clear and claim" land as their own, as well as acquire land through renting, collective access of communal land, purchase, and registration. Irrespective of any socio-cultural and administrative bottlenecks (gender-biased norms, high cost, bureaucracy, etc.) associated with women's land purchase, Anglophone women have been able to circumvent these obstacles by using male relatives to buy land or "courting" both traditional and state authorities to buy land in their name (Van den Berg 1996; Pemunta 2017; Faith 2019). Although possible variability in terms of income levels, class, educational level, and social relations influence their land claims and rights enforcement, women (state bureaucrats, elites, and "business" women) own about 3% of the registered land in the Anglophone communities (Pemunta 2017). Furthermore, regrouping themselves into farmers organizations to access communal land and also pool resources to purchase land for collective food production and market gardening is an important strategy for which Anglophone women have proven to exert more power in bargaining and enforcing their land claims within both state and non-state normative orders (Fonjong et al. 2013; Pumenta 2017; Faith 2019). Although, variations exist in terms of access to land and security of tenure, most Anglophone women have more or less "secured" property rights and can therefore make pertinent management decisions to undertake long-term sustainable investments on their farmlands and reap the benefits. They are therefore more likely to adopt sustainable climate smart practices to cope with the adverse effects of climate change.

Francophone Communities

A Francophone woman's primary duty within the household (in accordance with socio-cultural norms) is to provide labor support on the family farm. Hence, access to land is conditioned on her "relationship" with the men in the family. Daughters assist in farming activities as well as the collection and processing of NTFPs. Upon marriage, wives acquire a share in the land of her mother-in-law or husband, on which they can cultivate food crops and vegetables (Fonjong 2012; UICN-PC 2015). Although men hold superior power over women (daughters and wives), household decisions over crop production and labor allocation are jointly made by husband and wife. Furthermore, the sociocultural norms generally protect the land claims of all farmers irrespective of gender, social identity, or ethnic origin (women can and do inherit land), although in some rare instances, widowhood and divorce may lead to loss of farmland by women (Gyau et al. 2014; UICN-PC 2015). Besides relying on family relations for land, women (wives and widows) also engage in temporary arrangements such as renting and sharecropping as alternative means of accessing additional farmland with limited management rights over these lands. Nevertheless, some financially viable women occasionally purchase land for construction or other non-agricultural developmental purposes in urban areas as evidenced in the Center Region where women (mostly state bureaucrats) own about 15% of all registered land (Gyau et al. 2014; Pumenta 2017). Thus, Francophone women generally have secured property rights that provides them with the power and means to equitably negotiate the diversification of their livelihoods and adapt to climatic changes.

In summary, despite the diverse socio-cultural norms across the country, the land rights of most Cameroonian women are co-dependent on male relations. However, the effective rule-in-use over land management as well as the intra-household decision-making power varies across these communities. Nevertheless, women contribute substantially in agricultural production and other livelihood activities, and are primarily responsible for household subsistence despite the gender-differentiated access and rights to resources.

Intersectionality and Climate Change Adaptation

Beyond the binary division of men versus women, a combination of other societal norms and socio-economic factors influence women's adaptive capacity. Consequently, an intersectional analysis is required to understand the underlying norms, power relations, and socio-economic factors that conditions the daily/seasonal adaptation practices, and strategies employed by women (Kaijser and Kronsell 2013; Carr and Thompson 2014). In Cameroon, with over 50% of the female population relying on agriculture and natural resources for sustenance (Molua 2011; Pumenta 2017), women constitute an important group for whom risk aversion is vital for household welfare. However, the degree of vulnerability and effects of climate change on the livelihood activities of women depends on their location (agro-ecological zone), the diverse socio-cultural norms that prescribe access to and control over land, and decision-making power (as presented in the previous sections). Consequently, the adaptation strategies of women will vary across the country based on an intersection of gender, ethnicity, and agro-ecological location, as well as other factors such as educational level, access to information, access to extension services (technical assistance), income (including access to credit), social capital, etc. Hence, based on the findings of the previous sections, this section analyses the effects of an intersection of gender, ethnicity (in terms of land governance and decision-making power), and agro-ecological location (and other factors) on women's adaptation options within the northern Muslim community, southern Francophone and Anglophone communities. Figure 2 highlights the spatial distribution of these communities across the different agro-ecological zones.

Women and Climate Change Adaptation Within the Muslim Community

The Muslim community of Cameroon is predominantly located in the northern semi-arid agro-ecological zones, comprised of the Sudano-Sahelian and Guinean Savannah agro-ecological zones. Climatic variations and extreme weather events such as droughts, heat weaves, dry spells, and occasional floods lead to decreased crop yields/productivity and increased population migration to other regions (mostly men) (Yengoh et al. 2010; Pumenta 2014; MINEPDED 2015). In line with their domestic/reproductive roles, Muslim women are generally involved in food crop production (on marginal lands acquired through male relations), processing and marketing of livestock and fishery products but lack control over how the proceeds are used (Van den Berg 1996; Ahidjo 2012; Njoh et al. 2017).

The temporary migration of Muslim men during periods of transhumance and in search of off-farm employment in other regions implies an increase in the number of de facto female-headed households with increases in the reproductive and productive activities of wives who are left to care for ("sick") family members while ensuring sufficient food production for the household. Although some women are engaged in petty trading, the increased workload of domestic activities limits their possibility of

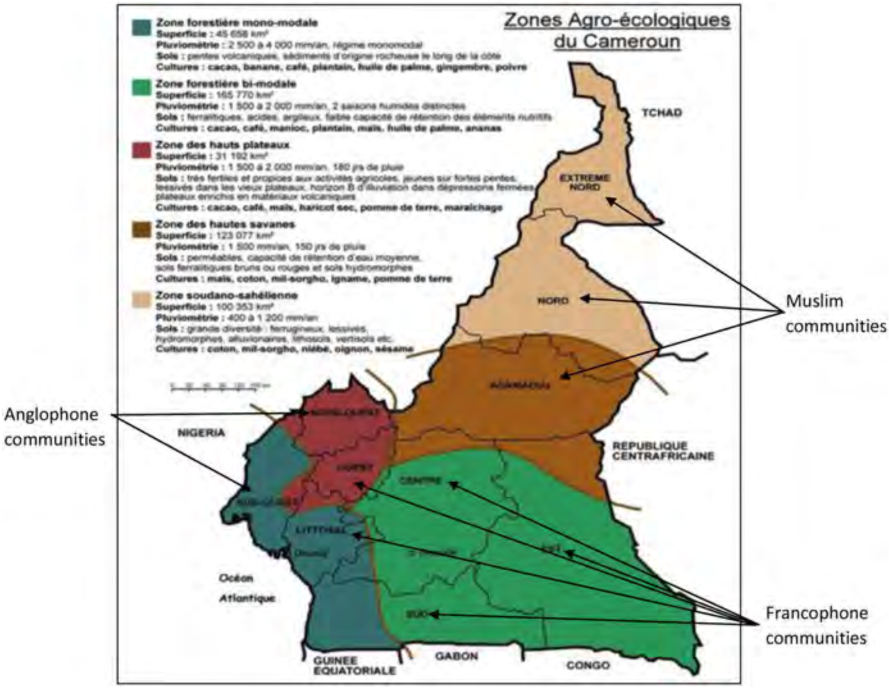

Fig. 2 Spatial distribution of the various communities across the different agro-ecological zones. (Source: Adapted from MINEPDED 2015)

diversifying their livelihood strategies and undertaking off-farm activities that could contribute to the household income. This is further exacerbated by the high illiteracy level among Muslim women, due to the gender ideology that prioritizes early marriage over girls' continuous education, thereby limiting their options of off-farm employment (Van den Berg 1996; Pumenta 2014). Furthermore, men generally hold decision-making power over the wife's labor and income allocation. Thus, for most Muslim women (wives, widows, mothers, and divorcees), their livelihood activities and adaptation strategies are centered around on-farm activities.

The on-farm adaptation strategies of Muslim women are constrained by religious and sociocultural norms that "forbid" ownership of land by women. Since women (daughters, wives, widows, and divorcees) only have usufruct rights on family or rented/sharecropping land, and "limited" decision-making power, their on-farm adaptations strategies are therefore limited to seasonal crop management practices and farming operations such as alterations in planting dates, use of drought tolerant or early maturing hybrid seeds, and mixed cropping. Furthermore, because of the limited property rights and temporal tenure arrangements (renting or sharecropping), Muslim women are unlikely to cultivate cash crops (except millet) that could increase their income (Van den Berg 1996; Molua 2011, 2012). The exception seems to be the case of widows with minor sons who have "limited" control rights over land held in trust for their sons. These widows can therefore undertake long-term investments such as tree planting (agroforestry) and soil management to safeguard the land while ensuring continuous household food production. As Van den Berg (1996) highlights, tree planting was used by widows as a means of securing and enforcing their land claims.

Beyond security of tenure and decision-making power, the choice of on-farm adaptation strategies implemented varies among women and is influenced by other factors such as income (to purchase drought tolerant or early maturing hybrid seeds), access to climate information and technical assistance. While farmers may generally have knowledge of the weather forecast and expected start of farming seasons (Molua 2011, 2012), Muslim women generally have limited access to agricultural extension services, as these services often target cash crop producers who are predominantly men. This limits the effective implementation of State's adaptation initiatives as stipulated in the country's NAPA, by sidelining the female population of farmers. Furthermore, while promoting tree planting in semi-arid zones is an essential adaptation initiative of the State (MINEPDED 2015), the limited property rights of Muslim women is a disincentive to engage in tree planting as they may not reap the benefits agroforestry provides in the long run. Thus, a gap exists between the national institutional framework and realities on the ground. Together, the aforementioned factors coupled with the limited livelihood diversification strategy of women and socio-cultural constraints on their adaptive capacity tend to increase the household and community vulnerability, thereby accentuating poverty in the regions.

Women and Climate Change Adaptation Within the Anglophone Community

The Anglophone community is comprised of the North-West and South-West Regions of Cameroon spread in two different agro-ecological zones. The North-West Region (NWR) is located within the western highlands zone, while the South-West Region (SWR) is located within the mono-modal forest zone. Climatic variations in the NWR leads to soil degradation (through leaching and erosion) and consequently drop in crop yields. In the SWR, extreme weather events, such as floods, lead to increased proliferation of malaria parasites, high incidence of waterborne diseases, saline water intrusion and destruction of salt-intolerant crops (MINEPDED 2015; Innocent et al. 2016; Beckline et al. 2017). In line with their reproductive roles, ensuring household food security is the responsibility of Anglophone women. Thus, farming (food crop and vegetable production) is the main livelihood activity of most women in these communities (Van den Berg 1996; Fonjong et al. 2013).

Health issues resulting from malaria parasites or waterborne diseases implies an increased workload on the domestic/reproductive roles of women (wives, mothers, widows, and divorcees) to nurture and care for the sick family members. This also increases their workloads in agriculture since they are tasked with ensuring household food security. However, Anglophone women as wives, widows, and divorcees decide and control how their labor or any proceeds from their farms is allocated (Van den Berg 1996; Pumenta 2017). They therefore have the possibility of diversifying their livelihood strategies and engaging in other flexible off-farm activities to generate income that could caution the adverse effects of climate change on their agrarian livelihood base. This is further facilitated by their relatively high literacy level (compared to the Muslim women) that enables them gain off-farm employment. From the researcher's lived experience, the high literacy level within Anglophone women may be considered the result of a trade-off wherein the education of female children serves as compensation for their limited inheritance rights.

Although an interaction of sociocultural norms and state "laws" dictate women's access to land and other natural resources, some Anglophone women have been able to manoeuver and "forum shop" from both systems to acquire more or less "secured" property rights over their farmland. While "high" income women such as state bureaucrats, elites, and "business" women have been able to purchase, title, and effectively own land, rural women with limited financial capital rely on their social networks/capital to regroup themselves and gain "secured" access to community land. Furthermore, by virtue of being the "breadbaskets" of the family, women generally have secured access to "family" land whether as a daughter, wife, mother, or widow (Fonjong et al. 2013; Pumenta 2017). Thus, the security of tenure provides an incentive to adopt and invest in sustainable soil management and agricultural practices such as agroforestry, recycling of dead organic matter, mulching, and reap the long-term benefits. Nevertheless, Anglophone women also engage in seasonal farming practices such as making "mounds," mixed cropping, off-season replanting, use of improved seed varieties, changing planting dates, etc. as coping strategies to the fluctuating climates in these zones (Beckline et al. 2017).

Beyond security of tenure and decision-making power, access to climate information and agricultural extension services also influence the on-farm adaptation strategies implemented by Anglophone women. Although both women and men get access to climate information from formal (weather observatory officers) sources through radios, print media, and televisions, as well as informal sources such as friends, family, and self-help groups (Molua 2011; Fonjong et al. 2013), access to agricultural extension services is correlated to group membership, social status, and class. While extension services target farmers groups/cooperatives (irrespective of the gender composition of the groups), "working class" women have the possibility of networking with and obtaining assistance from extension agents. Thus, being a full-time "housewife" and belonging to no farming group impinges on a woman's access to technical assistance. However, most Anglophone women belong to self-help and community saving groups ("njangis") which serves as a buffer against financial crisis in times of disasters and emergencies on one hand, and as a platform of socialization, information sharing, and peer learning within the communities on the other hand (Molua 2011; Fonjong et al. 2013; Innocent et al. 2016). Thus, Anglophone women seem less vulnerable and more proactive in adopting conservation and protective on-farm practices compared to their Muslim counterparts.

Women and Climate Change Adaptation Within the Francophone Community

The Francophone community is made of five administrative regions spread across three different agro-ecological zones. It is comprised of the West Region (located in the western highlands zone), the East, South, and Center Regions (located in the bimodal forest zone), and the Littoral Region (located in the mono-modal forest zone). Seasonal weather fluctuations in the western highlands and bimodal forest zones lead to soil erosion and drop in crop yields, and increased scarcity of NTFPs. In the mono-modal forest zone, sea level rise and extreme weather events, such as floods, leads to increased proliferation of malaria parasites, high incidence of waterborne diseases, saline water intrusion and destruction of salt-intolerant crops (Yengoh et al. 2010; Sonwa et al. 2012; Bele et al. 2013; MINEPDED 2015).

In addition to their reproductive roles, a Francophone woman's main duty as a daughter or wife is to provide labor support on the family farm. Although cash crop (mainly cocoa) production and fishing by men are the main livelihood activities, Francophone women (wives, mothers, divorcees, and widows) are involved in food crop and vegetable production on farmland acquired through diverse means. With both the state and non-state normative orders protecting the land and natural resource claims of women, the security of tenure provides women with the power to negotiate the diversification of their livelihoods. Being educated and earning an income is a bonus as it influences the intra-household bargaining power of women. Women therefore engage in diverse off-farm employment and income-generating activities such as petty trading of food crops, collection, processing and marketing of NTFPs, as well as processing and marketing of fishery products (Sonwa et al. 2012; Brown and Sonwa 2015; UICN-PC 2015; Beckline et al. 2017; Pumenta 2017). This off-farm income helps caution against the negative effects of changing climatic conditions on the agrarian livelihood base of the household. Furthermore, Francophone women engage in precautionary loan-savings schemes ("tontines") which provides women with easy and flexible access to credit that is used for on-farm and/or off-farm income-generating activities. This contributes in enhancing household income and general welfare, as well as provide financial insurance in times of disasters and emergencies. Francophone women also engage in community labor-sharing groups that provides mutual labor support on their farm. Since membership to these are based on trust, solidarity, and reciprocity, these groups are indicative of the social capital within this community, which can serve as an entry point for distribution of information, peer learning, and technology adoption (Molua 2011; Bele et al. 2013; Brown and Sonwa 2015), and thereby enhance their general well-being and adaptation potential.

Like the Anglophone and Muslim women, the incidence of malaria and waterborne diseases implies a disproportionate burden on the reproductive activities of women to nurture and care for the sick family members. However, since household farming decisions are jointly made (Gyau et al. 2014), wives have the possibility to trade-off their on-farm labor support with domestic care roles.

In summary, although female farmers across Cameroon seem to opt for relatively low resource (cost and labor) on-farm adaptation methods which can contribute to yield stabilization (Molua 2011), a variability exist among these women influenced by a combination of other socio-cultural norms and socio-economic factors. This aligns with growing literature on gender, intersectionality, and climate change which has shown that socio-cultural norms including gender relations and power dynamics which determines resource allocation and use, division of labor, and decision-making within and beyond the household influence the adaptation strategies of women. Furthermore, an intersection of other socio-economic factors jointly determines the adaptation options and choices available to women. These factors include income/wealth, educational level, place/location, marital status, class, ethnicity, group membership, access to information, technology, extension services, etc. Nevertheless, irrespective of any constraint posed by societal/sociocultural norms and other socioeconomic factors, female farmers continue to exercise their agency and adapt to changing climatic conditions in diverse ways as the circumstances present. Thus, the adaptation strategies of women within agrarian societies in Cameroon are context specific.

Caveats/Limitations of the Study

This desk study adopts a critical theorist (feminist) stance, which guides the scope of analysis and recommendations with an undeniable bias of the researcher's position. This chapter is led by a female agronomist, with lived experiences of the daily struggles Cameroonian women encounter over land and natural resources. Although the authors aim to limit the researcher's influence through self-reflective honesty and interaction with the second, more distant author, it cannot entirely erase the influence of this specific positionality, but this should not be considered a problem in this exploratory study. Furthermore, because this study relies exclusively on secondary literature (with minimal sex disaggregated data), its analysis is not exhaustive of the current realities, dynamics, and complexities of climate variability/change on agrarian livelihood systems on the ground, an in-depth field research will be needed to achieve this. Nevertheless, the conclusion and modest recommendations will shed light on the ongoing debate on intersectionality and climate change adaptation, and propose alternatives that can work in Cameroon.

Conclusion

In line with the growing debate on gender, intersectionality, and climate change, this study set out to examine the adaptation strategies of women in Cameroon using an intersectional lens. As discussed, the vulnerabilities and effects of climate change differs across the five agro-ecological zones of Cameroon with the Sudano-Sahelian zone being the most vulnerable zone. While the National Adaptation Plan of Action (NAPA) provides an institutional framework for agrarian adaptation strategies, limited coordination among sectorial ministries impedes the effective implementation of these strategies at regional and local levels. Furthermore, by classifying women as a monolithic group, the NAPA ignores the various institutional arrangements (gender norms, resource ownership, property rights etc.) and socio-economic factors (education, income, marital status, etc.) that determines the vulnerabilities and adaptation strategies of women. Thus, the national adaptation initiatives targeting women are poorly designed and seems destined to fail from its conception. Nevertheless, farmers (women inclusive) have a wide range of on-farm agricultural practices and off-farm adaptation strategies that are used to counteract the adverse effects of climate change while enhancing their livelihoods and well-being.

With land being a crucial production factor within agrarian communities, resource ownership and property rights constitute an important determinant in the adaptation choices and options of farmers especially women. However, the analysis shows that land tenure/governance across the national territory is diverse and embedded within a complex web of gendered identities, norms, roles, ethnicity, and power dynamics, for which women have to negotiate resource access with other actors. The outcome of these negotiations translates differently for women across the Muslim, Anglophone, and Francophone communities of Cameroon, and therefore influences the on-farm adaptation options and choices of female farmers in these communities.

Beyond gender and security of tenure, we have shown in this study that a range of other factors influences the adaptation strategies of female farmers across the different agroecological zones of Cameroon. These factors include decision-making power, income/wealth, level of education, access to information, access to technical assistance, group membership, and social identity/status (daughter, wife, mother, widow, or divorcee). A variability therefore exists in both the on-farm and off-farm adaptation choices and options available and adopted by women within and between communities be it in the northern semi-arid agro-ecological zone or the Southern savannah and forest agro-ecological zones. Hence, the adaptation strategies of female farmers in Cameroon is highly context specific. These findings are not unique to Cameroon, as research elsewhere have shown the intersection of socio-economic factors on climate change adaptation across Africa (see Boltana (2017) for group membership in Southern Ethiopia, Elum et al. (2017) for access to information in South Africa, Van Aelst and Holvoet (2016) for marital status and intra-household decision-making in Tanzania, etc.). Nevertheless, the study contributes to the current global debate on gender, intersectionality, and climate change by providing insights from the Cameroonian context.

Recommendations

Despite the limited sex-disaggregated and quantitative data, this study could serve as an “eye-opener” and a foundation for further research on intersectionality and climate change adaptation in Cameroon. Thus, an in-depth and contextually grounded analytical research is recommended to shed more light on the existing variabilities among female farmers within and between the different communities and agroecological zones. Nevertheless, based on this study, a few modest policy recommendations can be proposed as a way forward in enhancing the adaptation strategies of female farmers in Cameroon.

First, ensuring secured access to land for women especially within the Muslim communities can create a window of opportunity to strengthen their bargaining power and enhance their adaptation strategies. While the national land tenure reform proposed in the NAPA seems apparent as a solution, there is need to incorporate "Muslim doctrines" and make special legal provisions for Muslim women who seem to be the most disadvantaged in relations to property rights compared to their Anglophone and Francophone counterparts. Bearing in mind that security of tenure goes beyond state recognition to a matter of power struggles and social relations, sensitizing women on their "constitutional rights to property" and putting in place (or revamp existing) accompanying institutions to ensure effective implementation and gender justice will go a long way to improve the agrarian livelihood and adaptation strategies of female farmers. Also, promoting female farmer groups, cross-country exchanges and engaging with ideological debates about gender and land rights is a step in the right direction towards secured property rights for women.

Second, as education and income have shown to enhance the bargaining power and off-farm adaptation options of women within the Anglophone and Francophone communities, improving the literacy levels and socioeconomic capacity of Muslim girls and women is necessary. Beyond improved literacy levels and socio-economic capacity, education can serve as an empowerment strategy geared towards creating pathways of transforming gender norms in the long run. Thus, affirmative action through educational and vocational training scholarships could be a policy measure of the Ministry of Women Empowerment and the Family (MINPROFF) to improve overall livelihood and adaptation strategies within Muslim communities. Nevertheless, girls from rural areas, especially of enclaved areas within the Anglophone and Francophone communities, should be considered too.

Third, access to information and technical assistance has shown to be significant factors determining the on-farm agricultural adaptation practices of women. Thus, governmental effort by the Ministry of Scientific Research and Innovation (MINRESI) and Ministry of Agriculture and Rural Development (MINADER) in revamping existing meteorological services and making information and extension services more readily and widely available is crucial to enhance the adaptation decisions that women make. While priority should be given to the northern semi-arid zones with frequent droughts and floods as well as the coastal lowlands with frequent floods, storm surges, and mass movements, the other agro-ecological zones should not be neglected as the impacts of climate change in one agroecological zone inherently affects the populations in the other zones.

Fourth and last, community groups (farmer's cooperatives, self-help, "tontines," and "njangis") seem to be a viable option for peer learning, information sharing, financial assistance, and mutual support in Anglophone and Francophone communities. These groups could also serve as a transformative tool to mobilize the power of collective action in strengthening the bargaining power of women within the communities, as illustrated by Anglophone women groups in relation to access to land. The potential of these groups should be explored and supported to collectively build the adaptive capacity of women and community resilience, through initiating and training members on income-generating entrepreneurial activities, and linking these groups to microfinance institutions/banks for financial assistance through credit. Also initiating such groups within the Muslim community (if none currently exist) could be beneficial too in reducing their vulnerability and enhancing that adaptive capacity. Both MINADER and MINPROFF could spearhead such initiatives.

Abstract

Poor physical and land use planning underpin the chaotic evolution and expansion in cities and towns in sub-Saharan Africa. This situation amplifies urban vulnerability to climate change. Worse, urban landscapes are rarely considered part of the discourse on urban development in sub-Saharan Africa, let alone in climate change adaptation. Yet, landscapes are known to play crucial roles in social, economic, and cultural resilience in cities and towns. Hence, designing basic forms of appealing and functional urban landscapes that support multiple

ecosystem services is essential to the drive towards resilience, which relates to the ability to maintain or improve the supply of life support services and products (such as food and water) in the face of disturbance. In this chapter, the idea of transforming idle urban spaces into multifunctional edible urban landscapes is introduced and explored as instrumental for cost-effective adaptation and resilience to climate change in cities and towns in sub-Saharan Africa. *Multifunctional edible urban landscape* is defined here as a managed landscape that integrates food production and ornamental design, in harmonious coexistence with other urban structures to promote or provide targeted, multiple services. These services include food security, scenic beauty, green spaces for active living and learning, jobs and livelihoods support, environmental protection, climate adaptation, and overall urban resilience. This approach constitutes a triple-win multifunctional land use system that is beneficial to landowners, city managers, and the general community. This chapter explores the benefits, challenges, and prospects for practically transforming urban idle spaces into multifunctional edible urban landscapes using an example project from Ghana. The chapter shows that multifunctional edible urban landscape transformation for resilience is practically feasible, and sheds light on the possibility of the food production component paying for landscaping and landscape management. It concludes with thoughts on actions required across sectors and multiple scales, including mobilizing stakeholders, laws, policies, and incentives, to actualize multifunctional edible urban landscapes as key transformational components of resilience in sub-Saharan Africa.

Introduction

The Challenges of Urbanization, Climate Change, and Resilience in Africa

Urbanization has its promise and value in terms of concentrating resources and capital to improve physical development and human well-being; but it has its perils too as it increases the demand for basic necessities of life (such as food, water, shelter, employment, and recreational opportunities) and the complexity of managing the resources and the socioecological processes that underpin ecosystem services and quality of life. Urbanization creates and alters landscape attributes and functions, which in turn affect the environment and quality of life in urban areas. Compared to the rate of urbanization in other regions, Africa is said to have achieved an urbanization miracle (Lwasa 2014). Africa has experienced an unprecedented rate of urbanization in the last two decades, resulting in the emergence of several megacities

(Lwasa 2014; Güneralp et al. 2017). From the year 2010, African urban population has increased at an average rate of 3.2% per year, compared to global average of about 1.2% (African Union 2020; UN DESA 2012). Africa currently has 43% urban population and, together with Asia, will account for about 90% of the projected increase in the world's urban population by 2050 (UN DESA 2019). By mid-century, more than half of Africa's population is expected to live in urban areas. Sub-Saharan Africa will host most of the largest cities that will arise from the projected population growth in Africa, most of them in coastal areas (Di Ruocco et al. 2015). These underscore the challenge and importance of sustainably managing the quality and resilience of urban environment and life by maintaining and enhancing the integrity and functionality of the systems that underpin resilience, particularly food systems (Russo et al. 2017; Haberman et al. 2014).

Already, cities and urban communities in Africa face formidable challenges, including high levels of food insecurity, unemployment, poverty, and environmental degradation (African Union 2020; Lwasa 2014; Güneralp et al. 2017). Provision of livable urban spaces, including green and recreational spaces, has proved particularly challenging and elusive. Increase in food production in Africa has substantially lagged behind the rate of population growth, resulting in protracted food insecurity (African Union 2020). The number of hungry people in Africa is estimated at 256 million and the continent might not meet key global targets on malnutrition or eliminate hunger by 2030 (FAO, ECA and AUC 2020). Projections suggest that an increase of about 112% in food production (over 2015 baseline) will be required to meet the food demand of sub-Saharan Africa alone in 2050 (African Union 2020). Urbanization will not only increase the quantity of food demanded, but also alter the composition and patterns of food consumption, with likely increase in demand for fresh fruits and vegetables. At the same time, urbanization will increase competition with agriculture for land and water which underpin food production.

Climate change presents an additional developmental burden and complicates existing challenges for all regions. However, Africa is considered a highly vulnerable continent to the adverse impacts of climate change (IPCC 2007; Chapman et al. 2017), and the continent is already experiencing the impacts of climate change, through highly frequent and severe episodes of droughts and floods (African Union 2020; Batchelor and Schnetzer 2018; Van Rooyen et al. 2017; Lwasa 2014; Armah et al. 2011). This vulnerability stems partly from Africa's poor physical planning and environmental degradation, and overreliance on agriculture, which is hypersensitive to climate change (IPCC 2007). These challenges raise the imperative for exploring several response options, including the planning, evolution, development, and uses of urban landscapes for reducing vulnerability and enhancing resilience (Russo et al. 2017).

Evolution of Urban Landscapes and Idle Spaces in Africa

Urbanization can be instrumental in amplifying vulnerability or enhancing resilience. Unfortunately, urbanization in Africa is rapid, unplanned, unregulated, and chaotic (Lwasa 2014; Güneralp et al. 2017), a situation that will compound vulnerability. Especially in sub-Saharan Africa, physical development and land use are poorly planned (if at all). Weak land administration and poor municipal services add to the challenge of discontinuous expansion and poor-quality urban landscapes and environments (Mensah 2014). Urban landscape planning and management are rarely considered important in the discourse on sustainable and resilient development (Yawson 2020). Urban landscapes have, therefore, evolved organically and chaotically with urbanization, and are poorly managed. This poor planning and management of urban landscapes has resulted in the degradation of the biophysical and sociocultural significance of urban communities and diminished the overall resilience to environmental shocks. If this trend remains unaddressed, it can substantially amplify urban challenges and vulnerability to climate change (Di Ruocco et al. 2015). One visible result is the considerable proportion of land surfaces poorly covered by either natural or man-made covers (Mensah 2014). Consequently, very dusty, bushy, and unsightly land surfaces are visible in both the urban core and the periphery, resulting in high exposure to dust during the dry season and mud or sediment transport during the wet season, and other unhealthy elements (Yawson 2020). These have consequences for resilience and sustainability in both the short and long term. For example, long-term exposure to $PM_{2.5}$ (dominated by dust) can contribute to ischemic heart disease, cerebrovascular disease, lung cancer, and respiratory diseases (Health Effects Institute 2019). The number of deaths associated with $PM_{2.5}$ in Ghana and Nigeria in 2017 were 5,190 and 49,100, respectively (Health Effects Institute 2019).

Land ownership in Ghana can be used to illustrate the evolution of urban idle spaces in urban landscapes in sub-Saharan Africa. In Ghana, just as in almost all sub-Saharan African countries, urban expansion occurs largely through private action in an informal context. There are two broad types of land ownership in Ghana: customary and state ownership, accounting for 78% and 20%, respectively of total land (Larbi 2008; Yawson and Armah 2018). The remaining 2% are vested lands (split ownership between the state and customary authorities). Customary lands are owned by traditional authorities (stools and skins), clans and families, with chiefs and clan/family heads as the custodians and supported by principal elders of the given community or family (Larbi et al. 2004). The government of Ghana can apply the power of eminent domain to acquire land for national development or security purposes. It is believed that this system of land ownership constrains effective land administration, land use planning and management, and is a major driver of informal land transactions and development. It also partly accounts for the numerous intractable land disputes and conflicts from parcel, through community to tribal scales. Although the Town and Country Planning Department is responsible for physical planning, chiefs or owners of large tracts of land are expected to make and present a parcelled plan of their lands to the Lands Commission for the purposes of registration and titling. However, this is not mandatory or enforced. This means parcelling and layout of residential areas largely evince from landowners, independent of infrastructural and municipal service planning, delivery, and management. This results in incoherent physical development, with scattered pattern of settlements in developing areas. Due to weak property markets, insecurity of tenure of residential or commercial properties, and weak financial support system for rapid development of individual properties, there is inordinate pressure on land for low-density housing and other commercial activities in urban areas. As a result, persons buy parcels of land and slowly develop these, or simply leave the parcels of land idle until they are financially capable of developing the land. Some also buy land out of speculation, with the view to selling the land later at higher prices. Undeveloped parcels of land do not attract property taxes and there are no mechanisms to ensure management regimes fit for the landscape or the environment. As a result, and partly due to informal planning of space, there are several open spaces and undeveloped or partly developed but idle parcels of land that are poorly managed (if at all) in both the urban core and periphery. These, together with poor infrastructural planning, management, and municipal services, diminish the natural, cultural, and scenic beauty of urban landscapes and escalate vulnerability.

These idle parcels do not only detract from the urban beauty and landscape services, but are also sites for a range of activities, both positive and negative. In some cases, these parcels are used by itinerant farmers for food production, occupied by petty traders or informal settlers (squatters), or simply left bushy or bare and exposed to the erosive forces of water and wind (dust generation and transport). In most cases, these parcels are used for nefarious activities such as littering, defecation, and criminal activities, or habitat for vermin. However, these spaces can be sites for urban greening and human production to transform the landscape to support multiple environmental and developmental goals such as jobs or income generation, food security, environmental protection, and scenic beauty, and thereby contribute to overall urban resilience and well-being.

Multifunctional Edible Landscape Approach to Resilience

Resilient development and adaptation planning have become more urgent for social groups, ecological systems, and geographic regions for which there is high certainty of vulnerability (Stern and Treasury 2007). Resilience has been conceptualized as the capacity of a dynamic system to maintain its structural and functional integrity, or change for the better, in the face of disturbances that threaten the viability, functioning, or development of that system (Masten 2014). Urban resilience, from a socio-ecological perspective, removes constancy and introduces flexible, adaptive, and multilevel approaches for responding to persistent or short-term threats and stresses across the entire urban space. The scale of challenges outlined in section "The Challenges of Urbanization, Climate Change and Resilience in Africa" constitute a major source of disturbance that threatens the viability, functioning, and development of urban landscapes and communities, deserving resilient, multilevel responses. Globally, landscape-based approaches are being promoted, in both policy and academic circles, as an integral component of the responses to urban sustainability challenges (Säumel et al. 2019; van Noordwijk et al. 2014; Russo et al. 2017; Panagopoulos et al. 2016; Matsuoka and Kaplan 2008).

Landscapes can have different meanings for different persons or professionals (Fischer et al. 2016; Scott et al. 2009). However, in the urban context, landscapes can be considered as the physical environment shaped by human-nature interaction. The "nature" component comprises the biophysical cover of the land surface that underpin ecological productivity, while the "human" component comprises man-made surfaces and structures such as houses, roads, and other infrastructure (Grêt-Regamey et al. 2015; Panagopoulos et al. 2016; Russo et al. 2017), together with human action on nature. These components are intertwined and provide reciprocal services and or feedback effects on each other. Landscapes, therefore, provide first impressions of the complex processes and interactions between social and ecological components that underpin the provision of ecosystem services, which, in turn, underpin human well-being and resilience (Yawson 2020). These ecosystem services are classified as provisioning (e.g., food, herbs, and clean water or air), supporting (e.g., nutrient, energy, or material cycling), regulatory (e.g., flood, erosion, and climate control), and cultural (e.g., heritage, spirituality, visual aesthetics, and recreational opportunities) (Grêt-Regamey et al. 2015). A landscape reflects the status of cultural sophistication, development, and well-being, as well as the vulnerability of its inhabitants or users to a given external or environmental shock (Yawson 2020). Landscapes that are subject to unsustainable management practices can be very vulnerable to shocks and, in turn, deepen the vulnerability of its inhabitants or users to environmental shocks.

Multifunctional edible urban landscapes are being promoted as instrumental for sustainably intensifying the production of ecosystem services and products, improving livelihoods, and optimizing the use of limited land resources as opposed to straight intensification of farming and commercial forestry (Säumel et al. 2019; Panagopoulos et al. 2016; Fischer et al. 2016; Bustamante et al. 2014; van Noordwijk et al. 2014; Santika et al. 2015). Multifunctional edible urban landscape refers to a managed landscape that integrates food production and ornamental landcover, in harmonious coexistence with other urban structures to promote or provide targeted, multiple services such as food, erosion and flood control, scenic beauty, and recreation. A multifunctional edible urban landscape approach, thus, helps generate ecosystem goods and services to meet the basic but multiple demands of urban communities while limiting expansive use of land. It helps reconcile competing interests and goals that put urban land under constant and intense pressure. Multifunctional edible urban landscapes will arise from and be enhanced by land use planning approaches and innovative transformations that harmonize the functions of landscape components in order to derive multiple benefits across varying spatial and temporal scales. Multifunctional edible urban landscapes have considerable promise to contribute to urban resilience and long-term sustainability or adaptive capacity if the structure and functions of components are well aligned, interconnected, and harmonized to generate specific products and services (Säumel et al. 2019; Panagopoulos et al. 2016; van Noordwijk et al. 2014). This implies urban planning should be deliberate in shaping multifunctional landscape performance in order to derive optimal outcomes from every inch of ground. This can be enhanced or constrained by land use intensity and the scale of opportunity for landscape innovations in existing urban zones. It could be argued that several aspects of landscapes are multi-functional in nature. However, developing countries require special attention for multifunctional landscape planning to impose desirable landscape structure with increased capacity to contribute to addressing the multiple challenges in urban communities in the short term, while enhancing resilience and adaptive capacity in the long term.

Increasingly, this realization has given rise to the calls for expanded urban green infrastructure as a nature-based solution or ecosystem-based approach to resilience and climate change adaptation (Russo et al. 2017). Urban greenspace or cover can contribute to food security, urban aesthetics, thermal regulation, air quality (by suppressing dust and removing pollutants), water quality, and mitigate against flood and erosion (Wolch et al. 2014; Eschobedo et al. 2011; Thompson 2011; Nowak et al. 2006). A review by Laille et al. (2014) showed a strong evidence for contribution to physical and psychological health, biodiversity, thermal regulation, and urban attractiveness. In fact, poor access to urban greenspace could be associated with increased mortality (Coutts et al. 2010) and other adverse health outcomes (e.g., Villeneuve et al. 2012; Thompson 2011; Barton and Pretty 2010). This emerging evidence supports the view on the value and utility of urban green cover to strengthen resilience and adaptation to climate change (Dai 2011). Accordingly, research interests in green infrastructure, ecosystem services, or nature-based solutions have increased substantially as options for strengthening urban sustainability and resilient response to climate change (Haase et al. 2014). While a large body of literature has emerged from this research interest, these studies are largely conducted in isolation without considering the need for integrated systems that include food production and general landscape management in urban contexts (Russo et al. 2017). Critically, in developing countries, the role of human production activities as part of green cover in urban landscapes to support multiple goals, including support for livelihoods, food security, environmental protection and aesthetics, and provision of recreational and learning opportunities, needs to be emphasized (Yawson et al. 2019).

Elsewhere, there have been calls for embedding multifunctionality into agriculture and other land use sectors in rural landscapes (Mander et al. 2007; Nair and Garrity 2012). Even though interest in urban agriculture has been increasing substantially (Csortan et al. 2020; FAO 2012; Urban Agriculture 2009), this has often been studied or articulated in isolation from general landscape management goals. In Africa, the need for deliberately incorporating human production activities in urban landscapes to serve multifunctional purposes is urgent and critical due to increasing urban poverty, food insecurity, and poor-quality landscapes (FAO 2012). Due to poor urban planning, landscapes evolve chaotically with urban development and are hardly managed (Lwasa 2014; Mensah 2014). Poor financial resources and land administration combine to raise the challenge of creating and managing curated landscapes to preserve the scenic beauty and improve the social, economic, environmental, and cultural significance of urban zones. A way out is mobilizing policies, regulations, incentives, and stakeholders to adopt landscape management approaches that permit a sensible balance between economic activities and profitability on one hand, and ecological functionality and productivity on the other hand, so that the latter is maintained by the former and, together, support overall urban well-being and development goals. In other words, producers become landscape entrepreneurs and managers whose obligation include the maintenance and management of ecological productivity and functionality, profitability, and scenic beauty. In this case, the scenic beauty, which is a desirable public good or noncommodity output, for example, is paid for by the economic production which is private activity (Mander et al. 2007). This twin system can be applied to multifunctional landscapes where food production supports urban food security, jobs, and poverty reduction, while general landscape management, as part of the production obligations, provides ecosystem services such as scenic beauty, environmental protection, and recreational opportunities.

In Africa, innovations in existing urban spaces are required to improve livability and overall resilience and human well-being, through increased capacity for intensive delivery of multiple ecosystem services. Because land is finite and the value of urban land parcels increases rapidly, preserving spaces for a single purpose is extremely difficult (Säumel et al. 2019; Güneralp et al. 2017; Mander et al. 2007). This difficulty is heightened by poor land administration, speculation, informal land transactions, and urban expansion. Additionally, the constraint of funding makes it difficult for African governments to invest in the development and maintenance of curated landscapes to improve the scenic beauty of the urban space and contribute to resilience and well-being. As a result, improving landscape contribution to resilience would require approaches that balance or optimize ecological productivity through human production, economic profitability, and scenic beauty or delivery of other ecosystem services which are public goods. To this end, it is important to adopt innovative approaches to impose specific multifunctional landscape character in existing urban spaces, and multifunctional land use planning for the future. Multifunctional landscape approaches that include human production are promising options for enhancing resilience in poorly planned urban zones in Africa (Säumel et al. 2019). Particularly, food production integrated in properly designed and managed landscapes to support multiple development goals, including food security and jobs, would be crucial. This is particularly important since land is finite, urban land has high value and is constantly under intense pressure from competing interests and goals. Multifunctional edible landscape approach provides opportunity for balancing competing interests and goals, both ecological and socioeconomic, in the African urban space. However, a multistakeholder mobilization of policies, resources, and regulatory and financial instruments will be required to ensure inclusivity, broad-based acceptance, and long-term sustainability (Yawson et al. 2019). The purpose of this chapter is to illustrate the workability and utility of this innovative approach to urban landscape transformation, and the requirements for scaling out, for resilience in Africa using a case study from Ghana.

Structure of the Chapter

Section "Introduction" above has provided background and contextual information about urban challenges and evolution of urban landscapes in Africa, as well as the utility of mutifunctional edible landscapes for enhancing resilience. The rest of the chapter is organized as following. Section "Multifunctional Edible Urban Landscape Transformation in Practice" presents a case study of practical implementation of multifunctional edible landscape in existing urban areas in Ghana and the outcomes. Section "Lessons and Insights for Scaling Up" builds on the case study outcomes to provide lessons and insights on practical expansion of multifunctional edible urban landscapes in Africa. Finally, the chapter presents some conclusions and recommendations in section "Summary and Conclusions".

Multifunctional Edible Urban Landscape Transformation in Practice

Promoting innovative landscape transformation can play a catalytic role in addressing urban challenges and enhancing resilience to climate change in Africa. Proceeding from the context and belief presented in the prior section, a practical example of an edible urban landscape transformation activity Ghana is presented in this section. This example is aimed at demonstrating the utility and practical approach to transforming idle spaces into multifunctional edible landscapes in existing urban areas. It also highlights key challenges and levers of change for wider implementation or adoption of this approach to support multiple development goals and enhance resilience. A question of interest inherent in this example was whether the food production component, from a multifunctional perspective, could incentivize and pay for maintenance of scenic beauty and management of landscapes in existing urban areas.

The practical example referred to is derived from a pilot project by the Agriculture for Food Security 2030 (AgriFoSe2030, theme 2) sponsored by the Swedish International Development Agency (SIDA) through the University of Gothenburg. The project, firstly, tested the idea of using vacant, idle parcels of land in the urban area to produce food, enhance the scenic beauty of the surrounding landscape with ornamental plants, while providing jobs for young people and women. This concept was referred to as multifunctional edible urban landscape (a managed landscape that integrates food production, ornamental aesthetics, and other urban structures in a harmonious coexistence to deliver targeted, multiple ecosystem services – Yawson et al. 2019). The edible urban landscape pilot project was conceived as a potential path to climate adaptation and resilience in urban centers in Ghana. The pilot project took place in the year 2018 in the City of Cape Coast in the Central Region of Ghana. Several idle parcels suitable for the project were identified in Cape Coast. Owners of the identified parcels were contacted to negotiate permission to use their lands for the pilot project. Other considerations for the final selection of sites included trust of landowner, safety of the project activities and assets (for e.g. safety from praedial larceny), access to water, and ease of monitoring by the researchers. Based on these, two sites were eventually secured at Akotokyer (1°17′36.28″W, 5° 8′8.61″N) and Kwaprow (1°18′7.02″W, 5° 7′26.98″N), two communities that border the University of Cape Coast.

The city of Cape Coast is the capital of the Cape Coast Metropolis (CCM) and the Central Region of Ghana. The CCM covers an area of 122 km^2 and is very urbanized as only 23% of its 169,894 inhabitants live in rural areas (Ghana Statistical Service 2013). The study communities are among several that border the University of Cape Coast and, together, make up the largest spatially distinct continuum of communities outside of the core of the city of Cape Coast which is densely built up and has limited space for new development. Due to the proximity to the University of Cape Coast, Kwaprow and Akotokyer are among the fastest-growing urban communities in Cape Coast as demand for facilities and services for students, staff, and the associated itinerant workers of the University of Cape Coast keeps growing. However, the communities lack planned physical development and so the physical expansion is haphazard and chaotic, with spatially scattered property development and several idle, unmanaged spaces contributing to undesirable landscapes. A section of urban landscape in Kwaprow is shown in Fig. 1. The communities have poor infrastructure and municipal services are vulnerable to floods and are highly exposed to dust pollution during the dry season. This situation presents an opportunity to generate evidence for the value and feasibility of landscape transformation to support multiple development goals and enhance resilience and well-being.

Implementation of the Pilot Project

The project goals and activities were explained to relevant stakeholders. The sites for the pilot project were bushy and unkempt (Fig. 2). The site at Akotokyer had sparsely distributed apartment buildings while the site at Kwaprow had neighboring low-density houses and amenities such as a school and a clinic. The sites were cleared, ploughed, and harrowed (Fig. 3).

A greenhouse, measuring 9 × 15 m, was installed at each site (Fig. 4). Solar-powered fans were used for ventilation and to control humidity in the greenhouses. Seedlings of the tomato genotype Eva Purple Ball were grown in pots in the

Fig. 4 Greenhouses installed at sites with grasses and border plants grown around the greenhouses

Fig. 5 Young tomato plants growing in pots in the greenhouses

greenhouses and recommended agronomic practices on integrated production and protection (IPP) were used (Figs. 5 and 6). The area surrounding the greenhouses were planted with grasses and border plants (fruit trees for shade were planned but land lease terms did not permit this immediately) and maintained to improve the scenic beauty of the site, control erosion and dust, while providing recreational and educational opportunities for neighboring families (Fig. 4). Eight young people, four females, and four males aged between 18 and 35 years were employed to work in the greenhouses and to maintain the surrounding landscapes.

Fig. 6 Matured tomato plants in the greenhouses

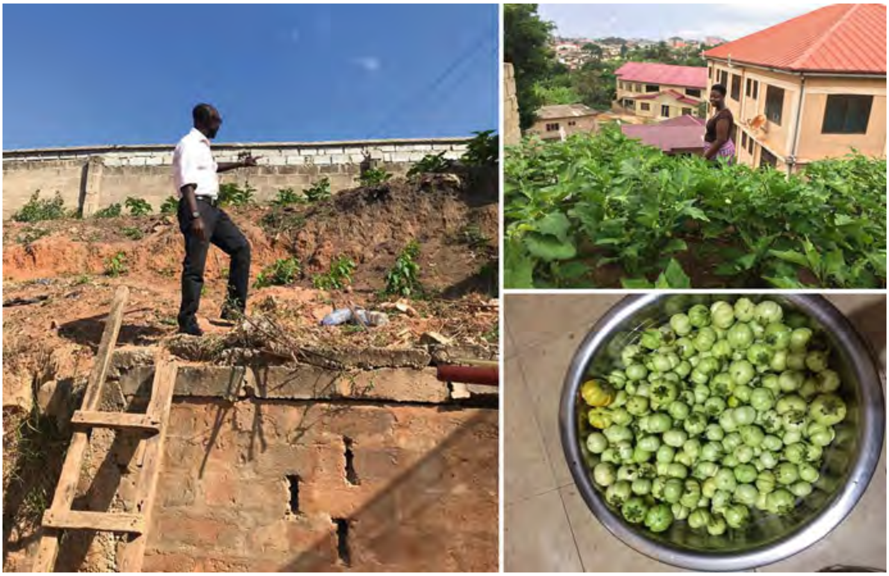

Fig. 7 Degraded, idle backyard space (left) turned into a productive site for eggplant (right)

In addition, the project encouraged individuals to transform small spaces in backyards or urban areas into green, productive areas. For example, one woman turned a degraded, idle backyard space into a productive site for eggplants (Fig. 7).

When the tomatoes were ripe and partly harvested, a stakeholder engagement or dissemination event was held at the sites, involving the communities and other stakeholders, to showcase and discuss the relevance, challenges, and opportunities for scaling up the project (Fig. 8).

Project Achievement

Multifunctional Edible Urban Landscape

The association between urban greenspaces and environmental quality and human well-being is well established and the need for planning to incorporate greener spaces in urban areas is being actively promoted (Panagopoulos et al. 2016; Laille et al. 2014; Mensah 2014; Bratman et al. 2012; Matsuoka and Kaplan 2008). However, in Ghana, and largely across sub-Saharan Africa, outdoor landscaping is a private matter and overall management of public spaces and the general fabric or structure of the urban landscape does not feature in discourse on sustainable development or resilience. There is evidence that greenspaces in urban Africa is declining at an alarming rate due to neglect and poor land use planning and controls (Mensah 2014). Poor urban landscapes can diminish resilience as they can contribute to flooding and sediment transport, thermal stress, air pollution, garbage accumulation, and transmission of diseases. Landscapes expose most urban residents to environmental conditions that undermine health, well-being, natural resource sustainability, and overall resilience (Säumel et al. 2019). It has been reported that the informal, chaotic, and discontinuous pattern of urbanization in Africa, together with poor social services, is a mark of vulnerability to extreme events (Di Ruocco et al. 2015). Dust, for example, is a major component of particulate matter in the air. In most urban zones and rural communities in Africa, people live literally in dust arising not only from industrial or human activities but mainly from bare surfaces (including roads, see Fig. 1) due to poor physical, infrastructural, and landscape planning and management. While the adverse health outcomes of exposure to dust are known and have been of considerable interest in some jurisdictions (Khan and Strand 2018), there is poor information on the contribution of dust to air quality and human health in West Africa, for example, where dust pollution and morbidity rates are higher (De Longueville et al. 2010) and over 20% of infant mortality is due to respiratory infections (Bryce et al. 2005; Morris et al. 2003). In the recent state of global air report, it was shown that annual death from air pollution (principally from $PM_{2.5}$) is on the rise in sub-Saharan Africa, reaching 5,190 and 49,100 for Ghana and Nigeria, respectively, in 2017, while others suffer various morbidities due to long-term exposure (Health Effects Institute 2019). Malaria is a major cause of morbidity in the case study communities. Africa remains the largest global hotspot of death from malaria, accounting for about 90% of all deaths from malaria in 2017 (WHO 2018). In addition, heat stress events would likely increase in intensity, frequency, duration, and spatial spread (Chapman et al. 2017) and humid tropical countries could have high sensitivity and exposure to these events. Enhancing resilience in urban communities implies taking verifiable steps to minimize the exposure of populations to these environmental stressors and hazards. Innovative landscape management approaches can help increase infiltration, reduce floods and sediment transport, and exposure to dust and vector-borne diseases such as malaria. These conditions are expected to be amplified by climate change; and taking remedial measures now through cost-effective landscape transformation or management approaches, as demonstrated in this example project, is a reasonable investment in achieving multiple development goals and enhancing resilience and long-term adaptive capacity.

Through their natural, cultural, and scenic beauty, urban landscapes provide a range of services (or disservices) that contribute to social, economic, and cultural resilience and overall quality of life. Landscapes embody and reflect the state of well-being and vulnerability of inhabitants to shocks. Hence, designing basic forms of appealing and functional urban landscapes that support multiple ecosystem services is essential to the drive towards resilience, which relates to the ability to maintain or improve the supply of life support services and products (such as food and water) in the face of disturbance. Just like many cities and towns in Ghana, the evolution of Cape Coast can be described as chaotic, contingent, discontinuous, and informal. Poor planning has combined with pressure on land for housing to create discontinuous physical expansion of the city, resulting in several vacant, idle parcels of land in the city. Several areas in both the core and periphery of the city are degraded, with visible signs of erosion, red-earth (iron-rich) dusty surfaces. Other places are simply covered by unmanaged bush, which becomes breeding grounds for mosquitoes and other vermin. Because of poor drainage systems, the project communities easily succumb to floods and sediment transport (Tham-Agyekum et al. 2019), and have conducive surfaces for breeding of mosquitoes. In the example project presented, the sites acquired for the pilot project were idle, bushy, and unmanaged (Fig. 2), detracting from the scenic beauty and ecological utility of the area, as well as posing physical and health hazards to residents and those who passed through the area, especially women, at night. Residents and those who pass through the area harbored fear about the high probability of attacks from criminals and/or vermin. There were signs of nefarious use of the sites as litter, human faecal matter, and other vermin were observed during land preparation. This pilot project opened up the area, improved the ecological functions, safety, scenic beauty, and social utility of the area (Figs. 3 and 4). The landscaping around the greenhouses were generally part of the integrated preventive environmental strategy of beautifying and protecting the landscape, reducing environmental degradation by ensuring soil cover and increasing the delivery of ecosystem services, both directly and indirectly. The idea of the project was to maintain a beautiful landscape or urban aesthetics while producing food and supporting incomes for the landscape managers. In this way, food production and basic landscaping are integrated, in a multifunctional edible urban landscape perspective, to deliver multiple ecosystem services. The project sites became attractions to the residents, the communities, and others who simply passed through the area. The grassed surroundings were used for recreational purposes by families and for curiosity learning (especially by children). The project sites became the largest curated, managed outdoor area considered by residents as beautiful and safe space for recreation by children in the communities. Generally, residents and those who passed by were happy about the project as they realized that it is possible to produce so much food in a small area and, at the same time, maintain a beautiful landscape or communal outdoor space in hitherto idle, unmanaged urban areas. The experience from the pilot project reported in this chapter suggests that persons have innate desire for beautiful urban landscapes but are denied of these due to poverty of municipal services. It also suggests the existence of a desire for recreational opportunities in safe, well-kept urban landscapes due to the use of the site for recreational purposes. Some nearby residents were happy because the improved landscape also meant improved security and safety in the area. In all, the example project demonstrated the idea and utility of multifunctional edible urban landscape and the feasibility of achieving this through transformation of idle spaces in existing urban areas.

Urban Food Security and Livelihoods

Food insecurity, unemployment, and poverty are major developmental challenges in urban Africa. Urban poverty is increasing in Africa and so is food insecurity (African Union 2020) as urban areas rely on rural food supplies. With poor supply chains, fresh food deteriorates rapidly both in transit and in urban markets and food safety also becomes a concern. This constrains access to fresh food as availability and prices become affected. Tomato, for example, is a climacteric crop which is an essential ingredient in almost every Ghanaian dish. Tomato is produced under rainfed conditions and long-distance transport and storage under poor conditions result in high losses. Prices of tomato in the dry season can be as high as three to four times the prices in the rainy or main harvesting season. This raises the need for producing food close to urban markets or point of consumption. Although urban agriculture is practiced in Ghana, there are concerns about the safety of the food produced and its environmental impacts due to the quality of water, other inputs, and management practices used (FAO 2012; Redwood 2009). Because urban agriculture has yet to gain a desirable level of quality and policy attention and thereby become mainstreamed in the urban landscape architecture, urban agriculture is practiced informally and in isolation from landscape management goals (FAO 2012), let alone from a multifunctional perspective. Just as with food, even where municipal services are available, poverty constrains access to these, resulting in increased vulnerability (Armah et al. 2018). Overall, there is a need to boost policy and operational or practical innovations for landscape transformation that integrates urban agriculture and landscape management goals in a singular, cost-effective framework to support resilience to climate change and better response to challenges in existing urban zones. These challenges include food security, jobs and income-generating activities, and aesthetic, livable, and recreational spaces. Embedding human production in the management of urban landscape and scenic beauty in this way is a useful integrative framework for landscape transformation and management as it can ensure that human production pays for the intangible ecological functions and services (such as scenic beauty) that are public goods while enabling a better response to development demands and climate change. This approach is consistent with recent calls for multifunctionality in agriculture, forestry, and other land use sectors (Russo et al. 2017; Nair and Garrity 2012; Mander et al. 2007).

Inherent in the pilot project was the idea of demonstrating the feasibility of twining human production and maintenance of beautiful landscapes such that the former (as a private good or activity) pays for the latter (as a public good) while supporting urban food security. The human production aspect was fulfilled by the production of high-quality tomato fruits in the greenhouses, with low external inputs such as water and pesticides. The system used in the pilot project produces 2000 kg (2 tonnes) tomato per cycle per greenhouse, and there could be at least three cycles per year. If properly planned with market access to high-end users (such as supermarkets, hotels, and restaurants), three cycles are enough to recover the full cost of installation and operation and generate profit. In this project, eight young men and women were employed for the duration of the project, to work in the greenhouses and maintain the surrounding landscapes. Their initial wages were part of the initial investment cost for the first cycle while payment of wages in subsequent cycles would be paid for by revenue from previous cycles. The initial idea was that these young persons work without wages but receive payment from the postharvest revenues. However, this idea was not acceptable to prospective workers, even those who were already in urban farming. So, in the end, their wages had to be worked into the initial investment cost. The tomatoes produced in the greenhouses were sold locally in the study communities, University of Cape Coast and beyond. Those young persons who worked in the greenhouses also had some tomatoes for their own household consumption. This possibility of paying for ecosystem services, as public good, by human production in urban landscapes to support multiple environmental and development goals was demonstrated during the dissemination event, to stakeholders including representatives from the Cape Coast Metropolitan Assembly, Ministry of Agriculture (regional office), town planning, chiefs and elders of the project communities, tomato retailers association in local markets, academics, and the general public. This approach was intensely discussed during the dissemination event and the consensus was that if this approach is well planned for out- and up-scaling, it can considerably augment urban food security and environmental and human resilience. The members of the project communities indicated how the landscaping could help reduce floods or dust exposure in the communities and improve scenic beauty to bring them some dignity, happiness, and recreational opportunities for children. In all, the project shows a possible pathway for urban employment and livelihoods in food production, landscaping, and landscape management while supporting food security.

Projections suggest that urban food demand will increase substantially due to a combination of increase in population and incomes, increased awareness of food health and safety, and dietary shift (Alexandratos and Bruinsma 2012; Yawson et al. 2020, 2017). A resilient urban community should be food secure and have landscapes that minimize socioecological vulnerability. One way of addressing food safety and security concerns is local supply where the food is transparently produced and freshly supplied to consumers or retailers. Tomato, for example, is almost indispensable in Ghanaian dishes or diets. Tomato production is very seasonal and can be very expensive or simply unavailable during the dry season. Suppliers and market women travel to neighboring countries to bring tomatoes to urban centers in Ghana especially during the dry season. The same can be said of several other vegetables. Yet, there are idle, unkempt spaces in urban areas that currently pose risks and dangers to urban populations and substantially detract from the scenic beauty of urban landscapes. This project demonstrates the fact that a multifunctional edible urban landscape approach can be applied to transform these spaces to productive and livable landscapes to support the multiple goals of food security, jobs and poverty reduction, environmental quality, and human well-being. This approach is not only feasible but also cost-effective and presents a triple-win opportunity for landowners, landscape entrepreneurs and workers, and city managers. It improves landscape structure and ecosystem services to enhance resilience and well-being. In terms of adaptation to climate change, transformation of idle spaces in urban zones to multifunctional edible urban landscapes can be instrumental in strengthening resilience and adaptive capacity in the areas of food insecurity, incomes and livelihoods, and environmental quality.

Lessons and Insights for Scaling Up

Landscaping and maintenance of public outdoor spaces have traditionally been the responsibility of governments. In sub-Saharan Africa, this arrangement seems to be generally absent due to weak financial capability and poor physical planning, resulting in distasteful landscapes that amplify vulnerability to shocks. Although urban agriculture or farming has been practiced for a long time throughout the world, and there is a growing interest and worthy calls for its integration in urban planning (Redwood 2009), it does not necessarily and deliberately integrate landscaping for the purpose of scenic beauty, environmental protection, and recreational use. Similarly, the idea of edible landscapes has been around for a while and practiced in different formats and context, including home or kitchen gardens and agro-parks. However, in Africa where poor financial capability weakens public landscape management, there is scope for exploring the requirements for creating edible landscape entrepreneurs who simultaneously produce food and maintain aesthetic landscapes, with the former paying for the latter. The practical example presented in this chapter tested this idea in parallel with the idea of transforming the idle spaces to multifunctional edible landscape. This project suggested that young persons would not easily defer payment for their work until revenue is generated from sales of produce. Perhaps, they did not consider the project as their own but only as workers, a situation worthy of further exploration. Nonetheless, on a balance, the project result showed that, with careful planning and successful harvest, it is possible to cover this cost from initial revenue and generate profit from the second or third cycle. Hence, the project gives indication that multifunctional edible landscape entrepreneurs can be developed to maintain idle and public spaces that are poorly managed (or not at all) by either the state or private owners due to inadequate resources. Further exploration of this idea would be useful for policy, practice, and research in multifunctional edible urban landscapes to help improve the general landscape character and resilience of urban zones in Africa.

The project used greenhouse system for crop production. This is expensive and could be unaffordable to potential multifunctional edible urban landscape entrepreneurs who would likely be resource-poor. As a result, some form of financial support or business case could be investigated to inform large-scale implementation of this system. While non-greenhouse-based production systems are viable, such as seen in conventional urban farms, the landscape beautification and opportunities for recreational and educational use might give cause for security concerns. Uncontrolled visit or recreational use of the site can expose the crops to unintentional damages. Praedial larceny could also be increased. In addition, because of the quality and safety concerns over vegetables from urban farms in Ghana (Redwood 2009), greenhouse production might be more acceptable to consumers. Finally, because greenhouse production is highly productive, it will not require large area of land to produce profitably and can be more suitable for small idle spaces or where only a small space can be used for food production while the rest of the land area is landscaped. As a result, the use of a greenhouse system as presented in the example project, or otherwise, should be informed by local circumstances, including security concerns.

While Africa is known to be highly vulnerable to climate change, the local-scale impacts of climate change in Africa is poorly understood (Di Ruocco et al. 2015). Cape Coast lies in the coastal savannah agroecological zone and so drought, water scarcity, and heat stress are persistent problems. Cape Coast is the capital of the Central Region, which is the fourth poorest region in Ghana. These challenges would be exacerbated by climate change, population growth, and urbanization. The urban challenges of Cape Coast might not differ significantly from other cities in Ghana. There are numerous opportunities for implementing multifunctional edible urban landscapes in Ghana and sub-Saharan Africa as the characteristics of urban landscapes tend to be similar. The project demonstrated the promise of a multifunctional edible urban landscape approach to strengthening resilience through food production, land cover management, improving urban aesthetics, environmental protection, providing greenspace for recreational and educational opportunities, as well as jobs and livelihood opportunities in cities and towns.

Despite the huge potential of this concept of multifunctional edible urban landscape to contribute to resilience and adaptive capacity, there are success factors that need to be in place and challenges that need to be addressed to ensure success. These are discussed below to help identification of opportunities for innovation and mitigation of challenges and risks that might arise, and guide efforts at implementing or scaling up similar landscape transformation projects in similar contexts.

1) Trust and legitimacy: The first lever of change is developing a strong trust between city authorities (government), landowners, and landscape entrepreneurs. As indicated earlier, the land sector in Ghana is riddled with disputes, protracted litigation, and conflicts (sometimes violent conflicts) due to poor land administration and inordinate pressure on land for housing, commercial, and industrial activities. A parcel of land can be sold to two or more persons by the same or multiple parties. The courts are unable to deal with land disputes or litigation swiftly. Protecting a parcel of land can be more expensive than the cost of the land itself, and sometimes comes at a great cost to parties in a dispute or conflict. In the example project, though earlier verbal assurances were given by landowners to the researchers, the landowners later showed deep distrust and insecurities with releasing their lands for the project. Urban landowners feel insecure granting their lands for temporary projects as there might be limited or costly paths to peaceful recourse to their lands. The first step to successful implementation of this landscape transformation is, therefore, to establish an institutional framework that fosters and deepens a three-way trust between landowners, city authorities, and landscape entrepreneurs. This institutional framework should formalize and render transparent land transactions and use. This is necessary to legitimize the ownership of resources, the process of transformation, formal rights and responsibilities, and benefits sharing. Minimizing insecurities among landowners and strengthening tenure security of landscape entrepreneurs are key to freeing up the numerous idle spaces in existing urban zones for edible urban landscape transformation projects. This, in turn, will require a stronger connection with and improvements in the land administration system at local or national scale to guarantee the security of ownership and access to land by landowners without jeopardizing the tenure security of those who produce on and manage the landscapes.

2) Incentives: Beyond institutional arrangements for land ownership and tenure security, specific incentives can help ease the process of committing idle spaces to edible landscape transformation. As indicated earlier, idle lands do not attract any meaningful taxes and there are no management responsibilities enforced on landowners. There is a need for land management mechanism that encourages owners of idle parcels or spaces to actively manage their lands in a manner that fits the broad urban landscape and ecosystem or transfer such management responsibilities to edible urban landscape initiatives. As part of the institutional arrangements and improvements in land administration, policies and regulatory instruments that impose and enforce land management and tax obligations on landowners would be essential. This needs to be tightly coupled with improvements in land administration structures and procedures to make the process of land registration and titling less cumbersome. In this context, incentives such as free land registration and/or titling, reduced or waving of land taxes, and transfer of land management responsibilities from landowners to landscape entrepreneurs can help catalyze freeing idle lands for multifunctional edible urban landscape initiatives. Neighbors would be supportive of edible urban landscape projects if they become aware of the numerous benefits it can generate to the public, landowners, and the edible landscapists, especially if neighboring residents know that the project would not lead to conflict over land, and that they can benefit from fresh food, recreational and learning opportunities, or aesthetic value of the project sites. The argument of neighborhood landscape improvement could also be made and used to derive small margin of revenue from neighboring properties whose owners or inhabitants could benefit from the aesthetics and the recreational and educational opportunities. A major incentive to landscape entrepreneurs would be a strong connection to markets: local residents, fresh produce retailers, supermarkets, hotels, restaurants, and processors. Local authorities or city managers could facilitate this as part of an integrated approach to serving the multiple goals of urban development demands, including food security, jobs and poverty reduction, and scenic beauty. This will also mean supporting private or individual developers to complete their housing or property development projects quickly to support the achievement of a desirable landscape as a whole.

3) Formal edible landscapes in urban planning: Beyond innovations of landscape transformation in existing urban zones, there is a need to arrest the current chaotic and informal evolution or growth of urban zones and landscapes. This calls for compact urban planning approach that opens up a zone for development at a time, reduces the preponderance of idle spaces, and formally integrates multifunctional edible landscapes in the urban fabric. In the interest of the challenges and threats posed by climate change, resilient cities need to have the capacity for resource efficiency, circular economy, and material transformation or flows. This formal incorporation of multifunctional edible landscapes into the development plan will amount to a formal recognition and practical articulation of the high capacity of urban agriculture for material cycling while supporting multiple socio-ecological services in urban areas (FAO 2012). When greenhouse production is chosen, landscape entrepreneurs might need support as the capital requirement might be high for some. To this end, support for formal access to financial resources and technical support would be helpful and a great incentive to landscape entrepreneurs.

4) Recognition and articulation of landscape needs and services: The first challenge is the need for policymakers, regulators, and urban management authorities to recognize and strongly articulate the fact that the appearance and structure of landscapes in which people live are strongly connected to a sense or state of poverty, powerlessness, vulnerability, despondency, ill-health, and distrust of government (Scott et al. 2009). Urban landscapes can deter or facilitate nefarious or some criminal activities. Urban landscapes can confer confidence, dignity, and a sense of pride (or otherwise) in its inhabitants or users. Recognizing these fundamental relationships between landscapes and people by public authorities is a prerequisite for moving towards policies and management decisions aimed at transforming landscapes to transform lives. People have landscape needs (Matsuoka and Kaplan 2008). These landscape needs are directly linked to the material and existential needs of the landscape inhabitants or users and, by addressing these needs, vulnerability can be reduced, and resilience enhanced (Yawson et al. 2015). A formal recognition and articulation of the linkage between landscapes and urban challenges or people's needs are a prerequisite for innovative planning and transformative approaches that enhance resilience and adaptive capacity. Next to this recognition is the need for political will to tackle the issue of integrated urban planning that can incorporate multifunctional edible urban landscapes, dignity and resilience considerations, or tackle land management in general in urban areas using the approaches or instruments proposed earlier in this chapter. While poverty and undesirable landscapes can have spatial delimitations, their impacts can be diffuse across sectoral, spatial, and temporal scales. The fabric and connectivity of landscapes in urban zones should, therefore, be considered holistically as to ensure broad-based resilience and adaptive capacity across the entire urban space or city. To this end, recognition and articulation of the role of urban landscapes to development and well-being would gain acceptance and support among urban residents and pave the way for mobilizing multiple stakeholders for transformational projects and implementation of planning measures adopted. In Ghana, for example, the Department of Parks and Gardens, which hitherto is responsible for public landscaping and landscape management, seems to be weakened and inactive. Recognizing the link between landscapes and urban resilience and human well-being would also mean revitalizing the appropriate units, such as the Department of Parks and Gardens, Environmental Protection Department, and Agricultural Extension Services, that can provide technical support to landscape entrepreneurs. For example, the Department of Parks and Gardens in Ghana can be a source of genetic or planting materials that helps design the edible landscapes and provides training to prospective landscapists. Context-specific arrangements would be necessary to respond to local challenges or needs. In this way, bottlenecks associated with production and technical assistance in the context of human production and landscape management entrepreneurship can be addressed during planning and operational phases of multifunctional edible landscapes for urban resilience.

Summary and Conclusions

Urban zones in Africa face considerable challenges, including floods, droughts, high rates of poverty, unemployment, food insecurity, and environmental degradation. Climate change, population growth, and urbanization would escalate these challenges. People's landscape needs, poverty, and vulnerability are directly interlinked. This chapter used evidence and insights from a pilot project to promote the feasibility and the instrumental role of a multifunctional edible urban landscape transformation approach that balances land productivity, economic profitability, and human well-being to strengthen resilience and adaptive capacity in poorly planned or managed urban zones in Africa. The pilot project simply tested the idea and workability of incorporating food production into ornamental landscape design, so that the former pays for the latter while maintaining profitability and supporting urban food security, jobs, and livelihoods, and maintenance of scenic beauty and environmental protection to enhance resilience. The findings from the pilot project show that urban spaces which are hitherto idle, unmanaged, and unkempt can be successfully transformed into green, productive, and aesthetically appealing landscapes to support the delivery of multiple ecosystem services and, therefore, contribute to urban resilience. The example project demonstrated the possibility of producing fresh, quality tomato fruits from a small area using a greenhouse, providing jobs or income for young persons, and maintaining ornamentally landscaped surroundings that provide public goods (scenic beauty, safe space for recreational and learning opportunities, and environmental protection). This demonstrates the workability of this landscape transformation approach to resilience and adaptive capacity using spaces which are currently idle and unmanaged in poorly planned and managed urban zones in Africa. The chapter argues that the multifunctional edible urban landscape transformation approach presented in the example project is innovative, cost-effective, and a feasible avenue for green transformation of undesirable landscapes in sub-Saharan Africa to improve lives and well-being. The multifunctional edible urban landscape transformation in this chapter can be adapted and scaled in similar jurisdictions, where limited public funds constrain investment in landscape and scenic beauty management, so that human production (as a private activity) can pay for public goods or ecosystem services. This idea, which requires further exploration, makes multifunctional edible urban landscape transformation, as presented in this chapter, insightful and relevant for policy, practice, and research. The chapter also sheds light on challenges and levers of change critical for successful transition to multifunctional edible urban landscapes as a pathway to enhancing urban resilience in Africa. These include a formal recognition and articulation of the link between urban landscapes and a sense or state of poverty, powerlessness, and vulnerability of inhabitants. This recognition, coupled with political will and a genuine commitment to confronting the problem, can pave the way for building trust and legitimacy for transforming idle spaces, providing incentives for landscape transformation project, and formally incorporating multifunctional edible landscapes in compact urban development planning and processes. Achieving this will, in turn, require multistakeholder mobilization of policies, laws, and institutional arrangements that (i) ease access to idle or formally demarcated spaces in urban zones in a manner that protects or guarantees the security of ownership and tenure for both land owners and landscape entrepreneurs, (ii) incentivizes multifunctional edible urban landscapes in the context of urban planning and management for resilience and adaptation to climate change, (iii) provides support for access to productive and technical resources, and (iv) promote reliable market for produce from multifunctional edible urban landscapes to sustain the human production and the payment for the ecosystem services which are public. Altogether, the landscape transformation approach presented in this chapter demonstrates an innovative path that balances ecological productivity and protection, scenic beauty, and socioeconomic profitability and well-being in existing urban zones, and constitutes a triple-win option for urban managers, landowners, and landscape entrepreneurs. If well planned and effectively managed, it can enhance urban resilience and contribute to long-term sustainability of urban zones in Africa. Hence, multifunctional edible urban landscapes should be integral to the suite of responses to the challenges of climate change.

Abstract

Lagoons are a common feature of the low-lying West African coastline. These lagoons are resource-rich and biodiverse. The small-scale fishing communities, which border them, are dependent on the resources and ecosystem services for their livelihoods and well-being. Climate change has had significant and diverse effects on both the lagoons and their surrounding communities. Sea level rise has caused erosion of the coast and increased the risk of floods. Changes to rainfall patterns have caused shifts in lagoon ecosystems and physical cycles. Of particular relevance to lagoon fishing communities is the fluctuation in quantity and distribution of fish catch that they rely upon for economic livelihood. Understanding the vulnerability of these communities to the effects of climate change is critical to supporting and developing successful adaptations. Using a case study from Ghana, sustainable livelihoods approach (SLA) and vulnerability framework are used to characterize the community vulnerability, giving insight into the temporal and spatial dynamics of vulnerability and how subsections of the community may be identified and prioritized for adaptation interventions. A scalar analysis of the relevant coastal and environmental frameworks and policy to support climate change adaptation in coastal communities reveals the common challenges in implementing adaptation interventions and strategies in the region. A policy gap exists between high level, institutional coastal, and climate directives and implementation of climate adaptations at the local level. That gap might be bridged by a participatory approach that places coastal communities at the center of creating and enacting climate change adaptations.

Keywords

Lagoon · Vulnerability · Adaptation · Fishing communities

Introduction

Coastal lagoons, and the wetlands that are often associated with them, are estimated to occupy 13% of coastlines worldwide (Duck and De Silva 2012). They are found at low-lying, sandy coastlines where they support highly productive ecosystems that provide a wide range of natural functions and ecosystem services to the communities living around them. Lagoons along African coastlines are often home to fishing communities, whose livelihoods are entirely dependent on the resources supplied by them. In West Africa, lagoon communities take advantage of highly productive coastal fisheries that are supported by upwelling along the Gulf of Guinea, which brings nutrients to surface waters. The fishing communities here tend to fish in both shallow coastal waters and coastal lagoons (also known as coastal lakes). Climate change is affecting lagoons and the fishing communities that live around them, in multiple interconnected ways. Sea level rise has eroded coastal land and increased the risk of flood. Changes to rainfall and temperature patterns have altered natural lagoon cycles and coastal ecosystems. The resultant changing ocean and lagoon conditions have altered fish catch and fishing practice. The effects of climate change thus have significant implications for the well-being and livelihood of lagoon fishing communities. Understanding how climate change affects lagoon fishing communities is critical to supporting and developing successful adaptations. In this chapter, the impacts of climate change on the lagoons of West Africa, specifically in Cote d'Ivoire, Ghana, Benin, Togo, and Nigeria (Fig. 1), and the fishing communities they support are discussed. How the vulnerability of these communities is characterized, assessed, and connected to climate change is explored. A case study of a fishing community in Ghana is used to exemplify how understanding vulnerability is critical for effective and nuanced community-level adaptation planning. Current international, regional, and national frameworks, governance, and policy to support the creation and implementation of successful adaptation strategies for lagoon communities are presented. The gap between coastal- and climate-related policy and successful implementation of adaptations to climate change in coastal communities is considered and the participatory approach required to bridge that gap presented.

Fig. 1 Map of West African coastal countries with key urban area and lagoons shown

Lagoon Environments and Communities

Lagoon Environments

Lagoons are highly dynamic coastal environments, vulnerable to changes in oceanic and meteorological conditions associated with climate change. They are bodies of coastal water fully or partially separated from the open ocean by a natural barrier. This barrier is of low elevation, often less than two meters above sea level, and consists of sand that is easily eroded and transported. Lagoon barriers can entirely separate the lagoon from the ocean, or they can have one or more breaks, known as breaches or tidal inlets, which connect the lagoon to the ocean. The breaks are important as they act as channels that allow ocean water and biota to enter the lagoon. The barriers can change from whole to breached, and vice versa, in response to variations in weather conditions, hydrological conditions, availability of sediment, and sea level. A seasonal cycle of opening and closing of the sand barriers is common. Natural breaching usually results from overtopping of the barrier from the lagoon when the lagoon is full of freshwater at the end of rainy season. The opening of a lagoon to the ocean allows seawater to flow into the lagoon, resulting in rapid shifts in water temperature, salinity, dissolved oxygen content, and concentration of anthropogenic pollutants. Opening can also alter the tidal amplitude and influence in the lagoon as well as the amount and location of erosion and sediment deposition. Opening can also have an effect on the incidence, amount, and location of flooding. Such fluctuations in the physical environment can create unstable and stressful conditions for lagoon organisms at the species, community, and ecosystem level that can then negatively affect their health and productivity. This in turn influences the availability of natural resources, including fisheries.

Lagoons, or coastal lakes as they are sometimes known in the region, are found at low-lying coastal areas throughout Africa. Along the West African coastline of focus here, there are more than 200 lagoons from Cote d’Ivoire to western Nigeria. This coastline experiences the Guinea Ocean current, which flows from west to east along the west-east trending coastline, creating similar ocean conditions in the region. The lagoons along this coastline vary in size and shape as well as the nature of their connection to the ocean. Two of the largest are Lake Nokoué in Benin and the Lekki Lagoon complex in Nigeria (Fig. 1). Lake Nokoué lagoon covers an area of 120 km^2. A former estuary of the Ouémé River, a sand barrier has now enclosed the estuary (Anthony et al. 2002), preventing permanent connection to the sea. The Lekki-Lagos lagoon complex in Nigeria parallels the coastline for approximately 200 km (Bernacsek et al. 1990) incorporating two separate lagoons: the Lekki and Lagos lagoons. The majority of lagoons, however, in the region are much smaller than these two, with an areal extent from a few to tens of square kilometers.

Lagoons have high biodiversity in tropical and subtropical regions and are often the site of species-rich wetlands. West African lagoons are no exception with high productivity and biodiversity. The key natural resources of these biodiverse lagoons are fisheries and mangroves. According to the USAID, lagoon settings play a key role to fisheries in the area and have been recognized as contributing $400 million annually to the regional economy (USAID 2014). However, the West Africa Regional Fisheries Program (WARFP) indicates that incomes for artisanal (small-scale) fishers have dropped by as much as 40% over the last decade (The World Bank 2015). This has knock-on effects for the livelihood and well-being of these small-scale fishing (SSF) communities, with the potential to increase their vulnerability to the impacts of climate change. Mangroves are the key lagoon wetland vegetation and provide a variety of ecosystem services: shoreline protection and storm buffering through trapping sediment and dissipating wave energy, regulation of water quality, and provision fish habitats and nurseries (Blankespoor et al. 2014). Through the ecosystem services they provide, mangroves are estimated to contribute approximately 3 billion US dollars annually to the West African economies (Boateng 2018). Despite the importance of mangroves to lagoon communities, they have been decimated due to overexploitation, clearance, and pollution (Boateng 2018; Djihouessi et al. 2016). The impacts of climate change at the coast (sea level rise, changes to temperature, shifts in rainfall patterns, and increased storminess) have further contributed to their demise.

Lagoon Communities

Coastal towns are Africa's most developed, most densely populated urban areas (State of African Cities 2008), and migration to the coast has been and remains a long-term trend (Ochiewo 2004). The major cities of Abidjan (Cote d'Ivoire), Accra (Ghana), Cotonou (Benin), Lome (Togo), and Lagos (Nigeria) are all situated around one or more lagoons (Fig. 1). Cote d'Ivoire has a coastal population of 8.2 million, which accounts for 36% of its total population (World Bank 2019). The economic capital and largest urban area of Cote d'Ivoire is Abidjan, which is built around the Ébrié Lagoon. Seventy percent of Ghana's approximately 25 million population (Ghana Embassy 2014) lives in the southern part of the country with maximum population density at the coast. The Korle Lagoon has played a significant role in the development of its capital, Accra. Benin has a short coastline compared to the total area, yet half of its population live in Cotonou, the capital, which is located around Lake (lagoon) Nokou (World Bank 2019). In Togo, the City of Lome lies on the eastern shores of Lake (lagoon) Togo. Lagos, Nigeria's largest city, sits on the Western shores of Lagos Lagoon, part of the Lekki lagoon-barrier system. These lagoons have been an important source of natural resources, including fisheries, supporting the development of the surrounding urban areas. Fishing communities have traditionally lived around the shores and along the lagoon barriers of these highly urbanized areas. Despite the rapid growth and population increase of urban coastal areas, fishing communities still have a strong presence. For example, in Cotonou fishing remains a mainstay of the economy (Dossou and Glehouenou-Dossou 2007). Lagoons located in less urbanized (rural or peri-urban) areas of the coast are also home to large numbers of small fishing communities. Between 40% and 45% of the rural work force of Lagos State of Nigeria engage in SSF, and it is the dominant type of employment (Akanni 2010). At Aby Lagoon in the Cote d'Ivoire, fishing is noted as the most important activity for the economy and livelihood of families in the region (Njifonjou et al. 2006), and in Ghana 66.5% of household livelihood activities in coastal communities are classified as fisheries-based (Evadzi et al. 2018). No matter where they are located, whether in urban or rural areas, these fishing communities are dependent on lagoon and ocean fish stocks for their livelihood and food security. In addition, lagoon fishing communities depend on the myriad ecosystem services that a lagoon system provides such as water resources, flood mitigation, washing and bathing, and wood resources, all of which are subject to the impacts of a changing climate.

Impacts of Climate Change on Lagoons and Lagoon Communities

Sea Level Rise

Climate change negatively affects lagoons and the communities they support through sea level rise, changes to rainfall, and increased ocean and air temperatures. During the twentieth century, global average sea level rose by 3.2 mm/year (Rahmstorf 2007). During the twenty-first century, rates of SLR are expected to increase with estimates varying greatly from 0.4 meters to 2.5 meters (Hauer et al. 2019). Historic data for SLR in Africa has been limited, and its impacts have been understudied across the continent at both national and sub-national levels (Brown et al. 2011). However, there are an increasing number of studies relating to SLR and its impacts along the coast of West Africa. Coastal management in Ghana has focused on physical processes; thus, most information on SLR and erosion in the region is from here. The average rate of sea level rise over the twentieth century measured at the Takoradi tidal station in western Ghana is 3.34 mm/year (Sagoe-Addy and Appeaning Addo 2013), and by inference, the rate along this coastline is likely to be similar. Evadzi et al. (2018) noted that on average, sea level in Ghana has risen by about 5.3 cm over the last 21 years, and SLR accounted for approximately 31% of the observed annual coastal erosion rate (approximately 2 m/year) in Ghana. The lagoon-barrier coastlines of West Africa are particularly susceptible to erosion associated with SLR because of their low coastal topography and their composition of loose, easily erodible sand. Sea level rise can cause erosion of lagoon barriers, increasing the probability of lagoon opening to the ocean. Average rates of coastal erosion for the coastline between Cote d'Ivoire and Nigeria are around 1.5 meters/year (World Bank 2019; Wiafe 2010). However, rates of erosion vary greatly along the coast with erosion hotspots recording more rapid shoreline loss. In eastern Ghana, close to the border with Togo, rates of erosion of up to 3.9 m/year have been recorded (Boateng 2012), and up to 4 meters/year has been recorded along parts of Benin's coastline (World Bank 2019). High rates of erosion have also been observed near the Lekki lagoon, along Nigeria's lagoon-barrier coast (Danladi et al. 2017). At all these locations, rates of erosion are often exacerbated by the loss of mangroves (Diop and Sherin 2016; Boateng 2018), and in a negative feedback loop, coastlines with high erosion rates often experience increased mangrove loss as the root structures of the plant become compromised due to the loss of substrate through erosion. Erosion associated with SLR affects not only natural coastlines, including the lagoon barrier integrity, but also the stability of human structures. This includes dwellings but also fishing-related structures. In Ghana, the loss of fish landing sites in Accra is already recognized (Appeaning-Addo 2014) resulting in the collapse of artisanal fishing.

Flood Risk

Flood risk for lagoon communities is enhanced by sea level rise, and there are multiple examples of this recorded for the countries considered here. Several Nigerian coastal states are recognized as having high flood risk for an SLR of less than a meter with the barrier lagoon coast of Lagos-Badagry-Seme in the southwestern part of Nigeria noted as particularly vulnerable (Odunga et al. 2014). Also in Nigeria, flooding and associated intrusion of salt water from the ocean have been recorded at the Lekki lagoon-barrier system since the early 1990s (Awoskia and Ibe 1993). The lagoon at Abidjan was highlighted as having a high risk of flooding associated with SLR (Adelekan 2010). In Ghana's central coast, a study of the Muni Lagoon indicated that a 1 meter rise in sea level would almost completely submerge its barrier and inundate the lagoon (Davies-Vollum and West 2015). The poorest communities are those most at risk from flooding, which includes those engaged in SSF. Temporary relocation is the main strategy adopted by members of the communities to adapt to coastal flooding. Some communities also use cheap materials for the construction of their houses as an adaptation to minimize economic loss during inundation (Evadzi et al. 2018). Increased water salinity associated with SLR and inundation inhibits biota in coastal ecosystems, including mangroves, and in a study of coastal wetlands in LEDCs, Blankespoor et al. (2014) estimated that up to 68% of these would be lost if subject to a 1 m rise in sea level.

Rainfall and Temperature

Rainfall projections for the West African coast indicate that during the twenty-first century, precipitation will become extreme with dry seasons becoming drier and wet seasons wetter. Along the West African coast, the major rainy season occurs from approximately March to July, with some geographic variation. Precipitation changes for West Africa include a projected variability in seasonal monsoonal rains (Adeniyi 2016), and there is evidence that the timing and amount of rain that falls during the rainy season have changed (Dossou and Glehouenou-Dossou 2007). In southwestern Nigeria, the rainy season appears to have shifted from March–November to May–October (Adelekan and Fregene 2015), and in Ghana, there seems to be less predictability in the onset of monsoonal rains (Koomson et al. 2020). Changes to the amount and timing of precipitation during the rainy seasons can modify the amount of freshwater input to lagoons and disturb the natural cycle of lagoon opening. Increased rainfall during the wet season results in more water impounded behind the barrier. This not only causes flooding but also increases the probability of lagoon waters overtopping and/or breaking through the barrier. Rainfall that is more evenly distributed throughout the year results in decreased risk of overtopping and lagoon opening. More evenly distributed rainfall patterns also lead to a more constant input of freshwater, increasing homogeneity of lagoon water conditions throughout the year and stabilizing salinity fluctuations. This in turn affects lagoon ecosystems including fish stocks (Diop and Sherin 2016).

Lagoon and shallow marine ecosystems are also affected by changing water temperatures. A general warming of coastal waters has been noted for the Gulf of Guinea (Druyan 2011). Although there is limited data on the impact of this warming on fisheries in the region, marine species in equatorial regions in general have seen a decline, as they are unable to respond to rapidly increased water temperatures (Hastings et al. 2020). Deoxygenation and acidification of ocean waters are also a consequence of climate change, and both are expected to indirectly reduce maximum fish catch. How fishing communities deal with the physical and ecological changes related to climate change is dependent on their vulnerability to those changes and their ability to adapt to them. Vulnerability and adaptation are inextricably linked, and any discussion about climate change adaptations warrants an overview of the architecture of the vulnerability of lagoon fishing communities.

Vulnerability of and Adaptation to Climate Change in Lagoon Fishing Communities

Vulnerability can be defined in several different ways in line with different epistemological orientations. However, whether grounded in physical science and human or political ecology, the key concept in vulnerability is the potential for loss or susceptibility to harm. The vulnerability of a community to climate change can be considered as its susceptibility to all the collective changes it experiences. The vulnerability of lagoon fishing communities is related to several multi-scalar factors or causes. The causes of vulnerability in lagoon fishing communities might be categorized into four sources: international, intrinsic, internal, and institutional. International sources refer to global climate and physical environmental change processes such as sea level rise, increase in sea surface temperature, and others, as outlined in the preceding sections. These processes, inter alia, reduce fish catches and revenue (Lam et al. 2016; Dey et al. 2016). Reduced incomes, in neoclassical economic terms, imply reduced purchasing power and so low material well-being (i. e., possession of natural, physical, financial, human resources). Intrinsic sources of vulnerability are those unique to coastal fishing communities and directly linked to their fishing activities. These factors are diverse and include the hazards encountered during fishing (e.g., storms), the seasonality of fish catches, as well as the high unpredictability of making catches. It also includes their high susceptibility to macroeconomic changes. For example, they are forced to accept the market cost of fuel and other necessary resources.

While intrinsic sources refer to features, which are uniquely associated with the small-scale fishing livelihood itself, internal sources refer to features commonly associated with coastal fishing communities. These include overfishing, gender and income inequality, intra-community conflicts, lack of cooperation, mistrust, and limited livelihood diversification opportunities (Béné 2006). Because artisanal fishing is mostly done in crews and lagoon fishing communities are usually small, trust, camaraderie, and solidarity are essential to sustaining the fishing activity and the community. When these sociocultural factors are missing, the very survival of the fishing livelihood is threatened. Moreover, these internal factors create differentiated experiences of vulnerability within fishing communities (Zacarias 2019; Koomson et al. 2020). Lastly, institutional sources are those related to rural planning, infrastructural development, and encroachment of industrial trawlers. Fishing communities do not usually participate in fisheries planning and management decision-making, have little social amenities, and often must deal with encroachment of large trawlers in local fishing waters. This list of vulnerability sources is by no means exhaustive. It is only a sample of the common features of artisanal lagoon fishing communities, which interact in complex ways with the impacts of climate change to make them susceptible to socioeconomic losses.

Whereas vulnerability refers to the susceptibility to harm, adaptation is the process of adjusting to the actual or expected harm and associated impacts, in order to either moderate the harm or exploit beneficial opportunities. The term adaptive capacity is used when considering how capable an individual or community is of adapting to harm or change. The adaptive capacity is based on an individual or a community's available resources that can be drawn on to achieve adaptation. The specific ways in which those combinations of available resources are enacted to moderate harm or exploit beneficial opportunities are then referred to as adaptive strategies. When considering and assessing adaptations and adaptive capacity, there are several critical concepts that should be accounted for. Firstly, it is rooted in the definition of adaptation. An adaptation is an adjustment to moderate actual or potential impacts, not to eliminate or "overcome" them. Secondly, the definition itself makes no value judgment about the legality of the adjustment process or on how the moderation of actual or potential impacts is achieved. In normative terms therefore, any action that has some moderating effect on impacts would qualify as an adaptation strategy. Thirdly, from the definition, adjustments to moderate impacts or benefits from opportunities would not be limited to actions only but also prohibitions. Communities themselves may spontaneously enact adaptations and adaptive strategies. These are referred to as autonomous adaptations.

Community-Level Autonomous Adaptations

Autonomous adaptations enacted to reduce or moderate harm in SSF communities might also be considered in the context of reducing risk to those communities. Risk reduction strategies that are spontaneously developed by communities whose livelihoods depend on natural resources, such as SSF communities, can be divided into five categories: over time (*storage*), across space and time (*mobility*), across asset classes (*diversification*), across households (*communal pooling*), and *market exchange* (Agrawal 2008). Communities and individual households may choose to combine and enact any of these strategies to achieve their desired outcomes. This is central to the concept of sustainable rural livelihoods and is important to examine when considering adaptations and adaptive capacity.

One of the earliest discussions on sustainable livelihoods (Chambers and Conway 1992) provided a similar list, which also included reduction of current consumption (*stinting*), preservation and protection of the asset base for recovery (*protection*), and making claims on relatives or NGOs (*claiming*). In a similar discussion on sustainable livelihoods, Scoones (1998) describes two more livelihood strategies: increasing input per unit area (*intensification*) and expanding the area under production (*extensification*). These livelihood/adaptation strategy typologies were developed predominately from the study of rural agrarian communities. However, they are also useful for characterizing adaptation strategies reported for commonly reported stressors experienced by fishing communities worldwide, not just in West Africa. These stressors are noted in Table 1. Not all stressors listed are directly related to climate change. Physical stressors like storms and floods and decreasing fish catches are a consequence of climate change. However, encroachment of industrial trawlers into artisanal fishing zone causing competition is not. Competition from trawlers is noted here because of the large impact it has on SSF communities and their vulnerability to climate change. An "experimentation" grouping in the table captures adaptation practices that are less well-established and in an initial learning phase of development (Table 1).

The most common adaptation strategies adopted by SSF communities are intensification strategies (Béné 2006). When fish catches are low, the first and immediate response of SSF communities is to put in more effort either by going further out at sea, spending longer hours at sea, changing fishing gear (equipment) to target fish species that may be relatively more abundant, or increasing the frequency of fishing activities. For example, in a coastal lagoon fishing community situated on the Muni Lagoon in Ghana, the major fishing season, which traditionally lasted from August to April, has been extended by some fishing crews by starting their fishing activities from July to May of the following year. This is largely in response to an erratic rainfall pattern in the major rainy season in southern Ghana. For supplemental incomes, lagoon communities may increase fishing in lagoons and use gears or methods considered illegal. In Benin, Acadjas (a purely ingenious practice of creating a favorable microclimate within a lagoon with sticks and leaves for recruitment of big fish) and médokpokonou (another traditional method which uses nets with fine and tight stitches) are both prohibited, but they are commonly practiced. This is because the former reduces overall fish species richness, and the latter removes small and juvenile fishes (Dossou and Glehouenou-Dossou 2007; Niyonkuru and Lalèyè 2010). The use of mosquito nets in fishing communities has also been observed in Cote d'Ivoire, Ghana, and several other sub-Saharan African countries (Short et al. 2018). This diverts the use of nets away from their role in protecting coastal communities from mosquitoes and negates efforts to reduce

Table 1 Examples of autonomous adaptation to key stressors of small-scale fishing livelihood in West Africa

Stressor	Examples of adaptations
*Physical (*e.g., *storms, floods and SLR)*[a]	Use of sandbags and rubbish to form defense walls Change of building materials (from wood and thatch to cement blocks and galvanized roofing sheets) Landward relocation of buildings
Reduced fish catch[a–g]	*Intensification strategies* Spending longer times at sea Use of small meshed nets (e.g., *médokpokonou and "*wan" practices in Benin) Fish trapping (e.g., the *Acadja* practice in Benin) Change of gear and fish species harvested Increased frequency of fishing in lagoons Extended major fishing season *Extensification strategies* Going further out into the sea Fishing in neighboring coastal communities during taboo days in own community (practiced in some beach-seining communities in Ghana) Temporal migration *Diversification/occupational mobility strategies* Taking wage labor jobs during lean seasons Adding supplementary livelihoods like livestock rearing Sand winning (extraction) Planting, harvesting, and sale of coconut fruits *Storage strategies* Preservation of fish for sale in lean seasons and/or to sell in new and fairer markets Reducing household expenditure in order to save money Borrowing from money lenders Remittances *Experimentation strategy* Varying the hours within the day when fishing expeditions are made
Encroachment of industrial trawlers into artisanal fishing zone	*Experimentation strategy* Studying to precede trawlers or waiting a long while after they have gone

malaria. Intensified fishing efforts in response to declining catches are the main reasons behind accusations of SSF as being overexploitative and unsustainable.

Adaption studies from Ghana show that SSF communities also extend efforts by going further into the sea, fishing in areas outside those of their own fishing communities, or moving temporarily to other towns or even countries to fish (Perry and Sumaila 2007; Freduah et al. 2018). Some small-scale fishers maintain contact with fishers from other communities through mobile phone communication to share information about the location of big catches. The fishers respond quickly by moving to that location to fish for a day or two. It is common among West African coastal fishing communities to have indigenously instituted no-fishing (taboo) days (Adjei and Sika-Bright 2019). By way of extensification, some fishing crews move from their communities on taboo days to fish in nearby communities as a strategy to increase catch and thus their weekly earnings. These strategies thrive on good social networks and camaraderie between communities.

Adaptations that are based on diversification of livelihood in SSF communities involve either taking on additional sources of income or changing and acquiring different types of fishing gears or both. Daudu et al. (2020) have shown that gear and occupational diversification are priority strategies for some fishing communities in Nigeria. Some members of a fishing household may take up wage labor jobs as complementary livelihood sources all year round or during some parts of the year. However, for households that have temporary non-fishing livelihoods, fishing is an activity to which they always return. Few artisanal fishers ever leave fishing permanently. Fishing, for them, is not just a livelihood activity; it is their culture, an important part of their identity and something they take pride in. West African coastal fishing communities do not have a strong tradition of farming as an additional source of income. However, recent increase in demand of specific products has provided opportunities for the diversification of livelihoods into harvesting local products. For example, in Ghana, the rise of demand for coconut fruits in large cities has created opportunity for fishers living in coastal areas to harvest and sell coconuts from coconut trees in their vicinity. Others harvest from trees growing on "no man's lands." This has become an important complementary source of income for fishing communities. In some instances, community members might engage in illegal activities to diversify sources of income. Sand winning (extraction of sand from beach areas) is a prohibited activity in most communities and illegal in accordance with national policy in most West African countries. However, some members of SSF communities are involved with sand winning for income.

Evolution of storage strategies is commonly reported as an autonomous adaptation in lagoon communities along coastal West Africa. Storage strategies have been identified in fishing communities in Cote d'Ivoire (Njifonjou et al. 2006), Ghana (Freduah et al. 2018), and Nigeria (Adelekan and Fregene 2015). Storage strategies are usually in the form of securing household sustenance by processing (commonly by smoking or drying) and storing fish to be sold in the lean fishing seasons, borrowing from credit lenders, and/or saving money during the major fishing seasons. This money-saving strategy differs from conventional money-saving practices that aim at saving disposable income. It is an active and often necessary saving against lean seasons, unexpected periods like stormy conditions, or close fishing seasons. It has also been widely observed that some rural households are cushioned by remittances from household members who have migrated either temporarily or permanently from their original community. While this may be true for some communities, it may be a largely missing income stream in other communities. For example, Atti-Mama (1998) reported in a study of nine communities around Lake Nokoue in Benin that more than 95% of households did not receive any remittances.

In response to the encroachment of large trawlers into local fishing waters, coastal fishing communities have no clear strategy. As this is a longstanding but still evolving problem, identified adaptive strategies are, at best, experimental. This may be more conveniently termed a coping mechanism rather than an adaptive strategy. Some authors have particularly highlighted that adaptation strategies are different from coping strategies noting that the former are permanent and long-term changes in practices, while the later are temporary and short-term changes in livelihood practices (Scoones 1998).

The Muni Lagoon and Akosua Lagoon community are used as a case study to illustrate the importance of understanding the vulnerability of an SSF community when planning adaptations.

Understanding Vulnerability for Effective Adaptation Planning: Muni Lagoon Case Study

Internal factors can differentiate the experience of vulnerability in fishing communities. This phenomenon presents both challenges and opportunities for effective adaptation planning in fishing communities. A case study of Akosua village, a lagoon fishing community in Winneba, Ghana, demonstrates this (Koomson et al. 2020).

Akosua village is a small migrant fishing community located on the central coast of Ghana on the outskirts of the town of Winneba (Fig. 1). The community is situated on the sandy barrier that separates the Muni Lagoon from the Atlantic Ocean. The lagoon has been well studied as it was designated as a Ramsar (protected wetland) site in 1992 (GEF 1992). The economy of the community is based predominately on beach seining. This is a fishing method that involves the deployment of seine nets into the sea and hauling them back to shore by hand. Beach seining is done mainly by men. The women in the community are the fishmongers, mostly engaged in the processing and selling of fish. In addition to the predominantly fishing-based livelihood, some women engage in petty trading, and some men engage in daily wage labor jobs within the town of Winneba. Farming and livestock rearing are uncommon in the community due to the sandy and saline nature of the land. The poor quality of the land for farming is common to all lagoon communities and limits opportunities for alternative livelihoods. To understand how vulnerability is manifested within the community, the structure of the fishing activity must be appreciated. Fishing crews are typically made up of the “net owner” (i.e., the owner of the boat, outboard motor, and seine net), boat crew (the net owner’s permanent employees), and net draggers (casual workers who haul the net to shore). This crew hierarchy delineates households’ economic class as profit is typically shared in the ratio 4:2:1 among the net owner, boat crew, and net draggers, respectively. Crews range from about 12 to 35 men depending on the size of boat and net. The major fishing season starts from the end of the major rainy season (July/

August) to its beginning (March/April) the following year. The period in between (April–July) is the major rainy season characterized by stormy conditions. Thus, no or very limited fishing activities take place during that part of the year. The community major fishing seasons are considered the “good season” when catches are big and incomes are high and the “bad season” when catches are small and incomes are low. This is purely subjective but reflects the community’s perception of their well-being during the year. Besides the interruption of fishing activities and income flows by unpredictable stormy conditions, sudden rainfall is a major problem to fish processing. The major fish processing method used in the community is drying in the open fields (Fig. 2). Unexpected rainfall, therefore, results in losses as the half-dried fish in the open fields deteriorate upon contact with water. Besides this, long periods of dryness cause the surface area of the lagoon to decrease in size and reduce the lagoon’s water quality. Changes to the lagoon size and water quality have knock-on detrimental effects on fish productivity and species diversity.

The study integrated the concepts of vulnerability and the capital assets component of the sustainable livelihoods approach (SLA) to understand how the lives and livelihood of the community are impacted by climate variability. Drawing upon the IPCC’s definition of vulnerability as a function of the magnitude of climate variation to which a system is exposed (E), its sensitivity (S), and its adaptive capacity (AC), a simple equation that multiplies E, S, and AC was used to quantitatively estimate the vulnerability of each household. This is a commonly used methodology according to the Intergovernmental Panel on Climate Change (IPCC 2014). The SLA is a framework designed to identify combinations of livelihood resources, which give people the ability to adopt livelihood strategies that produce their desired outcomes, as well as the institutional processes that mediate their ability to carry out such livelihood strategies within defined policy and ecological and socioeconomic

Fig. 2 Drying fish on a dry lagoon bed in Winneba, Ghana. (Photo D. Koomson)

contexts (Scoones 1998). At the heart of the SLA is the concept that rural communities draw upon and combine five main capital assets (natural, physical, social, human, and financial) to build their livelihoods and respond to shocks. An assessment of the levels of these capital assets and barriers to their access gives insight into what policies are necessary to expand the livelihood platform, thereby improving adaptive capacity and reducing vulnerability (Freduah et al. 2018).

Understanding the experience of vulnerability and autonomous adaptations to climate change in the Akosua community, and the role that internal factors play, has implications for adaptation planning in the community and other communities with similar contexts along the West African coastline. The scale of economic impact that bad seasons have on the household incomes is very important in determining vulnerability. Comparing incomes in good and bad seasons shows that household income drops by about 90% in a bad season (Koomson et al. 2020). With good seasons becoming rare with increasing climate change, food security is threatened. Vulnerability to impacts is not felt in the same way across the community. It is differentiated depending on the gender and wealth status of a household head. For example, in bad seasons, a household in a lower wealth rank and headed by a woman may be comparably less vulnerable than a household of a higher wealth rank and headed by a man. Thus, the most vulnerable are not necessarily female-led and poorer households, as might be expected. Adaptation planning, such as the introduction of alternative/complementary livelihoods, therefore, must be flexible enough to respond to the cyclical and yet unpredictable nature of bad seasons and prioritize the most vulnerable. Such an intersectional understanding of vulnerability is essential for effective adaptation planning because the factors that are responsible for determining who is more vulnerable in the community differ depending on how households are categorized for study (Koomson et al. 2020). An intersectional understanding means that each household’s experience of impact should be understood based on the different social identities that characterize that household. For example, a poor household, headed by a woman who is a migrant, may experience impacts differently from a poor household, headed by a woman who is indigenous to that place. Achieving optimum success in adaptation implementation would require that important nuances in differential vulnerability, as identified through an intersectional lens, be leveraged to prioritize critically vulnerable households. This detailed understanding of vulnerability in SSF communities is key to informing interventions that support successful adaptations to climate change. The development, implementation, and inaction of adaptation intervention strategies to address climate change in SSF communities can be realized on the large scale by embedding concepts of adaptation and adaptive capacity in regional and national coastal governance and policy.

Policy Implementation and Participatory Governance

Along with the community-level adaptation, there are policy and governance structures that aim to implement sustainable adaptive capacities for SSF communities. Coastal policies create strategies and establish governance processes and mechanisms to enable coastal fishing communities to implement adaptations to protect and deal with climate change. Well-informed and wide-ranging coastal policies acknowledge that subsistence and resource-dependent SSF communities are faced with climate change impacts and need to undertake sustainable practices for their livelihood, well-being, and development. There are a number of overarching international frameworks that influence and guide regional and national coastal governance and policy in West Africa. These directly or indirectly inform strategies for and governance of adaptation to climate change in lagoon communities.

International Policies and Frameworks Influencing Coastal Governance and Policy

At the global level, the Intergovernmental Panel on Climate Change (IPCC), Sustainable Development Goals (SDGs), and Ramsar Convention provide overarching frameworks for considering coastal governance. In addition, the concept of integrated coastal zone management establishes guidance on managing coastlines holistically. The IPCC highlights the need to explicitly address coastal communities in any climate change policy. The SDGs, specifically 1, 6, 7, 12, 14, and 15, draw attention to the threats posed by climate change in coastal communities in countries of the Global South (UN 2015). Sustainable Development Goal 14, "Conserve and sustainably use the oceans, seas and marine resources for sustainable development," is particularly pertinent for the resources, economy, and livelihood of these coastal communities (UN 2015). This is manifested through the vision of the "Blue Economy": the sustainable use of ocean resources for economic growth, improved livelihoods and jobs, and ocean ecosystem health (World Bank 2015). The concept of integrated coastal zone management (ICZM) arose from the Earth Summit (Rio Convention) in 1992. The aim of the ICZM was to enable governments to create national agendas to understand and find solutions to managing the complex and dynamic nature of the coastal environment. The ICZM concept is embedded in the ecosystem approach, a strategy for the integrated management of land, water, and living resources that promotes conservation and sustainable use in an equitable way. Both the ICZM and the ecosystem approach require that management of the coastline incorporates the impact on and implications for coastal communities of resource usage, pollution, livelihoods, and hazards (including climate change). The aim was to merge physical and environmental aspects of coastal management with human needs, with the ultimate benefit of maintaining coastal ecosystems and environments. However, embedding both the ICZM and the ecosystem approach in decision-making and implementation in the Global South, including West Africa, has not proved to be successful, and considerable challenges remain. The International Convention on Wetlands of 1971, otherwise known as the Ramsar Convention, was established as an international cooperation with national action for the conservation and wise use of resources in wetlands (both coastal and inland) of global significance, including coastal lagoons. Of the countries discussed here, Ghana became a member state of the Ramsar Convention in 1988, closely followed by

Togo (1995) and Cote d'Ivoire (1996). Benin and Nigeria became contracting parties in 2000 and 2001, respectively. The ways in which the Convention mandates are implemented by respective governments differ vastly as the Ramsar Convention gives national governments a broad scope for implementation that relies on effective, dynamic and multilevel processes of implementation (Mauerhofer et al. 2015). The Convention does provide a platform for knowledge transfer as well as management oversight and some level of resources for the protection of specific coastal lagoons.

Along with these international conventions, frameworks, and treaties, there have been regional collaborative initiatives relevant to coastal fishing communities. These regional partnerships include measures to sustainably manage marine and coastal resources, including fish stock and coastal habitats, which help augment the resilience of coastal communities to climate change (FAO 2018).

Regional Frameworks and Governance

At the regional level, West African countries have undertaken different collaborative initiatives and frameworks related to aspects of coastal management and governance. These include the West Africa Coastal Areas Resilience Investment Project (WACA ResIP), the Guinea Current Large Marine Ecosystem (GCLME) program (GCLME 2006), the Fisheries Committee for the West Central Gulf of Guinea (FCWC), and the West Africa Coastal Areas (WACA) Management Program.

The West African countries of Benin, Cote d'Ivoire, Togo, and Senegal are part of a six-country West Africa Coastal Areas Resilience Investment Project (WACA ResIP) aimed at strengthening coastal communities in West Africa. This program assesses coastal damages in terms of economic impacts, environmental implications, and social effects of changing climate. Since 2005, the joint United Nations Development Programme-Global Environment Facility-United Nations Industrial Development Organization (UNDP-GEF-UNIDO) regional collaboration known as the Guinea Current Large Marine Ecosystem (GCLME) program has existed to reduce poverty and enhance economic development of coastal communities through the provision of country-driven mechanisms to support marine and coastal goods and services. It comprises 16 countries of West Africa, including Cote d'Ivoire, Ghana, Benin, Togo, and Nigeria. The GCLME has its roots in the late 1990s when the ecosystem approach was introduced to assess and manage marine resources in West Africa. It provided a framework to promote the ecosystems approach and broaden the scope of coastal management in the region. It prioritized five aspects of coastal communities and environments: (i) productivity, (ii) fish and fisheries, (iii) pollution and ecosystem health, (iv) socioeconomic conditions, and (v) governance. The GCLME enabled large investments to combat coastal change and implement management strategies for coastal issues in the region. An emphasis was placed on monitoring physical processes and hard engineering solutions with little recognition of lived experience of coastal communities. Coupled with weak assessment and governance and an inadequate understanding of the complexities facing coastal communities, the programs put in place through the GCLME have not been successful.

The FCWC and WACA have focused on small-scale fishing. Goals of these programs have been to promote sustainable fisheries management, build strong fisher folk associations, support women in fisheries, ensure efficient fisheries value chains, and identify the challenges of overfishing and other competing uses for coastal areas. The Fisheries Committee for the West Central Gulf of Guinea (FCWC) is a regional integration plan for the Food and Agriculture Organization to ensure the "the blue economy" of the region is based on the participation of small-scale fishers in resource management. It was created by the nations of Benin, Ghana, Togo, Nigeria, Liberia, and Cote d'Ivoire to boost the fisheries sector, by ensuring the sustainable management of their fisheries resources for export and small-scale fishing communities. The West Africa Coastal Areas (WACA) Management Program was launched in 2018 by the World Bank. At its center, the WACA provided access to knowledge and technical expertise, made political and financial commitments, and supported a coordinated, regional approach for coastal resilience in West Africa to enhance adaptive capacity of fishing communities. While these multiple regional and international efforts have been well-intentioned, they suffer from some major drawbacks. Multiple initiatives have led to overlapping governance efforts, with complex organizational structures, funding, and implementation processes that have hampered the success of the initiatives. A top-down approach with limited local input and ownership of projects also meant that the long-term success of initiatives was restricted (Wiafe et al. 2013). All of these initiatives and frameworks emphasized management of the coastline and near-shore environments rather than focusing on climate change. The National Adaptation Programme of Action (NAPA) plans do specifically address adaptations to climate change in countries of the Global South and inform climate change policy relevant to coastal environments and communities.

National-Level Coastal and Climate Change Policy Mechanisms

The National Adaptation Programme of Action (NAPA) is national-level adaptation plan submitted to the United Nations Framework Convention on Climate Change (UNFCCC) secretariat by the least developed member states in 2007 and 2008. These documents outline the threat to individual nations and their planned priority adaptation actions. Development of the Intended Nationally Determined Contributions (INDC) followed, submitted in 2015. The INDC outline the priority adaptation sectors and interventions for a country and run from 2016 to 2030. The National Adaptation Programme of Action (NAPA) for coastal West African countries acknowledged the adverse impacts of climate change on SSF communities, signposting threats to these communities and their livelihoods and creating adaptation plans (Table 2).

The selection of priority adaptation interventions for NAPAs (and INDCs) was based on a multi-criteria analysis that included monetary cost and benefit, potential economic benefits and synergy with other environmental policies, as well as potential contribution to poverty alleviation. While it is noteworthy that SSF communities and their livelihood are quite significantly acknowledged in national policies, none

Table 2 Climate change adaptation plans for coastal SSF communities across West Africa

Country	Stated adaptation plans for SSF communities
Ghana[a,b]	Enhance fisheries resource management Develop alternative sources of livelihoods for fisher folk Promote fish farming
Nigeria[c,d]	Enhance artisanal fisheries and encourage sustainable aquaculture Encourage the provision of social welfare programs by faith-based and civil society organizations to address the climate change-induced needs of vulnerable groups
Togo[e]	Protect the coastal zone Strengthen infrastructure resistance to climate change in coastal zones Strengthen community resilience to climate change in the coastal zone
Benin[f]	Ensure the protection of the shoreline against the risk of sea level rise Reduce the vulnerability of human settlements and resources located in the coastal area to sea level rise Ensure continuously the protection of marine and lagoon ecosystems
Cote d'Ivoire	All policy documents for this country are in French (official language of the country) thus not accessible for review purposes

[a]Ghana's INDC (2015)
[b]National Climate Change Adaptation Strategy (2010–2020)
[c]Nigeria's INDC (2015)
[d]National Adaptation Strategy and Plan of Action on Climate Change for Nigeria (NASPA-CCN, 2011)
[e]Togo's INDC (2015)

of these actions made it into the priority actions for any of the countries, which were mostly focused on agriculture, transportation, energy, and health sectors. The MCA approach is likely responsible for the prioritization of other livelihoods like rural agriculture over SSF fishing. As is widely noted in the SSF literature, the contribution of SSF to national economies, in terms of GDP, is relatively small. Poverty alleviation, food security, and rural economic development are the most significant contributions of SSF. However, it is also acknowledged that in comparison to other rural livelihood activities like farming, SSF has higher exposure and sensitivity to climate change impacts. While the MCA process is not completely described in the reviewed documents, it could be conjectured that if the disproportionately higher vulnerability of SSF communities had been considered and higher weights assigned to poverty alleviation and food security, adaptation interventions for SSF communities would have risen in priority. Countries differed in which aspects of coastal adaptations took precedent (Table 2). While some countries (Ghana and Nigeria) focused on livelihoods of coastal communities by establishing means for improving and enhancing income generations, others such as Benin, Togo, and Cote d'Ivoire concentrated more on hard engineering solutions to protect coastal infrastructure (Table 2). The NAPA were not as wide-ranging or successful as they might have been at addressing coastal adaptations to climate change.

All countries adopted a multi-sectoral approach to adaptation planning and demonstrate an appreciation of the need to connect adaptation planning with the broader national development agenda. However, the multifaceted and complex interlinkages between climate change, natural resources, and local development issues that underpin vulnerability of a community, and which are critical to successful adaptation interventions, were not fully appraised as part of the plans. In addition, NAPA implementation required strong cross-sectoral collaboration to realize the planned adaptation interventions, and this was not necessarily in place due to gaps between national policy and local implementation.

Adaptation to Climate Change in Coastal Communities: The Policy Gap

Institutional arrangements in Africa have conventionally followed a formal, top-down framework. The national and regional policy agreements in Benin, Nigeria, Ghana, Togo, and Cote d'Ivoire aimed at coastal management and enhancing adaptive capacity of coastal communities are managed and implemented by government organizations, often in partnership with nongovernmental organizations. This multi-organizational, top-down approach has resulted in several barriers to the successful implementation of policy-driven climate change adaptation strategies at the coast. Policy deployment through multiple national and nongovernmental agencies can often result in uncoordinated and overlapping strategies resulting in confused implementation at the local level and limited success of adaptation strategies. The current national governance top-down approach allows limited opportunities for local governance. This creates a gap, "the policy gap," between the well-intentioned policy discourse at the national government level and the actual implementation of policy at the village level. The top-down approach also results in failure to understand and address the highly localized and often community-specific conditions required to enact successful climate change adaptations. When multi-institutional governance structures include engagement opportunities for local communities, the success of coastal management plans and adaptation strategies is greatly enhanced. For example, an understanding of specific local environmental conditions and socioeconomic responses is needed when developing adaptations to sea level rise, but national policies currently do not support that local oversight (Hauer et al. 2020). In addition to the difficulties created by pursuing a top-down approach, the policies themselves have tended to have a disproportionate focus on physical and resource management of the coastline rather than adaptations that address the social and human impacts of climate change (Clarke et al. 2013; Butler et al. 2015; Cinner and Barnes 2019). The physical effects of climate change have been prioritized over livelihood, well-being, and cultural needs of communities. Such an approach requires reconciling lagoon conservation issues with the livelihood interests and local economy of lagoon communities. In Ghana, an example of the disconnect between national coastal resource policy and local community needs is seen in the mismanagement of mangroves. Mangroves are overexploited by lagoon communities, despite playing a vital role in the physical protection of coastal areas, and mangrove conservation plans at lagoons have suffered from a lack of administrative coordination across ministries and agencies (Boateng 2018). Conventional multi-institutional, top-down systems of government have not been very successful in resolving or managing coastal problems (Clarke et al. 2013). The need to shift to a human-centered, bottom-up approach to managing lagoon environments and their communities, where communities are participants to the planning, co-production, and implementation of coastal adaptations to climate change, is key to their long-term resilience and sustainability (Butler et al. 2015).

Participatory Governance

The recognition of the gap between national policy discourse and local implementation has prompted a shift to the development of a more participatory approach that ensures coastal communities are central to the joint management of their resources and local environment. In this participatory approach, community knowledge is used to bridge the gap between national policy, climate research, and lived experience of climate change (Clarke et al. 2013). The resultant integrated governance systems to support climate change planning and adaptations combine local participatory governance with multi-institutional government and nongovernmental organizations. This bottom-up approach ensures that community needs are addressed and local conditions are taken into account in adaptations to climate change and the management strategies that support them. In effect, a balance between "top-down" policy implementation and "bottom-up" community-driven needs that maps the top-down agenda to a community-based approach is recommended for successful adaptive strategies (Butler et al. 2015). In this approach, there is a recognition of the contextual factors through local stakeholder engagement as well as the integration of indigenous knowledge and local approaches to understand, manage, and create solutions for climate change adaptations (Cinner and Barnes 2019). Indigenous knowledge and traditional practices have developed over generations by communities coping with climatic variability and extreme weather (FAO 2018), such as in Nigeria, where SSF communities use their traditional knowledge of local meteorological variation to inform adaptations to the management of coastal flooding.

Most of the research about participatory governance of coastlines in West Africa focuses on Ghana and Nigeria with fewer studies from Benin, Togo, and Cote d'Ivoire. Ghana has many agencies with a top-down institutional framework, including those that govern the coastal and marine environment. However, progress is being made toward creating participatory structures for coastal management and climate change adaptation, specifically around the areas of resource management, environmental monitoring, and community education (Wiafe et al. 2013). The participatory approach is also being used in fishing communities along the Badagry coast of Nigeria to create and implement local adaptations to climate and environmental change (Olawepo 2008). Another example is from the Aby Lagoon in Côte d'Ivoire, where co-management of fishing resources has given fishing communities a sense of engagement, ownership, and empowerment that has supported sustainable livelihoods, enhancing resilience to climate change (Njifonjou et al. 2006). The success of these participatory approaches is encouraging for future implementation of climate change adaptations in coastal lagoon communities across West Africa.

Summary

The coastlines of Cote d'Ivoire, Ghana, Benin, Togo, and Nigeria are dominated by dynamic lagoon environments. Sea level rise and climatic changes are affecting those lagoons and their associated nearshore environments. The fishing communities that live next to lagoons depend on them for resources and ecosystem services that support economic livelihood and well-being. The vulnerability of lagoon communities to climate change is related not only to the physical and environmental effects of climate change but also to local resource use, sociocultural community structures, susceptibility to external factors, population growth, and governance infrastructures. The interconnected nature of climate-related challenges with development issues complicates the success of climate change adaptations and interventions. Adaptations enacted as part of a managed intervention plan require an understanding that vulnerability to climate change is not felt in the same way in different communities nor even across a single community and an acknowledgment of intersectionality is required when deciding how and where to place adaptation interventions.

Multiple frameworks exist in West Africa that are related to the management of the coastal zone, and National Adaptation Programme of Action (NAPA) plans in the region have included coastal communities. National coastal policy arising from such frameworks should be the vehicle for managing climate change adaptations in lagoon communities. However, where such policy exists, it has suffered from formal top-down approaches with gaps between policy and its implementation as well as uncoordinated approaches. Importantly, the policies themselves have failed to acknowledge the human experience of climate change, tending to focus on physical change at the coast. To rectify this, climate and coastal change policy must evolve to embed concepts of adaptation and adaptive capacity, giving the same consideration to community livelihood and well-being as to the physical environment. An integrated participatory approach, which allows lagoon communities to play a key role in the governance of the coastal zone, will enable such a human-centric approach and facilitate the integration of climate change adaptation into coastal planning and management.

Abstract

Namibia is the most arid country in sub-Saharan Africa characterized by the existence of two deserts, the Namib and the Kalahari. However, though being arid, agriculture still plays a critical role in Namibia's economy, which includes both crop and animal production. Furthermore, the country is endowed with vast marine resources, with its marine waters being equivalent to two-thirds of Namibia's terrestrial environment. In the face of climate change and a growing population, there is a need for Namibia to continue with its climate smart efforts which is critical in shifting the country from its current dependency on imports thus increasing the country's food self-sufficiency. This chapter highlights the threats posed by climate change, both on land and the marine environment of the country, which has potential negative impacts on the economy. Current research being undertaken in Namibia on ocean acidification, sea water harvesting, climate smart agriculture, and atmospheric science, is also highlighted in this chapter. The information presented in this chapter will be critical in guiding climate change mitigation policies in hyperarid African countries, thus reducing the burden caused by the global change in climate. Aspects on the direction of future research on climate adaptation with a holistic and multidisciplinary approach are also proposed.

Keywords

Climate smart agriculture · Aerosols · Shellfish · Marine environment · Clean energy · Seawater desalination

Introduction

Namibia is a very unique country within Southern Africa, being the most arid country in this region characterized by the existence of two deserts, namely the Namib and the Kalahari deserts. On average, Namibia receives 270 mm of

rainfall annually, with a wide variation of between 20 mm and 700 mm from the western to the eastern parts of the country, with only 5% of the country receiving more than 500 mm of rain annually (Sweet and Burke 2006). Within this hyperarid environment, only 1% of the total surface of the country has medium to high potential for rain-fed crop production. Interestingly, agriculture plays a critical role in the formal and informal economy of Namibia, supporting up to 70% of the population, with 90% of this agriculture being livestock based (MAWF 2015). Due to its hyperaridity, Namibia imports most of its food crop requirements from other countries. However, with the advent of climate change which threatens Africa's food production potential, hyperarid and food (especially grain and vegetable crops) importing countries like Namibia will require intensive research on how to mitigate against the threats paused by climate change.

Namibia has achieved some key milestones towards its response to climate change. Firstly, by being party to the United Nations Framework Convention on Climate Change (UNFCC), which meant it must institute policies and measures, informed by science, that reduce the changes on environment and humanity due to climate change (Mapaure 2011). In response to this, Namibia established the Namibian Climate Change Committee (NCCC) in 2001, to advice and make recommendations to government on issues of climate change. In 2011, Namibia developed the National Climate Change Policy (NCCP) which "outlines a coherent, transparent and inclusive framework on climate risk management in accordance with Namibia's national development agenda, legal framework, and in recognition of environmental constraints and vulnerability." (Lubinda 2015). In 2014, the country developed the National Climate Change Strategy and Action Plan for 2013–2020 which lays out guiding principles responsive to climate change that are effective, efficient, and practical (Lubinda 2015).

According to Mapaure (2011), Namibia has identified seven sectors where it is most vulnerable to climate change, and these include water resources; marine resources; agriculture; biodiversity and ecosystems; coastal zones and systems; and health and energy. Within the terrestrial agriculture environment, Namibia is most likely to experience more extreme weather patterns such as flooding and drought conditions under the changing climate. Furthermore, within the marine environment, it is predicted that the increase in northerly or easterly winds could result in suppressed upwelling in the nutrient-rich Benguela system, thus causing the accumulation of oxygen-poor water near the seabed and consequently suffocating marine life (Reid et al. 2008). Therefore, future changes in the distribution and intensity of winds under the changing climate have potential to negatively influence the fisheries sector of Namibia. Against this background, this chapter seeks to highlight some aspects critical for research on climate change in Namibia, while highlighting the current research being undertaken in Namibia at addressing climate change. This chapter focuses more on the coastal environment of Namibia, where climate change research on both terrestrial and marine environments is being championed at the Sam Nujoma Marine and Coastal Resources Research Center.

Namibia: A Vast Place

Namibia is located in the southwestern part of Africa between the latitudes of 17.5° and 29° South, occupying a total land area of about 824,000 km^2, with approximately 526,000 km^2 of ocean extending 200 nautical miles into the Atlantic Ocean (https://www.unicef.org/namibia). The country has a population of about 2.448 million people, making it one of the least populated country in the world. The country is characterized by a large coastal area, which covers the entire western border of the country with a length of about 1572 km. In Namibia, the cold Benguela Current has a moderating effect on regional weather patterns which are quite pronounced in the Namib desert, where it creates some unique climatic conditions. Just like most African countries, the contribution of Namibia to global atmospheric pollution responsible for climate change is very limited, though the effects of climate change will be quite pronounced. With Namibia's climate being already variable, climate change is expected to worsen this variability and amplify its adverse impacts (MET 2011). Therefore, with climate change, the focus for Namibia is more on mitigating its effects, which should be the focus of much research, as opposed to focusing on reducing greenhouse gas emissions as the country is not a serious contributor to this aspect.

Aerosol Monitoring in Namibia and Its Importance

Climate change poses great danger to the livelihoods of many people in Africa and Namibia is not spared from this phenomenon. The country recently experienced the worst drought in decades, that peaked from 2018 to 2019, with some areas receiving none to sporadic precipitation accompanied with floods. Since climate change is driven by several factors, many of these factors are a product of interactions in the earth's atmosphere. Due to these atmospheric interactions, it is important to do long-term baseline aerosol measurement in areas predicted to suffer most from effects of climate change. Though Namibia, like most African countries, does not contribute much to atmospheric pollution, aerosols from global pollution which include black carbon (soot), sulfate, nitrate, ammonium, organic carbon, elemental carbon, and mineral elements can play a critical role in Namibia's climate. Aerosols are suspended particles in the atmosphere, their sizes range from fine (particle diameter < 1 μm) to coarse (particle diameter > 1 μm). Aerosols play several roles of climatic importance as they influence the amount of precipitation by acting as condensation nuclei for cloud formation, while others depending on their nature may scatter and absorb solar radiation thus affecting radiative forcing (Heintzenberg 1985). Aerosol radiative forcing is defined as the effect of aerosols on the radiative fluxes at the top of the atmosphere and at the surface and on the absorption of radiation within the atmosphere (Chung et al. 2005).

The western coast of southern Africa, where Namibia is central, experiences persistent and extended highly reflective clouds mainly stratocumulus and high loads of light-absorbing aerosols from various sources (Formenti et al. 2018).

However, the mechanisms by which the reflective clouds and light-absorbing aerosols interact to influence the regional radiative budget is largely unknown (Formenti et al. 2018). In other words, the function of aerosols and cloud processes on climate models is still unclear. Due to the importance of different aerosols on regional climate, a ground-based aerosol monitoring station was established in Namibia known as the Henties Bay Aerosol Observatory (HBAO) in 2011 under the University of Namibia at their coastal campus (Sam Nujoma Campus) in collaboration with the Laboratoire Interuniversitaire des Systèmes Atmosphériques (LISA), CNRS/Universities of Paris Est-Créteil and Paris Diderot, France, and the Climatology Research Group of the North West University (NWU), Potchefstroom, South Africa. This research station focuses on monitoring various parameters influenced by the aerosols. The data generated will form part of the atmospheric baseline studies in Namibia and the southern Africa region, which is important in filling the wide gap in climate change modelling in the region.

The contribution of greenhouse gases on climate change is well investigated, but due to the complex nature of aerosols, their contribution to climate still remains an area of interest to many scientists. As an arid country, Namibia's atmospheric precipitation could easily be affected by the nature of aerosols. If the amount of hydrophobic aerosols increases in Namibia, this could result in reduced rainfall and changes in the fog patterns in the country, which will negatively affect productivity of this arid but unique ecosystem.

In Namibia, the HBAO is monitoring the various properties of aerosols like those originating from the ocean (which generates microscopic salt particles by evaporation of water from sea-spray), wind-blown dust from the surrounding desert areas, dust from the various salt pans and aerosols generated by veld-fires, and smoke from ships using the Walvis Bay port. Aerosols from each of these sources will have a different composition, and different characteristics such as size, light's absorption capacity, and reflectivity.

In a 3-year study at the HBAO, measurement of mass concentration of equivalent black carbon (eBC, which is a light-absorbing aerosol from biomass burning), it was noted that these aerosols have seasonal shifts that coincide with fire seasons in southern Africa (Formenti et al. 2018), a clear indication that regional sources have contributed to the observations. In addition to these long-term measurements at the HBAO station, an intensive field campaign named the Aerosol Radiation and Clouds in southern Africa (AEROCLO-sA) project using ground-based equipment and a SAFIRE F20 research airplane was conducted in August to September 2017. The results from AEROCLO-sA field campaign are summarized by Formenti et al. (2019). Even though the sources of aerosols in Namibia are less studied, local and subcontinental sources may contribute to the observed measurements since finer aerosols are transported over a long distance. The southwestern African areas experience persistent stratocumulus cloud deck, which increases the total of outgoing radiation, resulting in a generally cooler atmosphere. Increased amount of eBC will therefore result in warmer atmosphere and may affect cloud formation in the region.

With the projection of increased emission in the world, Namibia is in a region that is predicted to experience rising temperatures and it is expected that a large portion of the country will see lowered rainfall with increased number of dry days consequently affecting agricultural productivity negatively. In addition, in desert and coastal areas the rate of fog production may be impacted resulting in less water for plants and animals in these areas. The overall effects of aerosols on climate can be complicated to predict, it is only a long-term observation that can assist in modeling and predicting the climate change regionally and globally.

Climate Change and the Oceans: Implications for Namibia

Rising atmospheric carbon dioxide (CO_2) concentrations became evident after the industrial revolution in the 1800s as a result of increased anthropogenic activities such as combustion of fossil fuels, agriculture, iron and steel production, municipal solid waste combustion, cement manufacturing, deforestation, and other activities that contribute to emissions of greenhouse gases. The industrial production of CO_2 since the 1800s has increased the atmospheric CO_2 concentration from 280 parts per million (ppm) to 396 ppm, and continued increases are predicted to reach 800 ppm by the year 2100 (Branch et al. 2013).

The current atmospheric CO_2 concentration is rising at an increased annual rate of 0.5%, that is 100 times faster than any change during the past 650,000 years. The global oceans absorb 25% of the CO_2 released into the atmosphere, from the various listed human activities. The increased absorption of CO_2 by the oceans has caused changes in the oceanic chemistry where the concentration of dissolved CO_2 has been increasing and consequently resulting in ocean pH decrease. This reduction in pH, as seawater becomes more acidic, is predicted to decline from approximately 8.2 during the preindustrial era to 7.8 in the 2100 s (Wei et al. 2014).

When CO_2 is absorbed by seawater, a series of chemical reactions occur resulting in the increased concentration of hydrogen ions which causes the seawater to become more acidic and causes carbonate ions to be relatively less abundant. The solubility and distribution of CO_2 in the oceans highly depends on climatic conditions and other physical (e.g., water column mixing, temperature), chemical (e.g., carbonate chemistry), and biological (biological productivity) aspects. Assimilation of CO_2 into the ocean occurs via the ocean surface to air interface, where CO_2(aq) will react with surface seawater to form a weak carbonic acid (H_2CO_3) that quickly dissociates into hydrogen ions (H^+) and bicarbonate (HCO_3^-) ions, as indicated in the Eqs. (1) and (2) (Doney 2006).

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \tag{1}$$

Some of the free hydrogen ions (H^+) combine with free carbonate (CO_3^{2-}) ions normally found in seawater to form more bicarbonate (HCO_3^-).

$$H^+ + CO_3^{2-} \leftrightarrow HCO_3^- \tag{2}$$

This chemical reaction uses up important ocean carbonate ($CO_3{}^{2-}$) molecules needed by some organisms, such as mussels and oysters, to form shells. In addition, the increased acidity of the ocean, caused by the free hydrogen ions (H^+), causes shells to deteriorate, become thin and frail. Shells in marine organisms are formed by taking up carbonate and calcium in seawater to form calcium carbonate, or the tough cement-like layer we know as a shell, as illustrated in Eq. (3).

$$CO_3{}^{2-} + Ca_2{}^{+} \leftrightarrow CaCO_3 \tag{3}$$

Ocean acidification currently holds the world's attention due to the predicted adverse effects it poses on the marine ecosystems. Monitoring for ocean acidification is crucial in that it allows for forecasting future trends.

Ocean acidification is expected to impact marine species at varying degrees. While microalgae like dinoflagellates and diatoms may benefit from higher CO_2 conditions in the ocean, it has dramatic effects on calcifying species, such as oysters, clams, sea urchins, corals, and calcareous plankton. Increased sequestering of atmospheric CO_2 in the ocean would result in a lowering of the oceanic carbonate equilibrium. Carbonate ions are important building blocks for structures such as seashells and coral skeletons. Calcifying organisms such as corals are important in the ecosystem as they provide habitat and shelter to various marine organisms and their demise would endanger survival of most of those housed species. There are also other calcifiers that are vital food sources for most marine organisms. Since the calcification of seashells and coral reefs depends on the saturation of the carbonate mineral known as aragonite, it has been suggested that increasing atmospheric CO_2 could result in a decrease in the aragonite saturation state in the ocean by 30% (Takeo et al. 2012).

Namibia has a coastline that is largely uninhabited, unpolluted, and highly productive waters due to upwelling of the Benguela system. Upwelling systems are naturally acidic due to vertical movement of CO_2-rich deep waters to the surface and the acidity is increasing due to increased anthropogenic carbon dioxide that is being absorbed by the ocean. These upwelling systems are expected to undergo major changes in the near future due to steadily increasing atmospheric CO_2 and the resultant consequences on the ecosystem and fisheries are unknown. Mariculture in Namibia is reliant on shellfish culture with oyster farming being the most established activity, producing both the Pacific and Eastern oyster. Studies have shown how vulnerable mollusks are to acidification but there is still limited data on its impacts in Namibian waters (Waldron et al. 2009). Further research on the effects of ocean acidification on shellfish is being undertaken at the Sam Nujoma Marine and Coastal Resources Research Center, which promises better understanding of this phenomenon on marine life.

The Pacific oysters are farmed in Swakopmund, Walvis Bay, and Lüderitz (now known as !Nami‡Nûs). This industry is already under threat from the harmful algal blooms (HABs) that frequently occur along the Namibian coastline attributed by high plankton biomass decay that ultimately leads to anoxic events and in some cases eruptions of hydrogen sulfide from the seabed that led to 80% mortality of marine shellfish farmed in Namibia (Anderson et al. 2004). In 2008, sulfur eruptions impacted Walvis Bay marine shellfish farms leading to closure of some farms and relocation of other farms to Lüderitz (OLRAC 2009). With the Namibian marine industry already being influenced by the HAB, ocean acidification of the Southern Atlantic poses a far much greater threat to this industry.

Villafaňe et al. (2015) indicated that the predicated ocean acidification conditions, with increased nutrient and solar radiation could lead to the reshaping of the phytoplankton community, where it would have phytoplankton communities dominated by large diatoms with high growth rates and therefore marine phytoplankton could bloom more efficiently under future acidified conditions than the current conditions. Similarly, when conditions favor phytoplankton, it also infers good conditions for growing seaweed. This would also suggest that the Namibian mariculture industry would lose high-income businesses from oyster culture, loss of employment, and subsequently reduced contribution to the country's GDP. Most businesses would have to shift into seaweed culturing as this will utilize the abundant nutrients, solar radiation, and CO_2 in the Benguela upwelling system. Therefore, research that already looks at macro-algae culture for extraction of highly priced phytochemicals is important in Namibia.

Previous research has found out that influxes of iron from terrestrial origin into the ocean led to increased bloom activity in primary productivity (Pollard et al. 2009). Research that involves fertilizing certain oceanic regions with iron, as it is mostly a limiting nutrient, to enhance the sequestering of carbon onto the ocean floor can be critical in mitigating against increased CO_2 concentration in the ocean. The resulting blooms would counteract the growing concern of dissolved CO_2 and produce organic carbon that would sink to the ocean floor. Norton (2011) suggested the addition of powdered limestone to the ocean in order to react with the dissolved CO_2 as another potential mitigation to ocean acidification. As the limestone reacts with the CO_2 this will form bicarbonate which would in turn neutralize the acidic conditions of the ocean. These counter action would make calcium carbonate more available in seawater and readily available to calcifying organisms to build their shells. The process of increased calcium carbonate would increase the buffering capacity of the ocean and limit the sequestration of CO_2 by the oceans. However, though these researched measures are theoretically feasible, their practicality still requires lot of practical field-based research.

Alternative Water Sources in a Hyperarid Namibia

Availability of Water in Namibia

Due to pressures from climate change, global water resources have become vulnerable and scarce, and Namibia is not spared from this phenomenon. Water is a significant resource to human life, the environment and for development, but it is finite. Scientific consensus is that climate change will have a pervasive influence on the future demand, supply, and quality of fresh water resources in Namibia, and would add pressure to already stressed water resources and coastal environments (Lahnsteiner and Lempert 2007). Namibia frequently receives below average and highly variable rainfall with high temperatures that result in very high evaporation rates of between 2660 and 3800 mm per year, which makes Namibia one of the driest in sub-Saharan Africa (FAO 2005). More specifically, the central Namib Desert consists of a flat, gently sloping plain with few topographic features. The steady gradients affect rainfall, temperature, and wind patterns developing between the coast and the interior. The annual mean rainfall along the coast between Swakopmund and Henties Bay is less than 15 mm per annum, with coastal wind speeds averaging approximately 3 m/s in a south westerly direction (Pryor et al. 2009). Likewise, due to climate change, the occurrence of droughts has become more frequent and requires appropriate water management to ensure continued social and economic development of the country (COW 2019). Due to extremely poor rainfalls, the recent drought of the 2018/2019 rainfall season resulted in huge economic loses to the Namibian farmers as livestock and crops died due to lack of water.

The rainfall received accounts for only 2% and 1% surface runoff and groundwater recharge, respectively, while 97% is lost through high evaporation rates in Namibia (Christelis and Struckmeier 2011). The difference between national and regional averages reveals the growing need to seek and implement alternative water supply strategies, in order to secure adequate fresh water and cater for future demand in Namibia under a changing climate. Namibia relies heavily on underground water (aquifers) for the supply of fresh water, which are recharged not only by the rainfall from catchment areas within the country but also from neighboring countries. With such heavy reliance on underground water, particularly in the North Central Regions, the water is at times unsuitable for human and animal consumption due to high salinity (Wilhelm 2012). Climate change is expected to exacerbate this reliance on aquifers for fresh water due to limited recharging of underground water sources. Changes in rainfall and runoff further indicate that underground water recharge may suffer a reduction of 30–70% across Namibia. In order to adapt to the reduction in freshwater resources, other arid countries including Namibia have begun sea water desalination as a feasible source of fresh water. The reliance is expected to grow as a result of population growth and migration to coastal cities which do not have adequate freshwater resources. In Namibia, the coastal population's overdependence on aquifers constitutes its vulnerability to climate change. However, the vast coastal area of Namibia is also characterized by cool yet sunny environments, rough seas, and very windy areas, all which can be potential energy sources for powering the energy demanding and costly desalination process. Desalination would be a strategic alternative to ensure long-term freshwater supplies, more so when using renewable, clean energy sources for desalination.

Seawater Desalination in Namibia

On earth, about 70% of the area is covered by water which is mainly seawater, with only about 1% of the freshwater being available for human consumption and for agricultural purposes in the world's rivers, lakes, and aquifers (Darre and Toor 2018). The scarcity of fresh water resources and the need for additional fresh water supplies are critical in many arid regions of the world (Michou 2017). Worthy to note are the countries in the Arabian Gulf, which are located in an arid area with limited water resources. The region has the lowest availability of renewable water resources per capita in the world. To curb this shortage, the gulf countries invested in seawater desalination technologies that would ensure an adequate supply of freshwater for industries and the more than 300 million inhabitants. To date, the largest market for water desalination in the world is found in the Arabic Gulf (Ramadan 2015).

Even though it offers a sustainable solution to water woes, desalination is energy intensive and comes with environmental consequences. About 0.4% of the world's electricity consumption is taken up by desalination plants, with global emissions due to nonrenewable energy use in desalination, predicted to reach 400 million carbon equivalents per year. The carbon footprint for reverse osmosis (RO) desalination has been calculated to be between 0.4 and 6.7 kg CO_2eq/m^3. This means that desalinating 1000 cubic meters of seawater could potentially release as much as 6.7 tons of CO_2 (Tal 2018), hence efforts to produce freshwater should not forgo environmental safety. Desalination technologies must be enhanced to become cleaner and more efficient (Compain 2012).

Desalination needs are mainly in dry countries that receive high-intensity solar radiation, hence it makes sense in Namibia to exploit solar power for desalination. Namibia is a country which is abundantly rich in solar energy, as it receives on average of 300 days of sunshine per year, with very few cloudy days. Harnessing this energy from the sun would make it possible to supply the power needed to run desalination plants. The available solar energy makes research and development in solar desalination promising for Namibia. Although at present, renewable resources in Namibia play a very small role in the energy sector, there is potential for renewables to scale up in providing for non-electricity energy sectors. Other alternative and cost-effective sources of renewable energy can also be used for desalination. Renewable energy sources such as wind can be used to generate electricity for use in desalination plants as an alternative to for thermal electric plants. The above alternatives are already being explored in the east coast of Egypt where water resources are limited.

In Namibia, the first desalination plant belonging to Orano Mining Namibia was commissioned in 2010. The desalination plant was originally built to supply water to the Trekkopje Mine near Arandis but has now become part of the potable water delivery system belonging to Namibia's water utility, NamWater. The addition of desalinated water has allowed NamWater to keep meeting the Central Namib's water demand as it provides about 75% of the overall drinking water to the coastal town of Swakopmund, as well as the nearby uranium mines and other industries (Petrick and Müller 2019). Furthermore, communities of Akutsima and Amarika in the Omusati Region of Namibia benefited from small-scale solar powered desalination plants under the CuveWaters project. These plants aimed to supply the local population with safe drinking water by desalinating saline underground water. This was seen as a sustainable way of supplying safe drinking water to the local community, who for years consumed unsafe and salty water.

In an effort to reduce the carbon footprint of desalination, the University of Namibia piloted a 100% solar powered desalination plant that uses reverse osmosis technology. The pilot desalination plant is evaluating the feasibility of using renewable solar energy for seawater desalination in Namibia's coast. This pilot research project generates approximately 2300 L of fresh water per hour, which can be very sustainable for supplying water to local communities. Preliminary results of an assessment to determine the mineral composition and grade class of the desalinated water produced at the University of Namibia (UNAM) are presented in Table 1, which point to the suitability of this water for drinking and irrigation according to National and WHO standards.

With this research solar powered plant, the University of Namibia seeks to evaluate various scenarios which include:

- The short- and long-term suitability of solar power in water desalination in the Namibian coast.
- The potential of using this clean energy produced fresh water in desert greening and food production.
- The potential of using desalinated water in enhancing Namibia's contribution to carbon sequestration by using the water to irrigate high carbon fixing trees.
- The potential of accruing carbon credits using various indigenous and exotic tree species irrigated using desalinated water in Namibia.

Table 1 Preliminary results on the mineral composition and grade class of UNAM desalinated seawater

Physical constituents	UNAM	National limits	WHO limits	Units	Grade	Classification
pH	5.9	6–8.5	6.5–8.5		B	Good
Turbidity	0.3	<0.3	< 4	(NTU)	A	Excellent
Conductivity	45.2	<80	[a]	(mS/m)	A	Excellent

[a]Occurs in drinking water at concentrations well below those of health concerns (WHO 2009)

Alternative Food Sources under a Changing Climate: Mushrooms

Though Namibia is an arid country, with very limited terrestrial productivity, there has been a growing interest on mushrooms (edible macrofungi) as an alternative high-value food under the changing climatic environment. Edible macrofungi are highly nutritious with numerous therapeutic benefits as they are rich in proteins, minerals, and vitamins such as B, C, and D (Reeta and Dev 2019). In Namibia, foraging for edible macrofungi is done seasonally just like elsewhere in sub-Saharan Africa (Wahab et al. 2019). Edible macrofungi are mostly foraged for personal consumption but some individuals sell them for a small price, pointing to their potential economic value. Interestingly, those who sell them are unwilling to profit from their sale as they believe that macrofungi are God's given gift (Mshigeni 2001).

Just like other wild crops in Namibia, the availability of macrofungi is influenced by rainfall, with too little or too much having a negative effect on their distribution and abundance. Ethno-mycological studies have reported that Namibian people are aware of the link between the appearance of macrofungi with rainfall, since they refer to the macrofungi as products of a "lightning bird," because they appear after thunderstorms (Trappe et al. 2010). Of recent, wild edible macrofungi are diminishing with unpredictable rainfall events. The unusually heavy rains within a short period, followed by extended drought periods, is reducing the natural growing season of mushrooms. There is therefore a need to shift from the traditional way of exploiting this resource under a changing climate by focusing on cultivation technology. Mushroom cultivation has potential to contribute to diversification of traditional farming in Namibia. Despite the global trend in domestication and cultivation of macrofungi, the focus in Namibia to date has been on the cultivation of the exotic oyster mushrooms (Hausiku and Mupambwa 2018). Even with the oyster mushroom, their cultivation is still on a subsistence scale, partly due to shortages of suitable substrate. As for the indigenous macrofungi, a limited number of research has been done on characterizing their chemical properties and their domestication studies are still in infancy stage if there are any.

Climate Change Implications on Cultivation of Macrofungi in Namibia

Since macrofungi thrive underground or within substrate during their vegetative stage, their direct response to climate change is challenging to characterize. Consequentially, the timing of their fruit body production is used to study their phenological response to climate change (Bidartondo et al. 2018). Sato et al. (2012) defined phenology as the seasonal timing of life-history events of organisms (in this case, macrofungi). For the Namibian macrofungi, the only documented phenological response to climate change is that of the *Kalaharituber,* also known as Kalahari truffle (Mshigeni 2001; Leistner 1967) showing a later and shorter fruiting period. This observation is in agreement with long-term datasets documented elsewhere showing that the lengths of the macrofungi-producing season and their timing have changed relative to the changes in temperature and rainfall, as have their diversity and range (Bidartondo et al. 2018). It can therefore be deduced that the rising temperature and reduction in precipitation observed in Namibia over the years is having similar effects on macrofungi productivity in Namibia. Studies carried out in the laboratory confirm that temperature and moisture availability affect both the vegetative and fruiting stage of macrofungi. Mycelial growth has been reported to increase with temperature until an optimum temperature is reached, thereafter, the growth decreases (Fletcher 2019). Similar response has been observed in the presence of moisture, whereby insufficient or excessive moisture limits fungal growth. According to Wahab et al. (2019), the average optimal temperature and humidity for mushroom fruiting is around 20 °C and 80%, respectively.

Current and Future Research on Mushrooms in Namibia

The projected further increase in temperature and sporadic rainfall patterns coupled with extreme weather events are likely to threaten the already dwindling macrofungal resources of socioeconomic value in Namibia. A few studies have been documented on Namibian macrofungi as summarized in Table 2, and a lot more need to be done in terms of research.

From Table 2, it is obvious that Namibian macrofungi are understudied. All the documented studies on the edible macrofungi (*Termitomyces* and *Kalaharituber* species) were done on specimens that were bought from the market. Further studies are needed to address the distribution, ecology, phylogeny, pharmacology, phenology, chemical characterization, and domestication trials.

More studies are documented on nonedible macrofungi (*Trametes*, *Pycnoporu, and Ganoderma* species) compared to the edible ones. These studies addressed the phylogeny, indigenous knowledge, and the utilization of these fungi. Further studies are needed to zoom into the biochemical properties of the fungi to isolate and quantify the bioactive compounds responsible for their therapeutic effects reported by the respondents during these studies. Phenological studies would give an idea on the effect of climate change on the different species. Domestication trials would facilitate intensification of research on the fungi as field studies tend to be time-consuming and expensive.

Namibian mycologists are thus urged to make an effort to domesticate indigenous macrofungal species, especially the edible ones that have largely been neglected by science. Domestication and cultivation will ensure that availability of this resource is not dictated by precipitation or climate. It has been demonstrated by research that cultivation of macrofungi depends on agro-industrial material (e.g., cereal straws, wood chips, etc.) for substrate, and these materials are usually rain fed implying that drought effects on substrate material will trickle down to mushroom productivity. Recent research has been exploring the potential of using marine biomass as a source of organic material to be used as mushroom substrate. In a study by Hausiku and Mupambwa (2018), beach-casted seaweed was used to supplement rice straw in order to fruit oyster mushrooms. The incorporation of seaweed into substrate did not

only add value to the beach-casted seaweed but enhanced the nutritional benefits of the mushrooms.

Identification, collection, and domestication of native wild mushrooms is another aspect of fungal science that have been overlooked. Such studies are imperative in facilitating taxonomical and ethno-mycological studies of indigenous macrofungi. Furthermore, documentation on the traditional use of Namibian macrofungi and assessment of their local and international markets would expedite their industrial relevance (Shahtahmasebi et al. 2018). Besides domestication, value addition of macrofungi with socioeconomic importance such as the *Termitomyces* and the *Kalaharituber* is important. Food technologists need to find ways to increase the shelf life of this highly perishable commodity by creating new products that are different from the traditional forms in which macrofungi are consumed in order to contribute to the country's GDP.

Organic Agriculture and Its Potential Under a Changing Climate

With Namibia being an arid country, terrestrial biomass production is very limited, which has consequently resulted in very poor quality soils in most parts of the country. The soils in Namibia therefore lack fertility as they are mostly sandy and very old (Zimmermann et al. 2017). Under natural conditions, terrestrial biomass results in the generation of huge quantities of organic matter which is deposited into the soil, where it becomes part of soil organic carbon. Soil organic carbon or soil organic matter plays a critical role in soil quality, with the following functions:

- The non-humic substances produced during the decomposition of organic matter, e.g., polysaccharides encourage granulation – the binding of soil particles into aggregates. These aggregates help to maintain a loose, open, granular condition. This improves the aeration and water infiltration capacity of the soil.
- Organic matter can hold up to 20 times its weight in water. Its presence in the soil, therefore, improves the soils' water holding capacity. This is especially important in sandy soils.
- Organic matter (humus colloids) has a high cation exchange capacity (2–30 times as great (per kg) as that of various types of clay minerals). It therefore adsorbs and stores plant nutrients (K^+ Ca^{2+}, Mg^{2+}, etc.) and thus improves the fertility of soil.
- Humus colloids form stable complexes with Cn^{2+}, Zn^{2+}, Mn^{2+}, and other polyvalent cations. This may enhance the availability of micronutrients to higher plants.
- Decomposition of soil organic matter release NH_4+, $NO_3{}^{-}$, $PO_4{}^{3-}$, and thus serves as a source of nutrients to plants.
- Organic matter serves as a source of energy for both macro- and microfaunal organisms. These organisms in turn play important roles in soils, e.g., earthworms which are important agents for good soil structure, bacteria responsible for mineralization processes, etc.
- Humic acids also attack soil minerals and accelerate their decomposition, thereby releasing essential elements as exchangeable cations.
- In very acid soils, organic matter alleviates aluminum toxicity by binding Al^{3+} ions in nontoxic complexes

Soils with low organic matter are therefore prone to degradation and this is the major cause of reduced agricultural productivity and food security in countries like Namibia. With poor quality soils mainly due to low organic matter content, much of Namibian agriculture is more at risk of the effects of climate change such as reduced rainfall, flooding, increased environmental temperature among others, which will require more resilient soils.

From the Namibian perspective, a shift from the conventional agriculture that replicates the green revolution technologies such as intensive use of fertilizers, pesticides, and machinery is required, towards more organic-based agriculture systems is important. The current conventional agriculture practices have not focused on soil fertility but rather only on the crop fertility, which has actually seen crops yields in most parts of the country decreasing in the face of climate change. Organic agriculture practices are among some of the systems that are being promoted among others like ecological agriculture, sustainable intensification, and conservation agriculture, as these systems focus more on feeding the soil making it more resilient under climate change (Mupambwa et al. 2020). Organic agriculture is a more holistic production system which promotes agroecosystem health approach which promotes the use of management practices in preference to the use of off-farm inputs (FAO/WHO 1999).

Zimmermann et al. (2017) highlighted that Namibia has important resources that can be used in organic soil fertility which include animal manures, fertilizer trees harvestable from nature; marine resources such as seaweeds; bird guano and animal processing waste such as blood, bones, and fish waste. Technologies like composting and vermicomposting can be used in improving the fertilizer value of these waste materials, which can then be used as soil amendments. Current research being undertaken in Namibia on developing organic nutrient-rich fertilizers includes the optimization of the biodegradation and nutrient release during vermicomposting of various household waste, marine biomass, and farm waste materials. Such research is important in standardizing the production processes of organic fertilizers, thus allowing for greater uptake of these fertilizers among smallholder farmers. The lack of nutrient predictability and standardization of organic fertilizer production results in even those that are commercially available on the market being sold without any labeling that indicates nutritional composition as is mandatory for inorganic fertilizers. The specification of compost quality is more important as it enables compost users to more effectively manage their agroecosystems (Mupambwa and Mnkeni 2018).

Several researchers are undertaking research that is linked to organic agriculture in Namibia and these are summarized in Table 3 below.

Research on uses of organic soil fertility conditioners is currently happening in Namibia, though not much of it is not directly linked to mitigating the effects of climate change. There is a need to marry the two, so that such research can directly fit into the National Climate Change Strategy and Action Plan for 2013–2020 of Namibia. It is also important to note that there is very limited research available for Namibia on evaluating the potential of organic agriculture in improving soil quality, though several reviews are available on this subject.

Table 3 A summary of some of the studies that have focused on aspects relating to organic agriculture in Namibia

Study details and location	Key results	Climate mitigation effects	Future research	Reference
The study evaluated the used of three rates of cattle manure at 0, 31, and 62 Mg/ha within three cropping systems, i.e., pearl millet (*Pennisetum glaucum* L.) mono-cropping; cowpea (*Vigna unguiculata* L.) mono-cropping; and pearl millet-cowpea intercropping. The soil was a sandy soil from Ogongo, Omusati Region with a pH (H_2O) = 7.0 and 2.8 g total C/kg soil.	Application of manure increased soil organic carbon by 1.3 and 1.7 times under the 31 and 62 Mg/ha, respectively. Furthermore, manure application significantly increased the concentration of most macronutrients compared to the control. However, cropping system did not result in differences in most of these parameters. The study also observed that there was optimization on the benefits of manure addition at the lower rate of 31 Mg/ha.	Soil organic carbon (SOC) can be significantly increased by addition of cow manure, which has the potential to improve soil quality in sandy degraded soils. Higher SOC increases the resilience of soils and improves water and nutrient retention, which has potential to increase yields under smallholder farmers.	There is need to improve the quality of the manure applied through processes such as composting and vermicomposting and evaluating these improved organic nutrient sources. There is need for long-term studies evaluating the influence of animal manures on soil quality, which considers changes soil chemical, biological, and physical properties. Optimization of long-term application rates of animal manures which is informed by crop requirements is essential.	Watanabe et al. (2019)
The study evaluated an organic hydroponic nutrient solution prepared from goat manure processed through composting goat manure for 6 months and then extracting the nutrients from the compost by a process of leaching for 7 days. The study	The use of organic hydroponic solution did not result in significant differences in vegetative plant growth with the commercial hydroponic fertilizer, which were all different from the control with the lowest vegetative growth In terms of yield parameters,	Important vegetable crops like tomatoes can be grown in under hydroponic systems that are fertilized using organic nutrient sources. The use of hydroponics which are cheap allows for the production of crops under the smallholder farmers with limited water use	Evaluating more nutrient-rich compost types called vermicomposts as hydroponic nutrient sources. Evaluating the effectiveness of using amendments like rock phosphate, fly ash, and biochar in improving the fertilizer value of these organic nutrient sources.	Mowa (2015) and Mowa et al. (2017)

(continued)

Table 3 (continued)

Study details and location	Key results	Climate mitigation effects	Future research	Reference
had three treatments, i.e., the organic hydroponic fertilizer; a commercial hydroponic fertilizer, and a control of water alone. A floating deep water culture hydroponic system was then used for growing tomatoes. The study was done in a greenhouse in Henties Bay located within the coast of Namibia.	tomato plants grown under the commercial hydroponic fertilizer produced more than those grown under manure nutrient solution which in turn, produced more than the plants grown under the control.	and low fertilizer costs. Hydroponics are critical in increasing food production under a changing climate, where fresh water will become scare.		
The study was undertaken in Kavango East Region (Mashare Irrigation Training Center – MITC) and Zambezi Region (Liselo Research Station – LRS). Two experiments one with pearl millet (*Pennisetum glaucum*) and the other with maize (*Zea mays*); which were rotated with different Green Manure Cover Crops (GMCC) to evaluate their effects on the productivity (grain and biomass yields) among other parameters.	The GMCC lablab resulted in the highest biomass yield with a mean yield of 11,500 kg/ha while jack bean had the lowest yield of 1000 kg/ ha. Similarly, lablab in the pearl millet rotation resulted in the greatest grain yield of 3 tonnes/ha, with jack bean, bambara nut, and common sun hemp producing lower grain yields. At LRS, the greatest biomass yield was observed in the velvet bean treatment with a mean yield of 5900 kg/ha.	Green manure cover crops can significantly contribute to the addition of soil organic matter thus increasing the soil organic carbon of the soil, which consequently improves soil quality. The legume green manure cover crops can be effective in fixing atmospheric N into the soil, thus reducing the use of inorganic fertilizers.	Monitoring the long-term contribution of the GMCC to overall soil quality under various combinations. Evaluating the potential of agroforestry tree species in agroecology in Namibia.	Amakali (2019)

Conclusions

The contribution of Namibia and most countries in southern Africa to climate change through the global increase in atmospheric pollutants that are drivers of global warming is very minimal. However, it is apparent that the impacts of this global change in climate due to human-induced activities will influence everyone on earth, with the effects expected to be even more pronounced in already hyperarid countries like Namibia. Namibia has made huge progress at policy level with regards to issues of climate change. However, there is need for more urgent research that directly feeds into the climate change strategy and action plan for Namibia. This research will need to focus on understanding more on the effects of anthropogenic activities on the atmosphere, water, and land activities, in a holistic manner. With the country being hyperarid, research that is currently underway on using clean energy sources like solar, wind, and tidal power for sea water desalination can be critical in abetting the effects on climate change on fresh water availability in Namibia. However, there is need for research on engineering locally adaptable technologies that can take this fresh water from the coast to other places of the country for use in agricultural activities, thus creating green belts in Namibia, capable of improving the country's food self-sufficiency. With Namibia being blessed with a vast marine environment, research on the effects of climate change on this unique marine environment and how it will affect economic activities in this industry will also be critical. Overly, Namibia is making progress on generating research critical in mitigating against climate change, and the future will require more research with a multidisciplinary approach to feed into the country's climate change action plan.

Abstract

For their livelihood activities, rural farming communities depend more on extractive capital. Their capacity to cultivate sufficiently for their family maintenance is greatly impeded by the absence of either temperature or rainfall quantity pattern or uniformity. The divergent effects of recent extreme weather events around the world, including within relatively small geographical areas, exemplify the unequal impacts of climate change on populations. Akwa Ibom State has been found vulnerable to extreme weather events, such as flooding, severe storms, and rising sea levels, leading to homelessness, poverty, conflicts, and war for millions of people. All of these have resulted in social disturbances and dislocations among rural populations, especially in coastal communities, making them more vulnerable to climate variability. In the field of social vulnerability in the state, not much has been achieved. This chapter analyzes the vulnerability of the rural population to climate variability; the socio-economic characteristics of the rural population; the index of social vulnerability of rural dwellers to climate variability; social vulnerability factors; and the rural population's social vulnerability mitigation initiatives in Akwa Ibom State, Nigeria. Social science approaches to human vulnerability draw critical attention to the root causes and factors why people are forced to respond to risks from climate change. A complex social approach to vulnerability is most likely to enhance mitigation and adaptation preparation efforts, given that vulnerability is a multidimensional mechanism rather than an invariable state.

Introduction

Reading through Gallent and Scott's (2017) observations on rural development planning, it gives a great deal of concern and experience that rural planning has been reduced to the least topic of planning theory and practice in more than five decades. A topical issue of rural development planning in the developing countries of the world should be the improvement of the economy at the rural governance level, given that the area is abundantly endowed with human and natural resources. The vast majority of the population still resides in rural areas and depends on the area for food as well as the supply of basic industrial raw materials, regardless of the increased rural-urban migration rate in many developing countries, including Nigeria (UN 2018).

A 2018 United Nations report showed that a quarter of the population in the countries of the Organization for Economic Co-operation and Development (OECD) is mainly rural, while the rural population is 46% worldwide. Critically, the rural economy is characterized by its own people, cultural characteristics, the uniqueness of the natural resource base, social and political institutions, and a combination of rural life which promotes national development. Eighty percent of the population in Nigeria lives in rural areas and their livelihoods are essentially linked to the rural economy (Ering et al. 2014). In addition, the rural area is described as having a low population density, small geographical sizes, and relative isolation, where people are relatively homogeneous in their values, norms, customs, and culture (Ebong 2017). Ejue emphasized that Nigeria's rural areas are characterized by poor and dilapidated roads, inadequate health facilities, inadequate and poorly equipped educational facilities, poor social facilities, high levels of poverty, unplanned residential layout, and other bottlenecks that hinder human well-being.

Notwithstanding these negative aspects, Scott et al. (2019) found that the rural area can be a reservoir of potential such as serene environment, quality land mass, rich biodiversity, tourism entertainment sites, and indigenous local knowledge reservoirs. At the rudimentary level, Frank and Hibbard (2017) also noted that rural areas provide the backdrop for a number of critical planning issues, such as the distribution of renewable energy, the management and improvement of biodiversity services, food production and security, as well as the extraction and administration of natural resources.

Rural people live very closely with nature in rural areas and natural resources provide the basis from which their fundamental needs are derived. Most of the population in rural regions, for example, rely on rain to start farming activities. There is a unique ecosystem for every community in the rural area, valued, admired, and protected by the people living there. For their social, spiritual, and economic development, they rely on those resources. However, due to prevailing climate conditions and associated events such as floods, storms, droughts, and landslides, a good number of rural dwellers are dislocated, especially in the coastal regions (Gallent et al. 2017). For example, some households are known to have moved further inland from their original settlements in Akwa Ibom State, a southern Nigerian state, leading to geographical dislocations (Ebong 2017). In coastal regions, displacement and migration of people from and to different settlements has also been linked to either or both the incidence of drought and accelerated sea-level rise (Abaje et al. 2016). Developing countries are projected to have an uneven share of the impact of climate variability, and due to its geography, climate, vegetation, soils, population and settlement, energy demand, and agricultural activities, Nigeria is particularly vulnerable (Abaje et al. 2016).

Via extremes of weather and interannual fluctuations, climate situations influence both natural and social processes. In some rural areas, with drenching downpour, the capacity of rural households to generate enough to feed themselves is greatly impeded by short rainy seasons (Okpara et al. 2017). These weather patterns influence agricultural production, reduce crop yields, and, in response to the prevailing conditions, enable farmers to change their agricultural practices. In the work of Umoh et al. (2013), it was reported that Akwa Ibom State was vulnerable to adverse impacts of climate variability and change in the Niger Delta region of Nigeria. Considering the widespread poverty, unequal distribution of land, over reliance on rain-fed agriculture, low income, and poor institutional capability, this observation became evident. The State is also vulnerable to extreme weather events such as flooding, severe storms and rising sea levels, in addition to inter-seasonal and inter-annual climate variations, resulting in loss of food crops, household food shortages, homelessness, poverty, and exacerbating circumstances that would lead millions of people to violence, war, and misery (Umoh et al. 2013). In some communities in Akwa Ibom State, heavy and sustained rainfall beyond the absorption capacity of the soil and the flow capacity of rivers and streams is prevalent, and populated areas adjacent to these rivers and streams are subject to recurring flooding, making the region "flood-prone" and placing the population at risk. All of these contribute to social disruption and dislocation of rural populations, especially in coastal communities, making them more vulnerable to climate change.

There is really no consensus that the exact nature of vulnerability renders it a relative concept that is disputed. The word "vulnerability" is derived from a Latin word meaning to be hurt, "vulnerare." This demonstrates the vulnerability of persons and activities to physical violence and/or psychological harm. The vulnerability of a device, individual, or person to a threat is broadly related to the potential to be harmed by that threat (Calderon and Serven 2014). The Intergovernmental Panel on Climate Change (IPCC) describes vulnerability as "the degree to which a system, including climate instability and extremes, is vulnerable to or incapable of dealing with adverse effects of climate change" (IPCC 2014). Vulnerability can have some effect on physical and socio-economic characteristics that are not static. This implies that vulnerability is unique to those evaluating it in a place, context, time, and perspective. Social scientists and climate scientists also use the word "vulnerability" to mean various things, although social scientists prefer to see vulnerability as reflecting the collection of socio-economic factors that decide the capacity of people to cope with stress or change, allowing groups to differ (Allen 2011; Huynh and Stringer 2018). Climate scientists also view a human system's vulnerability as determined by the existence of the physical hazards to which it is exposed, the probability of the hazards occurring regularly and the level of human exposure to hazards, as well as the resilience of the systems to the danger impacts (Ruppert and Deady 2017; Sadri et al. 2017). Vulnerability, therefore, is a combined hazard, exposure, and sensitivity feature (Calderon and Serven 2014).

Most commonly, social vulnerability is described as "the differential ability of groups and individuals to cope with hazards based on their physical and social world roles" (Dow 1992) or as "the inability to take effective loss insurance steps" (Bogard 1989). This also indicates the degree to which the loss, injury, or harm caused by the effects of a climate threat is revealed to a population, physical infrastructure, economic assets, and the general well-being of individuals. Any of these consequences are due to the features of social relationships, organizations and structures, and cultural values. In contrast to the prevailing belief in vulnerability to the impacts of climate variation, which focuses on the physical dimensions, this concept draws more attention to the social dimension of vulnerability. Obviously, social vulnerability focuses on demographic, social, economic, political, and cultural factors that increase the effect of climate hazards on rural inhabitants. In terms of education, gender, income, health status, access to credit and information technology, formal and informal (social) capital, political power, and so on, people living in a group most often differ; these variables also trigger variations in their levels of vulnerability (Huynh and Stringer 2018).

Unfortunately, the social dimensions of vulnerability to climate hazards are rarely paid attention to in most recorded issues and corresponding measures, thus explaining the reason for the very limited studies on social vulnerability in Nigeria taken either at national or state level. In the disaster literature, social insecurity of people in rural areas is widely overlooked and tends to be the least documented condition, explaining why social losses are most frequently missing in estimates of postdisaster cost/loss assessment (White and Howe 2012; UN 2018). Not being able to assess all aspects of climate-related vulnerability would have a detrimental effect on the adaptability of populations and their resilience to climate-related risks. There has been a strong gap in the actual understanding of how socially vulnerable rural communities in Akwa Ibom State emphasize the need to assess their status as socially vulnerable to climate change, taking into account steps to mitigate social vulnerability in rural communities. In order to fill the void, this research came in.

Therefore, this chapter summarizes the report of a state-run study on the social vulnerability of rural dwellers to climate variability. The study described the rural population in the state as specific targets, identified the social vulnerability index of the rural population in the state, identified factors affecting the social vulnerability of the rural population in the state, and identified initiatives to reduce the social vulnerability of the rural population in the state.

Rural Population Characterization in Akwa Ibom State

Sex, marital status, age, educational qualification, primary occupation, monthly income, household size, form of housing, position of building, and health status were the selected socio-economic characteristics of the respondents considered in the sample. The respondents' sex distribution showed that there were more females in the areas than males. The dominance of women in the fields of study can be attributed to the migration of men to the source of alternative opportunities for urban jobs. It also means that with climate change, more women are likely to be affected because in the study region they outnumbered the men. During rehabilitation, women will have more difficult times than men, due to streamlined jobs, meager salaries, and responsibility for family care. In local and national decision-making, women often lack a voice and a representative and are isolated in political processes, affecting their exposure, sensitivity, and resistance to climate hazards (Mansur et al. 2016; Anderson 2014).

Women account for the greater majority of the world's poor in rural areas. They depend on natural resources for their livelihoods and survival more than men. Women tend to have lower earnings and are more likely than men to be economically dependent. For example, when droughts or unseasonable rains threaten agricultural production, men may use their savings and economic freedom to invest in or otherwise adapt to alternative sources of income (Omi and Winant 2015). But as household shock absorbers during periods of economic and physical deprivation, women extend their already highly undervalued working hours and may even decrease their nutritional status to increase that of the family (Maldonado et al. 2016).

The majority of respondents were married during the research. The high percentage of married respondents is consistent with Ekanem et al. (2020), who noted that among rural people in Nigeria, getting married is highly valued with the intention of using these women for unpaid family work. The high percentage of "married" marital status appears to impose certain restrictions on most female study respondents because married women are forced to adhere to certain requirements imposed by their husbands directly or indirectly by tradition. Men's dominant efforts make women feel inferior and unable to take part in life-affecting events. For example, a female respondent said, "When disaster occurs, without the consent of our husbands, we cannot move."

In the research area, the study found a certain percentage of widowed respondents. This may be attributed to a high mortality rate among men drowning in the high seas during an expedition to fish in the coastal parts of the state. During the analysis, the percentage of the separated according to the extracts from the FGD groups is due to the loss of housing during the flood time that makes couples absolutely powerless as they have to transfer to nonaffected areas. One of the women had to say, "Our husbands migrate from rural areas to cities to exploit perceived economic opportunities in the course of economic deprivation as migrants and indirectly dumb us at home to take care of children, elderly or sick family members and often remarry other women outside our culture."

The bulk of the respondents were between the ages of 61–80. Because of their health problems, those respondents who were within the age range of 60–80 years were considered to be economically inactive, rendering them unable to embrace new information or to engage in adaptation preparation in order to minimize their degree of social vulnerability to climate change. The educational level of rural residents can restrict their ability to understand and respond to climate information. The findings of our study showed that the majority of respondents (64.7%) did not have formal education, 23.7% had primary education, 11.0% had secondary education, while just 0.67% of respondents read up to tertiary level. This means that the majority (64.7%) of respondents would be more vulnerable to climate change due to their inability to access, read, and comprehend weather information literature, as posited by Davies et al. (2017), who noted that various climate threat information cannot be accessed or acted upon by the least informed community members in order to plan for recovery.

The majority of respondents had agriculture as their primary occupation, with few others taking on employment in commerce, crafts, and wages. Other occupations, such as boat mending, water transport, motorcycling, etc., constituted 1.7% of the primary occupation of the respondents. The outcome showed that 40.0% of the respondents were artisans engaged in various low-income activities. During catastrophes, this behavior is typically lost and therefore increases their vulnerability and resilience.

Most respondents had a monthly income of N1,000–20,000, with just 1% of respondents receiving a monthly income of N40,001–N60,000. The outcome indicates that 95% of low-income (1000–20,000) respondents had little to no financial support to mitigate their social vulnerability. Ekanem et al. (2020) and Anderson (2014) expressed the view that households with less access to energy are more economically sensitive to the impacts of immediate and eventual climate variability.

Household sizes are very high for rural dwellers in Akwa Ibom State. Our study found that most respondents had household sizes in the range of 11–15 individuals. Due to frequent flooding that damages residential apartments causing population displacement, it can be deduced that household size increases, which could result in more individuals sharing few habitable apartments. Some respondents, especially the coastal residents, pointed out that "we lost our houses when disaster hits and plead with neighbors to squat us." The standard of the housing is closely linked to the personal wealth of the respondent. That is why some rural residents live in badly developed houses that are vulnerable to heavy rainstorms and flooding (Hollesen et al. 2018). Our analysis has revealed 79. Nine percent of the respondents lived in thatched roof mud buildings, while 8.3%, 5.7%, and 6.3% of the respondents lived in zinc roof, zinc mud, and zinc cement, respectively. As Cutter et al. (2016) and Kintisch (2016) asserted that rural poor live in substandard and overcrowded houses vulnerable to the spread of diseases and the effect of disasters, the results indicate that respondents are mostly poor. Of necessity, this is a vital element in assessing the vulnerability of climate hazards. In rural areas, the value, quality, and density of residential buildings affect possible losses and recovery.

Observations have shown that, as demonstrated by the 2009 U.S. Hurricanes Katrina, climate threat and its aftermath have a significant effect on people with disabilities. Our analysis found that 19.9% of the participants were people with disabilities. These individuals are likely to be more vulnerable to the consequences of climate variability as "climate change causes increasing distress and reduced opportunities for them to access critical emergency information" (Cutter et al. 2016; Hollesen et al. 2018). The World Report on Disability also reveals that people with disabilities are particularly inclined to be neglected in emergency assistance and relief operations (World Health Organization and World Bank 2011) (Table 1).

Social Vulnerability of Rural Dwellers to Climate Variation in Akwa Ibom State

Table 2 indicates many factors that predispose households to the adverse effects of the state's climate variability. Ten elevated rank variables have been picked. The first three reasons were: dwelling place loss (x = 2.38; ranked 1), properties open to criminals (x = 2.32; ranked 2), and children's failure to complete their education (x = 2.29; ranked 3). The results suggest that the nature and location of housing makes individuals more vulnerable to risks. In hazard-prone areas, such as flood plains and slums, poor people are more likely to live. This

Table 1 Distribution of rural dwellers based on their socio-economic characteristics

Item	Selected variables	Frequency n = 300	Percentage (%)
1	**Sex**

	Hypertensive/diabetic patient	21	7.0

corroborates the earlier findings of Birkmann (2013) and Nelson et al. (2016), who recorded that hastily established settlements are more physically vulnerable in terms of subsistence and geographical position to immediate climate impacts. Nelson et al. (2016) further clarified that rural communities have less political voice in disasters such as severe flooding and windstorms, thus raising the likelihood of their residents being physically harmed. Brown (2016) argued that the most vulnerable to climate hazards are likely to be the least trained and low-skilled members of society and that government may pay little attention to their well-being. This implies, as Tall (2019) notes, that vulnerability is reduced by better education and knowledge. Suitable weather knowledge, for example, enables farmers to predict seasonal trends.

Variables in the 4th, 5th, and 6th ranks were loss of privacy ($x = 2.27$), blocked from health facilities ($x = 2.20$), local workshop destruction ($x = 2.18$). During floods, the privacy of people tends to be absolutely threatened, eventually subjecting them to immense social deprivation. The women had this to say in the study area (coastal region); in many cases, due to lack of privacy, we cannot respond to the call of nature. As a consequence, to defecate, we have to wait till night. In the case of pregnant mothers, disabled, and elderly people, the condition is getting worse. The study by Brondızio et al. (2016) and Hollesen et al. (2018) reinforced that during floods, disease outbreaks are prevalent; they submerge latrines and contribute to misery. They not only become victims of snake bites, but also suffer from skin diseases regularly. People in poor health and those who are undernourished will be more vulnerable to the immediate and secondary effects of extreme climate events, according to Hardy et al. (2017), since they are less likely to be able to plan for or cope with the impacts of climate hazards.

The ranked variables placed 7th, 8th, 9th, and 10th were: absence of services ($x = 2.16$), evaluation of relief materials ($x = 2.15$), loss of relatives ($x = 2.11$), and lack of drinking water ($x = 2.10$). These results have reinforced the assertions of Gamble et al. (2010), who identified the need to take into account the role of human and social capital in assessing climate impact vulnerability. They believed that human and social resources can contribute to the capacity of a society to overcome climate variability through coping and response capacities, whereas a lack of capital can leave individuals isolated and at higher risk of impacts such as severe heat waves being revealed.

Table 2 Social vulnerability of rural dwellers to climate variability

S/N	Statements	SD	D	A	SA	Mean	Rank
1	We hardly see our relatives as they have been dislocated because of constant flood	33(11.0)	72(24.0)	103(34.3)	92 (30.7)	2.1	9
2	Our local workshop has been destroyed by constant flooding	18(6.0)	110(36.7)	111(37.0)	61(20.3)	2.18	6
3	Peoples' houses are pulled down by strong wind in my community	5(1.7)	99(33.0)	108(3.0)	88(29.3)	1.90	15
4	There is no safe drinking waters in my community as a result of flood	44(14.7)	48(38(12.7)	113(37 3)	95(31.7)	2.10	10
5	People lost their homes due to severe storm	5(1.7)	38(12.7)	94(31.3)	163(54.3)	2.38	1
6	Our food crop is lost because of rise in water level	6(2.7)	49(16.3)	128(42.0)	117(39.0)	1.72	19
7	Our children cannot complete their education because school facilities are flooded	16(5.3)	30(10.0)	105(35.0)	149(49.7)	2.29	3
8	People are attack with different diseases such as skin infection, malaria, typhoid, and dysentery because of continuous inflow of water	70(23.3)	32(10.7)	69(23.0)	129(43.0)	1.86	16

22	Our traditional rulers do not inform government about our situation	31(10.3)	48(16.0)	97(32.3)	103(34.3)	1.67	21

KEY
SD = Strongly Disagree
D = Disagree
A = Agree
SA = Strongly Agree

Rural dwellers seem vulnerable because they cannot access the services of their society to cope with climate change shocks and stresses. Hardy et al. (2017) argued that their choices are limited and very difficult for them to think beyond their immediate needs, let alone make adaptation plans, if people do not have secured access to vital livelihood tools. Climate change disrupts social relationships, undermining family bonds, and social ties with loved ones.

Factors Affecting Social Vulnerability to Climate Variation

Factor analysis was used to examine and identify the factors affecting social vulnerability to climate variation. Sixty (60) items were initially generated during the instrument construction phase to reflect the objective after which it was subjected to factor analysis using principal component approach. This was done to reduce the number of items to major and sizeable significant number of factors using Eigen value criterion of ≥ 1 to select the underlying dimensions of the original 60 items.

The principal components method is an exact mathematical transformation of the original set of variables to a new set, with the later summarizing linear relationships exhibited in the data. The best linear combination of the variables gives the first component or factor of the variables. It means that this factor, more than any other, accounts for most of the variance or relationships observed in the data and hence is the best summary of the original data. The second component is similarly defined as the next best linear combination of the variables that would account for the relationships observed in the data after the effect of the first component or factor has been removed, provided both components are uncorrelated (orthogonal). Subsequent components are similarly defined until all the relationships or variance in the data have been accounted for. The factor can therefore be defined as:

$$F = aWA + bwB \pm \ldots kwK \tag{1}$$

where

Fa = factor a, being the best linear combination of all the variable A-K
aw-kw = are weights attached to variables
A-K = variables A-K

Other factors can be similarly defined, as explained earlier. When the factors are uncorrelated, they are said to be orthogonal and a variable "a" in the original data can be defined as:

$$Z_a = Wa_1F_1 + W_{a2}F_2 + \ldots + W_{a2}F_{2+} \ldots + W_{ak}F_k \tag{2}$$

where Z_a = Variable a in standard score format (mean = 0 and variance 1), W_{a1} to W_{ak} = Weights (normally called factor loadings) attached to factors, and F_1—F_k = factors I–K. Formula 2 simply means that in factor analysis employing the principal components methods, a variable is viewed as the sum of weighted factors derived from the data. When the data is initially factored, the concern is more on the possibility of reducing the data to a smaller composite set of factors. At this stage, the factors may not make any meaning until they are rotated to a final solution.

Empirically Defining the Underlying Dimensions of Factors Affecting Social Vulnerability

Seventeen (17) composite factors were mutually exclusive on the basis of the result of factor analysis performed and major trends were produced. Table 3 introduces these variables and addresses them below:

Local Support Factor

Inability to access community services is an important aspect of social insecurity, as it relates to the way rural dwellers are categorized on the basis of their income, according to literature (Birkmann 2012). Factor 1 accounts for 21.7% of variance and this is high. This outcome coincides with Passel's 2005 study that poorer households (low class) are not able to access resources fairly due to social factors (economic and political processes) that are custodians of upper class or wealthier people.

Table 3 Major dimensions of social vulnerability to climate variability

Factor	Names	Eigen values	% of variance	Cumulative %
1	Lack of local support	12.995	21.658	21.658
2	Knowledge barrier	3.762	6.270	27.928
3	Income/employment/replacement ability	2.581	4.302	32.230
4	Family structure	2.333	3.888	36.118
5	Demographic explosion	2.129	3.548	39.667
6	Age of residents	1.851	3.085	42.751
7	Gender inequality	1.710	2.849	45.601
8	Tribal issue/public assault and insecurity	1.564	2.607	48.208
9	Infrastructure inaccessibility	1.542	2.571	50.779
10	Loss of properties and accommodation	1.494	2.490	53.268
11	Mobility	1.407	2.346	55.614
12	Disability	1.291	2.152	57.766
13	Weak local institution	1.225	2.041	59.808
14	Cultural constraint	1.194	1.991	61.798
15	Poor climate information/communication source	1.173	1.955	63.753
16	Loosed social capital/social safety net	1.070	1.783	65.535
17	Environmental/social discrimination	1.051	1.752	67.287

Educational Challenge Factor

Training is related to socio-economic status and accounts for 6.2% of rural dwellers' heterogeneity. Noneducational achievement in the field of study makes community members vulnerable to climate danger because they lack the opportunity to grasp knowledge on warning and recovery. The outcome of the finding is consistent with Nelson et al. (2016), who stated that during floods, children's schooling is impaired as it is difficult to keep and attend classes under submerged conditions. The school appears to become the "front-line" flood shelter for displaced families anywhere the school building is not submerged. UNICEF (2011) confirms this finding by stating that children are forced out of school when natural disasters interrupt the educational system of the community, including teachers. The absence of experienced teachers and other main school staff is detrimental to the academic success of children.

Income /Employment/Replacement Ability Factor

Floods have a significant effect on the source of livelihoods, paralyze economic activities, deepen disparities in economic status, and access to sufficient food and services in the field of research. This explains the 4.3% difference between rural communities. The result supports Sultana (2017) who reported that when affected by a danger case, local individuals who are in primary extraction activities such as fishing, forestry, crop cultivation, and livestock rearing suffer great losses and are unable to rebuild their settlement.

Family Structure Factor

When tragedy occurs, large family size hinders evacuation and this impact increases social vulnerability. There is less time, resources, and energy for families caring for ill members to invest in activities that could minimize the impacts of external threats, help them recover from dangerous incidents, and be better prepared for them in the future. Sultana (2017) also acknowledges that members of large and dependent families – children under the age of 18, elderly and disabled members – need financial assistance, transportation, and disaster medical treatment, and these affect the resilience to risk recovery. This portion explains the variability of 3.8% among respondents.

Demographic Explosion Factor

Village habitation is adversely impacted by population migration and neighborhood disorder. When the flood effect of the community or household shifts to the non-affected area, there is a population influx leading to an increased risk of disease and sanitation system contamination. This is corroborated by McLeman (2016), who stressed that high population increases outbreaks of disease due to individual proximity to each other and contamination of human waste water sources. Increasing population density increases vulnerability, particularly where the density is high, according to local respondents. Increased population density limited access to land and exacerbated pressure on natural resources during challenging times, respondents clarified. Indeed, population growth means that growing numbers of people are exposed to the impacts of climate variations and that more people have to share scarce resources (e.g., water and food). This explains the 3.5% difference between rural dwellers.

Age of Resident Factor

Age is strongly associated to social disadvantage and 3.0% of the difference is clarified. There is also a rise in health challenges as individuals grow older, and these are compounded during times of dislocation or loss of livelihood due to climate change. The result confirms Omi and Winant (2015), who reported that due to adverse effects of climate variability such as hearing impairment, cognitive difficulties, rise in blood pressure (hypertension), etc., the elderly population experiences different health problems. This affects their potential for disaster management and recovery. Brondızio et al. (2016) also argued that children cannot protect themselves during a disaster, particularly the youngest age group, because they lack the resources, skills, or life experiences required to cope effectively with the situation.

Gender Inequality Factor

2.8 percent of the observed variance is explained by this factor. Sex is a powerful factor illustrating the susceptibility to impacts related to climate change. Factors such as lack of access to and power over basic resources and lack of entitlements exacerbate the vulnerability of women and weaken their capacity to cope with disaster effects (Sultana 2014). The result is consistent with Brown (2016) which stated that because of their distinct socially constructed positions as mothers and family caregivers, women suffer more from the impact of disaster. Faber (2015) notes that stream dries up during extreme situations, for example, when natural water sources, and women have to travel longer distances daily on foot in search of drinking water. The report shows that pregnant and lactating mothers make up a large proportion of these women. Furthermore, he added that women enumerated their experiences during constant flooding over menstrual hygiene management, especially in the coastal zone, resulting in genital injury, bleeding, infections, and other complications.

Tribal Issues, Public Assault and Insecurity Factor

2.6 percent of the variance among respondents is explained by this factor. Literature indicates that people who lose their homes during floods are absolutely powerless as they travel out to non-affected areas without any source of income. They lose the physical social security they once enjoyed in their native villages in their new housing as migrants. This, in turn, puts them in different kinds of adverse social circumstances; young girls in constant danger of sexual abuse and attack from the boys and men of that group who take shelter on embankments. Professional gangs are also coerced into prostitution by young women, with offers of work elsewhere (Maldonado et al. 2016). The outcome also agrees with Dunning (2011), who noted that, for example, people who do not speak the language of their host group have trouble understanding and reacting to the warning and evacuation order

Infrastructure Inaccessibility Factor

2.5% of the variance is explained by this factor. The outcome is consistent with Davies et al. (2017), who stressed that social deprivation is increased by inaccessibility to vital infrastructure such as highways, shelter, and telecommunication. He emphasized that poorly maintained local road networks rendered some roads impassable. The other part of the city, including the economy, is cut off and blocked from some areas that would promote income security.

Loss of Properties/ Accommodation Factor

This factor explains 2.4% of the difference in rural populations. The outcome is in line with Brondızio et al. (2016) who highlighted the flood "sweep off" farmland leading to crop and income loss. In particular, thatch houses are said to be damaged in coastal communities by floods in the upland or sea level buildings. He further claimed that, especially for poor households, loss of property is more difficult to replace. Some fishermen describe their bitter experiences during a sea pirate attack fishing trip on the high seas where their boat engines and other instruments are stolen and destroyed.

Mobility Factor

This portion explains the variation among respondents of 2.3%. The outcome of the results agrees with Cutter et al. (2016) who posited that for people who do not have cars, transport out of the evacuation zone is problematic. In coastal regions, the movement of people is distorted by the increase in sea level because canoes made locally cannot be paddled at high sea level, are victims of water-related diseases, and cannot access medical facilities and workers in upland areas leading to trauma of nonpathogenic hypertension and stroke conditions. Brown (2016) claims that when emergency strikes, people with disabilities have mobility restrictions, they have trouble finding safe places.

Disability Factor

This variable explains the difference of 2.2% among rural dwellers. The finding is synonymous with the World Disability Study (2011) that when emergency strikes, people with disabilities are left behind in a deteriorated community and are isolated from their families and friends, leading to crippling suffering on them, and they lack the social networks needed to take advantage of services that would speed up their disaster recovery. Hollesen et al. (2018) reported that disasters and their effects have a significant effect on people with disabilities due to the lack of assistive devices such as wheelchairs, crutches, white canes, or hearing aids.

Weak Local Institution Factor

2.0% of the differences among local dwellers are explained by this factor. Poor or corrupt institutions can contribute to ineffective and insufficient responses to disaster situations, slowing requests for government support and not actually delivering help to those most in need. This supports Ejue, who claimed that rural communities are limited by weak leadership and lack of freedom and decision-making power as their voices, needs, and desires are not integrated into government projects and this increases sensitivity for poorer households.

Cultural Constraints Factor

This element explains the variance of 1.99%. The result is the same with Ejue, who argued that the lack of traditional wisdom has caused elders to suffer contempt from the younger generation because the wisdom they carry is not as detailed as it used to be. This outcome also agrees with Mansur et al. (2016), who stated that as their ethnic cultural identity suffers from the risks of extinction as a result of climate-related risks, older people become more dissatisfied.

Climate Information/ Communication Factor

The lack of available, affordable, and appropriate sources of knowledge leads to social vulnerability. This explains 1.95% of the variance. It was found that respondents rely on their personal weather observation, past experience in their community and local institution due to irregularities, and untimely distribution of advance media information that they caption “false stories” or “fly news.” Their conviction is due to the fact that localities are not subject to weather predictions from radio and NTA stations. This result is consistent with d’Alpoim et al. (2016), which posits that in terms of reliability, timing, and languages, there are shortcomings in the knowledge distribution process. It is important to communicate, obtain, and interpret information about weather forecasts and climate predictions via multiple channels, including interpersonal contact, television, radio, the Internet, and social media (Morss et al. 2017). Before they make decisions, individuals combine data from these different sources (Sadri et al. 2017). Social networks help people access, personalize, and understand the importance of knowledge in a significant way.

Loosed Social Network and Safety Net Factor

1.78 percent of the variance is explained by this factor. The study agrees with Cutter et al. (2016) that it is difficult for displaced populations to re-organize and restore their former family connections and relationships. Some respondents share their feelings that floods are hindering social activities such as marriage, commitment to children, and funerals. This condition weakens social capital and loosens social relations with loved ones, causing the respondents to be mentally depressed. Kintisch (2016) argued that the loss of the network and lack of access to social gathering make people feel lonely, especially the elderly. Meanwhile, Davies et al. (2017) assume that if placed in place, the social security net will help prevent postdisaster starvation and assist affected households and communities to safeguard and restore their properties.

Environmental / Social Discrimination Factor

This element explains the variance of 1.75%. The outcome agrees with Cutter et al. (2016) and McDowell et al. (2016), who observed that a nation's inhabitants do not share the benefits of economic growth equally. Discrimination and social isolation result in this. And in rural areas, this is also true.

Measures to Reduce Rural Residents' Social Vulnerability to Climate Change

Table 3 demonstrates strategies that will reduce the social vulnerability of respondents in the study region to climate change. Ten of the most relevant high-rank indicators were chosen. The first four steps to mitigate social vulnerability to the effects of climate variation were: dam construction ($x = 3.62$; ranked 1), flood storage reservoir construction ($x = 3.57$; ranked 2), dam and bridge construction ($x = 3.56$; ranked 3), and gutter opening ($x = 3.54$; ranked 4). These initiatives agree with Eriksen (2012), who noted that one of the adaptation techniques widely practiced by flood victims is the construction of defensive outlets such as flood storage reservoirs, dams, and water transport channels from the affected areas. Davies et al. (2017) accept that for uprooted communities, the embankment acts as temporary shelter.

The fifth method is working to fill sand bags in groups ($x = 3.53$, ranked 5). This agrees with McDowell et al. (2016), who stated that for mutual benefit, societies with denser social support networks have more interaction between community members. Eriksen (2012) believed that societies with higher social and stronger social networks will be better able to cope with threats and their consequences because it is easier to analyze knowledge and other types of social support.

The sixth technique is the fund's payment ($x = 3.52$, ranked 6). The results confirm that Huynh and Stringer (2018) emphasized that materials for relief and assistance are especially helpful to those individuals who could not afford to repair damaged properties themselves. The seventh, eighth, ninth, and tenth steps were: environmental law enforcement ($x = 3.50$, ranked 7), flood-prone areas should not be developed ($x = 3.49$; ranked 8), weather signal recognition ($x = 3.47$; ranked 9). The result corroborates the view of Omi and Winant (2015), who said that individuals should be prevented from developing areas vulnerable to flooding and that defaulters should be punished. And the use of local dialects ($x = 3.37$; rank 10). The results indicate that the combination of extension agents, radio, and local agencies will be more effective in disseminating local dialect environment information and supporting services in insecure areas for vulnerable people.

The least significant steps were: raising consciousness of income diversification ($x = 3.34$; ranked 11), building a well-equipped hospital ($x = 3.30$; ranked 12), the proportion of local cultivars ($x = 3.02$ ranked 13), and the lack of equitable access to local services ($x = 2.96$; ranked 14).

Conclusion

It can be inferred from the results obtained that 52% of women were vulnerable to climate change in rural areas of Akwa Ibom State. Most of the respondents were between 60 and 80 years of age. The majority of respondents (64%) did not have formal education and are probably the least educated on climate issues. The most important steps to mitigate flooding from the perspective of the respondents were the construction of embankments, flood storage reservoirs, dams and bridges, and opening of gutters; and these were related to the position of respondent construction. The underlying dimensions affecting social vulnerability were lack of local support, information barrier, jobs, employment and replacement capability, family structure, demographic explosion, resident age factor, gender, tribal problems, public attack, and inaccessibility of infrastructure in the insecurity factor. Others included property and housing damages, mobility, disability, weak local institutions, cultural constraints; inadequate sources of environment knowledge and communication; loosened social networks and social security networks; and social discrimination. Rural residents in Akwa Ibom State were highly vulnerable to the effects of climate change because, as seen in the report, the higher the factors that lead to social vulnerability, the higher the degree of social vulnerability of the respondents.

Recommendation

The following recommendations are made based on the study's results and conclusions:

1. Agricultural extension staff, meteorological offices, and community-based agents should be assisted by policy makers and development partners to raise awareness of climate information forecasting and dissemination through usable and accessible communication methods such as local dialect radio, city critics, drama, newsletters, community workshops/seminars, and educational programs
2. Income diversification is an efficient way to reduce vulnerability by spreading risks. To minimize social vulnerability to extreme flooding and drought, less reliance on natural resources would help. Rural dwellers need to maintain and engage effectively in those value-added economic activities that will reduce food insecurity, increase jobs and income opportunities, and enable individuals to accumulate assets that will enhance their ability to cope with potential shocks without worsening poverty.
3. Adaptive planning is required to minimize the vulnerability of vulnerable coastal roads (ferry routes), low-lying buildings and assets, transport, and market connections and to improve legislation to safeguard hazard-prone areas. Adaptive planning is needed.
4. Local institutions should improve social capital, that is, family ties and friendly connections between members of the group should be revitalized so that individuals can collaborate and team up to resolve the effect and challenges of climate

variations for mutual benefit among themselves. In the meantime, friendly ties with relatives away from home should be established for remittances to act as a cushion when subjected to extreme events and also for the provision of temporary accommodation during displacement.

Abstract

The use of biomass and biofuels, such as wood, charcoal, petroleum, kerosene, and gas, is becoming competitive based on the level of development of each nation. However, charcoal production (CP) and marketing now tends to be a major business among many households in both rural and urban communities with no consideration of its effects on climate change adaptation. While the research question considers the various definition of climate change adaptation, and the importance of charcoal production in Nigeria, the manuscript speaks mainly of the problems of charcoal production, the lack of planning to address these problems, and the lack of planning to move the communities away from this practice and out of poverty. It addresses the impacts of charcoal production on agriculture, such as lack or loss of labor and destruction of arable lands. The paper discusses the effect of charcoal production on health. Also, the environmental problems of CP are highlighted in the manuscript. The policy frameworks on forestry by the Federal Ministry of Environment 2006 with its flaws will be included. Remedy such as the establishment of a Land Use Planning Agency (LUPAG) and panacea for greening the charcoal value chain issues will be discussed. Lastly, attention is given to the agricultural adaptation strategies to climate change which are capable of reducing charcoal production, such as mixed cropping.

Keywords

Climate adaptation change · Poverty · Deforestation · Policy framework · Alternative to charcoal utilization

Introduction

Definitions of Climate Change Adaptation

Climate change adaptation refers to the process of modification of the present and future impacts of climate change (United Nations Climate Change 2020). Due to the rapidly changing climate, coupled with economic, social, and technological developments, nations have no option but to look for a way to achieve a greater stride which further creates more tension in the ozone layer. According to the Victorian Centre for Climate Change Adaptation Research (VCCCAR) (2020), several views are expressed by scholars as follows: adaptation to climate change is the initiative to enable people and their surroundings to withstand the changing climate conditions (United Nations Framework Convention on Climate Change (UNFCCC) (2015). The Intergovernmental Panel on Climate Change (IPCC) refers to climate change adaptation as tampering with the natural or human systems so as to respond to actual or expected climatic stimuli or their effects. However, the UN Development programs defines it as the process through which strategies to moderate, and withstand with the subsequent effects of climatic events that are developed, implemented and improved upon. Conversely, the UK Climate Impacts Program defines it as the outcome of a process that creates limitation to the distortion or risk of problem or actualization of benefits that are related to climate variability. But the National Climate change Adaptation Research and Facility (NCCARF) views climate change adaptation as a composition of actions undertaken to reduce the negative effects of climate change, exploiting any beneficial opportunities. Lastly, the Victorian Government states that it is a conscious step to prevent, manage, or decrease the effects of a warmer, drier, and more extreme climate and to maximize the benefits which such changes are likely to provide.

Importance of Charcoal Production in Nigeria

Nigeria is a country that is endowed with crude oil, natural gas, and energy resources, such as solar, wind, biomass, and biogas. The country is gifted with human resources with a total population of 140 million according to the 2006 population census. The annual population growth of Nigeria is about 2.8% (National Population Commission [NPC] 2006). Currently, the national energy supply is almost entirely dependent on fossil fuels and wood fuel (The World Forest Movement 2006). For instance, the value of the charcoal market for 26 sub-Saharan African countries is said to purportedly exceed $1.8 billion per year (Food and Agriculture Organization [FAO] 2018). In terms of energy, charcoal consumption in many African countries is higher than the quantity of electricity consumed. The importance of charcoal lies in the following areas.

It is a source of considerable amount of employment in rural areas (Arnold et al. 2006). A significant number of rural dwellers relies on charcoal production as a good source of employment, especially in a devastating economy like that of Nigeria. Money realized from charcoal represents per capita income of between 24 and 14 dollars in 1990 and 2000, respectively, which are equivalent to between 1.8 and 4.8 times of per capita income from the sale of agricultural produce in the same years. Charcoal producers reveal that the average annual production in some countries is 160 bags per producer, whereas some produce significantly more than 500 bags. Also, income from charcoal is expended on food, farm inputs, and implements (FAO 2018).

Charcoal production is also one of the recognized economic drivers in some African countries aside from agriculture. However, it generates more income for the rural dwellers (Williams 1993). It also allows for quick return on investments (Stefan 2009). About 65% of the people in the rural areas have made wood fuel and charcoal production a source of income (Shackleton et al. 2006) because of its quick return on investments, unlike the involvement in arable crop production that will bring income in 3 months. In addition to its export value, charcoal trade at the local level provides income opportunities to pay education, health, feeding, and ceremony bills for most rural and urban dwellers through small-scale retail and wholesale (FAO 2018, Fig. 1). It is a reliable, comfortable, and easy form of energy for heating and cooking, with a relatively cheaper cost (Iloeje 2002).

Fig. 1 Plate showing charcoal depot in Saki derived Savannah zone of Nigeria from field study on April 19, 2013

Charcoal is produced for the poor in rural and urban areas to enable them to meet their energy needs, such as for heating and cooking. It is the most recognized commercial fuel derived from wood. It is smoke-free and can be used in small quantities during cooking (Adam 2009). Charcoal can also produce greater heat than wood, and it is useful for many industries in urban environments. In most developing countries, it is the chief form in which wood fuel is used in towns NL Agency (2010). Charcoal can be stored, takes up little space than firewood for heat generation, and does not deteriorate so easily. It is easier to handle during transportation and distribution. Therefore, it is more preferable to wood (World Bank 2004).

Furthermore, charcoal is used in African art to design various objects (World Energy Council 2004). Charcoal is the raw material for the manufacture of gunpowder and industrial and automotive fuel and for purification/filtration of the cottage industries, the main reason why several individuals continue to produce charcoal. It is also used by blacksmiths and for other industrial applications (Chris 2007). Various uses of charcoal greatly influence the standard of living of rural people who do not have access to agricultural inputs and finances. Charcoal has a higher energy density compared with biomass fuels, and it can be stored without fear of being destroyed by insects (Seidel 2008).

Charcoal is a cheap source of energy for both rural and urban dwellers. However, modern economic activities depend mainly on petroleum products and electricity (FAO 2018). The difficulty associated with the production and use of charcoal, the growing urbanization, and the choice of urban dwellers is at a heavy drain on local wood resources (Arnold 2001).

Factors Responsible for the Production and Utilization of Charcoal

The factors that affect the production and utilization of charcoal in Nigeria.

Poverty are discussed as follows. The increase in the poverty level among Nigerians causes drives the production and use of charcoal. Although it is very essential for all the rural dwellers to use improved energy for cooking and heating, they lack the financial wherewithal to purchase kerosene, which is an alternative. They rely mainly on charcoal, which is cheap and available but has serious environmental hazards. Long gestation period of agricultural products in contrast to charcoal production that takes a lesser period of two or three weeks. Thus, rural dwellers prefer to use it as an alternative source of income to other agriculture income generating activities.

The lack of employment may encourage the mass movement of rural dwellers into charcoal production. The absence of job opportunities, especially paid ones, induces rural dwellers to participate in charcoal production as an alternative source of employment. The current economic recession in the country has made it possible to lay off both rank and file staffs in our various industries. Also, urban rehabilitation is forcing most motorcycle riders to relocate to the rural areas. This makes charcoal production an alternative source of employment.

The lack of awareness on the environmental effects of charcoal production is a serious issue. Most rural dwellers are not aware of the negative effects of charcoal production on their environment which, in turn, results in climate change. Poverty and level of education, among others, also influence awareness of the negative effects of charcoal production on the environment. Since the focus of every rural dweller is to obtain a means for survival, they are not concerned about the implications of their action.

Insufficiency of basic amenities in rural areas may trigger charcoal production. Rural dwellers usually depend on the government for their basic human needs, such as electricity, cooking gas, and the likes, in their domain. The inability of the government to provide such basic amenities triggers high production and consumption of charcoal as a perceived good source of energy for cooking and heating. Thus, the quantity of wood charcoal production in Nigeria stands at 4022763 tonnes per annum (World Bank 2011).

The lack of proper implementation and enforcement "by successive government" may affect our environment. There are good policies that have been established on forestry and allied matters in Nigeria. It is unfortunate that the change in government and loss of focus often inhibit their effective implementation. Sometimes, evaluation units to ensure strict implementation are absent. The focus of successive government always differs from one to another. However, irrespective of their different interests, every government is expected to focus on the mitigation process of climate change adaptation.

Industrial revolution: Before the discovery of oil in Nigeria, agriculture was the main occupation of about 70% of the Nigerian population, with most farmers having less than 1 ha of farming land. With the advent of industrialization, lands are cleared constantly. Thus, trees are cut down and used to produce charcoal.

The high cost of farming input can also increase the number of charcoal producers. Some rural dwellers lack the purchasing power for farm implements. As a result, they see charcoal production as a cheap means of fending for themselves when the cost of farming is high.

Effects of Charcoal Production on Agriculture

It should be noted that charcoal production has different effects on agriculture, such as lack or loss of labor. When the same labor that is expected to till the land for agricultural activities still cut down trees and makes charcoal kilns, farming activities are hindered, especially when they get quick income. It results in the reduction in the number of people in agriculture. When there are more enabling environments available for charcoal production, charcoal producers feel more comfortable in the business operation, thus decreasing the number of people involved in farming. This act will definitely lead to food shortage in the country. Charcoal production destroys arable lands. When trees are cut for charcoal production, the lands become susceptible to wind and water erosion. These negative practices eventually destroy the structure of the soil and make it infertile for arable crop farming.

Health Implications of Charcoal Production

Aside from the effects of charcoal production on the environment, there are also human health-related challenges (UNDP 2005). These include backache, heat, and cough, among other ailments, which are experienced a lot by charcoal producers. Repetitively moving heavy woods during charcoal production induces lumbar pain and muscular soreness to the producers (Tzanakis et al. 2001). It is worth noting that some charcoal producers lose their lives during the production. Accidents may also occur during the cutting of trees, kiln preparation, and loading of charcoal onto lorries. Furthermore, producers inhale gases and smoke, and the heat produced during the charcoal production is a source of ailments, such as respiratory diseases and cough. They also experience sore hands, fatigue, and chest pain. Sputum production, dyspnea, and hemoptysis are other ailments suffered by the producers.

Effects of Charcoal Production on the Environment

The major environmental problems caused by charcoal production in Nigeria are discussed as follows. Deforestation is a product of charcoal production which has significant impacts on the environment, especially with regard to increased erosion. It can also worsen climate change and threaten biodiversity. Deforestation is the destruction of forest areas for several purposes, such as agriculture, urbanization, and wood fuel and charcoal production. Charcoal production requires commercial felling of wood, thus leading to deforestation (Eniola 2014). Greenhouse gas (GHG) emission is a dangerous phenomenon of charcoal production. The reduction of forest cover also minimizes carbon consumption and results in the release of already-fixed carbon. For instance, the effect of charcoal on forest reserves is disastrous on two grounds. First, the wood fuel equivalent is four to six times greater due to the lack of a professional production process (Fig. 2) (SEI 2016). Second, emission of gas during charcoal production is significant compared with charcoal burning. Aside from the above, ecosystem destruction has a long-term negative effect on the environment. Woods are obtained illicitly from land, and charcoal producers are compelled to harvest woods to enable immediate charcoal production (Emeodilichi 2018). Charcoal producers may sometimes gather dead woods, twigs, and branches and allow trees to regenerate. Due to the cutting of live trees for charcoal production, some important wood fuel species, such as mahogany and shea tree, which were abundant in the past years, are becoming scarce (Pabi and Morgan 2002). Charcoal production also affects the soil structure in two ways: first, it impacts on the kiln site (soil) where combustion takes place as a result of huge heat that is released from the covering process, and second, it affects the surrounding/environment of the production pit. Ogundele et al. (2011) and Oguntunde et al. (2008) revealed that the soil in the site of charcoal production has a slight increase in pH. It reduces bulk density of soil surface temperature, higher infiltration rate, and surface albedo compare to places that are not subject to charcoal production (Chidumayoa and Gumbob 2012).

Fig. 2 Image of the combustion process during charcoal production in Saki from a field study conducted on April 19, 2013

Policy on Charcoal Production-Induced Environmental Problems in Nigeria

The major objective of the Federal Ministry of Environment on Forestry Policy (2006) is to achieve an acceptable level of self-sufficiency in wood products through the use of sound management methods. Hence, the main thrust of the policy is consolidation and increase in the forest estate and its management for the usage of the future generation. Due to the human-induced environmental problems, which the present forest estate cannot cope with, more forest estate is an area of land covered by different species of trees should be created in the country to prevent future disasters. Forest conservation and environmental protection are important. Our forests are no longer preserved adequately, unlike in the past. Cattle herdsmen can now be seen ravaging our forests, and wood fellers easily enter the forest and destroy the ecosystem. Thus, governments must exert more efforts to conserve our forests.

There is a great contrast between forest exploitation and forest regeneration. There should be a more increased rate of forest generation than forest exploitation to achieve a sustainable environment. There should be proper utilization of both the forests and its products. In addition, research on how non-forest products can take the place of forest products in all human activities, such as building and other energy requirements, need to be conducted. This will make the future generations benefit the forests and their products. Forest estates should be protected from fires, poachers, trespassers, and unauthorized grazers. It should also be noted that hunters, unauthorized grazers, and farmers endanger forest estates by setting them on fire to obtain their daily needs. These devastating habits must be prevented to secure the forests. The establishment of private forestry can significantly improve our forests. Thus, the government should permit and encourage private individuals to establish plantations of gmelina, teak, cashew, shear, and many other economic trees that can help to preserve and protect the enviroment. Also, the establishment of manmade forests for specific end-uses is a good means to regain the strength of forests. The government should establish a specific type of forest mainly for a particular tree user where they can go to without hindrance. The development of secondary forest products that are important in local economies and that support agro-forestry practices will boost the economy of the nation.

A policy that encourages the establishment of forestry to provide employment opportunities also needs to be implemented. The only thing that can reduce the occurrence of forest encroachment is to create more employment for people. Otherwise, more rural dwellers will rely on the forest and its products. In addition, more national parks and game reserves need to be created, and the existing ones should be properly maintained. An efficient use of wood energy and alternative sources of energy to wood fuel is also required. Lastly, cooperation among the international community with regard to forestry development must be encouraged (Federal Ministry of Environment 2006). Any law, regulations, and agenda in ensuring the sustainable use of the environment introduced by the international community must be strictly adhered to.

Problems with Policies and Practice of the 2006 Federal Ministry of Environment in Nigeria which Warranted for Its Improvement by the Federal Parliament in 2019

There are so many flaws in the 2006 forestry policies which the new one to be assented to by the President of Nigeria is expected to cater for. Among them is the alarming widespread and increasing land and vegetation degradation. The policy failed to prevent indiscriminate destruction of forests and their products. Forest users enter the forests freely and take away useful products and by-products. These nefarious acts result in fast land degradation. Every day, the influence of humans on the forest continues to increase due to the search for means of income. There are escalating real supply and demand deficits for forest products. The demands for forests and their products are greater than the available resources, which is a serious problem for the future generations. In Nigeria, credible databases are lacking, and there are no records of the quantity of woods and other products removed from the forest, of endangered species, and of future woods requirements. Moreover, the ineffective management of forest reserves is not given sufficient attention. The present system allows unauthorized grazers and poachers to enter the reserves freely. This may be due to the lack of adequate personnel, especially at the state level, and equipment to assist them in their duties. Negligible private investment in forestry is recorded in the implementation of the policy. Due to the several bottlenecks in acquiring land titles, private investors become discouraged in investing in forestry. There is abandonment of trees biodiversity that yield a low level of protection of existing reserves. Most of the forest users only prioritize their own needs at the expense of other forest products. And the protection of other forest products is being neglected. Moreover, there is a conflicting management of forests and its resources in the northern part of Nigeria. The states and local governments still compete for the control and utilization of the forest and its resources. This may be due to the fact that the environment is predominantly a grazing zone for cattle rearers.

The Climate and Development Knowledge Network (CDKN) of the UNFCCC (2015) expressed that it is very difficult for the less-developed countries, such as Nigeria, to implement any forestry policies that will give room to tangible climate adaptation strategies due to the following challenges: It is not easy to create awareness on the need and benefits of action among stakeholders, including policy makers. This may be linked to the high level of illiteracy in the country. A serious concern is how to enhance and integrate climate change into national planning and development processes. A budget allocation for climate change adaptation strategies every year can be beneficial. Also, the methods for strengthening the links between different tiers of government plans on climate change may not be easily realizable. This is because both segments of the government may develop different approaches to climate change adaptation without considering the global implications of such actions. Another method is to build capacity, analyze, develop and make use of climate change policy. There is a need for the inclusion of sound researchers in the implementation of climate change policy. How to establish a realistic mandate to coordinate actions around NDCs and drive their implementation is important to climate change adaptation in Nigeria. The best ways to address resource constraints are to develop and implement climate change policy. Both human and nonhuman resources may be considered as serious constraints, especially where expertise on climate and equipment are needed.

Factors that Make It Difficult to Plan for Alternative Environmentally Friendly Energy in Nigeria

Nigeria, in particular, and Africa, in general, are mostly affected by climate change due to indiscriminate felling of trees, poor management of agricultural lands, and other environmental pollution activities performed by man. It may be difficult to properly plan on the energy requirements of the country due to the lack of an updated population census of the country. It should be noted that the last census in the country was carried out in 2006, which reported an estimated 140 million population, which some regions in the country view as a fraud (NPC 2006). Yet, it was suggested that another census should have been held in 2016. Today, it is already 2020, and this year is not included in the budget allocation of the country. An average of about 200 million people is expected, but it is just an assumption that is yet to be scientifically proven. Thus, if energy (for cooking and heating) requirement of the country is to be adequately budgeted for, the population of the country must know otherwise charcoal production and utilization will continue to increase.

One serious factor is the lack of unique and strategic climate change adaptation policies. Apart from the 2006 forestry policies of the country which have not been adequately implemented owing to its deficiencies, no other specific climate change adaptation policies have been made. Since charcoal production constitutes serious environmental hazard to the climate of the nation, it is expected that climate change adaptation policies will cater for charcoal production and utilization must be put in place (FAO 2010). Included in the factors influencing the choice of alternative environmental friendly sources of energy in Nigeria is the lack of recent and accurate climate information that can be used in the planning for the required energy of the teeming population of the country. Even where it is available, it cannot be relied on because the modern facilities and equipment to be used are not available. The lack of an adequate subject matter specialist to interpret climate information is also an obstacle. The government or relevant agencies cannot afford the required modern climate facilities; thus, effective climate change adaptation strategies cannot be developed in the country. This will also affect the effective dissemination of such data that can be used by farmers, charcoal producers, and other land users for future disasters. Another obstacle is the poor investment in scientific research on the impacts of climate change. It is the amount of human capital invested in the study of climate change impact by relevant professions to enhance the knowledge on how to address the challenges of climate change in the country. Another factor is that most African countries have weak governance. It should be noted that all the three tiers of our government are very weak in terms of the implementation of climate change adaptation policies. Since the federal government is weak, the local government abuses the forest resources. There is no effective monitoring at the state and local levels on climate change adaptation policies, which further creates serious damage to the climate.

Strategies to Review the Existing Forest Policy on the Provision of an Enabling Environment for Sustainable Forestry Management and Development in Nigeria

To achieve an effective forestry management in Nigeria, the following strategies must be implemented. A land-use planning agency (LUPAG) should be established, and it should be noted that the existing land-use plan attached to the Ministry of Lands is obsolete and cannot cope with the trend of development in the country; hence, it should be an autonomous agency. This will enable the agency to really find immediate and long-term solutions to the problems on land utilization in the country.

The forest sector policy should be redefined considering the concepts of cognizance modern forestry. In the past, individuals did not own a forest. People now acquire lands for the purpose of establishing plantation. Land tenure systems and tree onwership should be reviewed. This will make it easier for everyone to have unfettered access to land and improve forestry development in Nigeria. In the ancient tradition of land ownership, a female does not receive support to own land even by inheritance. This practice limits their ability to use their resources to acquire wealth. Emerging products and services should also be considered. Before, only few airports, railways, and other transport services were available in the country. With the increase in population, the demand for these services will also increase, which will definitely have a serious effect on forest resources (FAO 2011). The foresrty policy should embrace corporate protection and management measures that will give both the states and the local government areas absolute control of the forest resources. It has been noted that the local governments mostly affected by deforestation do not even bother to campaign for activities to mitigate this. Hence, specific roles should be given to states and local governments.

Another adaptation strategy includes the implementation of law on the regulation of felling of trees. This law exists but is yet to be fully felt. Fellers have a free day in the forest to the extent that they cut economic trees, such as shea, locust bean, mango, and cashew trees, among others. Thus, the “cut-one, plant four” approach should be adopted. All tree fellers must be required to plant four trees as substitutes for a tree that is cut down on their personal lands. Aside the use of governement agencies as task force, various community heads should be involved in tree head count and serve as a force to implement the approach. Regulations for the exportation of charcoal are imperative. It should be borne in mind that the consumption of charcoal in Nigeria is lesser than the annual exportation. Europe is taking much of Nigeria’s charcoal, and this has been made possible by the high amount of money paid to the suppliers. In addition, seaports and dry ports in Nigeria were also not properly monitored (Mbura 2015). Monitoring, inspection and enforcement of the modern method of charcoal production processes: charcoal producers still use obsolete means to produce charcoal and it has adverse effect on the environment in that it causes pollution and endangers the ozone layer (Bailis 2009; Bailis et al. 2015). In charcoal production, sustainably managed resources, such as natural forests, planted forests, and community forests, as well as improved technologies can be used to reduce GHG emissions (Adger et al. 2003; Olson 2009; Vos and Vis 2010). The use of other alternatives to energy, such as agricultural waste and residues of wood and twig outside forests, as well as agroforestry will be advantageous. It is noteworthy that wastes from various crops, such as maize, guinea corn, wheat and oat husks, chaffs of rice, and cassava peels, are left unused and are thus burnt instead of being converted to usable energy. Charcoal dust should be converted into briquettes. Large tonnage of the dust which can be turned into charcoal are left on charcoal production sites and loading stores. However, the rural charcoal producers lack the skills to do this. Better management of local kilns increases efficiency of charcoal production. During the monitoring stage, charcoal producers may not regularly examine the extent of the smoke formed, thereby giving the kiln the opportunity to burn without complete combustion (Otu-Danquah 2010). The use of fossil fuel for transportation should be minimized. The country should research on other energy sources aside from fossil fuel for both household and industrial energy requirements. Cooking energy such as gas should be optimally utilized. If this is achieved, the cost of cooking gas should be within the reach of the poor in rural areas.

Climate Change–Charcoal Chain Sector: The Policy Options

Charcoal climate adaptation value chain is in dire need of policy implementation.

Various government agency regulatory bodies environments are used by charcoal value chain and should be harnessed effectively (FAO 2017). Based on this, policies must be formulated to improve charcoal production technology that will further enhance the sustainable deployment of resources in the forest. Moreover, there is need for an enduring policy projection that will enhance the sustenance of charcoal value chain through diversification and democratization of clean energy alternatives to lessen the increasing demand for charcoal. Incentives, reward distribution, meaningful management of forestry resources, land use planning, landscape management, and a green economy are important to greening the charcoal value chain (Minten et al. 2013). Technological advancement is imperative due to the differences in taxation that could have assisted the incentivization of sustainable sourcing and production of charcoal through fees and licenses. Global fiscal devices related to climate change reduction, such as the clean development mechanism, and reducing emissions from deforestation and forest degradation can provide financial boosts. Effective forest law enforcement and administration are important to boosting government income generation and investments through sustainable forest management and efficient techniques for wood conversion (Sander et al. 2013). To limit the excess of charcoal producers, in May 2016, Nigeria banned charcoal production when producers and exporters failed to adhere to the cut-one, plant four policy. It was not more than 2 months when a serious outcry from the populace crippled the restriction since charcoal is the major source of energy in the country. “The problem is complicated because the Federal Government owns the policy and the machinery to enforce the law, but the states own the forest. The states also see logging as a form of revenue generation.” Since the government fails in that regard, a serious alternative, such as solar energy, has been targeted as it is environmentally friendly and economically viable. The big question is, how many people could afford it? Nigeria’s National Council on Environment reiterates that the country needs an effective policy to promote solar energy and efficient cooking stove. Although the focus on renewable energy is a right step forward, its success will largely depend on how Nigeria is able to sensitize the people to adopt it. Improved monitoring of rural dwellers can enhance their willingness and preparation to invest in enduring methods. Traditional leaders still hold much title on land acquisition even more than the government. They place difficult conditions on land acquisition which prevent long-term investment in forestry. The transfer of responsibility and provision of financial and human resources to grassroot authorities can boost sustainable forest management and charcoal production. Formulation of policies encourages private sector participation in the dissemination of improved technologies as well as the establishment of marketing system for sustainable products. The government, private sectors, producers, and consumers have a lot to gain through proper planning and decision-making process for charcoal management. Openness in revenue channels and accountability of all players in charcoal production are important to the growth of national and local economies. A solid institutional framework comprising of forest managers, tree growers, charcoal processors, and traders is inevitable to achieve effective coordination of initiatives that will help develop a sustainable charcoal value chain as well as elucidate the mandates of the stakeholders. Charcoal chain reform should establish a firm relationship among major actors. It should be conscious of the danger of corruption as well as protection of the few policies that are designed for the regulation and improvement of the value chain. Measures that will help secure and protect the rights to energy access of those who do not have options should also be considered. For instance, despite the fact that the 2013 European Timber Regulation (EUTR) stipulates that there should be no illegal exportation of any wood products to its members countries, they do not monitor charcoal importation. Charcoal bags are labeled with tags, such as sustainably cultivated, regardless of the type of wood the charcoal is made from.

Panacea for Greening Charcoal Value Chain

To improve the charcoal value chain, multiple concurrent interventions should be promoted to significantly lessen GHG emissions (Beukering et al. 2007). A green charcoal value chain needs financial viability that is best guaranteed through the improvement of tenure arrangements and legal access to resources. This will improve the purchase of wood and other biomass for charcoal production. It will also ensure the merits of a green charcoal value chain for the economies in the countries by placing financial premium on wood resources and incentivizing long-term practices and attractive investments that will induce a smooth movement. A comprehensive national foresrty policy framework should be developed for its sustainable administration and integration of charcoal with greater efforts across sectors to reduce the incidence of climate change. This will make climate change specific component of NDCs. Furthermore, governments and other key players should be supported in greening the charcoal value chain through research contribution. There should be holistic methodical examinations of charcoal value chain in major countries where charcoal is produced. In addition, information on GHG emissions at diverse levels of the charcoal value chain should be available (Bailis et al. 2005) as it will facilitate in the greening of the charcoal value chain. The role of charcoal production in deforestation and forest degradation, including other forms of deforestation and forest degradation drivers in urban should be assesed at everytime before leading to devastated level; socio-economic and environmental results and trade-offs of a green charcoal value chain at the local, subnational, national, and regional levels as well as the spread, results from pilot projects, success stories, and research within the entire charcoal value chain are essential.

Agricultural Adaptation Strategies to Climate Change that Can Reduce Charcoal Production

Great efforts must be exerted to encourage rural dwellers to go back to farming amidst the climate change that has destroyed the natural environment. Various agricultural adaptation strategies must be adopted to manage the soil resources such as mixed cropping. Mixed cropping is the practice of growing two or more crops together in the same field. It was derived from the traditional method of utilizing land particularly where there is shortage of land. For instance, cereals such as maize, sorghum, and legumes (cowpea and groundnuts) can be planted together. Mixed cropping is advantageous in that it varies in the period of maturity such as maize and cowpea, drought tolerance (maize and sorghum), input requirements (cereals and legumes) and final users of the products (e.g., maize as food and castor oil for cash). Hence, farmers should be encouraged to practice mixed cropping to maximize lands. Improved irrigation efficiency is required to make farming a business throughout all the seasons. Achievement in climate change adaptation depends on the access to adequate water in drought-prone areas. Knowing full well that water can be an inhibiting factor, improved irrigation efficiency is a significant adaptation device toward realizing food demands, especially during off seasons. Harvest during the dry season usually attracts good market price compared with that during the rainy season (Orindi and Eriksen 2005). Thus, there is a need for the adoption of soil conservation measures. Soil conservation deals with the proper timing of various farming activities that demand local experiences, burying of crop residues to improve soil fertility, burning of crop wastes to achieve quick release of nutrients, and allowing animals to graze on farmlands after harvesting crops to improve soil organic matter. Mulching is also important for controlling soil temperatures and extreme water loses. In addition, it prevents the emergence of diseases and harmful pests and conserves soil moisture. Before the advent of chemical fertilizers, rural farmers heavily depended on organic farming, which reduces GHG emissions. Planting of trees (afforestation) and agroforestry are mechanisms of soil preservation. Tree planting is the technique of transplanting seedlings for the following purposes: forestry, land reclamation, and landscaping. Tree planting in silviculture is called reforestation or afforestation, depending on whether the area that is used for planting is or is not recently forested. It involves planting of seedlings over an area of land where trees and plants have been removed by man, fire, or pest and diseases. The free distribution of tree seedlings to farmers to achieve quick afforestation is a method of adapting to climate change (Akinnagbe and Irohibe 2014; Bird et al. 2011). With the reduction in the quantity of available water for crop production, there is a need for crop breeders to provide varieties of crops that are resistant to drought. These crops can be planted in drought-prone areas to lessen their vulnerability to climate change. For example, oat and wheat require fairly less irrigation water compared with dry-season rice. Furthermore, drought resistant crop varieties have been subjected to test by smallholder growers as adaptation methods to climate change in Nigeria, Senegal, Burkina Faso, and Ghana (Ngigi 2009). Furthermore, crop diversification should be encouraged. medium or long time crop production is a possibility in diversification to high-value crops. The diversification of crop planting is an adaptation mechanism prioritized in areas where irrigation is used or not used. Thus, farmers should be encouraged to change the type of crop they plant to curb the risk of low yield from harvest on farm (Orindi and Eriksen 2005; Adger et al. 2003). Crop diversification can be a buffer against variations in rainfall. In addition to the changes in cropping patterns and planting calendars, long-term alterations in rainfall due to climate change can negatively impact crop production. Thus, it is important for extension agents to orient rural farmers. Such an orientation will enable the farmers to familiarize the trend of cropping patterns in their domains. Essentially, shifting from charcoal production to other livelihood activities will prevent our environment from further deterioration. Most rural dwellers consider charcoal production as their last resort to generate income (Eniola 2014). Hence, there is a need to create awareness on other livelihood activities, such beekeeping, mushroom farming, fish farming, and horticultural farming, among others, with special financial support from the government and other non-governmental agencies.

Conclusion and Recommendations

This chapter concludes that the government in Nigeria needs to exert more effort on climate change adaptation, especially in terms of the eradication or reduction of the threats posed by charcoal production to human health and the environment. Charcoal production cause severe damage to both the environment and humans, thus leading to the reduced number of people engaging in farming activities. Quick actions in ensuring impeding food shortage and rebuilding the forest must be taken so as not to jeopardize the future need of the forests by the coming generation. The country should strictly adhere to the laws, regulations, and policies of the international bodies on climate change adaptation. Alternative means of livelihood, such as fish farming, mushroom production, vegetable production, and other simple and cheap farming activities, should be embraced by farmers. The reduction of the number of rural dwellers involved in charcoal production will go a long way.

Abstract

Water resources will be significantly impacted upon by climate change, and these impacts will be transmitted to the many sectors and services dependent on them. The nature, extent, and timing of these impacts remain uncertain, but the long lifetime of water infrastructures requires that their planning, development, and operations should be resilient to climate changes. An effective approach is to focus on the management of current climate variability as it relates to water, which strengthens the ability of communities and countries to foresee, manage, and adapt to the impacts of longer-term climate change on water-related activities. This approach is illustrated by cases from Southern and Eastern Africa.

Current "stationary" stochastic methods of hydrological analysis can still be used under assumptions of a "dynamic stationarity" although more regular updating of hydrological data will be required. Methodologies to evaluate economic dimensions of risk reduction introduce additional uncertainties but may help decision-makers to understand the risks and opportunities. Diversification of sources and sequencing of resource development pathways are helpful strategies to adapt to climate change but must ensure that risks affecting different sources are not correlated. Attention must also be given to demand-side interventions in order to reconcile supply and demand, and these perspectives must be shared with social, economic, and political actors to ensure that strategies are communicated, understood, and supported by the wider community.

Introduction

There is international agreement at the UNFCCC about the need for collective action to address the likely impacts of global warming on human societies. One response has been to encourage all sectors of society to identify and implement actions that can help adapt to the emerging impacts of climate change and work to mitigate its drivers.

Water resources and the services dependent on them are an integral part of the climate system (Chahine 1992). Because of this, the managers of water resource systems and of the services that depend on them must develop appropriate responses to the potential impacts of climate change (Strzepek et al. 2011).The African continent is considered to be particularly vulnerable to these impacts both because of their magnitude and because African societies have less physical, financial, and human resources available to address these impacts.

A further challenge is that the impacts of climate change on water resources are local, diverse, and not well-characterized. Unlike the general global warming trend, for which there is robust evidence that is consistent with the predicted impact of anthropogenic activities, direct evidence of significant changes in hydrological variables is not nearly as strong and consistent.

For example, it appears that at a global level, precipitation is increasing (Adler et al. 2017). However, models predict increases in drought frequency over significant areas due to warming (Ukkola et al. 2020) although empirical evidence in support of this is limited (Hegerl et al. 2019) and predictions are based on various definitions of drought.

While warming trends are a direct result of anthropogenically induced atmospheric changes that act through a single dominant mechanism at global level, the impacts on the main hydrological processes – evaporation, precipitation, runoff, and infiltration – are secondary and tertiary effects that are further influenced by a wide variety of mechanisms at a local, regional, and global level. So while there is only a limited increase in global precipitation averages, there are more extensive regional variations and substantial changes in parameters such as rainfall intensity (Trenberth 2011) which, coupled with the impact of warmer temperatures on aridity, lead to changes in tertiary variables such as stream flow.

The likely impact of climate change on hydrological processes is generally still too uncertain to make it possible for water resource planners and managers to identify locally specific adaptive measures. So climate change models and predictions cannot usually guide well-founded planning and operational decisions although they do help to suggest the boundaries for extreme events.

However, policy-makers like the UN High-Level Panel on Water want to know what impacts global warming will have on water systems and how they will be dealt with. It is suggested that an appropriate response is to continue to build on the great strength of best practice in water resource science and management, which is its ability to characterize and manage climatic *variability*. This requires that the approaches used move beyond the assumptions of a stationary hydrology and can accommodate a changing climate (Brekke et al. 2009).

Yet water managers are already responding to climate change through their management of current climate variability. However, to make this case convincingly, they must demonstrate that current methodologies are adequate for the task. To address this in an African context, this chapter:

– Characterizes the "difficult hydrologies" that pose particular challenges in Africa and shows how climate change science has helped to understand the climate variability inherent in those hydrologies
– Considers some analytical tools that are used to manage under assumptions of "stationary hydrology" and whether they can be adapted reflect "dynamic stationarity"

– Presents six African cases that illustrate how the management of current variability is supporting adaptation to potential climate change impacts

Drawing on lessons from these cases, some conclusions are drawn about approaches that, while deriving from current hydrologies, are more explicitly adaptive and will be resilient in an uncertain future.

A supply-side focus is taken because the availability of water is most directly impacted upon by climate change. The demand side is equally important and challenging, but human behavior and social institutions that guide it merit separate consideration. The reconciliation of supply and demand remains the ultimate technical goal of water management.

Characterizing Hydrological Variability and Climate Change Impacts

Current Hydrological Variability

Climate warming due to anthropogenic activity is a global phenomenon, but its specific impacts on water resources depend on local conditions, including current climatic variability. Water resource managers need to characterize that current variability if they are to manage it successfully. This characterization provides the foundation from which to review the impacts of climate change on water resources and the hydrological cycle.

The primary driver of the hydrological cycle is the interaction between incoming solar energy and the large mass of water in the oceans. However, water managers necessarily focus on rainfall, whose duration, intensity, and distribution in space and time drive other elements of the hydrological cycle: surface runoff, infiltration, and evapotranspiration. The interaction between these variables then determines the stream and groundwater flows, whose magnitude and fluctuation are the "raw material" of water resource management.

"Easy" Versus "Difficult" Hydrologies

From this perspective, climate creates the hydrological context both for the "natural" biosphere and for human communities and their activities that depend on it. But it is the variability of climate as much as the average values of its component elements that determines whether the resulting hydrological context enables communities to establish and sustain productive and congenial environmental niches. Grey and Sadoff (2007) echo previous investigators, suggesting that climatic variability has been a determining factor in the social and economic development of different societies.

> A nation's hydrology will clearly affect the level of institutions and investment required to achieve water security. The absolute levels of water resource availability, its inter- and intra-annual variability and its spatial distribution, coupled with the demand for water, will largely determine the institutions and the types and scale of infrastructure needed to manage, store and move the resource. The resilience of the structure of the economy to water shocks, together with societal resilience and risk aversion will also be determinants of the level of investment required for specific countries to reach the tipping point of water security.

A distinction is drawn between "easy" and "difficult" hydrological legacies. An "easy" hydrology is characterized by adequate rainfall with little variation between seasons and years. Such hydrologies sustain predictable perennial river flows, supported by reliable groundwater availability. The predictability of the hydrology and its relative consistency makes the management of water for different purposes relatively easy, facilitating the conceptualization and operation of infrastructure as well as the establishment of the rules that govern the entitlements and obligations of water users.

Regions with difficult hydrologies require stronger institutions as well as higher levels of physical investments in order to support basic activities such as agriculture or even simply to meet domestic needs. One reason that many poor countries remain poor is that they could not accumulate the resources needed to achieve the water security on which higher levels of development depend. As summarized, difficult hydrologies include:

- Absolute water scarcity
- Low-lying lands subject to severe flood risk
- Markedly seasonal rainfall which requires the storage of water
- High inter-annual climate variability, where unpredictable risks require over-year storage
- A combination of extreme intra-annual seasonality and inter-annual variability

This crude distinction between difficult and easy hydrologies highlights the need to understand existing climate variability before focusing on the potential impacts of climate change. At the least, water managers need to understand the key systems that drive their local climate and the extent of uncertainty about the resulting rainfall patterns and related hydrological parameters in order to identify sustainable strategies for their water resource development and management.

Climate Change Science Has Helped to Characterize Climate Variability

Paradoxically, climate change science must build on an understanding of "normal" climate variability in order to attribute any phenomenon to climate change rather than simply a "normal" extreme. So while the Sahel droughts of the 1970s/1980s were often attributed to climate change, evidence of subsequent "rainfall recovery" suggests that this was simply long-cycle climate variability, perhaps aggravated by land- and water-use changes (Sidibe et al. 2018).

There are similar debates about changes in the intensity and frequency of the occasional and unpredictable tropical storms, an important factor in the hydrology of Southeastern Africa (Malherbe et al. 2012). Claims that those storms were becoming more frequent and intense due to global sea warming have subsequently been challenged, since the 35-year-long satellite data set on which they were based is relatively short; it is now suggested that tropical storm formation was mostly influenced by long-cycle variations in the phenomena such as ENSO and the Indian Ocean Dipole (Chan 2006).

The hypothesis that storm frequency is increasing due to global warming is also not supported by later studies, and it is even suggested that south of the tropic of Capricorn, where storm numbers were expected to increase, they have actually decreased (Pillay and Fitchett 2019). However, the debate continues, and there is continuing uncertainty about likely changes in cyclone frequency and their regional prevalence (Knutson et al. 2020).

Variations in lake levels are also often attributed to climate change with recent fluctuations in Africa's lakes Victoria, Chad, and others specifically cited, although with acknowledgment that human influence is also a factor. Yet many of Africa's shallower African lakes are known for their variable levels (Conway 2005).

Lake levels are arguably more useful as indicators of the impact of climate *variability* than climate *change* since they are determined by the climate over the lakes and their catchment areas as well as the impact of human activity. A recent global review found that background climate variation due to multi-decadal climatic oscillations such as ENSO accounted for 58% of the variation in lake levels; a further 10% variation was due to normal seasonal effects. It was concluded that apparent trends attributed to anthropogenic activities were often exaggerated by this "normal" background variation and that due attention should be given to background climate variation before claiming climate change impacts (Kraemer et al. 2020).

These examples show that it is necessary to correct the current popular (and academic) discourse in Africa and elsewhere which sees water managers, policy-makers and political heads attribute many extreme events to climate change, although climate records show that neither the event nor its frequency of occurrence is inconsistent with patterns evident in the historical record.

Predictions of Climate Change Impacts on Hydrological Processes

There is no doubt that global warming is already having a variety of impacts on hydrological systems. However, while some impacts are known, others are uncertain and are likely to vary significantly from place to place. These uncertainties need to be better understood and communicated by practitioners to policy-makers and publics.

Some climate change impacts are directly related to the impact of anthropogenic warming on specific hydrological variables. While the water-holding capacity of air increases with temperature, this does not necessarily mean that global rainfall will increase at the same rate. However, recent work concludes that observations confirm modeling predictions that rainfall does increase with rising temperatures and that this is associated with a change in the intensity and timing of rainfall events (Giorgi et al. 2019). It is also evident that there are regional changes in the distribution of rainfall although uncertainties remain about these important relationships (Herold et al. 2017).

Similarly uncertain is the impact of warming climates on soil moisture, a hydrological variable that underpins the agricultural activities on which human societies depend and which are, by far, the largest direct "users" of water. Aridity, the ratio between precipitation and potential evapotranspiration, is expected to impact on surface water runoff, a critical process for water management.

Aridity might be expected to increase with global warming since evapotranspiration is greater under higher temperatures, but this is not universal. Globally, some arid areas (in the Americas) have become wetter, whereas previously semi-humid areas (particularly in Asia) became drier. And significant discrepancies are reported between model predictions and direct observations leading to warnings that the general conclusion that climate change will result in "overall drier conditions across the globe" might be "at least partly misleading" (Greve et al. 2019).

The discrepancies are attributed, in part, to the fact that the increased CO2 that drives global warming also changes the vegetation types, which may use water more efficiently. As the authors explain, ". . ..changes in atmospheric CO2 break the existing correlation between hydrology and ecology by changing the water use efficiency of photosynthesis."

These issues are important for sub-Saharan Africa where bush encroachment is reducing the animal carrying capacity of semiarid rangelands although human changes in land use are at least as important as climate change in driving this process (Venter et al. 2018). What is important for water managers is that changes in aridity and land cover will change the relationship between rainfall and runoff, potentially affecting water resource availability (Zareian et al. 2017) and leading to significant stream flow reductions.

These processes are complex, and outcomes will be determined by locally specific conditions. The proportion of rainfall that reaches a stream or recharges groundwater is determined by the amount of rainfall, its intensity and duration, prior soil moisture, as well as temperature and land cover. One response to this complexity has been to apply catchment models, developed to provide guidance on rainfall-runoff relationships. But these models are based on historical circumstances that may not be appropriate under new conditions of climate and land cover. In Australia, historical rainfall-runoff models might produce valid results under future climates, but only if rainfall changes were relatively modest (Vaze et al. 2010). In Europe while runoff correlates closely with soil moisture, relations with precipitation and temperature are weaker, and a recent survey identified a better understanding of runoff dynamics as a priority "unsolved question" for hydrologists (Blochl et al. 2019).

Tools to Manage "Dynamic Stationarity"

There will clearly be continuing uncertainty about climate change-driven hydrological trends due to the wide diversity of water resource contexts in which hydrological processes occur. Furthermore, substantial "normal" variability will often mask smaller climate change impacts.

It is thus appropriate for practitioners to focus explicitly on managing climate variability. This is not an argument for "stationarity" (the assumption that climate is not changing) nor a suggestion that water resource planners should ignore warming-related climate change. Rather, it is a practical response. While it has long been accepted that hydrological analysis must reflect the changing climate (Moss and Tasker 1987), tools developed under assumptions of "stationary" hydrology may yet be used under the new conditions of hydrological dynamism (Milly et al. 2008).

Right Tools for the Right Job: But which Job?

Water resource practitioners use a wide variety of tools to guide their decisions, but their tools' limitations and their adaptation to address changing climates must be considered in the context of the functions that they support. These include:

- Monitoring and information management, about both resource availability and resource use
- Planning, to determine trends in resource availability and use and to inform options, identification, and analysis
- Allocation, to ensure that water use achieves society's objectives within the constraints imposed by the resource itself
- Development of infrastructure, to make water available for use as well as to maintain its quality
- Sustainable operation of complex infrastructure systems
- Protection of the environmental condition of the resource

The timeframe and nature of guidance that will be required vary dramatically between the functions, and the tools provided have to be appropriate for the purpose:

- Planning requires projections of the yield available from different sources and systems, often over very long time horizons (50–100 years in the case of large systems) with indications of assurance derived from assumptions about the variability of the resource. While climate change is clearly relevant over long time horizons, planning does not necessarily commit to specific actions until firm decisions are taken.
- Infrastructure must optimize output based on design requirements and be guided by estimates of the magnitudes of extreme events that could lead to failure. The long lifetime of water resource infrastructure limits the subsequent adoption of alternative options and enforces a degree of "path dependence" (Hüttl et al. 2016).

– System operation needs short-term (seasonal up to 5 years) guidance to maintain supply assurances, while flood routing requires real-time models.
– Water allocations to users must be informed by "normal" availability of supply but allow adjustment for contingencies such as drought as well as to cater for future climate change (which is often missing from legal frameworks despite earlier warnings (Trelease 1977)).

In summary, water resource managers must be enabled to (i) make reasonable predictions about the potential yield of sources and systems over time; (ii) provide guidance based on variability parameters to support system restrictions during drought; (iii) provide robust, conservative information about risks posed by extreme flood events; and (iv) operate their systems to achieve reasonably predictable outputs under variable conditions.

What Tools Are Available?

Simple rainfall-runoff models, developed to support urban drainage design and flood estimation, were of limited value in larger catchments, particularly in the absence of information on rainfall characteristics. The development of stochastic techniques to provide rainfall and river flow estimates and guide reservoir operation greatly expanded the analytical capabilities of water planners.

The complex relationships between hydrological variables, the diversity of situations, and the volume of data involved meant that key concepts could only be translated into tools for practitioners when modern computing power became available. The Harvard Water Program developed many methodologies using "synthetic" or stochastic hydrologies (Maass et al. 1962) not just to solve hydrological questions but also to support the economic optimization of water projects.

There is now a wide variety of hydrological tools and methodologies that have been applied. Loucks and van Beek's extensive compendium (2017) (Loucks and Van Beek 2017) links the technicalities of methodologies and models to their application in real-world planning problems. These are supported by new streams of data from remote sensing although this does not fully compensate for the decay in the physical observation network (World Bank 2018a). The challenges posed by climate change have led to suggestions that a new Harvard Water Program is needed.

To address some of the functions outlined above, tools used include the following:

Stochastic Methodologies to Estimate Flow and Rainfall

The stochastic methodologies described above have transformed water management. When applied with the requisite caution and skill, they enable planners to extend short flow or rainfall records to provide reasonable estimates of mean and extreme flows at different levels of assurance as well as to provide synthetic "records" for ungauged rivers and catchments. Stochastic models lend themselves to testing hypotheses about the potential impacts of changes in rainfall patterns and (given the computing power now available) can generate and test large numbers of synthetic sets of rainfall and flow to determine sensitivities to different climatic circumstances. Climate change does, however, mean that the value of such methodologies depends on the regular updating of the data on which they are based.

Catchment-Scale Rainfall-Runoff Models to Support Yield and Operations

Catchment-based rainfall-runoff models are also widely used to estimate the potential yield of different sources and systems and to support operations ranging from drought management to flood routing. The rainfall-runoff relationships can be extrapolated from known areas to similar, poorly gauged catchments to predict stream flows and guide water management more generally (Vogel 2017). Such models can provide a structured basis for yield estimation taking account of new flow and rainfall records and changes in land use (see, for instance, the South African framework which has evolved over the past 60 years) (Bailey and Pitman 2016). While the maintenance of these models requires consistent investment in both physical data collection and subsequent processing, they provide an invaluable basis for the planning, expansion, and operation of large systems. The evolution of the planning and operational models for South Africa's Vaal River System (see below) provides an instructive insight.

Methods to Determine the Scale of Maximum Probable Events

A particular challenge in designing large water resource infrastructure is to ensure that it is resilient to the most extreme event "likely." The primary determinant of the scale of the "probable maximum flood" is the probable maximum precipitation. Since the objective in determining the PMF is to identify a worst-case scenario, this is a case where the application of multiple climate models can be useful since there will be a strong argument for selecting the highest value generated (Gangrade et al. 2018). For these kinds of events, in large catchments, catchment dynamics and land-use changes have less influence.

Right Tools in the Right Place: At the Right Time

One consequence of the huge diversity in the local hydrological regimes on which societies' water supplies depend is that technical paradigms that work well in one context have often been promoted inappropriately in others (Woodhouse and Muller 2017). Aid-dependent African countries have been particularly vulnerable to this trend because approaches promoted often reflected donor country conditions or the educational system in rich countries simply assumes that its approach is globally appropriate (Briscoe 2010). The promotion of a reliance on "green infrastructure" rather than built infrastructure is a recent incarnation of this trend (Muller et al. 2015).

While environmentally focused approaches may be appropriate in temperate developed countries, they do not help communities under more challenging climates in Africa, Asia, and Latin America where populations and economies are growing rapidly. Aside from the socioeconomic conditions, there are dramatically different topographies, geologies, and climatic conditions of aridity and often greater inter-seasonal and inter-annual variability of temperature and precipitation.

There are stark contrasts in the physical context for water resource management even in developed regions, between Europe's temperate northern regions and its Mediterranean south and temperate northeastern USA, its humid, subtropical south-east, giving way to semiarid southwest. In each region, the character of water resources and thus the options available to address water resource challenges are different, and different tools of analysis will be used. A further key differentiator is the human and financial resources that can be brought to bear: "With increasingly 'difficult' hydrology, the level of institutional refinement and infrastructure investment needed to achieve basic water security becomes significantly greater than in temperate (and less variable) climates" (Grey and Sadoff 2007).

There must be appropriate responses to current variability and uncertainty before the particular challenges of climate change can be addressed. For many countries, the priority problems relate to present water insecurity, not future climate change. As the cases below show, responses to, for instance, urban water shortages are unlikely to be much altered by considerations of climate change.

When solutions proposed could increase future costs and risks, climate change considerations become important. What is most immediately important in (relatively) poor communities and countries that do not have acceptable levels of water security is the efficient and effective use of scarce resources to deal with current variability. Many recent water "crises" popularly attributed to climate change have been the consequence of a failure to prepare for current variability. Opposition to long-run investment decisions (Matalas 1997) aggravates immediate problems, with limited evidence of long-run negative consequences. Often, it reflects policy preferences rather than any well-founded evidence of harm or risk (Muller et al. 2015).

From Tools to their Application: Some Case Studies

Water management practitioners have available a plethora of tools of increasing complexity and cost (as measured in human resources, finances, and data) to help them to manage climate variability. Yet the extent to which these tools can help water managers to address the challenges of climate change is limited. How should the practitioners proceed?

This is more than a technical issue. Water is managed to achieve a wide variety of societal goals, and water managers operate under a range of technical, financial, as well as social and political constraints and produce a variety of economic benefits. Tools to analyze the performance of water projects are also needed to assess their financial risks and economic returns in many different contexts.

A new mining or agricultural business may require a secure water supply. Governments seek to reduce poverty and promote greater economic inclusion by providing irrigation water, enabling poor farming communities to improve their productivity. Power utilities seek competitive, reliable energy sources. Urban managers, concerned about the disruptive effects of water restrictions due to drought, want to enhance water security.

Water managers and their institutions must be able to respond authoritatively to both political decision-makers and their wider communities. Most stakeholders will be concerned about the risks that climate change is assumed to pose and will need some assurances that these have been adequately addressed.

In this section, a number of cases from Southern and Eastern Africa are presented that show how water managers have used available tools to achieve specific water management objectives by addressing climate variability and concerns about climate change. The cases locate climate variability and change challenges in a wider socioeconomic context and consider whether the approaches adopted have increased resilience to potential climate change impacts. Three of the cases were included in a World Bank study of resilience in African infrastructure which aimed to develop processes that support "robust decision-making" (RDM) (Cervigni et al. 2015).

Cape Town's Day Zero Drought: A Failure to Acknowledge Risks of Climate Variability

Between 2015 and 2018, droughts in the extreme south west of South Africa saw the City of Cape Town suffering serious water restrictions. It was widely reported that the city faced a "Day Zero" on which its water supplies would "run out." These events, copiously documented, were widely attributed to climate change.

However, over the previous decade, there had been repeated recommendations from national technical and planning agencies calling for investments to augment, by 2015, the supply capacity of the Western Cape Water Supply System (WCWSS), on which the city depends (Muller 2018). These recommendations were based on a long-term WCWSS strategy study, informed by a hydrologically based system model that had successfully been used for two decades.

The model's projections of the supplies reliably available from existing sources were set against projections of water demand in a "reconciliation" process. This identifies any requirement for increased supply, the primary driver being the needs of Cape Town's growing population. The interventions proposed were sequenced on a "least-unit-cost" basis. Records of meetings in 2013 and 2014 suggest that the city believed that its efforts to manage demand had constrained growth and that further supply expansion would only be required in 2022.

Even before the drought ended, implementation had begun of infrastructure projects that had earlier been rejected – including water reuse and groundwater development as well as additional surface water. Consideration is also being given to a large desalination installation which could be used during drought periods.

The vulnerabilities of the WCWSS are now obvious. The system depends on rainfall over a small (800km^2) area of mountain catchments supplying dams whose storage is less than 2 years of "normal" use. Climate change dynamics are also under review. Cape Town lies at the edge of dominant rain-producing weather systems and has long been identified as an area vulnerable to climate change-driven rainfall reductions (Archer et al. 2019). From an adaptation perspective, the questions are whether the shift of weather system is permanent and the nature of an appropriate adaptation response.

The city's new postcrisis strategy (Cape Town 2019) acknowledges continued dependence on surface water for 75% of its supplies for at least the next decade, while alternative sources such as reuse, groundwater, and desalination are developed to provide a greater proportion of supplies in the future.

Climate uncertainty is specifically addressed. The program aims to increase the assurance of supply from the system from 98% to 99.5% but acknowledges that there might be "a step change in rainfall due to climate change . . .. If this turns out to be the case, the programme will be both accelerated and expanded."

The strategy also acknowledges that water investments must provide regular supplies during periods of low rainfall: "All water schemes provide insurance against periods of low rainfall, which may become more frequent and more severe as a result of climate change." It recognizes that expensive supplies from reuse and desalination will not be used all the time but concludes: ". . .this will not have been wasteful expenditure. The future is uncertain, and the cost of very severe restrictions is much higher than the cost of insuring against this likelihood."

In this regard, the city's strategy now explicitly addresses climate change. But rather than placing reliance on forecasting future availability, it seeks to increase reliability (through infrastructure investment originally proposed to address variability) to "buy time" for implementing rapid interventions such as desalination if required.

Mombasa, Kenya: Climate-Resilient Designs Constrained by Institutions and Finance

Greater Mombasa, Kenya's second largest city, had a population of approximately three million people in 2018. It is Kenya and the East African region's primary port and is also a center for international beach tourism which complements the country's inland game park complexes.

Water supply is deeply deficient. Water requirements are estimated to be in the region 250 Ml/day, but the city is in a permanent state of water crisis, able to provide less than 30% of this potential amount (Foster et al. 2020). Small supplies from local coastal aquifers are at the limit of their available capacity and face problems of salinization. The city's primary supply comes from two distant groundwater sources, the Mzima Springs (200 km away) and Baricho (100 km).

Unusually, local surface water sources had not been tapped although the need for a new source had already been identified in the early 1990s. The preferred augmentation project, now in preparation, is a dam on the small, local Mwache River.

All five projects in the 2015 World Bank infrastructure resilience study (Cervigni et al. 2015) which included Mwache faced considerable uncertainty about future rainfall under climate change. In none was there even a consensus on whether it would be higher or lower than present-day averages, let alone by how much. This was a particular concern for Mombasa whose rainfall derives from a combination of systems since 61% of the 121 climate future scenarios generated for Mwache showed lower safe yields than the present-day design assumptions.

The World Bank study took a measured response to this systemic uncertainty. It distinguished between project *sensitivity* to climate change and project *vulnerability*; sensitivity refers to the possible reduction in physical "output," while vulnerability considers the impact on economic return. In this view, even if a project's performance is potentially sensitive to climate change, "the project's economic worthiness is not necessarily in question." This would include cases where the project was robust to a high degree of climate variability "and in the bargain, to climate change" so that its benefits and revenues would meet the required criteria.

"It is thus important to distinguish between climate sensitivity and vulnerability" emphasized the report, noting that both sensitivity and vulnerability would depend on the metrics used to assess performance and that factors other than climate change, such as price and demand, could be equally important.

For Mwache, although limited hydrological information was available, the design chosen was considered to have low climate risk since the river flow is considerably in excess of supply requirements and there is a low risk that the dam will not meet its target yield (World Bank 2018b).

Funding has not yet been approved, not due to climate change risks but because the financial and institutional arrangements for the dam's management must still be resolved. Kenya's 2010 Constitution makes water supply the responsibility of local counties. But Mombasa's current supplies come from other counties, and the Mwache Dam itself will be built in a neighboring county.

Current proposals are to establish a regional institution that would manage all the different sources into a single system, providing bulk supplies to the major centers of four counties. This would help to address climate risks since linking different sources into a single system would increase its resilience to climate variability, maintaining supplies even if one source in the system fails. But achieving financial agreement between four counties and national government is proving to be more difficult than finding a climate-resilient dam design.

Windhoek, Namibia: A Climate Secure Source Using Groundwater as Storage

Namibia's capital Windhoek, high in the center of the arid and sparsely populated country, was established in 1892 by German colonists, attracted by the secure source of water from local springs. This groundwater resource served the growing settlement well until the 1960s when, after a series of dry years, it became obvious that additional supplies were needed.

In 1968, a "direct potable reuse" plant was built that treats wastewater for reinjection into the city's main supply. Subsequently expanded, it can now provide 20% of the city's potable supply. An ambitious longer-term plan envisaged a phased regional scheme, the Eastern National Water Carrier (ENWC), drawing from

Southern Africa's third largest river, the Okavango, on Namibia's border with Angola, 700 km from Windhoek. The full project has not yet been completed, but growing demand has been met by intermediate interventions, including the development of new groundwater sources on the ENWC route. Throughout this period, the city's local groundwater complemented other sources.

The use of these multiple sources varies in response to the extremely variable climate, with surface water predominating in wet seasons and greater use of groundwater and reuse in dry periods. Local aquifer recharge has recently been introduced to store surplus water in wet periods, reducing evaporative losses from the surface reservoirs and increasing system yield (Murray et al. 2018).

However, while diversification of sources provides some additional resilience to inter-seasonal climate variability, the assured yield still depends on local natural recharge supplemented by surface water imports. Drought in 2015/2016 showed that despite tightly managed demand, additional supply was needed and attention turned once again to imports through the ENWC. Although capital and operating costs appear to be prohibitive, this would substantially reduce climate risk by diversifying to an unconstrained source.

In this difficult environment, available hydrological tools have consistently provided good estimates of the volumes of water available at different levels of assurance to guide system management. The technical analysis of the recharge and storage potential of the Windhoek aquifers has also provided the basis for implementation. Although the impacts of climate change on regional precipitation and Okavango River flows are uncertain (Hughes et al. 2011), Namibia's requirement is only around 2% of the total flow, suggesting that the objections of environmentalists in Botswana, the downstream riparian, are ill-founded.

The other long-term policy option is to break the "path dependence" since Windhoek was made the country's capital 130 years ago and promote economic development in Namibia's more humid northern region rather than increase the city's water supply. Absent such a radical policy shift, the incremental completion of the ENWC is a rational approach to making Windhoek's water supply more resilient since the scope for further savings through demand-side interventions is limited.

The city's century-long hydrological history and the acute nature of the water challenges that it faces have produced a good understanding of the options available to build systems that are resilient to the risks posed by long periods of multi-season drought. As a result, if adequate financial resources are available, the strategies already adopted to manage current climate variability will enable the city to meet its needs, even under conditions of climate change.

Beira, Mozambique: Sea Level Rise Will Compound Existing Challenges

Like Windhoek, the Mozambican City of Beira faces many climate-related challenges given its location which is regularly hit by tropical storms. Established in 1890 as a port and regional railway hub on low-lying land at the mouth of the Pungwe River, urban water supply is difficult because fresh groundwater is very limited and the river's estuary is saline. While river flow is adequate to meet the city's needs, extensive saline intrusion, exacerbated by growing upstream water use, required its intake 80 km from the city to be moved further 20 km upstream. However, water quality problems continued for a nearby irrigation scheme whose intake the city had shared. While the intake could have been protected by building a weir downstream to obstruct tidal influx or storage dams upstream to maintain minimum dry season flows, these options were rejected on environmental grounds (NORAGRIC 1997).

While climate change impacts are obvious, hydrological analysis has characterized the salinity dynamics and helped to identify appropriate responses to the impact of increased water utilization and sea level rise. The immediate water management challenges have been well-characterized, and the priority is to coordinate responses to protect economic activity. However, in the longer term, the city's vulnerable location may require radical relocation rather than water management solutions.

Polihali Dam and the Integrated Vaal River System: Sustaining a "Problemshed"

In economic terms, the Integrated Vaal River System (IVRS) is the most important water resource development in Southern Africa. It supplies water to around 20 million people in a region that produces almost 50% of South Africa's GDP and includes the country's administrative capital (Pretoria) as well as Johannesburg, its largest city. If its functioning is impaired by climate change impacts, the entire country will suffer.

The IVRS region lies across the watershed of the country's two largest rivers, the Orange and the Limpopo, which discharge into the Atlantic and Indian Oceans, respectively. By the 1960s, demand for water for domestic and economic purposes had outstripped the reliable flow of the main local source, the Vaal River, a tributary of the Orange River, which is also highly variable. A national policy review (South Africa 1970) recommended a system approach to identify and introduce new sources. This coincided with the emergence of new techniques to undertake the required analysis (Maass et al. 1962).

For four decades, system models guided decisions on expansion and operation (Basson and Van Rooyen 2001) that have successfully sustained water security in the expanding system. Throughout this period, the objective was to manage the extreme climate variability, with drought risk as the key metric since there was little useful information about potential climate change risks.

An important element of the system is the Lesotho Highlands Water Project (LHWP), a multiphase scheme which diverts water that flows south from Lesotho in the Orange River, northward to its Vaal River tributary. In terms of a binational Treaty, South Africa uses Lesotho territory to discharge the waters closer to the centers of demand, with considerable cost-savings. Climate variability and change are addressed in the Treaty only insofar as provision for joint action in the event of *force majeure*, covering "disturbance due to an extreme hydrological or other natural event, including extreme drought, and affecting the delivery of water to South Africa." Similarly, while the 1998 Appraisal Report on Phase 1B of the project (which was successfully completed in 2002) makes no explicit mention of climate variability and change, it locates the purpose of the project as "reducing drought risk" in the South African system.

The LHWP's further phases are seen as low-risk, least-cost alternatives to augment the system's capacity. Phase 2, the construction of the Polihali Dam on another Orange River tributary, was included in the World Bank's "RDM study" (Cervigni 2015). As with the Mwache Project in Kenya (see above), the study considered whether alternative configurations might be less economically vulnerable if climate change reduced project performance.

Noting considerable climate uncertainty, the study suggested an alternative design could reduce the risk of financial losses due to climate change by up to 30%. This only considered assumptions about water prices and demand and not the wider societal costs of supply failure, a conservative approach since, for many societies, higher water costs are preferable to the costs of unexpected supply failures (as is formally stated in the new Cape Town water strategy (Cape Town 2019)).

Subsequent studies concluded that the Polihali Dam would meet its intended delivery targets under a wide range of climate scenarios with deficits occurring only in the very driest 16 of 122 scenarios. The IVRS also illustrates the benefits of a "problemshed"-based analysis (Mollinga 2020) which encompasses the actual physical and institutional boundaries within which water is managed not simply an individual "watershed" approach. Whereas hydrological models are based on the natural "watersheds" before human activity intervenes, water management requires models that reflect the interaction between human activities and the natural system. The IVRS shows how hydrological tools can effectively be applied to manage substantial climate variability in complex multi-basin systems.

Zambezi River Coordination: Drought Risks, Discount Rates, and Batoka Dam Hydropower

The final case, the proposed Batoka Dam in the transnational Zambezi River Basin, illustrates the challenges of evaluating climate change's impacts in a complex system and uncertain economic and institutional context. In a basin that already suffers extreme climate events, the implications of climate change for hydropower expansion are a concern. Hydropower is the main source of electricity for the riparian countries and offers further opportunities to support their socioeconomic development. The Batoka Dam project illustrates the challenges of identifying adaptive approaches that optimize the benefits that hydropower can provide while minimizing the risk.

The history of Zambezi hydropower is as much about national and regional politics as hydrology or economics. Its potential was recognized early in the twentieth century, but it was only in the 1950s that it was decided to construct the Kariba Dam, creating what is still the world's largest dam reservoir by volume. Built by the Government of the Federation of Rhodesia and Nyasaland, Kariba's initial installed capacity of 1300 MW was sufficient to meet the needs of the Federation. It was controversial because a smaller project could have been built on the Zambezi's Kafue tributary in Northern Rhodesia, closer to the mines that were the main centers of electricity demand. But political imperatives supported the larger project to reinforce the Federation although Northern Rhodesia, later Zambia, withdrew in 1963.

Mozambique's Cahora Bassa Dam, with an installed capacity of 2075 MW, had similar political drivers to Kariba; it used cheap electricity to reinforce the political relationship between the Portuguese colonial power and South Africa. This relationship was even shorter-lived – Mozambique became independent in 1975, just as Cahora Bassa was completed and the reservoir began to fill.

With the development in Zambia of the 900 MW Kafue Gorge Upper Dam and some smaller projects, there is now almost 5,000 MW of installed hydropower generation capacity in the basin with an average total energy production of around 30,000 GWh/year, of which 23,000 is "firm energy," available at high reliability and very low cost, since most initial construction loans have long been repaid. This economic benefit of large water infrastructure is seldom accounted for although the resulting "path dependency" is often commented upon (Haasnoot et al. 2019).

The total energy production could be doubled to around 60,000 GWh/year through the extension of existing facilities and the construction of new dams. This would meet most of the current electricity demand of the eight riparian states although optimal production will require hydrologically informed cooperation between operators. The resilience of new schemes to climate variability and change has come under particular scrutiny as international development finance institutions consider their financial viability.

While individual projects have been assessed in some detail, it is important to understand how they would function in a future system, which includes irrigation and urban uses, under conditions of climate change. At present, evaporation from the Kariba and Cahora Bassa lakes is by far the largest "consumptive use" of Zambezi water, accounting for 85% of the 12.5 km^3 average "consumption"; all other uses (agriculture, urban, and industrial) account for just 1.9 km3, just 2% of the available runoff.

With the growth of population and economies, water consumption will reduce flows, impacting on hydropower production. A 2010 "Multi-Sector Investment Opportunity Analysis" (MSIOA) investigated the potential impacts of such new developments and the benefits for the riparian countries of coordinating their development plans, to reduce uncertainty about hydropower potential (World Bank 2010). The study included an economic assessment tool and considered possible climate change impacts. Its main finding was that coordinating investments and infrastructure operation could significantly increase the economic benefits compared to stand-alone project development. Beyond the hydrological uncertainties, the political challenge is to achieve an equitable sharing of the costs and benefits.

However, economic analysis is particularly challenging for investments such as water resource infrastructure which have a high initial cost but yield benefits over a very long period. The imputed value of long-term production depends heavily on assumptions about future prices as well as the "discount rate" applied in the analysis, and there is limited consensus about the appropriate approach, not least because the choice is usually determined by policy objectives (Fankhauser and Stern 2016) in which climate change adaptation strategies are not always adequately reflected.

These issues were illustrated in the analysis of Batoka in the 2015 RDM study (Cervigni 2015). The Batoka site is on the main stem of the Zambezi, downstream from Victoria Falls and upstream from Kariba. It has limited storage and will depend on natural river flows which, although moderated somewhat in the extensive wetlands of the upper catchment, are very variable and subject to drought, making it particularly vulnerable to climate change (Harrison and Whittington 2002).

In this context, the RDM study noted that:

> "In drier futures, smaller facilities yield higher net benefits, as less investment is underutilized during the dry periods. In wetter futures, larger facilities that can better take advantage of high flow periods yield higher net benefits."

Batoka it found,

> "shows significant sensitivity to climate change with up to a 33 percent decrease or a 15 percent increase in average power production." (Cervigni 2015)

Over 30 years, the difference between the worst- and best-case scenarios was estimated at around US$4 billion, in 2015 values, based on average energy prices in the Southern African Power Pool. But in a dry period, electricity prices would rise as all supplies would be reduced in a system that was dependent on hydropower. While in 2015 this effect was not yet evident because the region still had coal-fired alternatives, over the next five decades, coal-fired power will be constrained, and carbon taxes will increase its price, further supporting hydropower prices.

Even without these considerations, Batoka showed that "economics of projects of this type could be highly sensitive to the price of power" (Cervigni et al. 2015). Once again, it was emphasized that a project that was financially sensitive to climate change impacts was not necessarily financially vulnerable.

These economic studies are highly dependent on the discount rates chosen. The RDM study used a policy discount rate of 3% for assessing social policy objectives. But for Batoka, both the MSIOA and the RDM analyses used a "finance discount" rate of 10% (World Bank 2010) to ensure adequate financial returns to repay loans. The danger is that using present-day markets to estimate long-run prices ignores the potential increase in the value of output as a result of climate change policies, devalues the long-term benefits of cooperation, and thus does not adequately reflect the policy goals of climate change mitigation.

A final gap in these attempts to integrate policies for climate resilience more effectively fully into hydrological and economic analysis has been the failure to consider the "water use efficiency" of energy generation in the Zambezi Basin. Presently, over 10% of the Zambezi's flow is lost to evaporation from the two large hydropower reservoirs. Full development of the basin will not require the significant expansion of storage to manage hydrological variability, and the proposed cascade of three dams in the lower Zambezi will benefit from the hydrological security provided by the Kariba and Cahora Bassa reservoirs upstream. While the MSIOA notes with concern that the output of those projects could vary between +9% and − 13% by 2100 (World Bank 2010), it makes no allowance for value inherent in increasing "water use" efficiency by increasing the energy produced per unit of water.

These analyses of the Batoka Dam and the broader strategies to ensure optimum management of the Zambezi Basin's waters show that the challenges of assessing the economic benefits and risks of large water investments are at least as complex as those of managing the hydrological uncertainties.

Discussion: Principles to Guide Adaptation under Uncertainty

The cases presented illustrate the contexts within which major water resource investment decisions are taken and the limited contribution that can be made by emerging climate change science beyond the charting of the range of future uncertainty. Nevertheless, the focus on potential climate change impacts does provide useful guidance for the planners, developers, and operators of major water resource infrastructure working in "difficult hydrologies."

Principles

From these cases, some general principles can be identified that could help water resource managers to develop coherent adaptive strategies for the projects or systems for which they are responsible and assist them in communicating their approaches to their wider communities. In addition, some more operational priorities emerge that merit mention.

Uncertainty

Perhaps the most important principle to emerge from the cases is that uncertainty remains the dominant feature of potential climate change impact on water resource projects. This uncertainty must be recognized and reflected in analytical approaches, strategy development, and project design. Uncertainty does not mean that stochastic methods cannot be used to detect – and project – trends. For instance, where projections of precipitation are made using multiple GCMs and the range of future uncertainties can be constrained, stochastic methods are already usefully applied. More serious challenges arise where relevant variables are not well understood or constrained as is the case with modeling future rainfall-runoff in conditions where both land cover and precipitation intensities are both poorly understood.

Precautionary

The precautionary principle is usually understood to constrain developments until their impacts are understood. In the climate change context, a precautionary approach will ensure that decisions are taken in time to address possible future contingencies. This is explicitly stated in Cape Town's post-disaster water strategy which commits to make new investments which will not be used unless there is a dry period in which they are needed. This reflects the high costs imposed on the wider society by supply failure. Projects with lengthy implementation periods such as the IVRS augmentations should be implemented on a precautionary basis to avoid inefficient crisis responses that characterized many water sector investments. A precautionary approach would also introduce supply restrictions earlier rather than later although political resistance is always a factor in this – recent extreme power restrictions in Zimbabwe resulted, in part, from earlier decisions to continue generating at full capacity at Kariba, contrary to drought operating rules.

Path Dependence

A concern frequently raised about water resource developments of all kinds is that they commit their societies to particular development paths and close off other options. The difficulty with these discussions is that they frequently involve larger political issues about which there is little consensus. In large measure, Windhoek's current challenges are the result of century-old colonial spatial planning decisions; the option of refocusing economic development in a more propitious location is an important alternative. Similarly, South Africa's IVRS reflects the fact that the mining economy promoted extensive development in a location with limited water resources and that coastal areas would be easier to serve. Beira's location, which also served colonial objectives, is very vulnerable to current climate, and vulnerabilities will be aggravated by climate change. But these are not issues on which water managers can determine policy. At best, they can ensure that the concerns and constraints are well understood and thus influence wider development policy debates.

Flexibility

In response to uncertainty about future trends, it is helpful if strategies to meet future needs are sufficiently flexible to accommodate different futures. This principle has already been explicitly adopted in a number of the case study projects: Cape Town has identified a range of options that could rapidly be implemented in the event of a "step change" in climate; the ENCW scheme serving Windhoek can be implemented in a sequence of steps. Similarly, each step in the past and future development of South Africa's IVRS involved a choice from a set of different options.

System-Wide Approaches and Problemsheds

The importance of conceptualizing and operating linked infrastructure as a system rather than as individual units brings many benefits. The values of these benefits are explicitly determined in the Zambezi Basin MSIOA but are also evident in the IVRS, Windhoek, and, at a nascent stage, Mombasa and Cape Town's new strategy.

Linkages

The linkage of different sources and demand centers provides a variety of resilience benefits that can greatly assist adaptation to changing climate conditions. A benefit that could be achieved by operating Zambezi hydropower as a coordinated system is that extreme events are often not correlated. While in the south Victoria Falls and Kariba were running dry, Cahora Bassa which draws more resources from the north had to open its flood gates to manage inflows. South Africa's IVRS has already demonstrated that multiple sources provide greater assured yields than the sum of their "stand-alone" yields and Windhoek's situation is similar. Proposals for Kenya's Mwache Dam to form part of an integrated bulk system would replicate this approach.

Diversification

Diversification of sources provides further important resilience benefits and should be a guiding principle for climate change adaptation. Windhoek's surface water/groundwater mix has enabled it to withstand repeated drought crises. Cape Town's recent experience highlighted the risk of relying solely on surface water supplies, which although linked all derived their inflow from a single small catchment area. Alternative sources had not been developed because, individually, their unit costs were higher, but this calculation omitted consideration of the value of additional reliability that could be gained from diversification. Care must be taken, however, to ensure that apparently diversified sources are not correlated. Thus, while reuse is a useful option, it depends on the availability of wastewater which, in crisis situations, may be constrained.

Storage Vs Yield

It is widely recognized that storage is an integral element of any substantial water resource system, crucial to ensure adequate flows in dry seasons. However, it is often considered solely as part of river management infrastructure. Both Windhoek and the IVRS use strategic storage fed slowly by wet season surpluses from external sources to build a reserve that can be drawn down to provide a guaranteed supply during dry periods. This contributes significantly to their reliance against drought and other climate impacts at lower cost than would be required for the development of a new source.

Valuing Resilience and Reliability

One of the features of both water and power projects in Southern and Eastern Africa is how little recognition is given to the financial and economic benefits of reliability and resilience of supply. This was forcefully illustrated by the economic losses suffered by Cape Town due to 3 years of water restrictions. But the economies of countries dependent on Zambezi hydropower have also been significantly constrained by the power cuts and rationing, and Windhoek's economic activity has been curtailed by water shortages. There is a need for more nuanced analysis of the funding of schemes that enhance resilience and reliability of supply since these values are often not included in user charges and benefit a wider public than the direct users.

Operational Priorities

Institutional Capacity Will be Critical

Given the intensification of hydrological analysis and decision-making, water management institutions will have to ensure that they have the capabilities to respond to the emerging challenges. This will require appropriate structures as well as the development and retention of the specialist skills, often in collaboration with specialized institutions of higher education.

Adequate Finance Is Required

In all the water supply cases, current investment has been insufficient to achieve resilience to current climate variability. While this is often viewed as a problem that can be resolved by establishing effective markets for water (and also to power), the benefits of assured supplies spill far beyond the direct users to the wider society although they may only be fully realized in the longer term. This means that the full value of the water project outputs cannot be captured by prices alone and different financial arrangements are required that reflect the long-run economic benefits of secure supplies. Where water projects, notably hydropower, directly mitigate climate change by reducing greenhouse gas emissions, this should be reflected in financial terms. Current "green finance" proposals will only be of assistance if loan conditions address these structural constraints.

Communication to Achieve Sufficient Consensus

Water resource development occurs to a greater or lesser extent in the public domain and is thus subject to public scrutiny and political decision. One of the challenges faced by sector managers is that they address complex issues about which public perceptions may differ widely. Water management institutions need to develop and sustain communication with their stakeholder communities to ensure their support for demand-side interventions as well as for investments on the supply side.

Information for "Dynamic Stationarity"

The dynamic nature of hydrological systems under climate change means that analysis will no longer rely on standard sets of reference data from a fixed time period. The values of many hydrological variables will be changing in unpredictable ways that will require hydrological data to be updated on a regular basis. This will require an intensification of data collection and management. As one group of commentators remarked, "in a nonstationary world, continuity of observations is critical" (Milly et al. 2008).

Conclusions

The principles that emerged from this review support the initial hypothesis that adaptation to climate change in the water and hydropower sector will best be achieved by following strategies that address current climate variability. All of the principles enunciated are equally appropriate to current climate variability or climate change.

The proviso introduced by including climate change is that such interventions should recognize that uncertainties under future climate change are likely to be greater than at present. This reinforces the need for options that allow greater flexibility of approach, but it also highlights the need for a precautionary approach that will see interventions made earlier rather than later, as Cape Town found to its cost.

The idea that interventions should be made sooner rather than later will often meet opposition because it will be seen to reinforce current development trajectories and path dependence. The reason that alternative trajectories are not followed is usually that they are constrained by politics and economics. Even if the intent is to allow economic and social disruption to drive new trajectories, creating water and power crises is unlikely to create the conditions for change. Given the challenges posed by climate change, deliberate disruption of societies and economies is a high risk strategy with little certainty about the likely outcomes.

One consistent finding is that the challenges of planning, implementing, and operating large water resource schemes under difficult hydrologies will become more complex as climate change impacts intensify. While traditional hydrological tools can continue to be used, "dynamic stationarity" will require more intensive data collection, more frequent reviews and runs of models, and greater effort to communicate the findings and their implications to the wider community whose consent, trust, and support will be required for decisions. In most countries, this will require more capable organizations, better funded, staffed, and equipped than at present.

In all of this, the primary constraint to adapting to the impacts of climate change by building more resilient and less vulnerable systems will continue to be financial. A particular challenge for the water sector's practitioners will thus be to persuade their communities that additional support for planning and managing their countries' water will insure them against the larger costs of water and power supply failures.

Contents

Abstract

The effect of climate change on agricultural-dependent communities is immense. Ethiopia in which more than 85% of its population is agrarian is affected by climate change. Communities in different parts of the country perceived climate change and practice different climate change adaptation strategies. This chapter was initiated to identify adaptation strategy to the impact of changing

climate. Data on a total of 180 households were gathered using structured and semi-structured questioners. Focus group discussion and key informant interview were also used for data collection. Climatic data from the nearest meteorological stations of the area were collected and used in this chapter. The collected data were analyzed using descriptive and inferential statistical methods. The upshot indicated that all the respondent communities experienced at least one of autonomous/self-adaptation strategies to cope and live with the impacts of changing climate. Though 33.6% complained on its accessibility and pricing, 66.4% of the respondents reviled as they do not have any awareness on improved agricultural technologies. The major adaptation strategies identified were collecting and using of edible wild plants and other forest products, hunting, renting/selling of own farm lands, livestock sell, selling of household materials/ assets, collecting and selling of wood and wood products and depending on well-off relatives, using drought-resistant crop variety, changing cropping calendar, replanting/sowing, and increasing farmland size. Nevertheless, the communities are not yet fully aware and accessed to policy-driven options for climate change adaptation. Although they used different autonomous adaptation mechanisms, the households are not resilient to the current and perceived climate change. Finally, based on the findings, the recommendation is that besides encouraging the existing community-based adaptation strategies planned adaptation strategies have to be implemented: such as early-warning and preparedness programs have to be effectively implemented in the area, introduction of different drought-resistant locally adapted food crop varieties, and expansion of large-scale investment in the area has to be checked, and give due recognition to forest ecosystem–based adaptation mechanisms of the local community in the area.

Introduction of the Chapter

The world's climate has already changed and will change dramatically. Under the no emission scenario, the average global surface temperature is predicted to increase by 2.8 °C during this century (IPCC 2007). It is now a challenge for the entire world with growth, poverty, food security, and stability implications. The demand of the hour is to adapt to the changing climate and work together to find mitigation options so that no further damage is done (IPCC 2007).

However, the impacts of existing and predicted changes in climate vary across economies. Poor countries can incur huge costs from a small deviation in climate, particularly due to their dependency on climate-sensitive sectors (Agriculture), poor adaptive capacity, lack of necessary technology, and lack of resources to deal with the stress (Seo and Mendelsohn 2008). For instance, because of significant dependence on the agricultural sector for production, employment, and export revenues, Ethiopia is seriously threatened by climate change, which contributes to frequent drought, flooding, and rising average temperatures (Emerta 2013). Severe droughts often are followed by severe food insecurity, population dislocation, family separation, and erosion of the sociocultural fabric (Berhe and Butera 2012).

Like most parts of Ethiopia, climate change brings newer and more complicated challenges to people in Benishangul Gumuz region, having devastating implications for the peoples of the region in general and the Gumuz communities in particular (Emerta 2013). The incidence of crop pests and disease increased from time to time, the size of their forest ecosystem is threatened due to farmland and settlement encroachment by other ethnic groups (Abbute 2002). The existing socioecological system is reduced to support the Gumuz community to cope and live with the new climate stimuli as usual by traditional means. This coupled with their temporally and spatially cyclical agricultural system that involves clearing of land – usually with the assistance of fire – followed by phases of cultivation and fallow periods with the help of rudimentary labor-intensive farm tools threatened the lives of the people in the region. Particularly, the study area is highly affected by climate change and variability. As Sani et al. (2017) indicated the overall natural resources base of the region is highly degraded. Thus, people in the region are facing a variety of shocks and become vulnerable. However, the Gumuz community in the area has been responding to climate change through various adaptation strategies. However, there was no scientific study that substantiates or supports the existing adaptation strategies practiced by the Gumuz people in the area.

Identification of traditional risk mitigation and coping strategies that explicitly show elasticity of the community to existing disturbances in order to evaluate the suitability of current adaptive behaviors, as well as assess the adaptation deficit of local communities in view of increasing climate variability is very important. It would help in identifying those available adaptive measures/options that need to be built on and strengthened, as well as innovative adaptation strategies that add value to current climate risk mitigation and coping behaviors, by effectively addressing adaptation constraints experienced by communities (Berhe and Butera 2012). The knowledge of local adaptation strategies are essential to cope, adapt, and live with current and perceived extreme climate variabilities/changes through building their indigenous resilience mechanisms (WFP and FAO 2012). Therefore, knowing and building community adaptation practice is indispensable to live in the midst of the change. In addition, despite the huge potential that traditional knowledge offers for climate change adaptation, research efforts on the effectiveness and appropriateness of this knowledge have, so far, been limited. Furthermore, there are no proven approaches to integrate traditional coping mechanisms into mainstream development efforts (Berhe and Butera 2012).

Berhe and Butera (2012) indicated that drought and climate variability are part of the natural cycle in lowland Ethiopia, and the communities do have an array of traditional coping mechanisms. Indigenous peoples are excellent observers and interpreters of change on the land, sea, and sky. Moreover, indigenous knowledge provides a crucial foundation for community-based adaptation and mitigation actions that can sustain resilience of social–ecological systems at the interdependent local, regional, and global scales. However, the ability of a community to maintain a certain level of well-being in the face of risks depends on the resource options available to that community/household to make a living and on their ability to handle risks (Alinovi et al. 2009). Therefore, this study aimed at investigating the climate change adaptation strategies practiced by the Gumuz people in response to its adverse effects and analyzing determinants of the use of adaptation strategies in copping, adapting, and living with observed and perceived climate variability in the area.

Description

Location: Metekel Zone is located in the Benishangul Gumuz National Regional State (BGNRS) (Fig. 1). The zone occupies an estimated total area of 22,028 km^2. Geographically it is located between 09.17° and 12.06° north latitude and 34.10° and 37.04° east longitude. The zone encloses seven woredas/districts, namely Bullen, Dibate, Dangur, Guba, Mandura, Pawi, and Wembera. The Addis Ababa-Guba and Chagini to Wombera all-weather road provide the primary access to the area. In the present administrative context, most of the Gumuz inhabit Metekel zone to the north and Kamashi zone to the south of the Abbay/Nile River.

Agro-ecologically, the zone is mostly classified as 82% lowland (kola), 10% midland (woina-dega), and 8% highland (dega) with an average rainfall of 1,275 mm

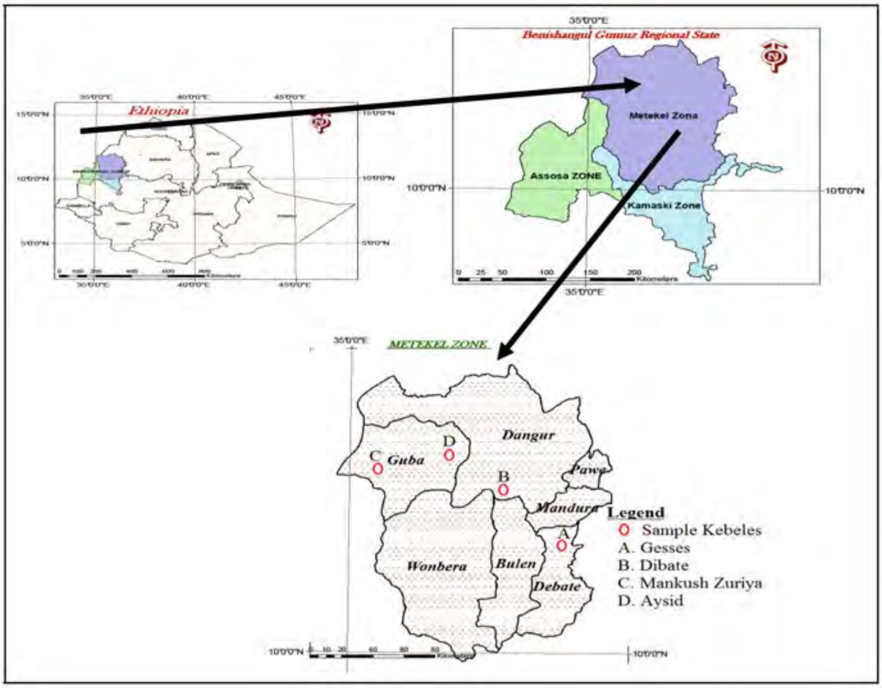

Fig. 1 Map of Metekel zone

per annum and an altitude range of 500–2731 meter above sea level. The Gumuz, who constitute the most numerous ethnic group of the area, mostly inhabit the lowlands in all seven districts. The total population of the zone was 276,367 (male 139,119 and female 137,248) of which 238,752 are rural setup while the remaining 37,615 are urban dwellers (BGRSDGA 2010). The land use pattern is estimated as 79% forestland, 7% cultivated land, 7% cultivable land, and 7% nonutilizable land.

The annual average temperature ranges from 16.2 °C to 32.5 °C with annual mean rainfall of 1,607.8 mm, where the annual rainfall months ranging from May to October (EARO-PRC 2000). The zone has a unimodal rainfall pattern, with an extended rainy season, from March to September. The peak rainy season is from July to August. The coldest months are December and January whereas March and April are the hottest months of the area (Esayas 2003). The mean monthly available meteorological data obtained from Ethiopian Metrological Agency for the four stations namely Bullen, Mandura, Debate, and Guba for the period of 1972 to 2013 is presented in Fig. 2.

Vegetation: Generally, about 55% of the total land area of the region is covered with different vegetation and forests. Bamboo, incense, and gum trees are the major forest types. Forests are important sources of construction material, fuel wood, and food, particularly for the indigenous communities (Benishangul Gumuz Region Food Security Strategy 2004). The original plant cover of the Metekel zone constitutes dense hyparrenia, dense bamboo thickets, and scattered trees and of arboreal and thick shrub by formations along the water ways covering areas of various sizes (Dieci and Viezzoli 1992). Degradation of forest resources is increasing at an alarming rate due to various limitations. Encroachment, forest fires, absence of well-defined land use policy, and intensive resettlement programs that took place during the past government regime are some of the main causes for the depletion of natural resources in the region.

Socioeconomic condition: The regional economy depends on agriculture which accounts for 93.2% of the economically active population. Shifting cultivation is the major economic activity of the Gumuz community. Shifting cultivation is broadly

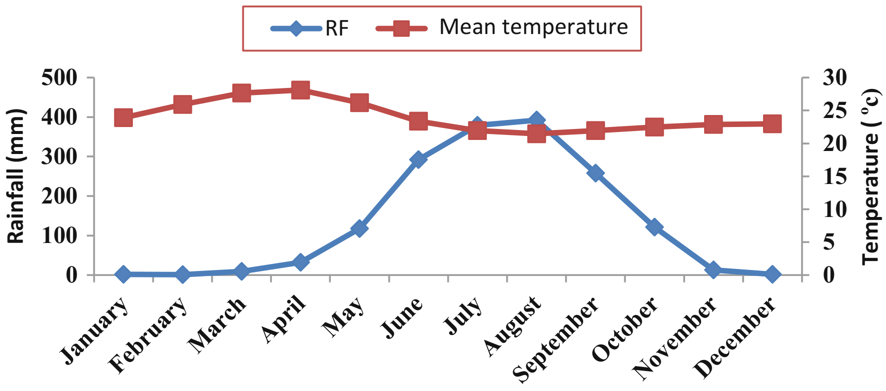

Fig. 2 Mean monthly rainfall and temperature of the study area

defined as "any temporally and spatially cyclical agricultural system that involves clearing of land usually with the assistance of fire followed by phases of cultivation and fallow periods. The subsidiary livelihood sources include livestock raising, gathering wild foods, fishing, honey production and collection, traditional gold mining, hunting, handicrafts, petty trade and charcoaling" (Anonymous 2004, 2011).

Rudimentary labor-intensive farm tools usage, prevalence of crop diseases, pests and weeds, declining soil fertility, inadequate use of improved inputs, erratic rainfall, human diseases such as malaria, poor rural infrastructure facilities like market and road, absence of credit services, and poor working culture of the communities largely due to use of labor-intensive farm tools and low awareness resulted very limited crop production and productivity in the area.

Information Assortment Techniques

A multistage sampling technique was used to collect information/data. In the first stage, out of the seven woredas (districts) where the Gumuz ethnic groups predominantly live in the zone, three woredas were purposively selected to include different attributes. The Gumuz community lives almost in the same agro-ecological zones in all woredas. Then within the zone Debate, Dangur, and Guba woredas were selected for this study. In the second stage of sampling, kebeles within the selected woredas were selected according to settlement patterns, farming practices, crop varieties, socioeconomic aspects, climate problems, and disasters besides biophysical features.

Accordingly, Gessess kebele consisted of 260 households from Debate woreda, Debate kebele consisted of 228 households from Dangur woreda, Aysid consisted of 244 households, and Mankush-zuriya kebeles consisted of 107 households from Guba woreda were selected. The numbers of farmers in each sample peasant association were different, specific numbers of respondents were selected with probability proportionate to size (PPS) random sampling technique to ensure representativeness of the population. Consequently, more than 20% sampling intensity was used from each kebele, accounting a total of 180 sample households and interviewed.

Data collection: Both primary and secondary sets of data were collected. The primary data were collected by using tools of household survey (using structured questionnaire and in-person interview), focus group discussion (FGD), and key informant interview (KII). The valuable secondary data were also obtained from various sources including previous scientific studies and reports from Zonal level agricultural department and other concerned organizations. In addition, the climate data (rainfall and temperature data) was obtained from the National Metrology Agency for the year 1972–2013.

Examination: SPSS statistical software (IBM-SPSS software; version 20) was used throughout the statistical analysis. Both qualitative and quantitative techniques were used to inquiry and presented in the forms of interpretations, comparisons, and arguments. In addition, the quantified information collected using PRA (Participatory Rural Appraisal) tools also presented in figures and percentage. The quantitative analyses made use of all descriptive, correlation, and inferential statistical techniques. The descriptive statistical techniques applied in the study include percentages and graphs. Correlation statistics was used to determine the associations of the major autonomous adaptation strategies, major determinants of community resilience in copping, adopting and living with the impacts of current and perceived climate extreme events, and the interaction of extracted community resilience building blocks presented in the form of tables.

In all cases the significance of the result was also tested using statistical T-test and chi-square Pearson test in determining the p-value to define the significant variation of the obtained results among sample woredas and relative wealth categories of respondent households.

Adaptation Strategy

Crop-Based Adaptation Strategies

Almost all (98.9%) of the respondent households practice rain-fed agriculture. Out of 180 respondents only two of them, 1.1%, reported to have owned an irrigated land of 0.5 hactar each. The major crop-based autonomous adaptation options include: (1) extension of fallowing period, (2) delaying of sowing period and/or sowing two to three times on a specific plots of land for a single harvest following availability of moisture, (3) adoption of hardy and early maturing crops varieties, and (4) increase farm land size (Table 6).

About 75% of the respondents use fallowing crop production system of farming practice (Table 1). Plots are cultivated for 1 or 2 years, then left to recover to woodland by lying fallow for 5 or more years. It is a system which involves clearing of irregular plots at some distance from the village by cutting and burning off trees and shrubs prior to tilling with the hoe. The FDG and KII participants indicated as farmers extend their fallowing period as an option to the effect of climate variability. They perceived that extending fallowing period will increase moisture holding capacity and soil fertility of the land which further increase productivity of the land through reducing weed and pest/disease infestation. The contribution of fallowing in reducing crop weed and pest/disease was mainly reported in Dangur woreda. It is also indicated by Nyong et al. (2007) as natural mulches moderate soil temperatures and extremes, suppress diseases and harmful pests, and conserve soil moisture. However, the practice may increase emission of GHG (Green House Gases) since it involves clearing and burning of forest covers. Though the advent of chemical fertilizers usage is highly encouraged by local level government, local farmers largely depended on organic farming with zero tillage practice which is also capable of reducing GHG emissions.

The FGD participants in GubaWoreda of both Mankush-zuriya and Aysid kebeles testified that almost 100% of the farmers changed the variety of their provenance local crop seeds as an option of adaptation to climate change to lead their subsistence life. As a result of increasing trends of temperature which is subjected to increase the drying period of the season and declining effects of rainfall amount, they forced to change the variety of their provenance crop seeds, locally named as "Bobbe/yeshenkuit" into "Tirkuwash," a sudan crop variety (both crops belong to sorghum bicolour crop type), because of its adaptation to drought and having short period of time on field for harvesting than the local variety. However, they also explained as they preferred the local variety of their own because of its test difference and ease of management on field. During the discussion, it was understood that the local verities were not easily managed to get and visualized. Besides all the respondent households and FGD participants indicated to sow crop seeds at least two to three times per a single season on a specific plots of lands due to irregular rainfall in the area.

Usage of diversified crop production system through mixed cropping (intercropping) is also mentioned by FGD participants and by 66.6% of respondent farmers (Table 1). This also includes planting more drought-resistant crops with traditionally adopted early-maturing varieties, for example, the farmers sow pumpkin with other lowland crops and start using of its leaf early at the time when it starts emerging leaf. Furthermore, 93.3% of the respondents have a plan to increase their farm land. The factor that drives respondent households to increase their farm land was mainly due to climate variability that induced food insecurity–related issues (Table 2). As indicated in Table 2, 69.9% of the respondent indicated shortage of

Table 1 Agricultural crop production system

	Yes		No

crop production both for market and household consumption, while 26.7% depicted the existence of food insecurity in general. The rest 2.3% of the households also reported as others (to support their dependents, ancestors).

To this end, as it was reported by one of key informant interviewee at Dangurworeda, and later confirmed by development agents of the surveyed kebeles, during the critical food shortage months the Gumuz farmers have been taking "one quintals of maize to return two quintals of sesame (locally named as Selit), the known cash crops of the area, aftershocks within the same harvesting year," unless he/she is forced to give a reasonable land of his/her own to the guy so that he/she can plow until return the amount of sesame as promised. This is obvious that it affects the capacity of the community to adapt to the current impacts of climate variability or changes, though they use the system to safe their life when the family face a food shortage induced by variation of rainfall.

Although all of the respondents are engaged in rain-fed agricultural practice, a limited effort made as a planned adaptation option. In this regards, Table 3 shows that 63.8% of the respondents do not used any kinds of agricultural inputs to maximize their production from agriculture sector, while the rest used either of agricultural inputs indicated in Table 3. As it was reported by KII the overall improved agricultural practice by the Gumuz people in the area are still at demonstration stage.

Table 4 also showed that almost more than 67.5% of the surveyed households did not have both access and potential to use agricultural inputs with no significance

Table 3 Improved agricultural inputs utilized/practiced or not (in %)

difference among surveyed woredas and/or kebeles, beside low level of the community awareness and skills on application of different improved agricultural technologies as depicted by FGD participants. The rest 32.5% appreciated their own autonomous means adaptation options. Among those who use improved agricultural inputs 36.2% are also reported that they use the inputs only for cash crop production not yet used for food crop production purpose because of its price. Also they are satisfied in using the existing natural soil fertility in the area with no significance difference among sample woredas and respondent wealth category, as reported. Hence, revisiting of promotional approaches/system in the way that the Gumuz community awareness level and capacity developed to adopt and use introduced technologies as a planned adaptation option to boost the return from crop production in the area which further builds the resilience of the community to adapt to the impact of current and perceived climate extremes.

Livestock-Based Adaptation Strategies

In addition to agricultural crop farm, 84.1% of the respondent households have at least one type of animal/livestock husbandry including chicken, with no significant difference among study woredas of sampled kebeles. The household survey and FGD verified as the farmers in the surveyed areas use a mixed farming system besides their dependency on the forest ecosystem to sustain their livelihood. Anonymous (2004) also indicated livestock plays a big role in the livelihood of the community in the areas.

However, 50.3% of respondents indicated the declining trends of livestock production since the last 5 years which is attributed to shortage of feed (73.6%) and stealing of animals (24.7%). Also 35.8% of feed shortage perception was associated with shortage of rainfall. In this regards, 97.2% of respondents use communal grazing land feeding system while 2.8% feed through hay/silage preparation/zero grazing by their own traditional means. FGD and KII indicated that except Debate woreda where stealing of animals was worthily mentioned and looks after their cattle, the rest sends their cattle to areas where permanent water flows exists, just like wild animals. The cattle return to the village at the beginning of June where new grass started to sprout out. Consumption of milk and milk products including eggs are not common for Gumuz people. However, almost all respondents reported they use selective keeping of livestock like goat and donkey since they have a capacity to adopt climate extremes through feeding leafs of bushes and other by-products of prepared local drinks, respectively. The discussion participants reported they use traditional medicine for their animal health care during their visit periodically.

As a means of adaptation options 91% of respondents indicated that they sell animals to adopt with the current climate change–induced stress Table 6. The correlation test results in Table 5 indicated selling of animals negatively correlated with hunting of wild animals and renting/selling of his/her own farm lands. This indicates if a household sells their animals their dependency participation/engagement in hunting of wild animals and renting/selling of his/her

farm land decrease and vice versa. On the other hand, selling of animals positively correlated with other autonomous adaptation option indicated in Table 5 where it is associated with selling of available household materials or equipments and collecting and selling of different wood and wood products are significant at the 0.01 level (Table 5). This depicted that livestock productions are playing a crucial role in copping the impact of climate change and building the resilience of the farmers in the area.

Forest Resources-Based Adaptation Strategies

The main autonomous coping responses of the household to food shortage caused by drought, erratic rain, and others are presented in Table 6. Most of the respondents (64.8%) indicated that climate stress/shock in the study area resulted in declining of crop and animal production. About 53.5% of the respondents revealed that decline of crop production was associated with variation of rainfall distribution and amount beside other factors. At the time of stress, due to climate change effects, the respondents stated that they are engaged in hunting (85.1%), collecting wild edible plants, and other forest products (88.1%).

On top of this Table 6 it specified that 65.3%, 43.2%, and 75.7% of respondents also engaged on fuel wood selling, charcoal making, and collecting and selling of wood and wood products, respectively. Except collecting and selling of fuel woods which was the same among all woredas and respondents wealth category, the rest of the two (charcoal making and selling of different wood and wood products) have a significant difference among surveyed woredas and wealth category of the respondents. Charcoal making and selling was reported only in Debate woreda. Meanwhile, the large number of respondents from Guba and Debate woreda also conveyed that they engaged on selling of different wood and wood products. In addition, the Pearson correlation test of the major autonomous adaptation strategies indicated in Table 5 shows the existence of strong negative correlation among selling of different wood and wood products with collection of edible wild plants and other forest products, and hunting of wild animals. This may be because of reduced forest resources both in coverage and in its composition to collect edible wild foods and to conduct hunting in Debate and Guba woredas which may be attributed to the existence of large-scale agricultural investment and population pressures than Dangur woredas. As a result, it is also estimated by FGD participants in Debate woreda that the existing tree species reduced by about 40% as an expense of the lost Bamboo species. Moreover, 16.5% of respondents depicted that they compensate any low local market prices, if any, by increasing exploitation of nontimber and timber forest products (NTFP and TFP) besides expanding their agriculture farm land.

Hence, forests are playing a pivotal role in climate change adaptation through building their adaptive capacity which further contributes towards building the resilience of the community in the study area beside its climate change mitigation role. Therefore, provision of due attention in this sector is indispensable to adapt to the current and perceived impacts of changing climate in a sustainable way.

Off-Farm Activities as an Adaptation and Other Copping Strategies

Besides crop, livestock, and forest resource–based adaptation strategies mentioned above, 65.5% of respondents also depend on loan from relatives, 70.6% on renting/selling own farm land, and 22.3% involve in different handcrafts and local beer making to cope, adapt, and live with the impacts of climate change in order to survive their family as another option. The FGD result also indicated that the households engaged on labor selling and renting their farm lands as a means of alternative to pass the food shortage gaps or to live with unexpected happening of climate-induced shocks/stress in the area.

However, it was indicated by respondents that selling or renting of own farm land for the long period of time may affect the monetary values of that land after a long period of time. Likewise, the existence of this problem was also reported by the FGD and KII participants, they stated that when the Gumuz farmers rent their own lands to other ethnic groups who have an experience in oxen farming they use the land intensively to maximize its return. However, they indicated that it is very difficult for Gumuz farmers to manage the land after renting since its pest and weed infestation increase which requires additional cost and labor to maximize the production to which the Gumuz do not have the experience and capacity to afford. Thought it do not have a legal ground, the Gumuz farmers prefer selling of their lands than renting; this may affect their adaptation ability after a long period of time.

In addition, 74.4% of respondents depend on their better-off relatives to sustain their subsistence life (Table 6). As indicated in the Table 5, looking after relatives for support is negatively correlated with collecting edible wild plants and positively correlated among selling of available household materials or equipments and collecting and selling different wood and wood products with 0.01% significant level. From this it is understood that farmers seek for support from their relatives after exhausting edible wild plants and actively engaged on selling of his/her household materials, and labor-intensive wood and wood products. The practice may have resulted in loss of self-esteems and ability besides affecting the capacity of their relatives too. The correlation result in Table 5 also revealed that the community considers hunting of wild animals as an alternative means even if it does not replace the food demands of the community in the area. In consistence with the declining trends of vegetation cover as a result of expansion in large agricultural investment, currently it is not easy for the community to hunt wild animals as they accustomed before, though it is positively correlated with other autonomous adaptation options except getting support from better-off relatives and collecting and selling of different wood and wood products.

Selling of available household materials/equipment positively correlated with collecting and selling different wood and wood products ($P<0.000$). Also getting support from better-off families affirmatively correlated with collecting edible wild plants and other products, while most of the others correlated negatively. This correlation synergy results indicated that most of "the traditional/autonomous adaptation strategies are not a choice of the community rather it is a means of survival." For instance, the correlation selling of animals are not significantly correlated with collecting edible wild plants and selling/renting of farm lands as indicated in Table 5. This means, when they sell animals and get money to adapt/cope with observed shocks/stress at a given time the household may be not encouraged in collecting of edible plants, hunting, and others. Hence, the correlation result indicated that the community experienced for ages traditional/autonomous adaptation strategies mentioned that are not a choice of the community, rather a means of survival without which their survival is in question. Hence, this analysis result accentuates the importance and timing of introducing the planned adaptation/copping strategies that influenced the community both by the government and/or other development actors.

However, since the community depends on their traditional means for ages, it is very difficult to influence them overnight to accustom the planned/policy-driven strategies; for instance, to transform from hoe farming to oxen farming or other alternative mechanism. Hence, the current situation of the community and the survey findings vigilant the policymakers to consider the subsistence means of the community while making a decision at macro-level to utilize the forest land of the area by providing for large-scale investors, where the life of the community depends on, to bring a better development options in the country as a whole.

Interaction of Policy-Driven and Autonomous Community Resilience to Climate Variability Adaptation and Mitigation

The Gumuz community has been excluded from much of the social and economic activities of the main stream society (Abbute 2002). However, there seem to be some changes in this regard in recent years. In view of this, 47.5% of the respondent households are not aware of having the right to get access to social services. This is despite the fact that our further probing in FGDs and individual interviews showed that their participation does not actually demonstrate equality in the complete sense of the term in any forms of development activities conducted in the area. The development effort seems a top-down approach which overlooks the consent of the beneficiary community. This may have questioned the ownership issues of the development effort under ways in the area. Supporting this statement, Sperling and Szekely (2005) revealed that striking the right balance between top-down command-and-control approaches offer stability over the short term but reduced long-term resilience.

Although limited, improved agricultural practices and technologies, and resettlement programs are the major planed/policy-driven adaptation options promoted to build the resilience of farmers in the areas. Hence, its interaction with community-based adaptation option has discussed.

Agricultural Practice and Technologies: It was generally agreed that the policy responses to climate change should support and enhance indigenous resilience (UNISDR 2009). In this regards, only 42 households in Guba (both in Mankush and Aysid kebeles), 37 households in Dangur, and 20 households in Debate woredas of surveyed kebeleswere reported as they used improved agricultural technologies since the surveyed period. In this regards, Table 7 shows comparison of the actual observed number of farmers started using of agricultural inputs and animals for farming activities with the total number of households in the sample kebeles. This indicated that only a very small number of farmers, 7.7% in Debate, 16.2% in Dangur, and 15.4% in Guba, started using animals for agricultural farm activities. Hence, the result suggest that revisiting of promotional approaches/system in the way that the Gumuz community awareness level and capacity developed to adopt and use introduced technologies as a planned adaptation options to cope, adapt, and live with the observed and perceived climate variability–induced shocks/stress is indispensable.

In addition, capacity building trainings and awareness rising programs were reported as key intervention underway by the government to improve farmers' perceptions towards improved agricultural technologies. However, 66.4% of the respondents reported as they lack awareness on the importance of agricultural technologies, while 11.2% complained unfairness of the available inputs and 15.4% appreciated the existing natural soil fertility than using the artificial once. FGD participants also indicated that the community also lacks their needs of improved and drought-resistant food crop varieties that require short period of time. In this case the existence of mismatching between the needs of the community to adapt the impact of climate change and the promoted agricultural technologies is acknowledged. For instance, the community needs locally adaptive drought resistance and high-productive food crop varieties than inorganic fertilizer. Indeed, the FGD and KII participants believe that the voices of the community are often unheard. Also they complained about the price of agricultural inputs, which they attributed to difficulties in reaching the poor community groups which is highly vulnerable and/or susceptible to the impacts of climate-induced shocks due to their low adaptive capacity.

Kebele/local-level development agents believed that although a limited effort has been exerted by nongovernmental organization, namely Canadian Physician for Aid

Table 7 Proportion of households who participated in new agricultural technologies

S.no	Name of sampled woreda	Sampled kebele	Total household	No of household participated in new agricultural technologies (Agricultural inputs)	%
1	Debate	Gessess	260	20	7.7
2	Dangur	Dibate	228	37	16.2
3	Guba	Mankush zuriya	107	14	13.1
		Aysid	224	37	16.5

and Relief (CPAR) and World Vision (WV) Ethiopia to change the deep-rooted saving culture problem of the Gumuz community in the area through organizing them into saving and credit groups, the involvement of local-level government structure is very limited to scale up this effort besides development of their awareness at all level to diversify means of their livelihood. On top of this, among introduced major agricultural technologies only 78% use veterinary services followed by pesticides (15%) and 6.6% ploughing by animals (Table 8). Though maximum efforts have been made by development actors at all level, only 6.6% used ploughing animals for farming practices.

Most of policy-driven agricultural technologies require intensive farming which do not fit with traditional Gumuz farming practice. They alleged that if they produce agricultural crops more than 2 years on a given plots of land continuously the weed and pest infestation increase which requires additional labor and cost. This also needs ploughing by animals than hoe farming where the Gumuz farmers do not have experience, capacity as well as willingness to adopt. In addition, using of a given plots of land for more than 2 years (for 3 and 4 years) requires seed every year which may also costs the farmers every year. Traditionally, once they sow on a given plots of lands they harvest for consecutive 2 years especially of food crops (sorghum). Although it needs further research, the practice seems to have a considerable role in reducing GHG emission through carbon sequestration.

Metekel zone administrator confirmed the existence of strong tension in breaking the traditional means and adopting the new practice. Shifting of hoe farming to animal farming is not achieved overnight. Enforcement of the existing regional land use polices to implement accordingly in the way that it reduces the existing population pressure on forest resources needs to be capitalized. Also the existence of illegal land grabbing in the zone which were initially entered along with legally registered large-scale agricultural investors as a daily laborer worker needs to be checked and corrected. Currently at local government level they considered the investors as a major cause for devaluation of the traditional Gumuz community means of land management and for the observed poor working culture of the indigenous/Gumuz community. The illegal land holders encourage/initiate the Gumuz people to sell, rent, and provide their lands for share cropping than own farm. In addition, the administrator acknowledged as one of the bottlenecks of providing lands for large agricultural investment in the area. Currently the Gumuz communities especially the youngsters considered themselves as investors, predominantly in Debate and Guba woredas as witnessed by FGD participants.

Table 8 Major agricultural technologies introduced and used by the farmers

	Yes		No	
Technologies	count	%	Count	%
Veterinary service	135	78	38	22
Pesticides	26	15	147	85
Artificial insemination	2	1.2	171	98.8
Ploughing by oxen/tractor (Agricultural implements costs)	41	6.6	57	93.4

Because socially in their community they have a right to use their clan land; but currently they started selling, renting, and give for share cropping their clan lands which is large in size/coverage even though traditionally land is not sold under any circumstances either inside or outside the clan of the Gumuz community (Patrick Wallmark 1981).

Hence, the traditional clan land management systems of the Gumuz community is changing with time which may be as a result of population pressures and the extreme climate conditions that forced the highlander immigration to find an alternative means of fulfilling their basic needs and/or provision of forest lands for large-scale agricultural investment.

To this end, it is noted that the community started questioning the government to hear their voice and close a reasonable size of forest land areas for the community. "Head of agriculture and rural development office of Guba woreda confirmed that the land allocation and provision systems for large investors in the area were not considering the local context. Also pointed as, the woreda/distrct officials are exerting their maximum effort in collaboration with zonal and regional government to create a situation in which the local voice should be heard and considered during allocation of large forest lands for investment works. As an adaptation option, promotion of technology transformation from the investor to farmers, establishment of local-level research centers, introduction of appropriate veterinary services, income source diversification through appropriate management of livestock's, and promotion and development of appropriate plan in which the available water sources like Beless, Ayma, and Abay rivers used for irrigation as a major development directions were set at woreda level."

Generally, all policy-driven technologies seem to improve the knowledge and capacity of the community to cope, absorb, and adopt with stress and shocks beside its contribution to increase emission from all land use practices unlike the traditional means. Its rate of promotion is overwhelmed by the current rate of climate variability–induced impacts that threatened the life of the Gumuz people in the areas.

Resettlement: With the objective to introduce improved technology and infrastructure for ensuring food security and to change the lifestyle of the Gumuz ethnic groups, villegization program was initiated by the government and implemented in the area since the year 2012. Most of the farmers were resettled into centralized villages where the water is available or planned to be accessed. However, the FGD participants testified that the community prefers to live in their traditional villages as practiced by their ancestors. Hundred percent of the resettled households whispered as they got no remittance payments made to the community for the resettlement programs. They also mentioned as they face difficulties in identifying what and where to get their needs from forest resources in the new areas since there is no other alternative options to support their ways of life. They also mentioned reduction of forest resources as a result of pressures induced by resettlement program that threatened their life. They reported that women sometimes leave newborns at home to go the whole days for collecting forest products; otherwise there will be no food for the family as a whole. Women were also got difficulties in getting resources to produce different handcrafts, the important economic activity in the area, especially for the women, both for home use and market. Besides its importance in accessing basic socioeconomic services, the program seems as it threatened the community traditional means of copping and living with the current and perceived climate variability–induced shocks/stress. In this regard, they are urging revisiting of the program and development of strategic plans that accommodate the interest of the community in supporting their ways of life means in their new areas.

The three key issues that would affect the successful implementation of the planned/policy-driven adaptations options which need the attentions of policymakers when making decision to use the area for other development purpose are identified. The first was the level of technical assistance, given the limited experience and lack of local language knowledge of the government extension workers in the study zone. As a consequence, extension agents do not have skills to train and influence farmers on the adaptations that could be implemented now, or to provide adequate technical support for routine agricultural production practices. Technical assistance from NGOs and community-based extension emphasize that farmer-to-farmer knowledge exchange supported by targeted technical assistance is needed to address the lack of formal extension services.

The second was poor working and saving culture of the community. Since they are highly dependent on forest and forest products they do not have even storage facility for their produces. They store in the farm at field and outside of their village. Also the mens do not have commitment to be engaged on agricultural farm activities alone with his family but women. Their farm activities have been conducted through a self-help group, locally named as "debbo." Debbo requires preparation of local drinks the self-help members to conduct agricultural activities for debbo owner. All arrangement and preparation of necessary materials for debbo is the duty of women in the community. Especially during clearing of forest lands, weeding, harvesting, and threshing of crops debbo is must. The farm land size and amount of crop harvested will be also determined by the number of the debbo that a given household would be managed.

Finally, Gumuz farmers lack experience in oxen/animal farming and conducting intensive farm operations besides lack of capacity to have animal or any other small technologies for agricultural farm operation purpose. Malone (2009) indicated that the adaptation process requires the capacity to learn from previous experiences to cope with current climate, and to apply these lessons to cope with future climate, including surprises. Hence, introduction of planned/policy-driven adaptation strategies based on the existing community-based adaptation options that influence the community is indispensable to cope and adapt with extreme weather- and drought-induced shocks/stress in a sustainable way through building their resilience. In this regard, any policy-driven adaptation options that address the above-mentioned key elements are required to improve the adaptive capacity of the Gumuz community in the area.

Conclusions and Recommendations of the Chapter

Conclusion

The focus areas of this chapter, Metekel zone, northwest Ethiopia, scrutinized how the Gumuz communities adapt the adverse effects of climate variability and investigated determinants of the use of identified adaptation strategies/options in the area.

The farmers perceived the declining trends of crop yield, livestock production, and the benefits that community gets from forest resources for the last 5 years. Although it is different among respondents' wealth categories, the existence of food shortage gaps in the community that extends up to 7 months has been identified. The situation is worse in the case of poor community members.

In response to climate change impacts, the Gumuz communities have been practicing different adaptation strategies. Many of the autonomous adaptation responses to the impacts of climate variabilitys/changes include collecting of wild edible plants and other forest products, selling livestock (particularly when they are not likely to get a good price), hunting, renting/selling of farm animals, selling of available household materials and/or equipments, getting support/relay on better-off relatives, and collecting and selling of different wood and wood products (Table 6). In addition, expansion of farm land, usage of drought-resistance crop varieties, replanting/sowing, and changing of sowing calendar are among reported strategies used in response to the impact of climate variability/change. However, the autonomous/community-based adaptation mechanisms have been declining both in type and amount. This is mainly due to provision of forest lands for large-scale agricultural investments and the progressively increasing population pressure. The few households are able to improve their farming practices, for example, in using improved agricultural inputs. Lack of awareness on improved agricultural practices, poor saving, and working culture and dependency on natural resources to fulfill their food shortage gaps were known as the main constraints to adopting these practices. These further resulted in declining of community resilience to the level of crisis which requires direct intervention and support. This calls for a planned action to ensure households meet their consumption needs.

Recommendations

- Unless communities actively engage in reflexive learning processes about the causes of systemic changes and the links between local and global processes, there is a risk that community resilience becomes nothing more than an illusion. Hence, introduction of awareness raising programs that improve working and saving culture and climate information appear to be important mechanisms as they support the adoption of several adaptation strategies that build community resilience. Special skills training program is keenly important for the local community so that they will participate and benefit from both government- and private sectors–initiated development programs which are underway in the area.
- The capacity of the community to adopt climate change by using autonomous adaptation is degrading. Therefore, greater effort is needed to increase the resilience of households to cope and adapt with climate variability, through maintaining their autonomous means systematically, and social safety net programming till the community transformed from their autonomous/community-based means to improved policy-driven adaptation mechanisms and adopt the

practice besides encouraging accumulation of assets and wealth through diversifying locally adaptive options.

- Given the effect of climate change on crop yields, animal production, and food availability, planned action by government is needed to ensure households meet their consumption needs. This may take the form of protecting the existing natural forest ecosystem where the community can get their day-to-day needs; for example, promotion of bamboo plantation using different plantation strategies since the community has a special attachment with the species to maintain their food security. Other public actions that would increase access to weather insurance for cash crops, of those currently adopted by the community (sesame production) and creating market linkage, early-warning preparedness, and increasing food stockpiles to be used during poor production years need to be considered.
- Besides the available potentials and the existing policy direction at national level, irrigation development interventions are overlooked both at individual and community level in the area. This suggests that investments in irrigation infrastructure would help farmers to engage in higher value crops, thereby increasing farm revenues besides creating alternative farm production for their subsistence life. There is also an identified need for greater investments in promoting appropriate agricultural extension services, locally adaptive and affordable technologies, and accessing local-level research institution to support the effort of the community in availing locally adaptive food crops variety to improve the future well-being of the community in the area.

the Hydroclimatic (HC) variables of the basin upstream the reservoir of Bin El Ouidane (Morocco), and the effects on the performances of its preoptimized MA. The applied Top-Down assessment procedure included CORDEX climate projections, hydrological, siltation, evaporation, and management models. Concerning the HC variables, the results obtained concord with those reported in the literature in terms of trend, but not always in terms of intensity of change. On the other hand, the projections expected a decrease in the performances of the reservoir, except for criterion allocations' standard deviation, calibrated during the optimization. Also, interesting conclusions have been found like: the change in precipitation dominant form, the accentuation of the pluvial hydrological regime, the advanced snow melting due to the temperature increase. This chapter presents a typical case study on how to use climate projections for reservoir MA adaptation, without being highly and negatively influenced by the climate model uncertainties.

Introduction

Dams' reservoirs play a crucial role in the attenuation of the intra and interannual water resources heterogeneity. In fact, either in arid or humid context, these hydraulic infrastructures permit the flood control and assure the satisfaction of different water demand. In Morocco, the dam construction policy had helped in mitigating the impacts of intra-annual precipitations variability, drought periods, and massive flood events. Nonetheless, according to global and national climate projections reports (IPCC 2014; MEMEE 2016), the potential impacts of climate change (CC) can alter partially or totally this role of water regulation. Moreover, the adaptation to future CC effects should be considered in both design and exploitation phases of dams' reservoirs. On one hand, the adaptation in the design phase should focus on the change of the available water supply (Nassopoulos et al. 2012), the frequency and intensity of floods (Tofiq and Guven 2014), and the sediment yield volumes (Bussi et al. 2014). On the other hand, the adaptation during the exploitation phase is more oriented toward the regular update of the MA, and of its parameters (Zhang et al. 2017). Nonetheless, the update of MAs should not be limited to historical data, but the use of future climate projections resulting from global and regional climate models (RCM) is a path that requires further investigation (Brown et al. 2012). Several methodologies were attempted to adapt water planning to CC (Borison and Hamm 2008; Morgan et al. 2009). Nevertheless, managers still have a suspicious attitude toward climate projections (Means et al. 2010). Nowadays, it is clear that with all the problems related to observational data quality and accessibility, some models' aspects inefficiencies, uncertainties, diversified range of projected impacts, greenhouse emissions scenarios diversity, and the deduction of conclusions from the usage of climate projections is risked and limited (Brient 2020; Sellami et al. 2016).

Other than the use of climate projections to assess a preupdated MA, they can also be beneficial to highlight some negative aspects of the management to correct, or other positive points to enhance.

This chapter presents an assessment of the potential impacts of future CC projections on the Hydroclimatic (HC) variables on the basin upstream the dam reservoir of Bin El Ouidane, and the impacts on the future performances of the preoptimized Management Approach (MA) of this reservoir. In addition, the chapter aims to converge to conclusions that can be useful in the enhancement of the preoptimized approach. Furthermore, a comprehensive procedure that can be generalized to adapt reservoir MAs of other reservoirs worldwide is proposed.

Overview of the Adopted Framework of Analysis

Presentation of the Dam of Bin El Ouidane and the Impacts Assessment Framework

The hydraulic complex of Bin El Ouidane-Ait El Ouarda (named hereafter “BEO-AEO”) is located in the high Atlas of Morocco, and composed of the major 1500 Mm^3 reservoir of Bin El Ouidane (BEO), and its 4 Mm^3 compensatory reservoir Ait El Ouarda (AEO). BEO-AEO was constructed in 1953 to satisfy the water demand of: (1) irrigation perimeters of Beni-Moussa and Tassaout-Aval; (2) drinking water of Afourer, Beni-Mellal, and neighboring villages; (3) production of hydroelectricity; and (4) flood control (Fig. 1).

The BEO-AEO reservoir complex is located at the outlet of an upstream basin of 6500 km^2. The analysis of the past hydro-climatologic variables evolution within the

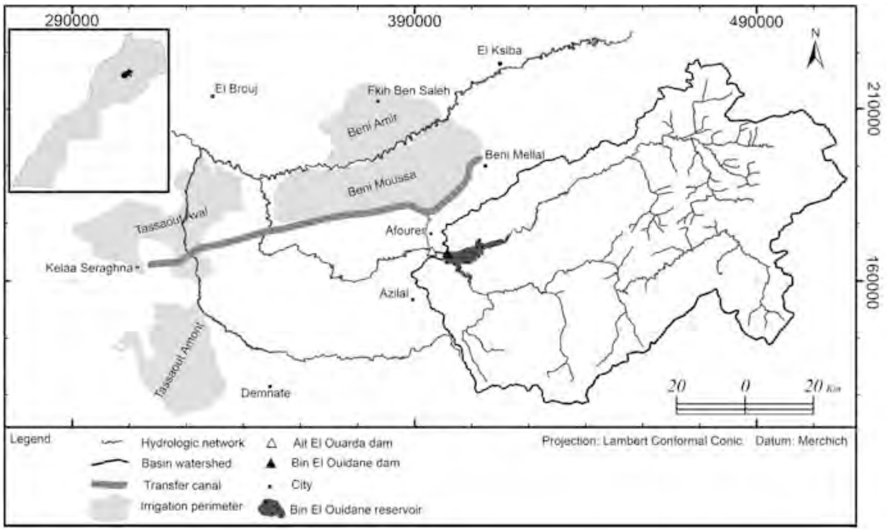

Fig. 1 Geographical map locating the basin of BEO, the dams, and the irrigated perimeters

basin of BEO (Ahbari et al. 2017) shows an augmentation trend of the annual temperature (+0,4 °C in 1989–2013 and of evaporation from the reservoir (+470 mm in 1976–2006), as stagnation of annual rainfall (around 400 mm during 1976–2014) and a substantial drop of the annual water supply to the reservoir by almost 50% after 1976 (from 1350 Mm^3 during 1939–1976 to 750 Mm^3 during 1976–2014).

In order to assess the impacts of future CC effects on the HC variables inside the basin located upstream the complex, the management variables of BEO-AEO and the performances of BEO-AEO, the typical Top-Down procedure described in Fig. 2 is used.

As shown in Fig. 2, the starting point is to choose a climate scenario. The appropriate way to proceed is by testing at least two opposite scenarios: one optimistic and another pessimistic. This will permit to have an idea about the variation interval of the eventual impacts. Then, the selected climate scenario will drive a climate model in order to output the future projections of temperature and precipitations for a given area. In general, the regional climate model is more suitable for the assessment of CC impacts assessment in basin-scale studies (Singh et al. 2019). After that, the resulting climate projections series will be used as direct entries for a prevalidated hydrologic and evaporation models. Once the projected water supply series are calculated, they will be inputted to a prevalidated siltation model to estimate the projected annual siltation volumes. The next step is to run the reservoir management model using the projected series from the hydrologic, siltation, and evaporation models, in association with the projected water demand. Finally, by using representative performance criteria, the results of the projected reservoir behavior are analyzed and compared to the performances outputted by the pre-optimized MA described in detail in Ahbari et al. (2019).

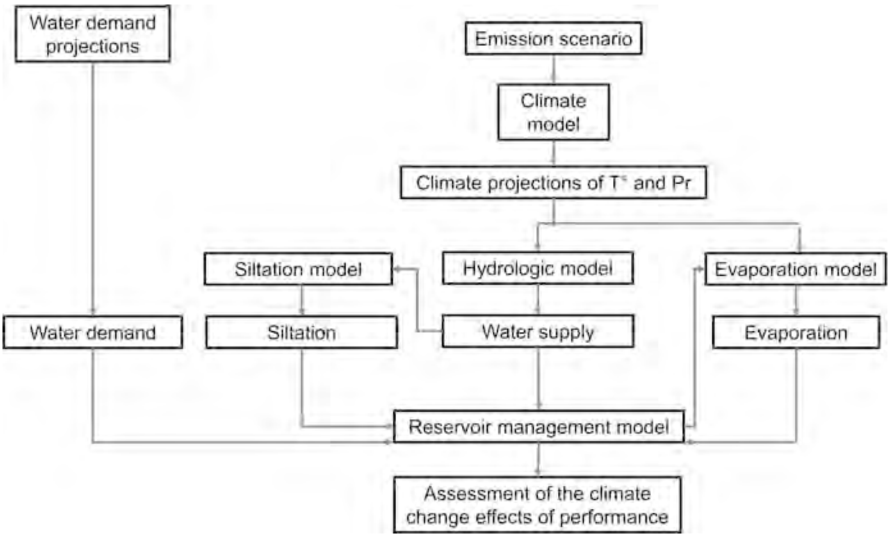

Fig. 2 Typical top-down procedure to assess the CC effects on reservoir performances

Since this chapter is more concerned about the daily management behavior, a daily time step is adopted. The reference period is between 1 March 1986 and 31 August 2015 (similar to the IPCC reference period for its AR5 report), and the projection period occupies the period between 1 March 2020 and 31 August 2049. The following subsections introduce the different components and models used in order to apply top-down assessment procedures to BEO-AEO.

Performance Criteria Used to Assess the Performances of the Reservoir

The Reliability

This criterion is calculated in relation to the duration of the demand satisfaction, as proposed by McMahon et al. (2006) in Eq. 1:

$$Rl = \frac{Nb\_\text{of}\_\text{times}\_D_t = 0}{n} \tag{1}$$

where D_t is the deficit at time step t; n is the number of time steps.

The Resilience

It is the probability that a state of demand's satisfaction follows a state of demand's dissatisfaction (Sandoval-Solis et al. 2011). The formula used is described in Eq. 2:

$$Rs = \frac{Nb\_\text{of}\_\text{times}\_D_{t+1} = 0\_\text{follows}\_D_t > 0}{Nb\_\text{of}\_\text{times}\_D_t > 0} \tag{2}$$

The Vulnerability

It is the likely deficit value of the system if a state of demand's dissatisfaction occurred (Hashimoto et al. 1982). In this chapter, the formula that estimates an average value of the likely deficit is adopted as shown in Eq. 3 (Sandoval-Solis et al. 2011):

$$Vul = \frac{\sum_{t=1}^{n} D_t \big/ Nb\_\text{of}\_\text{times}\_D_t > 0}{\text{water}\_\text{demand}} \tag{3}$$

The Sustainability

It is a criterion that attempts to unify in a unique value the information driven by more than one performance criterion. The reformulated Looks (1997) sustainability formula suggested by Sandoval-Solis et al. (2011) is the one used in the chapter (Eq. 4):

$$Sus = \sqrt[3]{[Rl \times Rs \times (1 - Vul)]} \tag{4}$$

The Allocations' SD

This criterion permits to unveil to what extent a specific management approach has an unpredicted and unstable water allocations (Ahbari et al. 2019). Equation 5 details the calculation expression:

$$SD = \frac{\sqrt{\sum^{t=1} {(X_t - X_m)^2}/{(n-1)}}}{\text{Water\_demand}} \quad (5)$$

where X_t is the allocated volume at time step t; X_m is the average allocated volume; n is the number of time steps.

Description of the Climate Models and Scenarios

As it was mentioned before, two representative concentration pathways (RCP) were used (Van Vuuren et al. 2011): the optimistic scenario "RCP 2.6" and the pessimistic scenario "RCP 8.5." The selection of the RCP 8.5 and 2.6 as assessment scenarios is driven by the fact that the objective of the chapter is to track the potential interval of plausible changes resulting from all levels of mitigation policies (no policy, weak, modest, below 2 °C policies). Therefore, the RCP 8.5 is chosen to represent the pessimistic trend, even though it is a highly unlikely case (Hausfather and Peters 2020), and the RCP 2.6 to simulate the optimistic tendency willing to keep the global warming below 2 °C. Concerning the climate projections, the data from the COordinated Regional Climate Downscaling EXperiment (CORDEX; Giorgi et al. 2009) were employed. The data output used are the bias-corrected climate projections over the EUR-11 domain which contains our studied area. The bias-corrected CORDEX data are accessible via the link https://esgf-data.dkrz.de/search/cordex-dkrz/. By respecting the same specifications during the data filtration (same Regional Circulation Model (RCM) and driven Global Circulation Model (GCM)) for both RCP scenarios, only two RCM were available for use: RCA4 and REMO2009. These RCM are driven respectively in their boundaries conditions by the GCM: ICHEC-EC-EARTH and MPI-M-MPI-ESM-LR. The NetCDF files containing the bias-corrected projections were downloaded for each variable-RCP-RCM triple, for the projection period 2020–2049. Since a global hydrologic model was used to simulate the streamflow in the basin, the calculation of the average projected series for the basin for each Variable-RCP-RCM triple was mandatory. So, the 6500 km^2 basin upstream BEO-AEO is divided into a 11 km grid cells, and the projected series of each triple variable-RCP-RCM at the center of each cell are extracted. The transformation of the cell center coordinates from regular to rotated was done using the software AgriMetSoft (2017). Then, the average basin series for each triple are calculated by averaging the projected series for all cells. To get the projected series for each variable-RCP couple, an ensemble mean was calculated using the series of the two RCM, and then converted to IS units (°C and mm).

Description of the Models Embedded in the Framework

The hydrologic model used is the hydrologic modeling system (HMS) model, with a simple canopy and surface formalisms, the soil moisture accounting (SMA) as the loss method, the Clark Unit Hydrograph (Clark UH) as the transform method, and the exponential recession method to simulate the baseflow component. The model was calibrated and validated over the basin in previous works (Ahbari et al. 2018a, b). The HMS model of the basin was obtained after a training–validation and a detailed sensitivity analysis processes that permit to converge to the best HMS model in terms of efficiency. Nonetheless, it is necessary to highlight that this rainfall–runoff model exhibits some deficiency in the simulation of some flow peaks as described in Ahbari et al. (2018b). This deficiency was taken into consideration while interpreting and discussing the results of this chapter. About the siltation process in BEO reservoir, it is modeled using a preestablished model (Ahbari et al. 2018c) integrating sediment yield to the reservoir and the sediment consolidation phenomena. As described in detail in Ahbari et al. (2018c), the preestablished siltation model was able to simulate the observed time series of siltation in BEO using a genetic algorithm optimization process. For the evaporation from the reservoir water plane, it is estimated using a multiple linear regression model between the monthly evaporated volume as a dependent variable and the monthly average temperature, the monthly potential evapotranspiration (ETP) and the reservoir water level at the beginning of the month, as explanatory variables. The mentioned evaporation model was calibrated and validated for the purpose of this assessment study, and the results are shown in the results section.

Concerning the BEO-AEO management model, it is represented by an optimized version of the current MA practiced in BEO-AEO. The optimization of the current MA was done using the genetic algorithm, and its performances were evaluated in a two-step process: a training-validation and a sensitivity analysis processes. For brevity purposes, more details about the reservoir operations fulfilled by this model please refer to Ahbari et al. (2019).

Evaluation of the Water Demand and the Impact Assessment Criteria

Due to the lack of detailed data about the projection of the daily water demand for each user for the projected period of 2020–2049, the series of the projected daily water demand was constructed by extrapolating the current hypothetical water demand, using the available projected evolution ratio of the basin of Oum-Er-Rabia. In fact, the basin of BEO-AEO is part of the basin of Oum-Er-Rabia for which the projected evolution ratios in 2020, 2025, and 2030 are available. Beyond 2030, the same ratio as for 2030 is applied till the end of the projected period. The current hypothetical water demand refers to an annual water demand series represented by the year on which the releases from BEO-AEO are maximal. This hypothetical series should be the best to represent the current water demand series (which is inaccessible for the authors) since the daily deficits will be at their minimal values ever recorded. Nevertheless, it is important to notice that the constructed annual water demand at the 2030 horizon (constructed using the concept described above) is almost equal to the only information publically available about the annual water demand for BEO-AEO for the same horizon (annual water demand at the 2030 horizon).

To evaluate the impacts of CC on the HC variables inside the basin of BEO-AEO and on its management variables, two assessment criteria were used: the average values between the reference and the projected periods, and the intra-annual evolution of the HC variables. Additionally, the following criteria were used to assess the change in the performances of the BEO-AEO complex in satisfying the water demand: the deficit, the reliability, the resilience, the vulnerability, the sustainability, and the standard deviation of allocations.

The Observed Impacts on Hydro-Climatology and Reservoir's Performances

The Elaborated Evaporation Model

The calibration period starts from March 1986 to February 2002, and the validation begins in March 2002 and finishes in December 2008. Figure 3 shows the linear regressions during the calibration and the validation periods.

As seen in Fig. 3, the linear regression is clear, important ($R^2 = 0.72$ for calibration and 0.76 for validation), and statistically significant at 5% level (p-value <0.0001). The resulting multiple linear regression relates the monthly evaporated volume from the reservoir of BEO to three explanatory variables as described in Eq. 6:

$$V_{EVP} = -46.03 + 0.06^{*} H_{WL} + 0.26^{*} T + 0.25^{*} ETP \tag{6}$$

where V_{EVP} is the monthly evaporated volume (Mm^3); H_{WL} is the water level in the reservoir of BEO at the beginning of the month (m); T is the average monthly temperature (°C); ETP is the monthly potential evapotranspiration (mm). H_{WL} and T are both based on observed values of water level in the reservoir of BEO and the average temperature at the gauge of Tilouguite. The ETP was calculated based on the formulae (Eq. 7) dedicated for rainfall–runoff modeling purposes proposed by Oudin et al. (2005).

$$\begin{aligned} ETP &= \frac{R_e}{\lambda.\rho}\frac{T_a + 5}{100} \Rightarrow \text{if } \ T_a + 5 > 0 \\ ETP &= 0 \Rightarrow \text{otherwise} \end{aligned} \tag{7}$$

where ETP is the rate of potential evapotranspiration ($mm\ day^{-1}$), R_e is extraterrestrial radiation which depends on latitude and Julian day ($MJ\ m^{-2}\ day^{-1}$), λ is the

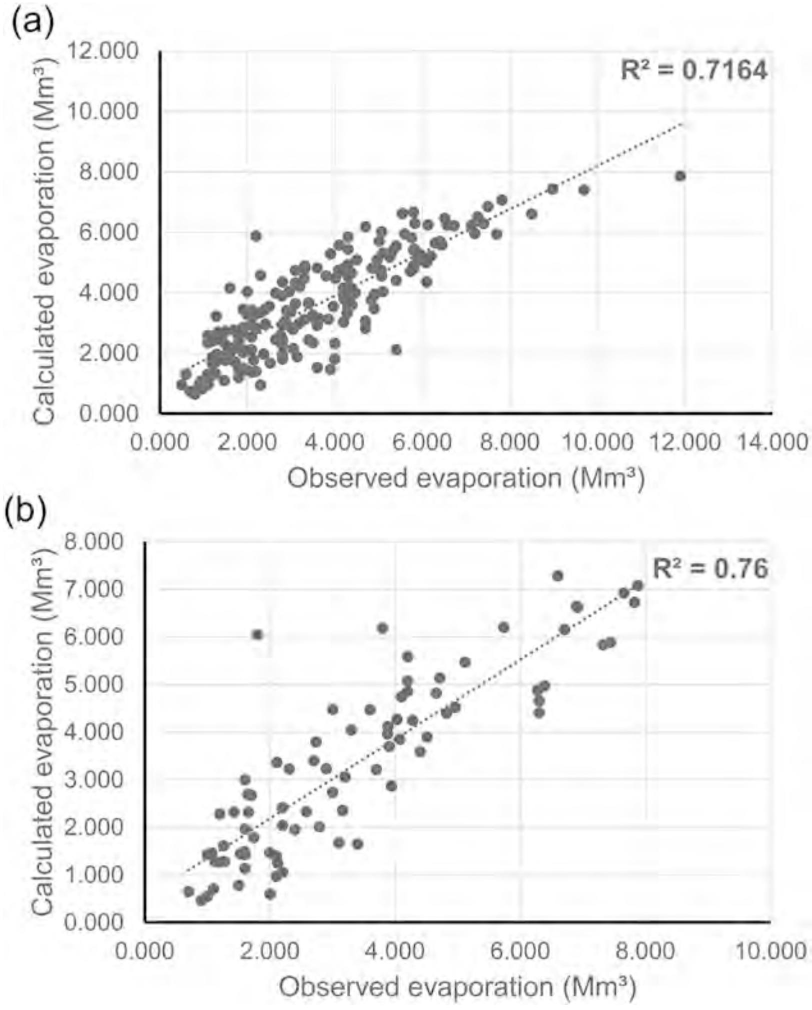

Fig. 3 Linear regression between observed and calculated evaporation during (**a**) calibration and (**b**) validation periods

latent heat flux equals 2,45 (MJ kg^{-1}), ρ is the density of water (kg m^{-3}), and T_a is mean daily air temperature (°C).

By integrating the water level as an explanatory variable, the obtained equation implicitly integrates the most important parameter that controls the evaporation from the reservoir: the surface of the water plane. The regression would be more substantial if other variables data were available like humidity and wind speed (Condie and Webster 1997).

CC Impacts on HC and Management Variables

Change in Average Values

Table 1 resumes the change in the average values of different HC and management variables between the reference and the projection periods.

The six key observations extracted from Table 1 are:

Firstly, negative impacts (qualified as negative because they alter directly or indirectly the performances of the reservoir) are suggested by both RCP for all variables, except for evaporation which will decrease. In fact, this first observation is an expected result and a concordance with the observed negative impacts of CC at both global (IPCC 2014) and national (MEMEE 2016) scales, especially for temperature and precipitation. Those negative impacts include: the increase of the average air temperature by at least +3.70 °C, the increase of ETP by at least 18.46%, the decrease of precipitation by 54.16% (RCP 2.6), the decrease of water supply by not less than 59%, the diminution of the stocked volume by 65.19% (RCP 8.5), and most importantly, the decline of water allocations to users to reach 60.07% (RCP 8.5). That said, what does not concord with global and national tendencies is the evaporation evolution trend. In fact, the downward trend of evaporation is explained by the decreasing trend projected for the variable water stocked in the reservoir, caused by the decrease of precipitations and water supply to the reservoir. The evaporation here is not to confound with the evaporation part of the evapotranspiration, which as it is seen will increase.

Secondly, except the temperature and the ETP which are related, the two RCPs drain practically the same impact on HC variables. Regarding this second observation,

Table 1 Change in the average values of the HC and the management variables between the reference and the projection periods for both RCP 2.6 and 8.5

		Reference period	Values		Difference (%) to the reference period	
		1986–2015	RCP 2.6	RCP 8.5	RCP 2.6	RCP 8.5
HC variables	Temperature (°C/day)	16.61	20.32	20.71	+3.70 °C	+4.10 °C
	ETP (mm/day)	2.96	3.51	3.56	+18.46	+20.08
	Evaporation (Mm^3/day)	0.118	0.082	0.080	−30.52	−31.81
	Precipitations (mm/day)	1.16	0.53	0.53	−54.46	−54.16
	Water supply (Mm^3/day)	2.25	0.90	0.88	−59.89	−60.82
Management variables	Stocked volume (Mm^3/day)	599.89	221.02	208.84	−63.16	−65.19
	Allocated volume (Mm^3/day)	1.88	0.797	0.75	−57.92	−60.07

the similar impacts of both RCP in terms of intensity and trend can be related to three reasons: (1) the horizon of projection 2020–2049 is probably far enough to sense a difference between an optimistic and pessimistic scenario in terms of warming, but it is not far enough to let the RCP 2.6 decreasing emissions to take effect on other aspects of climate much more complex like precipitations (Giorgi et al. 2019); (2) The used RCM and their driven GCM models are likely capable of simulating air temperature directly correlated to greenhouse gases concentration, but still have problem with the simulation of climate variables indirectly related to these gases like precipitations (Schliep et al. 2010); (3) since the projected period is located in the first half of the twenty-first century, it is expected that the difference between scenarios remains small (IPCC 2014; Hawkins and Sutton 2009). This last reason can be more highlighted by looking at the variables evaporation and water supply (obtained using the validated evaporation and hydrologic models), for which the difference between the RCPs is more important, even though they both integrate in their calculation the climate models outputs. For the ETP, more difference between the two RCPs is obtained since it was calculated by the formula of Oudin et al. (2005), which relates the ETP to the temperature directly without requiring any other climate variable. Moreover, the difference between the ETP values for the two RCPs is statistically insignificant at 5% level (p-value = 0.058), which supports the two reasons mentioned.

Thirdly, the difference between the optimistic and the pessimistic RCP is more pronounced for the management variables than the HC variables: Concerning the third observation, it highlights a valuable conclusion: if following the RCP 2.6 emissions limits will not have immediate and important repercussions on the climate system (IPCC 2014; Marzeion et al. 2018), it would be more likely beneficial to other systems like the capacity of dam's reservoir to regulate water volumes interannually. This conclusion can be supported by the more interesting difference between RCP 2.6 and RCP 8.5 impacts on stocked and allocated volumes. In addition, the cause behind this difference between RCPs impacts for management variables is that the optimized MA has acquired some adaptation capabilities during the sensitivity analysis done in Ahbari et al. (2019). In fact, the optimized approach was defined after testing different scenarios of pluviometry (low, moderate, and high) and water demand (normal and high scenarios).

Fourthly, unlike other variables, the RCP 8.5 would induce less impacts than the RCP 2.6 for the precipitation variable. With regard to this fourth observation, statistical significance tests were applied to the difference between the RCP 2.6 and 8.5 precipitation values, and found it statistically insignificant at 5% level (p-value = 0.878). The 95% confidence interval on the difference between the two RCPs values of precipitation is]−0.047; 0.040[. Therefore, one cannot be sure about the cause responsible of this apparent anomaly: Is it the RCM and the GCM used or it is just a question of sampling.

Fifthly, even though directly related, the precipitations and the water supply variables are not similarly influenced by the RCP selected. In other words, the fifth observation stipulates that while the precipitation is more impacted by the RCP 2.6, the water supply variable is more influenced by the RCP 8.5. This may sound intriguing, because since the two variables are highly related then they are supposed to behave similarly when they are trained by a given RCP scenario. However, this apparent anomaly could be explained by these two reasons: (1) as it was mentioned before, the difference between the RCP 2.6 and 8.5 for the variable precipitation is not statistically significant; (2) also, the difference between the two RCPs for the variable water supply is statistically insignificant. Thus, the causes behind this situation can be, in addition to a problem in RCM or GCM functionalities, a problem in statistical sampling related to the projection period chosen.

Sixthly, the percentage of change between the reference and the projection periods for all variables is very high. About this last observation, it is necessary to note that all variables values for the RCP 2.6 and 8.5 are statistically significant compared to the reference period at 5% level (p-value <0.0001). This means that according to the used RCMs, a statistically significant CC during the period 2020–2049 is expected in the basin upstream BEO-AEO compared to the reference period 1986–2015. Moreover, a statistically significant negative impact on the management variables will take place during the same period. For the high intensity of difference between reference and projection periods, it should be known that the values obtained include the uncertainties related to the climate, hydrological, siltation, and evaporation models. So, unlike the direction of change trend, the values of change obtained require a delicate interpretation before making any conclusion.

Intra-annual Evolution of the Variables

As demonstrated in the subsection before, the projections expect a substantial change in the average value of all studied HC variables. However, it is necessary and beneficial to analyze the intra-annual evolution of this change, to detect the most impacted months, and to deduct constructive conclusions for some eventual adaptation strategies. Figure 4 represents the intra-annual evolution of the average air temperature in the basin of BEO-AEO.

It is clear from Fig. 4 that the increase of temperature would not concern all months, and the difference between the two RCPs monthly temperature is practically zero. In fact, the hydrological year can be divided into three zones, differentiated by the intensity of temperature increase. Thus, three zones are recognizable: (1) zone 1 (December–January–February) characterized by a very limited increase; (2) zone 2 (November and March) which surrounds zone 1, and it shows a moderate increase of temperature; (3) zone 3 (April to October) known for its high-temperature increase compared to the other zones.

This zonation in the temperature augmentation was also observed in other basins using different RCM and GCM (Bannister et al. 2017; Santer et al. 2018). According to these case studies, the zones' length can change from one month to several months, but the common conclusion is that the winter season had never shown any increase of temperature. The reasons proposed to explain this unique behavior are: (1) climate models are deficient in simulating the Arctic oscillation and the north hemisphere winter climate (Cohen et al. 2012); (2) the high monthly bias was found

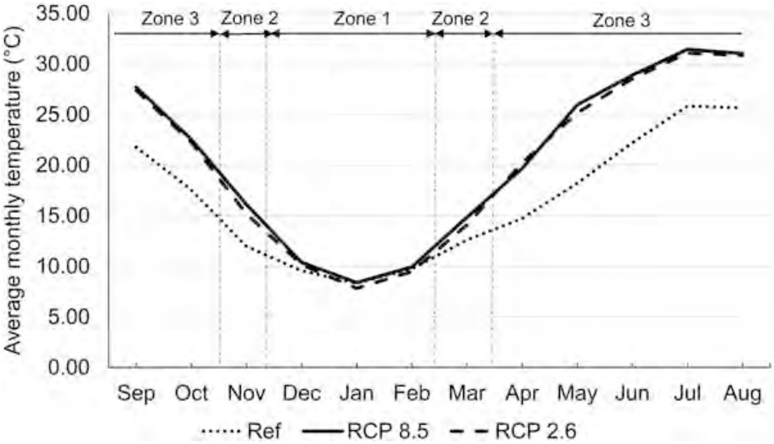

Fig. 4 Intra-annual evolution of the average air temperature under RCP 2.6 and 8.5 in the basin of BEO-AEO

correlated to climate models characterized by sparse horizontal resolution, and thus, to topographical factor (Bannister et al. 2017); (3) the surface-cloud feedback process might be incorrectly represented in climate models (Jiang et al. 2015); (4) the natural cause is not excluded either, because Osuch and Wawrzyniak (2016) have found a comparable seasonality in temperature evolution via the analysis of historical data.

Concerning the difference between the RCPs impacts on monthly air temperature, it was found that the difference between the RCP 8.5 and 2.6 temperature augmentation is statistically significant for November and May only (at 5% level, p-value equals 0.002 and 0.005, respectively). On the other hand, the monthly temperature increase compared to the reference period is statistically significant for all months, apart from January and February (p-value equals 0.818 and 0.626, respectively). These 2 months belonging to zone 1, confirm the characteristics of zone 1 showing, in terms of increasing values, a very limited change.

Like the air temperature, the ETP intra-annual variability presents the same zonation configuration (Fig. 5). Nonetheless, in the case of ETP, the zones' disposition has changed. Hence, the very limited increase zone (zone 1) covers December, January, and February (the change is statistically insignificant for January and February with a p-value reaching 0.926 and 0.672, consecutively at 5% level). Then, comes the moderate increase zone (zone 2), which gained some months previously occupied by zone 3 in Fig. 4 (March, April, September, October, and November). Finally, there is zone 3 starting on May and finishing on August, which shows a high increase of ETP compared to other months. All the differences between the reference period and the RCPs are statistically significant for all months covered by zones 2 and 3.

In reality, the ETP in this study was calculated using a formula that requires only the temperature and the latitude. By consequence, it was expected that the ETP intra-

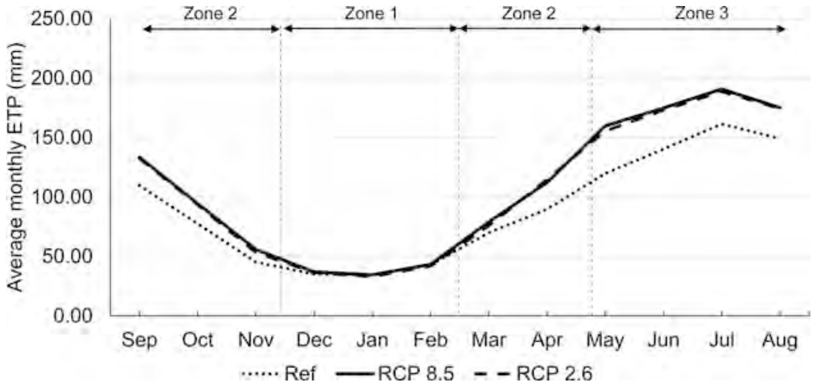

Fig. 5 Intra-annual evolution of ETP under RCP 2.6 and 8.5 forcing in the basin of BEO-AEO

annual variability would be similar to the temperature one. Hence, one can wonder why the pattern of intra-annual variability of temperature and ETP is different? In fact, this is related to the other parameter of the ETP calculation equation: Latitude. Thus, the translation of zones in Fig. 5 compared to Fig. 4 is related to the influence of the latitude parameter, and to its implicit factors such as the global radiation received by the studied area.

Other than the impact zonation, Fig. 5 indicates also that the differentiation between RCP 8.5 and 2.6 impacts on monthly ETP is visually hard to spot. In fact, statistical tests confirm this observation for all months, November, December, and May excepted (p-values equals 0.002, <0.0001 and 0.005 respectively). Hence, if an issue of climate modeling reason is expulsed, and the natural cause confirmed, this may indicate an interesting classification of months in terms of their ETP responses to greenhouse gases emissions. Consequently, once confirmed, this conclusion might be useful to take into consideration in the adaptation of reservoir operations approaches, so that they became prepared to future CC effects. The zonation remark is also to consider in those adaptation methodologies, since it is repeated in both temperature and ETP results.

For the variables temperature and ETP, the months covered by each zone can be seen differently by each reader, but it is sure that a zonation representing different intra-annual variability is present, and should be investigated further, and eventually taken into consideration in future adaptation strategies.

Regarding the intra-annual variability of evaporation from the reservoir of BEO, Fig. 6 describes a different monthly response of this variable compared to temperature and ETP. In fact, instead of showing months where the change is zero or very limited and others more impacted by CC, the evaporation intra-annual variability concerns all months with a slight difference in intensity from one month to another. That said, it is easy to spot months (December to March) where the difference between projections and reference curves is more pronounced than others (May to September). This is explained by the evolution of water stocked in the reservoir throughout time, it self-controlled by water supply and precipitations seasonality.

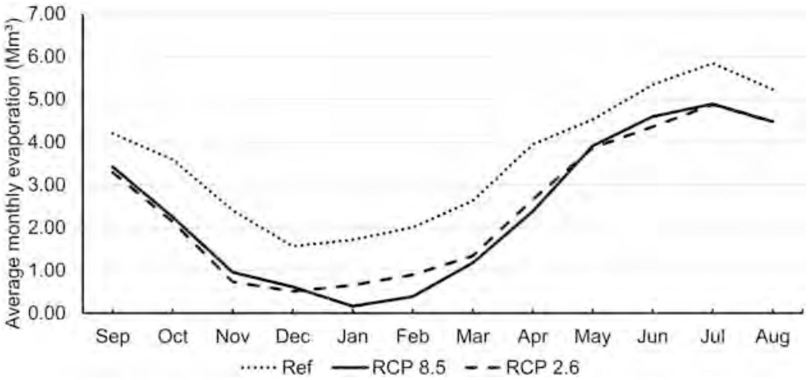

Fig. 6 Intra-annual evolution of evaporation under RCP 2.6 and 8.5 forcing in the reservoir of BEO

As seen, the downward trend of the average evaporation changes detailed in the subsection '3.2.1 Average values change' is detected in all months without exception, in opposition to the variables temperature and ETP. The monthly evaporation diminution shown in Fig. 6 are all statistically significant for all months at 5% level, with p-values ranging from 0.006 for September to <0.0001 for months between October and April. On the other hand, the difference between the two RCPs impacts on monthly evaporation seems to follow a differentiation by months. Hence, there is November, January, and February where the difference between RCP 2.6 and 8.5 is visible and statistically significant (p-value equals 0.044 for the first and <0.0001 for the lasts), and the other months where the type of scenario do not apply any statistically relevant difference.

With regard to the variable precipitations, Fig. 7 resumes the evolution of it under reference, RCP 2.6 and RCP 8.5 scenarios. By reading Fig. 7, four fundamental remarks can be deducted: (1) the diminution tendency affects all months, under the two RCPs; (2) the period covered by the rainy season is getting short, especially for the RCP 8.5; (3) The months with very low pluviometry are more frequent (For instance, from June to September); (4) the RCP 8.5 expects a delayed rainy season, while the RCP 2.6 suggests that it would be advanced temporally.

These remarks mean that the basin of BEO-AEO will experience a change in terms of the dominant precipitations type depending on the RCP considered (more solid for the 2.6 RCP, and more liquid for the 8.5 RCP), a change in the intensity and/ or frequency of summer storms (since the precipitations will be reduced considerably during this season) and of course all the repercussions that will be sensed in the hydrologic regime.

Statistically speaking, although the visual difference between the RCP 2.6 and 8.5 curves for some months (November and March for example) is clear, no significant difference was found for any month.

About the water supply to BEO-AEO and its variation through time, Fig. 8 compares the intra-annual evolution during the reference period and under the

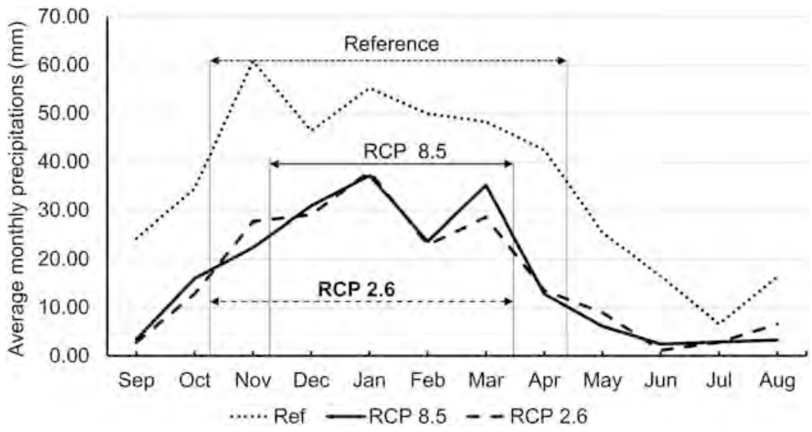

Fig. 7 Intra-annual evolution of precipitations under RCP 2.6 and 8.5 forcing in the basin of BEO-AEO

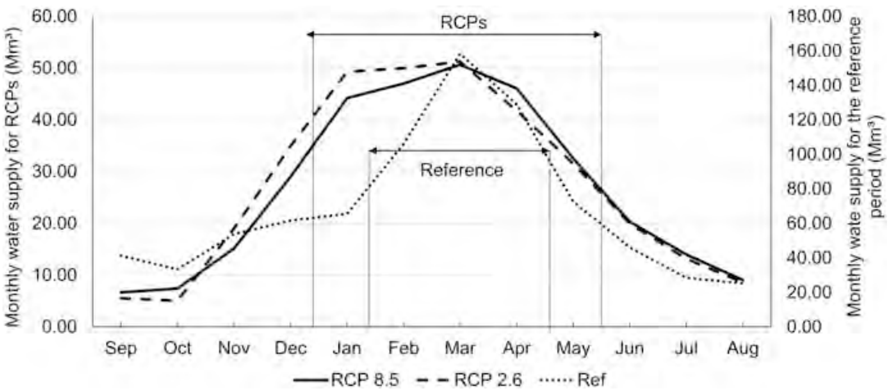

Fig. 8 Intra-annual evolution of water supply under RCP 2.6 and 8.5 in the basin of BEO-AEO

RCPs scenarios. The evolution of water supply concords with the conclusions of Fig. 7 and Table 1, assuming that future water supply will decrease in terms of volume and temporal distribution. In addition, Fig. 8 demonstrates that in parallel with the reduction of its volume drained, the season of "high supply" will prolong temporally compared to the reference period of 1986–2015. Moreover, the change of hydrologic regime from pluvio-nival to pluvial, mentioned in Ahbari et al. (2017), will be accentuated in both RCPs. Thus, the hydrologic peak is located in March, after being culminating in April during the period 1939–1976 (Ahbari et al. 2017). The accentuation of the pluvial regime can be justified when observing the RCPs curves, which present a peak roughly in the form of a plateau, especially for the RCP 2.6, where the plateau covers the months January–February–March.

In addition, the difference during March between the water supply curves of the reference and the projection periods' is statistically significant (p-value <0.0001 at 5% level), while it was insignificant during the same month for the variable precipitations. This may indicate that the impact of climate projections on March water supply was not induced via a change in March precipitations, but it is caused by another factor. In fact, the presumed vector of change is an advanced melting of the solid precipitations that occurred in previous months (especially for the RCP 2.6 where the dominant form of precipitations is the solid one), accelerated by the projected temperature increase. Then, if this is the case, the conclusions mentioned by other studies and confirmed in this chapter, about the incapacity of the RCM and GCM models to simulate the winter temperature increase, are reinforced again.

Additionally, in contradiction to the observation about dominant precipitation seen in Fig. 7, the water supply evolutions for the RCP 2.6 and 8.5 do not match the type of regimes expected.

Even though the solid precipitations are expected in RCP 2.6, the hydrologic regime is almost the same as for 8.5 on which liquid precipitations are more dominant. This is explained by the fact that the solid precipitations will not wait too long to melt, since the increase in temperature already mentioned provoke an advanced melting, and will not wait until the spring season. If this explanation is correct, this means that the reasons stated before about the stability of temperature in the winter season are correct, and the models are really encountering issue with the simulation of climate during this season.

CC Impacts on the Performances of BEO-AEO Reservoir

After running the assessment procedure detailed in Fig. 2 for the RCPs 2.6 and 8.5, the performances of the optimized MA of BEO-AEO under CC projections were assessed, via the calculation of the six most important criteria. Table 2 details the results obtained at a daily time-step scale.

According to Table 2, except the standard deviation of allocations, all aspects of performance will be deteriorated under the two emissions scenarios. Therefore, the

Table 2 Average daily values of the performance criteria of BEO-AEO calculated for the reference and projection periods

	Values (%)			Difference to the reference (%)	
	Reference	RCP2.6	RCP8.5	RCP 2.6	RCP 8.5
Deficit	26.68	67.01	68.70	+151.16	+157.48
Reliability	25.50	8.58	7.96	−66.33	−68.77
Resilience	11.16	4.58	4.18	−58.98	−62.50
Vulnerability	47.76	75.87	77	+58.88	+61.24
Sustainability	24.59	9.82	9.15	−60.04	−62.789
Standard deviation of allocations	38.73	19.36	17.77	−50.01	−54.10

percentage of deterioration can reach +157.48% (RCP 8.5) for the daily deficit, −68.77% (RCP 8.5) for the daily reliability, not less than −58.98% (RCP 2.6) in the case of the resilience and sustainability and at least +58.88% (RCP 2.6) of vulnerability deterioration. Moreover, it is proved by Table 2 that the vulnerability is the less impacted aspect, and the deficit the most damaged one.

Oppositely, the standard deviation of water allocations will be improved and its daily value will fluctuate between 17.77% (RCP 8.5) and 19.36% (RCP 2.6). The reason explaining this improvement is that the establishment of the optimized MA included a phase where the optimization of the releases to users has been performed. So, performing this update permitted to the MA to acquire an attitude to keep the variability of allocations minimal, under stressing climate circumstances.

Furthermore, and unlike the HC variables, the type of the scenario chosen appears to have an effect more considerable on the performances displayed by the BEO-AEO system. This confirms the conclusion mentioned before that: if the RCP 2.6 emissions guidelines are followed, it is certain that the climate will need decades to restore its regular conditions, but the systems impacted by this climate (the reservoir operations in this case) will rapidly start to show substantial enhancement.

By consequence, in the case of BEO-AEO complex, the aspects of performance that will manifest intensively this attitude are the daily deficit and the resilience. In fact, the reason behind the fast response of the deficit criterion is similar to the reason behind the improvement of allocations variability. Regarding the resilience, it is related to the fact that the choice of this optimized approach as the best one (Ahbari et al. 2019), was preceded by a sensitivity analysis towards different conditions (including varying pluviometry and water demand scenarios). Therefore, the different scenarios tested had likely helped in adapting the approach to extreme conditions, and by consequence, they improved its resilience capacities. Furthermore, the rapid response of the resilience criterion to the change of RCP can also be explained by the fact that, as shown in Ahbari et al. (2019), the resilience of BEO-AEO was the aspect of performance on which the manager of this reservoir complex have focused while calibrating the MA for the last time. This may indicate that if a regular update of the current MA was done, by including the resilience criterion in the objective function, the resilience may show similar results as those shown by the standard-deviation of allocations.

Overall, the results of the CC effects assessment present a clear tendency to have negative impacts on both the hydro-climatology of the basin of BEO-AEO and on the performances of the complex. In fact, the impacts projected concord with those reported in the literature (McSweeney et al. 2010; Ouraich 2014; MEMEE 2016; Filahi et al. 2017) in terms of trend, but not always concerning the intensity of change. For instance, McSweeney et al. (2010) and Ouraich (2014) stated a range of temperature variation across Morocco oscillating between +1.5 and +3.5 °C for 2060, and a maximum decrease of precipitations reaching 52%. Nevertheless, MEMEE (2016) mentioned that by 2065, air temperature in Morocco would increase from +0.5 °C to +2 °C, and precipitations change is projected to vary between +10% and −20%, depending on the region and the RCP scenario.

Nonetheless, it is necessary to mention that while the projected temperature and precipitations are averaged over all the catchment areas, the temperature, precipitation, and ETP of the reference period are gauge-based series. Thus, this may be explaining some of the differences. Additionally, water supplies are also based on average precipitation over the whole basin during the projection period, while in the reference it is based on the average of six gauges. Moreover, since all the performance values are based on water supply, then even these performance evolution compared to the reference period is to take with precautions.

The differences observed could be caused by the bias-corrected climate projections used in this study. In this chapter, the use of the CORDEX bias-corrected and downscaled data was dictated by the fact that neither the availability of meteorological stations inside and around the basin (especially for temperature), or the accessibility to those data was possible at the time of completion of this study. Therefore, the use of the available ones in the training and testing of a statistical downscaling and/or bias-correction method will never converge to acceptable results. These problems of network representativeness and limitation on climate model validation were reported by several authors (Filahi et al. 2017). So, the intensity of change in these conditions will never be accurate, even without counting the uncertainties driven by the different models and data.

Nevertheless, the differences can also be related to the various uncommon aspects between the materials and methods used in this chapter, and those employed in other studies, including: (1) the choice of RCM, GCM, and all the specifications that go in parallel (domain type, spatial resolution, ensemble calculation...) (Fantini et al. 2018; von Trentini et al. 2019); (2) the climate and hydrological models characteristics (Lespinas et al. 2014); (3) the downscaling and bias correction methods used and all the uncertainties they drive during training and testing (Teutschbein and Seibert 2012; Räty et al. 2018); (4) the choice of the reference, the projection periods, and the time step of projection (daily, monthly, or annually) used; (5) the area studied by each chapter (whole country, neighboring basin, neighboring city...).

In addition, to attenuate this disagreement between impacts assessment studies, it is recommended to proceed to the accomplishment of the following guidelines: (1) simple RCM assessment via a validation of the RCM simulations over a historical period; (2) advanced RCM assessment via a sensitivity analysis of RCM tuning parameters (Bucchignani et al. 2016); (3) The use of ensemble RCMs simulations instead of single RCM outputs, due to the benefits proven by this option (Phillips and Gleckler 2006; Filahi et al. 2017); (4) the assessment and selection of the best ensemble RCMs prediction method (Duan and Phillips 2010) without being influenced by the eventual negative impacts of ensemble mean RCM use.

However, this disagreement between studies, about the magnitude of change, is not only specific to the basin of BEO, but it is well-known worldwide at catchment scale (Sellami et al. 2016). Furthermore, the projections of CC can also differ in sign not only in magnitude (Koutsouris et al. 2010; Nassopoulos et al. 2012).

In addition, the intensity of change is not the ultimate objective in CC assessment studies, nor it is the aim of this chapter. But, the important is to prove to managers that impacts are coming, and adaptation actions are highly recommended. Moreover, the manager should know that even with an optimized MA, without regular updates, the future performances will be heavily affected. In fact, with all the uncertainties trained by the climate, hydrological, and other models used, the use of these projections, directly, to adapt the current MAs would be useless, or even counterproductive.

In reality, the climate projections can be used indirectly by exploiting common conclusions like those mentioned in this chapter (the trend of change, the zonation in the impact of CC on the variability of temperature and ETP, the change in precipitation dominant form, the change in hydrologic regime, which months are more affected, which performance aspects are more responsive to adaptability, which ones are more impacted by CC. . .).

Hence, the current MA can be modified by adding additional parameters, and/or optimized by testing various operations conditions to take into consideration those expected change. Once those modifications are applied to the current MA, the manager can update his approach regularly to implement each time the trend of change and its intensity. Furthermore, the manager can look for the best update pattern of this new approach, by comparing different update configuration (each year, each n years. . .).

For instance, in our example, before evaluating the impacts of CC on the performances of BEO-AEO, Ahbari et al. (2019) proceeded to the update and optimization of the releases formulae. Thus, when analyzing the results of performance projections, the standard deviation of water allocations was the only criterion which had experienced an improvement of its daily value.

Conclusions and Perspectives

The aim of the chapter was to assess the impacts of future CC projections on the HC variables, management variables, and the performances of the complex of BEO-AEO. To accomplish this objective, a typical top-down CC assessment procedure was followed including the use of optimistic and pessimistic emissions scenarios, RCM ensemble-mean, and prevalidated models (hydrological, siltation, evaporation, and reservoir management models). The climate projections data used were from the bias-corrected CORDEX data specific to EUR-11 spatial domain. Once the typical assessment procedure was run, the results were analyzed via: average values change, intra-annual variability, and performance criteria.

The results obtained show negative impacts for both HC (evaporation excepted) and management variables and all the performance aspects (the standard deviation of allocations excepted) of BEO-AEO. In general, the trends of HC variables change concord with other studies focusing on Morocco. Particularly, the projections expect an increase of air temperature and ETP, a downward tendency of precipitations, water supply, evaporation, stocked volume in the reservoir of BEO, allocated volumes to users. In terms of performances, and except the standard-deviation of allocations, negative trends of evolution are projected for all performance criteria: increase of deficit and vulnerability and decrease of reliability, sustainability, and resilience. Oppositely, the variability of water allocations will be improved under the two RCPs. This improvement is related to the phase of optimization of the releases that preceded this work. Concerning the intra-annual variability of the HC variables, the following conclusions are the most important ones: the zonation in terms of the impacts of CC on the variability of temperature and ETP, the change in precipitation dominant form depending on the RCP chosen, the accentuation of the pluvial hydrological regime, the probable advanced snow melting due to the increase of temperature, the limited difference between the impacts of the two RCPs on the majority of variables and months.

Finally, it is sure that the intensity of the projected CC mentioned in this chapter, and the one reported in other papers are not similar, but all of them have a consensus regarding the tendency of this change: Negative impacts are expected. Therefore, actions should be taken in order to adapt these infrastructures to CC effects.

Urban Flooding, Adaptation Strategies, and Resilience: Case Study of Accra, Ghana

115

Kwadwo Owusu and Peter Bilson Obour

Contents

Abstract

Despite massive flood controlling investments, perennial flooding continues to be a major challenge in the Greater Accra Metropolitan Assembly in Ghana. Previous studies have mostly considered the vulnerability of Accra to flooding induced by urbanization and climate change. This chapter examined the impacts of and adaptation strategies to flooding in two flood-prone residential areas in Accra. A survey was conducted among 320 household heads to ascertain local impacts of floods and community adaptation strategies. To obtain a broader picture of government interventions and challenges, key stakeholders such as personnel from ministries, departments, and agencies who are involved in city planning, and

private urban planning consultants were interviewed. The study found that a notable driver of floods in Accra is blocked waterways, and flawed and ad hoc engineering works. About three-quarters of the households interviewed have suffered flood-related losses over the past decade such as housing damage, income, and even a death of a relative. Key flood control interventions included dredging prior to start of rains and sporadic demolition of unauthorized buildings on or near waterways to allow free flow of water. However, these interventions only seem to be ephemeral due to the rapid rate of littering and re-siltation of the waterways after few rain events. The study highlights the need for more pragmatic and robust engineering solutions to build resilience of Accra to floods.

Introduction

Urban flooding is one of the major hydro-climatic disasters which is increasing in frequency and intensity and affecting regions worldwide. Flooding causes serious economic, social, health, cultural, and environmental impacts that affect sustainable development (Kim et al. 2017), particularly in developing regions because of high poverty levels, and poor urban planning and building architecture. Different types of floods can be identified based on the source of water and the process giving rise to the flooding event (Viglione and Rogger 2015). This study focuses on urban floods occurring independently and/or in conjunction with flash and river floods. As at the year 2000, global urban land susceptible to floods was estimated to be around 195,493 km^2 (Güneralp et al. 2015). Africa is one of the continents highly affected by flood-induced disasters, particularly in urban areas. The vulnerability of African cities to urban flooding is partly due to the fast rate of uncontrolled urbanization and its associated problems which constrained flow of water (Amoako 2012; Aboagye 2012; Dewan 2015).

In Ghana, flooding is among the top 10 natural disasters and hazards and ranks second after epidemics such as bacterial and viral infectious diseases, affecting over three million people and causing huge economic losses each year (Okyere et al. 2012). The country has experienced increasing flood events over the years – the severest floods in the last two decades occurred in the years 2007, 2010, 2011, 2015, and 2020, which hit many parts of the country, particularly major urban areas. For instance, on June 22, 2010, 35 bodies were retrieved from flood waters across the country by volunteers and rescue workers (Daily Graphic 5 June, 2015), and on June 3, 2015, flooding with an associated fire killed about 200 people in the commercial hub of Accra (BBC 2015). The consequences of flood-induced disasters in urban areas include loss of properties and lives as outlined above, which also have short- and long-term adverse consequences on urban poverty and development.

Global climate change impacts are likely to increase hydro-climatic disasters like flooding in urban areas. The recent Intergovernmental Panel on Climate Change (IPCC) Special Report on the impacts of global warming of 1.5 °C above preindustrial levels and related global greenhouse gas emission pathways projects increase in the frequency and magnitude of flood due to changing precipitation patterns (IPCC 2018). Despite the large uncertainties in the magnitudes of climate change impacts on water-related shocks, increased frequency of extreme rainfall events will pose a serious threat to urban resilience and sustainability in many developing countries. The high vulnerability of these regions to extreme climatic events results from their low resilience and weak adaptive capacity (IPCC 2007). Adaptation to flood-related impact is not an option but a necessity, which must be embraced across all spheres of planning. However, while the vulnerability of urban areas to flood-related disasters is largely studied, the local impacts and, more importantly, multilevel flood adaptation strategies are poorly understood especially in developing countries.

To contribute to a better understanding of climate change impact on urban areas in Ghana to disasters, and identify key adaptation challenges to guide decision making and for prioritizing city planning needs, a study was conducted in two flood-prone coastal metropolitan areas of Accra and Sekondi-Takoradi. Part of the results recently published by Owusu et al. (2019) investigated the physical and social vulnerability of the two urban cities to climate-induced disasters. Key findings highlight the need to prioritize perennial flooding to safeguard lives and property and to strengthen the cities' resilience to flood-related disasters. Following up on the previous findings by Owusu et al. (2019), the present chapter investigates incidence of flooding, adaptation strategies, and resilience in Accra. Specifically, the study (i) examined impact of floods on socio-economic livelihoods and (ii) explores multi-level flood control measures and adaptation strategies, and associated shortfalls, that is, why interventions to tackle flooding in Accra have been ineffective? It is hoped that a better understanding of flood control measures and adaptation practices and pitfalls would provide essential information on successful adaptation options and help to identify the interventions that need to be improved to build the resilience of Accra and other cities in Ghana to flood-related disasters.

Accra's Vulnerability to Perennial Floods

The term vulnerability has been used by different authors to connote different meanings. Beyond the multidimensional usage of the term vulnerability, most comprehensive and accepted definition in the context of climate change has been given by the IPCC (2000) as: "the degree to which a system is susceptible to, or unable to cope with adverse effects of climate change, including climate variability and extremes." Thus, vulnerability of any system has generally been accepted as a function of three elements: exposure to a hazard, sensitivity to that hazard, and the capacity of the system to cope with and adapt or recover from the effects of those conditions (Jamshidi et al. 2019). Here, vulnerability is used to encompass both the exposure and susceptibility of population to floods. Thus, the chapter examines the exposure of residents in Accra to flooding and the ensuing burden on socio-economic livelihoods and sustainable development in the city.

Accra is a primate city in Ghana with a long history of flood-related disasters as illustrated in Table 1. Records of major flood incidence in the city date back to June 1959 (Daily Graphic 5 June, 2015). More than 16 deadly flood disasters have been recorded since 1959, all of which have caused severe damages to life and property. The vulnerability of Accra to flooding has been attributed to natural factors and processes like its low-lying topography, increase rate of coastal erosion, frequency of torrential rainfall in recent years, combined with anthropogenic factors such as rapid urbanization, chocked drains, and blocked watercourses (Jamshidi et al. 2019; Asumadu-Sarkodie et al. 2015; Appeaning Addo and Appeaning Addo 2016). For instance, on July 3, 1995, the Ghana Meteorological Agency (GMet) recorded 243 mm of rain with a peak intensity of 64 mm in 12 min. The rain lasted for approximately 5 h resulting in flooding in Accra and its environs (Kwarteng 2007) and on May 18, 2008, and October 25, 2011, ~156 mm of rain water was recorded in less than 10 h resulted in a deadly flood in many parts of Accra (The Weekend Globe 2013). According to Maskey and Trambauer (2015), the main process leading to flooding is precipitation falling over an extended period of time in an area which produces runoff due to saturation (antecedent soil moisture) and excess infiltration. The relationship between heavy downpours and incidence of flooding (due to rapid peak flows) has been explained using run-off models (e.g., Asumadu-Sarkodie et al. 2015). Jahanbazi and Egger (2014) stress that extreme rainfall leads to flooding when urban drainage system fails to drain the total amount of rainwater, resulting in what could be termed as an urban pluvial.

Considering that changes in precipitation patterns and extreme rainfall associated with climate change will increase the vulnerability of cities to flooding in many regions (Willems et al. 2012), flooding in Accra will continue to be a major socio-economic and development challenge more than ever. A better understanding of management of flooding and failures is vital to develop sustainable solutions and building the resilience in flood-prone areas in Accra.

Description of the Study Area and Methodology

Accra is the largest metropolitan area in Ghana and has been the administrative capital city of the country since 1877. It has a total land area of 201 km^2 (UN-Habitat 2009). The city has experienced a rapid growth and it is one of the fastest-growing cities in West Africa with an estimated annual average growth rate (2010–2020) of 2.2% (www.macrotrends.net 2020). Accra has physically developed very quickly particularly along the arteries of the major road network radiating from the city center to the countryside (Møller-Jensen et al. 2005). Another worrying trend is the increasing physical development along the low-lying coastal and flood-prone areas of Accra threatening the ecology of coastal lagoons and estuaries (Owusu et al. 2019). The population in the city has increased from about 177,000 inhabitants in 1950s to about 2.5 million inhabitants by the close of 2019 (www.macrotrends.net

2020) and accommodates approximately 8.4% of the ~30 million people in Ghana. Unfortunately, infrastructure and service provision is behind the physical development of Accra and has placed pressure on housing and worsened the already high housing deficit in the city (Rain et al. 2011). As a result, there are many areas that are unplanned or where inadequate planning has been carried out by the land-owners who attempt to integrate their development into the statutory land use plan of Accra leading to a proliferation of slums with about 38% of the city's population living in these underserved settlements (UN-Habitat 2011).

The physical location of Accra in the dry coastal foothills of the Akwapim ranges renders the city vulnerable to flooding. Accra is mostly low lying with average elevation around 20 m and bordered by few hills to the west and northwest. It is drained by many rivers like the Odaw and Dzorwulu that originate from the Akwapim hills. Rainfall in the Southeast of Ghana where Accra is located has high variability (with coefficient of variation of above 30%) which results in high frequent of rainfall extremes (Owusu and Teye 2015). Two residential classes in Accra, namely, second and third areas prone to perennial flooding (Owusu et al. 2019), were selected for the study. The specific neighborhoods were: second class residential areas (Kaneshie, Abelemkpe, and Asylum Down) and third class residential areas (Adabraka, Alajo, Avenor, Odawna, Mataheko, Nima, and Mamobi). The vulnerability of the neighborhoods to flooding is partly due to the low-lying topography (lies a few meters above sea level) and uncontrolled slums (Owusu et al. 2019). The geographical spread of the study sites (Fig. 1) was to ensure that we obtained a wide and representative data.

Primary data for the study were collected using the procedure described in Owusu et al. (2019). In brief, data on impacts of flooding on household livelihoods, mitigations and adaptation strategies, and barriers were collected at household and institutional levels. A combination of stratified and simple random sample survey were conducted in the neighborhoods located in the two residential classes. A total of 320 household heads were interviewed, which comprised 90 and 230 in the second and third class residential areas, respectively. Data collected included background information, experience, and narration of impact of flooding in the area of residence and individual and/or community preparedness and response.

Interviews were conducted with construction engineers and relevant institutions such as the Departments of Physical Planning, Development Planning, Urban Roads, and National Disaster Management Organization (NADMO), Geological Survey Department, and the Ghana Water Company Limited (GWCL) in Greater Accra Metropolitan Assembly (AMA) to provide further insights into the household surveys and preparedness and flood-mitigation measures rolled out by the metropolis to control perennial flooding in Accra. To supplement the data on flood-mitigation measures in the Accra, secondary data collection was done to obtain information on past and current public (government) invested projects to tackle flooding and its associated impacts on socio-economic livelihoods on the population. The secondary

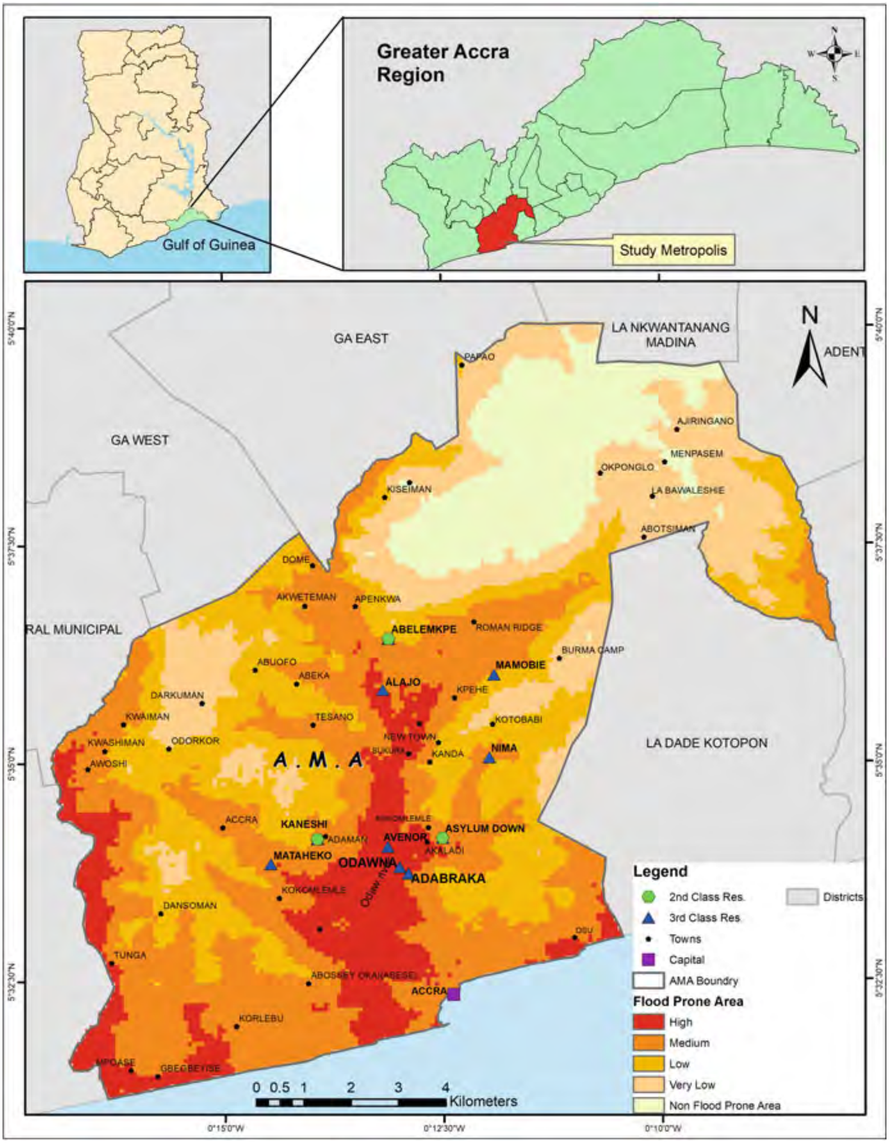

Fig. 1 Map of Accra showing the study locations and flood-prone areas. (Source: Authors)

data were sourced from newspapers, journal articles, and government documents. Both the primary and secondary data were manually analyzed to establish themes and patterns based on the objectives of the study.

Results and Discussion

Impact of Flooding on Socio-economic Livelihoods

Both the household and stakeholder interviews indicate that flooding has socio-economic tolls on households, the metropolitan assembly, and the nation. The impact on household livelihood reported included loss of property such as buildings and other personal belongings, and self-employed businesses. The respondents interviews in both residential areas investigated revealed that property damage during flood varied considerably between households, ranging from hundreds to several thousands of dollars across households in the seven study sites. However, for poor record keeping and reluctance of the respondents in providing information on economic losses, exact monetary damages to household could not be ascertained. Nevertheless, the estimates reported in the present study corroborates the information sourced from stakeholders and what has been reported in earlier studies. Previous studies in Accra estimated property damage due to flooding in the city on July 3, 1995, and on June 13, 1997, ranged from thousands to millions of dollars (Kwarteng 2007; Aboagye 2012). Interviews held with NADMO officials showed that the nation spends a lot of money on flood events in AMA – it constitutes expenses on relief items like blanket, mattresses soap, food, and sometimes temporary structures for flooding affected households.

Results from the present study showed that the magnitude of flood-related damages and losses largely depended on household characteristics such as the economic value of personal belongings of affected-households, and more importantly, whether flood warning were issued prior to a flooding episode. The main source of information on risk of flooding reported by the respondents was flood alert warnings issued by the GMet. Thus, the interviews revealed that reported flood-induced damages were high among respondents who own several and/or valuable properties such as electronic appliances, furnished homes, and those who were engaged in self-employed business in the same neighborhood where they lived or in another flood-prone area in Accra. Further, results from the household interviews demonstrated that economic impact of floods in terms of property damage, in general, tends to be low when households anticipated risk of flooding during a rain storm/event from warnings issued by the GMet. In that case they were able to move some of their belongings to relatives and friends who lived in low flood risks areas in the city.

Further, physical destruction of buildings means household loss their homes. Over 65% of the respondents in both residential areas reported that they or someone they knew had been homeless for a few weeks to several months after flooding in the last decade. The respondents mentioned that being homeless has both economic and psychological consequences on their households, though the latter could not be readily quantified. According to a respondent: "...Being homeless, especially when you have a family makes you feel like you have life without soul or sailing without direction."

In addition to property losses, all the respondents emphasized that flooding in Accra posed physical danger on lives and health of households, such as injuries on the day of flooding and an outbreak of cholera and other water-borne diseases after flooding. About 30% of the households, mainly in Alajo, Avenor, Odawna, and Adabraka, reported that they have lost a relative or someone they knew due to flood-related disasters in the past decade, probably due to the close proximity of the neighborhoods to the Odaw River which frequently overflows its banks during rainstorms. Cost of treating injuries immediately or a few days following flood-disasters was reported to be free of charge because AMA took care of the medical bills, whereas cases reported several days after flooding were not treated for free. This means "unless a patient is a national health insurance scheme participant, they have to pay for cost of health care services." The present study demonstrates that the overall impacts of flooding on household livelihood in Accra may be higher than previously thought. According to Maskey and Trambauer (2015), hydro-climatic hazards have tangible impacts that are easily quantifiable and intangible that are not easily quantifiable. Owusu and Teye (2015) found that property loss and death associated with urban flooding in Accra could be remarkably high, but evaluation is limited by lack of data. It is interesting and relevant for future studies to map and quantify the actual socio-economic, health, and psychological burden of flooding on households in Accra using proxy data such as cost of treating injuries and/or disease morbidity, lost wages, time spent for caring for sick or injured household member, etc., to provide a robust documentation and clear picture of impact of floods. Such information can be very useful for prioritizing government- and private-led schemes for supporting flood-affected households in Accra.

Flood Control and Adaptation Measures

Results from the interviews and detailed review of secondary literature demonstrating the detrimental impact of flooding on household livelihood and economic implications for the nation (e.g., Mensah and Ahadzie 2020; Ahmed et al. 2018) suggest that flood control in the short-term or adaptation in the long-terms is imperative. However, it is intriguing to point out that the long flood history of Accra has, indeed, shaped the interaction between local and/or metropolitan activities and development, and flood control and adaptation practices. In the following section, the individual and communities, and metropolitan flood control and adaptation interventions, as well as some pertinent barriers to adaptation, are discussed. To better understand the spatial dimensions of community interventions, that is, whether household flood control and/or adaptation strategies are influenced by their physical local or vulnerability to flooding, flood control, and/or adaptation strategies reported by the respondents are discussed in light of the two residential classes investigated.

Individual and Community

Results indicated that individuals in the study areas are coping by adopting a combination of flood control and adaptation practices. For respondents who lived a few meters away from main drains, a key control measure reported was the digging of temporary channels from their homes to the main drain to ensure free flow of water during torrential rain event. However, the practices, in general, were reported to be less effective and less reliable because the main river channel is often choked.

Eighty-five percent of the respondents in marginal areas like flood plains and swampy areas indicated that they have adapted to flooding by taken drastic accommodation steps. The key reported ones included: (i) changing from building expensive permanent concrete block structures to building cheaper temporary structures such as simple wood structures or metal containers. Fifty-eight percent of the respondents who lived in temporary structures held the opinion that living in those structures were necessary to alleviate huge capital losses when the structure is damaged or lost due either to demolition exercises periodically carried out by AMA to bring down unauthorized structures on and near waterways, or the structure is damaged during flooding. (ii) The respondents in both residential classes reported that they also controlled flooding by desilting drainage channels in their neighborhoods. The cost of dredging is sometimes fully supported by AMA through the local assembly. However, they emphasized that such a support was not regular. Therefore, the common practice has been organizing communal labor to dredge some of the sections of the drainage channels themselves. Further, the interviews revealed a few relatively rich individuals in both residential areas sometimes employed the services of private dredging companies to desilt all or a section of drainage channels closed to their homes to allow free flow of water, which helps prevent flooding. (iii) Another individual adaptation practice reported by 52% and 48% of the respondents in the third and second class residential areas was temporary vacation of homes located on and near waters during the rainy season, especially when the GMet issued an alert that flooding in Accra was imminent. Findings are consistent with previous observations (e.g., Mensah and Ahadzie 2020) showing that in flood-prone areas, people adopt reactive strategies like relocating and protecting properties, for instance, by practicing early transfer of personal belongings to safe places prior to onset of rains. The present study further showed that flood-forecasting by the GMet plays a crucial role in strengthening household seasonal adaptation practices and thus, helps to alleviate the negative impact of flooding on socio-economic livelihoods.

Households in the highly flood-prone residential areas, particularly in Alajo, Adabraka, Avenor, and Asylum Down, have adapted to the economic shocks of flooding by enrolling in life and property insurance schemes, which according to them provided an economic cushion in times of flood-related disasters. However, because premiums and monthly charges can be prohibitively expensive for, especially, low-income households, only a few of the respondents (18%) reported that they had life and/or property insurance.

Metropolitan Assembly/Government

The household and stakeholder interviews pointed out two key areas of institutional or government 'action plans" to managing flooding in Accra. A common approach, which has for many decades been adopted by AMA, was routine dredging of water channels, notably the Odaw River and Korle-Lagoon. The Odaw River has a wide catchment area and covers most parts of Accra and feeds into the Korle-Lagoon, which empties the content of the Odaw and other drainage channels into the Gulf of Guinea (Owusu Boadi and Kuitunen 2002; Ministry of Works and Housing 2019). Table 2 presents an overview of government flood control and adaptation projects in Accra in the last decade implemented during the rainy season before or after flood disasters. Table 2 illustrates two important considerations: (i) the state has spent substantial amount of money in the past decade on measures to prevent flooding in Accra, and (ii) flood prevention measures have mainly been dredging to unblock major waterways and drainage systems prior to the rainy season. Findings of the study highlight that although the dredging projects required massive capital investment, the persistence of flooding in Accra is a strong evidence that the project may be providing ad hoc solutions with very minimal long-term impacts as previously reported by Owusu et al. (2019). Evidence here suggests a need for government to rather consider massive capital investments such as the construction of more robust drain, which can offer sustainable solutions for controlling flooding in Accra and in other flood-prone cities in Ghana.

Another institutional intervention reported was the demolition of unauthorized buildings on or near waterways to allow free flow of water. Demolition of building is an exercise regularly carried out by AMA prior to the start of the rainy season, especially when torrential rains were expected in Accra and its surroundings. The interviews revealed that likewise dredging, demolition also only offers a short-term solution for managing flooding because the demolished structures are re-erected shortly after the AMA-led demolition exercise is completed.

Summary Types of Adaptation Measures to Flooding in Accra

Alcamo and Olesen (2012) proposed that climate change adaptation measures could be classified into the following: autonomous vs. planned, anticipatory vs. reactive, centralized vs. decentralized, and gradual vs. abrupt. Although these classifications were originally proposed in relation to climate change, they could be applied in the present study to classify the adaptation measures to flooding. Results showed that adaptation at the individual level encompasses both autonomous and planned adaptation practices. Decisions taken by households on where to relocate to when flood warnings are issued by GMet are mainly taken at the family level. The planned adaptation measures adopted by the individual included the construction of improvised channels from homes to main drains to ensure free flow of water. Dredging of drainage channels by community and/or government prior to the onset of rain is both anticipatory (i.e., in anticipation to control risk of flooding during the rainy season)

Table 2 Overview of government investments (2010–2020) to control flooding in the Greater Accra Metropolitan Assembly

Project	Date (period)	Description	Cost (US$)	Sponsors	Reference
Greater Accra Resilient and Integrated Development Project	2019–2025	Phase 1: mitigating the flood risk for a 10% annual exceedance probability flood in the Odaw River Basin	200 million	Dutch Government and the World Bank	The World Bank (2019)
		Phase 2: expanding flood mitigation and drainage improvements to additional priority basins (such as Lafa, Sakumo, Kpeshie, and Densu asins)	300 million	Dutch Government and the World Bank	The World Bank (2019)
		Phase 3: scaling up the project to the remaining priority basins of the Greater Accra Region (GAR) to mitigate flood risk in the entire GAR	400 million	Dutch Government and the World Bank	The World Bank (2019)
Korle Lagoon Ecological Restoration Project	2015–2016	Dredged the Odaw drain and Korle Lagoon to solve the perennial flooding in Accra in order to save lives and property	10 million	–	Arthur-Mensah (2017)
Relief and Repair Project	2015	A relief and repair efforts following flooding with an associated fire killed about 200 people in the commercial hub of Accra	12 million	Government of Ghana	The Economist Group (June 23rd 2016)
Accra Sanitation, Sewer, Stormwater and Drainage Alleviation Project	2013	Improving the drainage system in Accra to control the perennial flooding and sanitation challenges in the city	595 million	Loan facilities with the EXIM Bank of the USA and Standard Chartered Bank	BBC (2015)
Dredging the Odaw River	2011	Improving the drainage system of the Odaw	1.2 million	–	The Daily Graphic (2012)
Dredging Committee for Chemu Lagoon	2010	Improving the drainage system of the Chemu	2 million	–	Business Ghana (2010)

and reactive (i.e., to avoid similar flood-related damages and loss experienced during previous floods). Centralized adaptation measures to flooding in Accra encompass AMA or government sponsored projects carried out to dredge principal drainage channels; the commonly reported were the Odaw River and Korle-Lagoon. The decentralized adaptation measures involved dredging minor drainage channels sponsored through community fundraising. Finally, gradual adaptation measures to flooding are evidenced by the individual's decision to change from building more permanent and expensive homes on or near principal waterways to avert high economic losses when the structures are damaged due to flooding or government demolition. Further, as mentioned previously, a few of the respondents have adopted gradual adaptation strategy by enrolling in life and property insurance schemes against accidents and life-threatening disasters. Conversely, AMA- or government-led demolition of structures before onset of rains to reduce risk of flooding and associated damages and causalities is mainly an abrupt adaptation measure.

Limits and Barriers to Adaptation to Flooding

A notable limitation to individual and community funded dredging reported was noncooporation and noncompliance among some community members. It was reported that, often, people are unwilling to contribute financially to enable the community leaders hire the services of private dredging companies. A major reason cited for noncontribution was "to some people this whole dredging activities is the responsibility of the local assembly and the government" [An assembly man at

Fig. 2 (**a**) Location of residential buildings near open drainage and (**b**) excavation and disposition of dredged materials to drainage banks, which lead to rapid re-siltation and increases flood risk in Accra

Alajo]. Therefore, there was no need for the individual to take over what the government must do for the community or city.

Further, despite community and/or government massive investments in dredging and related projects, the impact of these projects, in general, seemed to be short-lived because as illustrated in Fig. 2, (i) the open drain system results in faster accumulation of silt and solid waste, (ii) the dredged materials are often left on the banks of the drainage, which leads re-siltation of the waterways after few rain events, (iii) lack of enforcement of town plans and building permits, and (iv) there is also a societal habitat of massive littering and disposing of domestic and industrial waste into drains, leading to rapid refilling of dredged drainage channels. According to Mensah and Ahadzie (2020), improper urban disposal of waste can heighten flood events. Findings here suggest a need for AMA to invest in the construction of more robust drainage systems to build flood resilience in Accra. Interviews with planning and private urban planning consultants emphasized the urgent need for more sustainable development infrastructure in Accra and in other flood-prone cities, for example, by switching from open drain to close drainage system to abate using drainage channels as dumping sites.

Conclusions and Perspectives

Findings illustrate the perennial flooding in Accra that continue to cause massive property damage and occasional loss of lives. The main cause of flooding in the city was found to be the siltation of the Korle-Lagoon and the Odaw River and its tributaries, the construction of houses on waterways, and flood plains due mainly to lax enforcement of building permits. The very nature of development, that is, the building of open drains coupled with poor sanitation attitude among residences, results in the blockage of drains in the city that accounts for most of the flood episodes. This is supported by the fact that the Accra plains where the city of Accra is located is actually the driest part of Ghana with average annual precipitation totally 800 mm yet Accra is the most flooded city in the country.

Findings showed that flooding in Accra has enormous adverse impacts on household income, property, and employment. The main adaptation measures at the level of the individual, community, and government include building less permanent and inexpensive structures to reduce economic cost of flood-induced damages, dredging of drains ahead of rainfall and demolishing of buildings on or near waterways. Nevertheless, the adaptation measures, in general, were reported to be ineffective to make the city resilient to flooding. A major contribution of the study is showing that flood forecasting by GMet plays a crucial role in mitigating the devastating impact of flooding on household socio-economic livelihoods in Accra. Findings also points to the need for city authorities to implement robust measures to make Accra more resilient to flood in the era of climate change. It is suggested that, in the short-term, effort of making sure that dredged materials are not deposited on the banks of the drainage channel to prevent rapid re-siltation is needed. The dredged material could be put into good use in construction and landfill. However, because of high level of pollution, more studies on how safely to dispose of or potentially use the dredged material should be done. Long-term adaptation such as robust engineering solutions, for example, covering open drains and building of retention ponds that will reduce surface runoff in the city, should be considered. There are a few green spaces like the Achimota forest and large undeveloped land near the city that can be created as retention ponds to help solve the perennial flooding problem in Accra. A potential limitation of the study is that the conclusions presented in the present work are based on a sample size of 320 from 10 flood-prone neighborhoods. It is recommended that future similar studies are conducted in other flood-prone neighborhoods in Accra and elsewhere in Ghana to expand the present work to improve the generalization of the findings for spatial planning and interventions to alleviate impact of flooding on urban livelihoods.

Abstract

The daunting effects of climate change are more visible and acute among rural people in most developing countries. Smallholder farmers in rural communities are more encumbered by climate change impacts and they have been reeling with climate induced shocks for some time. Their vulnerability to climate change impacts is aggravated by high dependence on the climate volatile natural resource base, high poverty levels, lack of adaptive capacity, low educational levels, and lack of technoscience-based technologies among other key compounding factors. In the light of this, Zimbabwe is still crawling to implement and administer effective climate change management measures aimed at disaster risk reduction and management, vulnerability reduction, social resilience, and capacity building because of political and socioeconomic quagmires trapping the country. Consequently, rural people are the hardest hit by these developments. Climate change management connotes a human intervention to reduce the sources or enhance the sinks of greenhouse gases and adjustment to actual or expected climate and its effects, in order to moderate harm or exploit beneficial opportunities through mitigation and adaptation. Nevertheless, rural people are on record of engaging in a plethora of activities to manage climate change and its actual or potential risks. However, their efforts are marred by an avalanche of setbacks which serve as barriers to climate change management. Against this backdrop, this book chapter intends to delineate the factors serving as barriers to climate change management in Zimbabwe's rural communities.

Introduction and Background

Zimbabwe like many other developing countries is highly vulnerable to climate change impacts due to livelihoods that are climate sensitive. The country's vulnerability is also catalyzed by low adaptive capacities among its citizens (Zvamasiya et al. 2017). On that note, the multifarious impacts of climate change are visible and felt in different sectors which beacons the country's economy namely; agriculture, health, water resources, transport, energy, tourism, wildlife, and biodiversity (Dube and Nhamo 2019). The precarious impacts of climate change are taking a toll in rural communities where rainfed agriculture is a key livelihood factor. Furthermore, rural people are more vulnerable to climate change impacts because they lack adaptive capacity in the wake of climate change induced shocks (Nyahunda et al. 2019). In the light of this, Mubaya and Mafongoya (2017) opine that the manifestation of climate change impacts through erratic rainfall patterns and excessive temperatures is resulting in dwindling of crop yields placing rural people at a perilous position of food insecurity. As for Chanza (2014), due to climate change, rural communities have been saddled by successive droughts, desiccation of water sources, floods, distribution of pathogens causing diseases and death of livestock, deterioration of the natural resource base including grazing lands for livestock, and widened poverty levels.

This chapter derives from empirical research on climate change adaptation among rural people in Chivi south and Umzingwane districts. It also benefited from a conceptual review of literature on climate change adaptation studies conducted in other rural parts of Zimbabwe. This was done to extract best adaptation practices and also to document the constraints faced by rural people in their adaptation efforts. In this regard, this is meant inform policy measures that could be devised to circumvent adaptation constraints among rural people. For empirical purposes, the study was qualitative in nature guided by the multi-case study design. Data was collected through transect walks, focus group discussions and individual interviews with 40 participants that were purposively and conveniently selected in Chivi south and Umzingwane districts. In September 2019, the Government of Zimbabwe declared a national state of disaster over drought as crop yields dwindled owing to climate change. In response, the government appealed for international funding to cater for famine affecting more than 6.5 million people (Dube and Nhamo 2019). Matebeleland South and Masvingo provinces which were the focal point of this study were identified as the most vulnerable provinces to the vagary impacts of climate change (Phiri et al. 2014). These provinces are situated in the agro-ecological regions that are volatile to climate change. As such, agricultural production has been stymied by long dry spells, hot temperatures and erratic rainfall patterns owing to climate change (Jiri et al. 2017). Earlier studies conducted in Chivi south (Masvingo province) and Umzingwane (Matebeleland South province) districts revealed that climate change risks are rampant such as water stress, drought, increased incidences of pests and diseases, and death of livestock (Mudzonga 2012; Dube et al. 2016).

As mentioned above, Dube and Nhamo (2019) posit that among other precarious impacts of climate change is the successive episodes of drought seasons in Zimbabwe particularly in rural communities where an estimated number of seven million people were declared food insecure by September 2019. Despite the Zimbabwean government's acknowledgement of the impacts of climate change on its socioeconomic sectors and vulnerable groups such as rural people, little has been done to cushion rural people and their livelihoods from the vagary impacts of climate change. As such, efforts to manage climate change and its impacts through broad-based adaptation and mitigation processes in rural communities are still far from being lived realities. In order to substantiate this exposition, this book chapter provides evidence of climate change impacts, response strategies and challenges faced by rural people in responding to climate change impacts in Umzingwane district in Matebeleland South Province and Chivi south district in Masvingo province of Zimbabwe. This shall be juxtaposed to the experiences of rural people in other parts of Zimbabwe where climate change is taking a toll. As elsewhere in rural Zimbabwe, smallholder farmers in Umzingwane and Chivi have been reeling with the impacts of climate change for some time complemented by a myriad of challenges to triumph over climate change impacts (Mashizha 2019; Mutandwa et al. 2019; Nyahunda and Tirivangasi 2019). The most daunting setbacks are the soaring poverty levels, low adaptive capacity and unemployment levels in these rural communities and climate change impacts is exacerbating the situation (Nyahunda et al. 2019).

In the foregoing, a plethora of studies in the climate change discourse in Zimbabwe's rural communities, Chivi south and Umzingwane districts included, testifies that rural people are not passive victims to the vagary impacts of climate change but they are responding to it through a plethora of adaptation and mitigation strategies (Gukurume 2013; Dube and Phiri 2013; Ndebele-Murisa and Mubaya 2015; Bhatasara 2018; Nyahunda et al. 2019). These adaptation strategies are aimed at insulating their lives and livelihoods from climatic shocks. What should be highlighted is that, in the process of embarking on a cocktail of adaptation strategies, rural people are still confronted by a myriad of challenges serving as barriers to effective adaptation (Nyahunda and Tirivangasi 2019). In the ongoing, Chanza and Gundu-Jakarasi (2020) opine that Zimbabwe is showing an avalanche of gaps towards climate change adaptation and mitigation. This is because, evidence of climate change in Zimbabwe portrays a predominantly challenging situation. As a result, climate change adaptation efforts in rural communities remain on the onslaught because of lack of adaptive capacity among rural people. Also, the socioeconomic plagues bedeviling Zimbabwe connotes that efforts to enhance modest climate change management through effective adaptation and mitigation remain constrained. This is because there is no evidence of studies dedicated to unravel the efforts being made to address the barriers to climate change adaptation in the rural areas. From this background, this chapter is predetermined to delineate the barriers to climate change management in Zimbabwe's rural communities in a quest to influence the development and implementation of responsive climate change adaptation policy practices. Against this backdrop, the next sections provides a brief overview of barriers in the context of climate change. This is followed by the overview of climate change management where broad definitions of adaptation and mitigation are dissected. Subsequently, climate change management efforts made at national level in Zimbabwe are presented followed by the discussion about localized climate change management efforts. Furthermore, the chapter shall delve into the determinants of adaptive capacity before providing the barriers towards effective climate change management in Zimbabwe's rural communities. Lastly, the chapter shall capture measures to be undertaken to circumvent the identified barriers as Zimbabwe strives to foster adaptive capacity and resilience to climate change.

Barriers to Effective Climate Change Management in Zimbabwe's Rural Communities

An array of definitions about barriers have been propounded in the climate change discourse. In the light of this, Biesbroek et al. (2011) define barriers as impediments amidst the implementation of climate change adaptation strategies. Barriers could be factors or conditions that are largely insurmountable which render adaptation to climate change ineffective (Kruse et al. 2013). Yaro et al. (2015) view barriers as reasons why adaptive capacity is not attainable or being translated into action in the climate change discourse. Also, barriers can be institutional facet, normative or cognitive factors that restrict individuals or groups from implementing appropriate or sustainable forms of adaptation measures (Muzari et al. 2016). In the ongoing, Eisenack et al. (2014) regard barriers as obstacles that make adaptation to climate change less effective or less efficient. Earlier, Biesbroek et al. (2011) opined that barriers are different from limits as highlighted in some climate change literature. This is because barriers are mutable, avoidable, overcome, or reduced whereas limits are seen to be unsurpassable. In support, Yaro et al. (2015) denote that barriers can be overcome by individual or concerted collective effort, changed way of thinking, reprioritization of resources, institutional support, and political will. From the view point of Chanza et al. (2019), barriers are human or natural factors that impede adaptive efforts. As for Bhatasara (2018), barriers in the context of climate change adaptation are constraints faced during the adaptation processes. Despite a plethora of definitions and characteristics of barriers submitted by different scholars, in this study, the researchers paid homage to the definitions of barriers that point to conditions or factors rendering adaptation less effective or factors behind low adaptive capacity of rural people. In light of the above, several studies on climate change adaptation reveal that rural people are saddled by an avalanche of challenges serving as barriers to effective climate change management (Chanza et al. 2019; Nyahunda and Tirivangasi 2019). The understanding of barriers is an important escapade to gain ambient grounds to propose ways of dealing with them. Based on this, the barriers reported in this study were found to be restricting the process of adaptation and decreasing the adaptive capacity of rural farmers.

Overview of Climate Change Management

In this section, climate change management refers to response mechanisms employed human systems to address climate change and its associated risks through adaptation and mitigation measures. In the light of this, the Intergovernmental Panel on Climate Change (IPCC 2014) defines climate change adaptation as response strategies employed by human or natural systems to reduce exposure to climate change risks and to minimize harm or exploit its beneficial opportunities. On the same note, adaptation entails changes and adjustments effected in response to perceived or actual negative stimuli's (climate change) which breeds opportunities for sustainable change and development (Chanza 2014). The United Nations Framework on Climate Change Convention (UNFCCC 2014) defines climate change mitigation as strategies employed by human systems to reduce greenhouse gasses and emissions that cause climate change. To shade more light, Muzari et al. (2016) posit that mitigation involves technological and behavioral adjustments which promote land conservation and preservation, managing deforestation and resorting to renewal energy sources aimed at enhancing greenhouse gas sinks.

From the above expositions, what should be highlighted is that mitigation and adaptation play complementary roles. This connotes that mitigation is poised to stabilize the climatic system thereby minimizing pressure on adaptation (Chanza and Gundu-Jakarasi 2020). Earlier, Chanza (2014) argued that when mitigation fails, adaptation becomes a bone of contention. However, it is important to note that mitigation is more costly to implement for smallholder farmers because it requires technological advancements and modern infrastructural development which are still far from being a lived reality particularly in Zimbabwe. As such, several studies in Zimbabwe's rural communities have captured an avalanche of evidence that points to climate change adaptation in rural communities (Gukurume 2013; Ndebele-Murisa and Mubaya 2015; Nyahunda and Tirivangasi 2019). The implementation of adaptation strategies in the wake of climate change is an interplay of natural perception that the climate system has changed and there is need to adapt, influence of indigenous knowledge systems about the changes in the natural environment which informs possible management measures through the utilization of available resources and the presence policy practices that influence adaptation.

In the ongoing discussion, it is important to emphasize that a plethora of climate change impacts and a vicious vulnerability circle bedeviling most rural communities is making adaptation an inescapable discourse. Due to the fact that responding to the causes of climate change (mitigation) will take time, adaptation becomes a necessity to save people's lives and livelihoods. Most importantly, adaptation to climate change impacts is now a cardinal requirement to reduce its daunting risks and reap the benefits of adaptation (Nyahunda et al. 2019). Furthermore, there is a ubiquitous acknowledgement that without adaptation, climate change and its precarious impacts become detrimental on people's lives and livelihoods. Thus, if people fail to adapt to climate change impacts, they become vulnerable to social disruptions, ailments and deaths brought about by climate change. Based on this, Chanza (2014) provides a synopsis of types of adaptation in the climate change discourse as follows;

(i) Anticipatory adaptation: This type of adaptation takes place before the eruption of climate change and its impacts are observed. In other cases, this type of adaptation is called proactive adaption.
(ii) Autonomous adaptation: This is also referred to as spontaneous adaptation common in most communities where climate change is at the epicenter of people's lives. As such, this type of adaptation is triggered by the observation of ecological changes in the natural or human systems which encumbers people's welfare.
(iii) Planned adaptation: This type of adaptation is influenced by policy measures out of the acknowledgement that the climate system has changed or is about to change and strategic action is required to minimize its impacts.

To extrapolate from the above, earlier arguments denoting that adaptation and mitigation play complementary roles means proactive (anticipatory) adaptation may suppress the climate change phenomenon from occurring which is also the purpose of mitigation. Proactive adaptation is still a challenge in Zimbabwe's rural communities because it requires strategic planning, early forecasting determinations, suppression of anticipated hazards through technology. Importantly, successful climate change management through adaptation is a product of adaptive capacity which refers to the ability of a social ecological system to organize itself and respond to climatic induced damages, learn from them and make use of the advantages present to moderate the risk (IPCC 2014). To this end, the ongoing discussion in this chapter shall navigate on efforts made by the Zimbabwean government to manage climate change impacts at national and local levels before delving into a brief discussion about the determinants of adaptive capacity.

Climate Change Management Efforts at National Level in Zimbabwe

The Zimbabwean government has not been complacent in responding to climate change despite presenting challenges in the country's economic trajectory. Accordingly, the country recognizes the critical contribution of climate change variability in stalling its developmental aspirations (Chanza and Gundu-Jakarasi 2020). In response, the country came up with a gamut of strategies and policy measures signaling a broad-based commitment to tackle climate change and its impacts. Based on this, the Zimbabwean government developed the Zimbabwe Climate Change Response Strategy in 2014. The strategy provides guidelines on coordination and mainstreaming of climate change factors into the country's developmental trajectory to be implemented at local, district, provincial, and national levels (Dodman and Mitlin 2015). The development of the National Climate Change Response Strategy was the first step which subsequently led to the development of the country's National Adaptation Plans (NAPS), National Adaptation Programme of Actions (NAPAs), and Nationally Appropriate Mitigation Actions (NAMAS) as mandated by the Kyoto Protocol and the UNFCCC (Dodman and Mitlin 2015). Zimbabwe's NAPs are aimed at mainstreaming climate risks into national developmental planning, programs, and policies.

Furthermore, the strategy identified key sectors that are vulnerable to climate change such as energy, water, health, agriculture and food security, land usage, forestry, livestock production, industry and commerce and transport. Responsively, the strategy explicitly provides key actions to be undertaken to enhance either adaptation or mitigation in the identified sectors (Makaudze 2016). To add on, in 2016, Zimbabwe developed and promulgated its Climate Change Policy to be supported by the National Climate Change Response Strategy. In the light of this, Zimbabwe's climate change policy draws lessons from the international instruments and protocols which Zimbabwe is a signatory such as the UNFCCC, the Kyoto Protocol, and the Paris Agreement. These instruments provide emphasis on the importance of strategic measures to curtail climate change impacts through crafting, implementing, and regularly publish and update regional and national measures fostered to mitigate climate change effects complemented by facilitation of sustainable climate change adaptation (Zhakata et al. 2017). In the ongoing cluster of arguments, Murombo (2019) denotes that Zimbabwe's climate change policy provides a framework for addressing climate change-related impacts through the development of national adaptation and mitigation efforts. Among other key principles encapsulated in the climate change policy include: the government's commitment to encourage the use of efficient irrigation technologies, promotion of climate tolerant crop varieties and provision of livestock insurance, creation of climate conscious societies that would scale up collective participation in climate change interventions including adaptation and mitigation and upscaling the provision of climate extension services to the farming rural communities especially those depending on climate sensitive resources.

Through the harmonization of the dictates of Zimbabwe's Climate Change Response Strategies and the National Climate Change Policy, the Zimbabwean government created Local Area Adaptations Plans (LAPs), District Adaptation Plans (DAPs) and Provincial Adaptation Plans (PAPs). These provide a database of weather conditions and events in every area, past and present climatic trends and their risks, the area's vulnerability, projections of future climatic scenarios and resources in the areas that can be used for effective planning that builds resilient communities to climate change impacts (Zhakata et al. 2017). Notwithstanding the daunting fact that Zimbabwe's gamut of climate policies and aspirations are devoid of implementation owing to lack of strategic coordination and financing plans, the country is committed to undertake a comprehensive analysis to understand the barriers to climate change adaptation in its policy frameworks. Once again, this stance is not yielding any positive outcomes because rural communities have been saddled by barriers in their efforts to adapt to climate change (Chanza et al. 2019).

Climate Change Management Strategies at Local Levels

This section provides a catalogue of adaptation strategies employed by rural people in Chivi and Umzingwane districts and other rural communities in the wake of climate change and its related shocks in Zimbabwe. As articulated earlier that efforts to manage climate change through mitigation are not feasible in rural communities that are trapped by the doldrums of poverty, underdevelopment and deficiency of infrastructures that warrant mitigation, this study captured adaptation strategies at play among rural people because adaptation despite its insurmountable barriers is feasible even in poor marginalized communities. Despite being located in different provinces, Umzingwane and Chivi districts are susceptible to a myriad of climatic stressors which have compounded majority of households into abject poverty. The soils in these districts are prone to soil erosion making crop production unattainable. To worsen the situation, in Masvingo and Matebeleland South provinces where these districts are located, erratic rainfalls are predominant which are around 500–600 mm (Mudzonga 2016).

In Chivi south and Umzingwane districts, communal farming is a major source of livelihood but the vicissitudes of climate change are rendering rainfed agriculture a futile exercise (Chanza et al. 2019; Muzari et al. 2016; Phiri et al. 2014). Nevertheless, this study established that rural farmers are not passive victims to the vagary impacts of climate change but they are responding to it through a cocktail of adaptation strategies either individually or collectively. Having said that, adaptation to climate change in Chivi and Umzingwane districts is in two-fold that is; independently through the realisation by the community members that they need to adjust their practices in response to the changes and to a limited extent through the influence of the government and nongovernmental organization measures.

In the foregoing, this study captured the adaptation strategies employed by smallholder farmers in both districts in comparison with other studies conducted in other rural communities of Zimbabwe in the wake of climate change induced shocks. This process was important to identify the gaps towards effective adaptation for rural people. In that regard, this study found that crop diversification was a common adaptation strategy to climate change impacts in Umzingwane and Chivi south districts. What emerged is that, smallholder farmers have come up with contingent responses through amalgamation of farming strategies and diversification of crop varieties. In the light of this, most smallholder farmers have resorted to drought tolerant crops that could withstand the long dry spells caused by climate change. The growing of small grain crops such as pearl, finger millet, sorghum and rapoko is on the rise in these two districts. Similar findings were reported by Chanza et al. (2019) in Silobela district that farmers diversified their cropping strategies in response to climate change impacts. To add on, intercropping and crop rotation are common farming practices complemented by changing of planting dates, zero tillage and mulching practices. Diversification of cropping systems is also complemented by the increase in the domestication of drought tolerant livestock such as goats, sheep, guinea fowls and indigenous chicken. A study conducted in Bikita district by Nyahunda and Tirivangasi (2019) revealed that some farmers are growing legumes such as cow peas and beans because they mature early. With the assistance from NGOs such as World Vision Zimbabwe and Action Faim, 45 boreholes and 11 shallow wells were drilled in Chivi south district to support gardening activities and address water stresses. On the same note, in Umzingwane district, the Matebeleland Enhanced Livelihoods Agriculture and Nutrition Adaptation (MELANA) program drilled four solar-powered boreholes to support gardening activities. In Zvimba district, Mashizha (2019) found that even without knowledge of climate change people have adapted at least one strategy and crop diversification was the common one. In Chimanimani district, Mutandwa et al. (2019) established that farmers have diversified their farming methods through varying crop plating dates. Conservation farming was also reported complemented by the use of contour ridges and mulching activities.

Results from a study conducted in Gwanda district by Ndlovu et al. (2020) reveal that pit planting is a key adaptation strategy and this is complemented by mulching activities to retain soil moisture. Conservation farming was also identified in Mutoko district by Bhatasara (2018). Also, in Mutoko, micro irrigation systems through the syphoning of water manually from the rivers was on the rise when water sources are not dry. In Chundu and Nyamakate resettlement areas, Kupika et al. (2019) established that rural farmers are cultivating in the wetlands and digging of wells along river beds to supplement agricultural activities. Rearing of small livestock such as goats, sheep and indigenous chicken was also reported in Zvimba, Hwedza, Bikita, and Kariba districts (Mubaya and Mafongoya 2017; Zvamasiya et al. 2017; Nyahunda and Tirivangasi 2019).

The uncertainty of agriculture production has ignited most rural farmers to diversify their livelihood activities. In the light of this, livelihood diversification is a process by which rural households embark on diversification of a portfolio of activities and social support capabilities for survival and in order to improve their standard of living (Gukurume 2013). Majority of smallholder farmers are embarking on ex-post adaptation mechanisms from main activities such as agriculture which has been decorated by dwindling harvests and droughts emanating from climate change occurring in the communities. These activities are meant to improve their income streams and guarantee food security threatened by climate change. To that end, livelihood diversification activities that were captured include; petty trading of fruits, vegetables and firewood, menial jobs such as brick molding and thatching of houses (among men), gold panning (common in Umzingwane district), cross border trading, beer brewing and artisanal fishing. Kamwi et al. (2018) affirm to this exercise by denoting that diversification of livelihoods warrants resilience in the face of adverse trends or sudden shocks such as climate change. In Silobela district, Chanza et al. (2019) found gold mining, bee keeping, selling of mopane worms and brick molding as common livelihood strategies. Brick molding and selling of firewood were also identified by Nyahunda and Tirivangasi (2019) as common livelihood strategies among rural people in Bikita district. Arguably, these activities have a backlash on the environment which people should protect from land degradation and deforestation. In the Middle Zambezi Biosphere Reserve, Kupika et al. (2019) established that rural people are taking menial jobs in nearby commercial farms. To add on, in Zvimba district, Mashizha (2019) identified casual labor and artisanal mining among the livelihood diversification strategies. Soropa et al. (2019) established that in Tsholotsho and Chiredzi districts, the selling of mopane worms is very common as a supplementary economic activity to compensate the losses incurred from failed harvests.

Furthermore, migration emerged to be another adaptation strategy to climate change in Zimbabwe's rural areas commonly among men. The pervasive patriarchal dominance and social ascribed roles and care giving responsibilities of women limit them from migrating when climate change related disasters strike. This study found that most male figures in Chivi south and Umzingwane districts had either migrated to nearby cities or neighboring countries such as Botswana and South Africa in search for greener pastures. These migrants are remitting their incomes to support their families back home through securing of food, paying of school fees and medical bills and buying of essential farming inputs. Migration has been identified as a common adaptation strategy to the vagary impacts of climate change across Zimbabwe (Chanza et al. 2019; Soropa et al. 2015; Mugambiwa and Rukema 2019; Mubaya and Mafongoya 2017).

The reliance on Indigenous Knowledge Systems (IKS) emerged to be another cardinal adaptation strategy among rural people in Chivi south and Umzingwane districts. Chanza (2014) defines indigenous knowledge as a body of knowledge accumulative based on practice, belief and coordinated adaptive techniques passed through generations on cultural transmission basis denoting how human beings create a relationship with the environment. Through the use of IKS, rural people in Chivi south and Umzingwane districts have developed meticulous systems of gathering, predicting, interpreting and making decisions related to weather. In the same wavelength, they are using this knowledge to devise modest agricultural practices, observation and forecasting of potential impacts of climate change thereby planning proactive adaptation measures, protection of crops, livestock and other assets against climate change induced disasters. On the same note, this is commonly done through a meticulous observation of animal behaviors and sounds, wind direction, astronomy correlation between movements of stars and haze circles around the moon to predict good and bad harvests. In Murehwa, Tsholotsho, and Chiredzi districts, Soropa et al. (2015) opine that rural farmers are using IKS to predict the quality of the season before the onset of the rains. In light of this, IKS indicators are observed early before the season commences. Similar findings about the usage of IKS as a determinant for climate change adaptation were reported by several scholars in studies conducted across Zimbabwe (Mubaya and Mafongoya 2017; Gukurume 2013; Nyahunda and Tirivangasi 2019; Chanza et al. 2019; Mashizha 2019).

What should be noted is that the use of trees and availability of certain wild fruits as a determinant of good and bad seasons was reported in Chivi and Umzingwane districts as in most parts of Zimbabwe. In the same line of argument, the trees, birds and wild fruits used to make seasonal forecasting differ from district to district. In Chivi and Umzingwane districts, IKS is relevant through reading the abundance of wild fruits and flowering of certain plants as a guarantee of the quantity of rain expected. In Zvimba, Bikita, Gwanda, Mutoko, and Murehwa districts, plenty of wild fruits guarantees a good season and a few wild fruits signals drought (Bhatasara 2018; Soropa et al. 2019; Mashizha 2019; Nyahunda and Tirivangasi 2019; Ndlovu et al. 2020). In Chiredzi, early flowering of trees and many mopane worms signals good harvests. Also, in Tsholotsho, heavy sound of animals such as lions in October guarantees a good season (Soropa et al. 2019).

At local levels, this study further found that people are harnessing social capital as an adaptation strategy to climate change. Gukurume (2013) defines social capital as a social web of networks created through interaction which strengthens trust and social norms. In light of this, norms, trustworthiness, and networks that tie people together through kinships, friendship and neighborhood defines social capital (Aldrich and Meyer 2015). Through harnessing of social capital, rural people in Chivi south and Umzingwane districts are making collective efforts to withstand the climate change aberrations by sharing scarce resources such as water and food. It further emerged that there are community savings clubs initiated to improve the income streams and generate funds to buy agricultural inputs, small livestock which are drought tolerant, construction of quality houses that can withstand floods and drilling of wells. In the same vein, rural people are embracing social capital through collective field (Nhimbe) work where they converge to work on certain tasks mainly planting, cultivation, and harvesting. Rural people are on record of utilizing social capital to share skills and problem-solving knowledge in the wake of disasters. Further, Aldrich and Meyer (2015) argue that social capital fosters community engagement, cooperation and participation which are essential in addressing community challenges such as climate change. In corroboration, Musavengane and Simatele (2016) posit that social capital can be a vehicle through which the accumulation of different forms of capital can be achieved and contribute to environmental management.

Chanza et al. (2019) found social capital as a determinant for climate change adaptation in Silobela district through community lending and saving clubs called *mikando*. This was also identified by Nyahunda and Tirivangasi (2019) among rural people in Mazungunye communal lands and the activity is called *Fushai*. In the Nyaminyami area of Kariba rural district, Mubaya and Mafongoya (2017) found the harnessing of social capital in the wake of climate change aberrations manifesting through the Zunde raMambo project. Zunde is a Shona word that may mean a large gathering of people taking part in a common activity or may refer to plenty of grain stored for future use by people in a community (Chanza 2014). This is a traditional grain reserve where the harvest becomes useful in times of hunger. This practice is designated by the Chief (Mambo) (Nyahunda and Tirivangasi 2020). In the Muzarabani area, Chanza (2014) found the Zunde raMambo as the system that serves as a local social safety net for the poor and vulnerable members of the community from food insecurity caused by climate change. In Gutu district, Ndebele and Murisa- Mubaya (2015) found the Zunde raMambo as an important practice against climate change risks and the weakening of national social security schemes attributed to resource constraints and erratic food relief supply chains.

In continuation, in Chivi district as reported in Hwedza and Mutoko districts by Zvamasiya et al. (2017) and Bhatasara (2018), the predominance of social groups is also the hallmark for climate change adaptation. Similar findings were made in Chimanimani district by Mutandwa et al. (2019) that community members were creating social networks and mutual relationships for the purpose of sharing climate responsive strategies and sharing of information as well as best practices. In summing up this section, it is important to note that the presence of adaptation strategies documented in this study doesn't mean that rural people are effectively adapting to the impacts posed by climate change rather they are confronted by a myriad of conundrums serving as barriers to effective adaptation. The capture of adaptation strategies at play in these rural communities was essential to signpost the gaps in the process of adaptation. Having said that, the following section shall delve into determinants of adaptive capacity.

Determinants of the Ability to Adapt to Climate Change (Adaptive Capacity)

This section shall navigate on indicators of adaptive capacity. This is important to create a barometer that can be used to assess whether rural people are effectively adapting to climate change or not. The presence of the determinants of adaptive capacity connotes that there is effective adaptation while the absence of all or some of its determinants imply that there are barriers to effective adaptation to climate change.Accordingly, this study juxtaposed the circumstances in Chivi and Umzingwane districts against the indicators of adaptive capacity as contemplated in a plethora of climate change adaptation literature. In the light of this, Yaro et al. (2015) denote that adaptive capacity is determined by an array of factors which are neither mutually exclusive nor independent but as a result of a combination of these factors. Based on this, the determinants of adaptive capacity were examined following the previous assessments of adaptive capacity made at local levels by Hinkel (2011), Abdul-Razak and Kruse (2017), and Yaro et al. (2015). As such, the following are the determinants of adaptive capacity in the climate change discourse.

Economic Resources

Farmers with a diverse source of income stand a better chance to adapt to the impacts of climate change than those without. Economic resources can be through a confluence of remittances and access to credit facilities that give the smallholder farmers the ability to be responsive in the wake of climate change and its related impacts. It is important to note that, economic resources can be gained through diversification of livelihood activities hinged on access to opportunities. Thus, farmers with economic security can be easily insulated from the precarious impacts of climate change. This is because they can afford to buy climate sensitive farming inputs including hybrid seeds, pesticides and stock feed for livestock. Economic security is the hallmark for food security even under circumstances where agricultural returns are low owing to climate change. On the same note, farmers with economic security have the ability to insure their crops and other assets in the wake of climate change induced disasters such as floods, hurricanes and veld fires.

Training and Awareness

Training as an indicator for successful adaptation implies that farmers with vast farming experience and access to extension services that enhances training, knowledge and skills about climate change stand a higher chance of adapting to climate change impacts than those that lack farming experience and training. Experienced farmers have etiquette indigenous adaptation practices and they have the ability to identify and react to climatic fluctuations. In the ongoing, there is a positive correlation between literacy levels and ability to adapt to climate change. This speaks to farmers with high literacy levels having the ability to adapt than those with lower or without literacy levels. What should be underscored is that knowledge that warrants successful in the climate change terrain is a product of education either formal or informal. Hinkel (2011) posit that education, training and public awareness on climate change is essential for influencing the society to jointly participate in climate change management that is adaptation. In this regard, the availability of knowledge influences decision making peculiar for adaption. To add on, climate knowledge includes evidence-based beliefs and practices about the causes and effects of climate change. In support, Bowen et al. (2012) aver that availability of information allows every population to deduce that something has taken a paradigm shift hence there is need to adapt. This helps to foster an intrinsic assessment on the severity of the disturbance and devise amicable solutions respectively. Lastly, exposure to knowledge enables rural people to evaluate possible actions to be undertaken and pay attention to those that are useful in tandem with their circumstances.

Social Capital

Social capital is one of the many resources available to individuals in every community despite presenting circumstances. This is a web of social networks created through interaction with other members of the community which serves as a hallmark of adaptation when people share resources, information and collective norms to build resilience against climate change. Adaptation to climate change rests on a social component as individuals interact with other network members to share resources, gain information, build new institutions and create collective norms, in order to provide resilience to climate change. As such, social capital serves as a public good in supporting whole communities through extreme events such as climate change (Dussaillant and Guzmán 2014). In the history of climate change strategies, social capital serves as an important vehicle used to acquire agricultural resources, shared problem-solving techniques, information dissemination, knowledge generation, sharing of experiences and solutions for disaster management. This connotes that people with social capital ties can easily adapt to climate change perturbations. Notably, social capital begets social protection.

Equity

Communities with contingent equity practices have ambient environments for successful adaptation to the climate change impacts by all members. In as much as this is an unlikely situation in most rural communities in Africa, adaptation is also a product of equity where there is fairness and equality in sharing of climate change burdens and benefits, equal distribution to resources and opportunities including climate change information, early warning awareness regarding disasters across gender constructs. Issues of equity as an indicator for adaptive capacity means men and women are equally involved in the planning and implementation of climate change interventions at all levels. This also speaks to the inclusion of other vulnerable groups in societies that is the elderly and people with disabilities.

Availability of Technology

The availability of technologies that enhances the farmers' knowledge about climate change crop varieties, soil moisture and fertility retention techniques is a panacea for climate change adaptation in communities where they are present unlike in those without. Relevant technologies in the climate change discourse are techno-science mechanisms aimed at assisting people in adjusting to changes for instance irrigation systems, drought resistant crops, use of remote sensing, local weather forecasting and early warning information systems.

Availability of Infrastructures

For successful adaptation to take place, there is need for infrastructural and technological support systems (IPCC 2014). The availability of the same infrastructures plays a pivotal role in providing early climatic warning information and weather forecasting. Basically, they form part of relevant networks that are important aspects in curbing climate change impacts and foster the ability to respond to natural disasters associated with climate change which manifest through droughts, floods and hurricanes. Important infrastructures that can facilitate successful adaptation to climate change include; irrigation facilities, water catchments, boreholes, schools, quality roads, health care facilities and transport. Despite all these fundamentals (infrastructures) missing or being inadequate in rural communities, in cases where they are available, they foster successful adaptation in the wake of climate change.

Availability of Institutions

The availability of institutions that support or enhance adaptation is the hallmark for adaptive capacity. Institutions play a cardinal role in the assessment of adaptive capacity and resilience building. These institutions include; public and private institutions that is the government and other stakeholders be it Nongovernmental Organizations or Community-Based Organizations. Institutional support that enhances adaptation to climate change can be through parallel practices between those institutions or through integration of their services. In the light of this, integrated institutional arrangements from local to national levels may provide essential support to the farmers to plan and implement contingent adaptation activities. In the same wavelength, strong institutions provide subsidies for agricultural inputs to rural farmers and disaster relief assistance in the wake of climatic induced perturbations. Hinkel (2011) strengthens the above by asserting that countries with modern social, private and public institutions have a high adaptive capacity level than those with no or low functional social institutions.

Barriers Towards Effective Climate Change Management in Zimbabwe's Rural Communities

Poverty

The conundrums of poverty are an albatross around the neck for majority of Zimbabweans in rural areas. Mhlanga and Ndlovu (2020) denotes that 73.3% of the Zimbabwean population are trapped under the manacles of poverty, majority of them in rural areas. As such, rural farmers in Chivi south and Umzingane districts lack adequate resources to leap back from the climate change induced shocks. Smallholder farming in these communities is under siege because of the high dependence on natural erratic rainfalls. Resultantly, the endemic agricultural stagnation is leading to protracted food crisis and accelerated poverty levels. What it means is that, rural people in these districts are running short of adequate economic resources which anchors the ability to adapt to climate change impacts. Basically, poverty is a product of low literacy levels and high unemployment levels particularly in Umzingwane district where majority of the farmers haven't gone beyond primary education while others haven't obtained any formal education at all. Similar findings were made in Silobela district by Chanza et al. (2019) and in Gwanda district by Ndlovu et al. (2020) that the predominance of gold panning activities is leading to high school drop outs amongst the youth. As such, most people are school drop outs or haven't received any formal education.

In Zimbabwe, social protection systems are weak and rural farmers do not have financial reserves either credit or loan facilities due to the economic quagmires characterized by skyrocketing inflation projected to be at 750% by May 2020 (Dzobo et al. 2020). Consequently, peasant farmers in Chivi south and Umzingwane districts as in other rural communities of Zimbabwe are sinking deeper into poverty meaning they are facing a proliferation of obstacles to adapt to climate change. Earlier, Chanza et al. (2019) denoted that different educational levels and income have an impact on adaptation practices.

This study found that efforts by rural farmers in these districts to withstand the vagary impacts of climate change are impeded by the doldrums of poverty which they are entrenched into. In Chivi south district, most villages haven't benefited from the smart agricultural practices such as irrigations systems orchestrated by some NGOs in other parts of the district. As such, farmers in Danamombe and Mandamabwe communities lamented that agriculture is now a futile exercise without technoscience based farming mechanism. Similar findings were reported in Mulungwane and Mzinyathini communities in Umzingwane district that farmers cannot afford the relevant technologies essential for adaptation owing to high poverty levels. In the same vein, most farmers in both districts are stymied by financial setbacks to be able to purchase climate resistant crop varieties and other agricultural inputs. Majority of Zimbabwean are embroiled in confusion of the legitimacy of the local currency called the Real Time Gross Settlement (RTGs) against the United States Dollar which is used to peg prices of all commodities in Zimbabwe including agricultural inputs. The most poignant stance is that income streams of most Zimbabweans and proceeds from the trading activities of rural people are in the valueless RTGs currency and the purchasing of farming inputs and other assets essential for adaption remain a big mountain to climb thereby making adaptation to climate change a nightmare.

The most daunting fact is that the absence of social protection systems and safety nets from the government of Zimbabwe is making rural farmers to dispose their little assets in order to withstand the pressure of drought and other household emergencies. In Bikita district, Nyahunda and Tirivangasi (2019) found that rural people were selling their livestock at economically low prices to curb the conundrums of food insecurity. This makes the vicious circle of poverty infinitive thereby inhibiting their efforts towards effective management to climate change. In the light of this, most rural people in Chivi south and Umzingwane districts are on record of selling of their livestock and other household assets at economically low prices to compensate loses from the agricultural activities. The economic tailspin bedeviling the country means there are also low remittances from local migrant workers to support their families. These dynamics validate the assertions made by the IPCC (2014) that most Southern African communities are trapped in a vicious circle of poverty which consequently make them vulnerable to climate change exacerbated by low adaptive capacity. Furthermore, poverty hampers rural people in Chivi south and Umzingwane districts from executing opportunities for climate change adaptation and they remain highly vulnerable to climate change and its impacts.

To extrapolate from the previous section which explored the determinants of adaptive capacity where economic security is one of them, it is important to note that most rural farmers fail to meet the standard measure of economic resources essential for climate change adaption. Thus, poverty is a barrier towards effective climate change management in Zimbabwe's rural communities. Chanza et al. (2019) denotes that in Silobela district, rural people's dependence on climatic sensitive livelihoods is exacerbating their poverty levels. The manifestations of climate change through recurrent episodes of drought, perennial dry spells, thunderstorm and desiccation of water sources has a direct impact on rural people's livelihoods. Nyahunda and Tirivangasi (2019) allude that in Bikita district, rural people lack resources to procure climate viable resources such as hybrid seeds. In Makonde communal lands, Nyahunda et al. (2019) established that poverty is serving as a backlash towards rural people's adaptation efforts. In Mutoko district, Bhatasara (2018) found that rural farmers have limited agricultural capital due to the doldrums of poverty that they are entrenched in.

Inadequate Information about Climate Change and Adaptation

In Chivi south and Umzingwane districts like in other rural communities in Zimbabwe and beyond, climate change information is still scant and in cases where it is available, climate information/knowledge is marred by mixed perceptions about its causes and consequences. This is attributed to inadequate information about the climate change discourse that is its causes, impacts to effective adaptation and mitigation strategies. Notwithstanding the visibility of NGOs and other government departments charged with disseminating climate change information to rural farmers, the efforts remain parochial because most rural farmers are still grappling to understand the concept climate change and its dynamics. As such, lack of adequate information about climate change and adaptation makes most rural farmers in Chivi south and Umzingwane districts unaware of what they are dealing with (climate change) and how. In as much as a significant number of participants acknowledged to have heard about climate change, they appeared to lack critical information about the roles they have to play to address their plights through active participation in climate change adaptation processes.

What should be underscored is that the way climate change information is disseminated doesn't suit the literacy prowess of most rural farmers particularly in Umzingwane, Gwanda, and Tsholotsho districts (Soropa et al. 2015; Ndlovu et al. 2020). Failure to grasp the tenets of climate change is transcending to the lack of understanding about the need for adaptation, challenges in perceiving the changes or grasping the impacts of these changes in the climate. It is important to infer that the determinants of adaptive capacity encapsulated in the previous section serve as barriers to effective adaption when they are not sufficiently available. In that regard, inadequate awareness and information about climate change adaptation is serving as a barrier towards effective adaptation among smallholder farmers in Zimbabwe's rural communities. In Chundu and Nyamakate resettlement areas, Kupika et al. (2019) established that seasonal forecasting is weak to enable farmers to adjust their cropping patterns. Climate change knowledge is regarded as cardinal to influencing the other determinants of adaptive capacity and this is missing among small holder farmers in Zimbabwe's rural communities. To add on, inadequate information about adaptation is making people not to take normative positions in responding to climate change. In light of this, some of the strategies employed by rural people especially in Umzingwane, Tsholotsho and Silobela districts such as gold panning is detrimental to the environment that must be protected from degradation and erosion (Soropa et al. 2015; Chanza et al. 2019). On the same note, the livelihood activities that involve selling of firewood are accelerating the cutting down of trees in Chivi south and Bikita districts causing deforestation (Nyahunda and Tirivangasi 2019).

In continuation, the molding of bricks as part of livelihood diversification is also serving as a backlash on the environment stemming from the lack of adequate information about viable adaptation in the wake of climate change perturbations. Besides causing land degradation, these activities also cause mass deforestation because people use biomass fuels for curing the bricks (Chanza et al. 2019). A study conducted in Hwedza district by Zvamasiya et al. (2017) revealed that farmers with access to climate change information adopted sustainable adaptation strategies than their counterparts. Bowen et al. (2012) posit that a myriad of barriers can arise in the adaptation process from understanding the adaptation problem to devising appropriate adaptation measures that goes beyond managing the planned measures and the outcomes. Furthermore, availability of sufficient information enables people to respond to climate change impacts in a manner that serve their interests and ability without compromising the environment for the benefit of the present and posterity. It is of paramount importance to infer that the availability of adequate and broad-based knowledge about climate change adaptation influences proper decision making thereby contributing to adaptive capacity. Thus, the deficiency of adequate information about adaptation is serving as a barrier towards effective climate change management in Zimbabwe's rural communities.

Lack of Adequate Institutions that Support Adaptation

The success of adaption and mitigation in the climate change terrain is premised on the availability of institutions that support these processes. Basically, the availability of institutions that stimulate adaptation means rural farmers have buffer zones in the wake of climatic shocks. As mentioned earlier, institutions essential for adaptation might be the government through promulgation of policies that enhance adaptation, Non Governmental Organisations, Civic societies and Community Based Organisations among others. Institutions that support adaptation may provide subsidies, insurance and credit facilities to smallholder farmers. It should also be noted that ensuring the needs of marginalized, vulnerable, and remote communities are fully integrated in the national adaptation mechanisms is still a challenge for the government of Zimbabwe (Chanza and Gundu-Jakarasi 2020). Earlier, Muzari et al. (2016) denoted that ensuring that the needs of vulnerable populations are fully integrated in climate change measures is still a challenge for the Zimbabwean government. The country's Climate Change Policy envisages the commitment to set up climate change hubs in every province for easy gathering and collating of information. Furthermore, these hubs are poised to serve as climate information dissemination points aimed at reducing vulnerability through establishment of climate resilient infrastructures, efficient irrigation technology, crop and livestock insurance systems. Conversely, such commitments, are still being deliberated in the boardrooms without them translated to benefit s rural people (Zhakata et al. 2017).

Chanza and Gundu-Jakarasi (2020) further opine that governments are seen as key actors to intervene and circumvent existing barriers to adaptation by changing legislations or providing additional resources but this is not the case in Zimbabwe. To substantiate this, Nyahunda et al. (2019) allude that, Zimbabwe has an array of good climate policies that are not being converted into action because of misdirected priorities. As such, humanitarian organisations close much of the climate change management gaps created by the government. What is evident in some parts of Chivi south and Umzingwane districts are institutional support from NGOs such as World Vision Zimbabwe, Action Faim and MELANA in Umzingwane district. These NGOs are standing in the gap through the facilitation and provision of small grain crops and borehole drilling for small scale irrigation which has seen some gardening activities running in some communities. In Kariba rural district, Mubaya and Mafongoya (2017) found that that various nongovernmental institutions were supporting rural people's adaptation initiatives with inputs and forecast information. This cannot be said in some communities in Chiredzi district where Mamombe

(2017) discovered that most impoverished communities remain marginalized in terms of support services that enhance climate change adaptation and resilience. As such, most smallholder farmers lamented that there is no support in terms of access to timely weather forecasts, information about adaptation and credit facilities to motivate them to participate even in adaptation strategies and this is constraining their ability to adapt. Similar findings were made by Nyahunda and Tirivangasi (2019) in Bikita district that rural people lack adequate support systems that foster adaptive capacity against the vagary impacts of climate change. On the same note, in Chimanimani district, Mutandwa et al. (2019) discovered that institutional support services were very minimal despite the visibility of climate change impacts in these communities.

The footprints of the tropical cyclone Idai which caused wanton death and destructions in March 2019 bears testimony to the deficiencies of institutional support in Zimbabwe's rural communities. This is because, early warning systems should have been disseminated to the communities since the tropical cyclone struck Mozambique weeks earlier before ravaging the eastern areas of Zimbabwe. Similar findings were reported by Chanza (2014) in the Muzarabani area that has a recurrent experience with floods. The author bemoaned lack of broad-based institutional support and disaster management systems before the floods strike and in the aftermaths of the floods. Furthermore, this study found that the institutional roadmaps at policy levels are a top down approach that disregard the local initiatives on adaptation. Consequently, this is constraining the local adaptation efforts devised at local levels which most smallholder farmers can define in tandem with their abilities and circumstances. Additionally, the lack of potential interventions to sustain livelihoods disrupted by climate change at institutional level is serving as a barrier towards effective adaptation. Policy measures are not being converted to become tangible deliverables meaning the poor marginalized communities remain trapped under unpleasant circumstances without means to leap back.

Gender Inequalities

In the history of climate change adaptation in countries with weak socioeconomic rights for women, gender defines who has the ability to adapt to the vagary impacts of climate change particularly between men and women. To shade more light, Mazuru (2019) posits that gender is an important variable in the relationship between climate change and its human impacts. On that note, men, women, children and the elderly have different roles, needs, interests and opportunities, therefore, they are affected by climate change differently. This study was conducted amongst people of Shona and Ndebele cultural descents where cultural prescriptions are predominant in sanctioning interactions, access to opportunities, developmental initiatives and decision making between men and women. As such, patriarchal dominance is still pervasive in these rural communities like in other rural communities of Zimbabwe (Nyahunda and Tirivangasi 2020). It emerged in this study that gender inequalities are acute between men and women where cultural gender roles tend to assign more household responsibilities such as cooking, laundry, water and firewood collection on women. The primary caregiving responsibility of women is making them to be predominant in the agricultural sector and reliance on the climate volatile natural resources to provide for their families. This is making them more vulnerable to the calamities stemming from the climate risks than men.

In light of the above, in Chivi south and Umzingwane districts, gender inequality is manifesting through discrimination of women from decision making planning processes, access to climate change information and opportunities, ownership of essential resources such as land and property rights. This study found that women have limited involvement in community politics and in other instances they face discrimination from decision making at household level particularly those from male headed households. In Gwanda district, Ndlovu et al. (2020) found that gendered responsibilities caveat the social mobility of women where they remain confined to the households as men exercise freedoms in up taking several adaptation strategies such as migration. To add on, in Mutoko rural district, Mugambiwa (2018) avers that women face cultural restrictions on mobility when climate change induced risks strike because culture require them to be confined to their homes and look after the family. Furthermore, in Marondera district, Garutsa et al. (2018) established that there are pervasive stereotypes embedded against women where their contributions even on cropping systems and livestock rearing are considered invaluable.

To worsen the situation, the measures taken by women in response to climate change are creating extra work load on top of other responsibilities that they shoulder mostly on food security, cooking, primary caregiving, water and fuel collection (Nyahunda et al. 2019). Rural women are spend most of their time scouting for scarce resources such as water, fuel and food. This is inhibiting them from being actively involved in decision making processes regarding climate change or embarking on income generating activities that warrants adaptation. In the Domboshava rural areas, Tanyanyiwa and Mufunda (2020) exposit that the social inequalities are making women vulnerable to drought because they shoulder the primary responsibility of securing and providing food amidst failed agricultural production owing to climate change. To extrapolate from the determinants of adaptive capacity premised on equity, evidence from this study bears testimony that there is no fairness and equality in sharing the burdens of climate change, distribution of resources essential for adaptation between men and women. The burden of walking farthest distances in search of water and firewood is detrimental to their health and this has a boomerang effect on their ability to adapt to climate change like men. Women continue to be absent from climate change decision making processes where adaptation measures are devised. The pervasiveness of patriarchal dominance in Zimbabwe's rural communities serve as a barrier for adaptation to climate change impacts for women despite them being heavily impacted.

Inadequate Extension Services

The commitment by the Zimbabwean government to promote training and extension support that would allow climate change management practices as encapsulated in its climate change policy is not being converted into tangible deliverables in rural areas. In Zimbabwe, the Agricultural, Technical and Extension services (AGRITEX) department is responsible for the agricultural advisory role, provision of crop and livestock management and food and input distribution from the Grain Marketing Board (GMB). Some extension services are shouldered by the Communal Area Management Programme for Indigenous Resources (CAMPFIRE). What emerged in this study is that most smallholder farmers in Chivi south and Umzingwane districts are running short of the training and awareness that influence adaptive capacity (Hinkel 2011). In several communities which this study investigated, it emerged that extension services are scant and in cases where they are available, they are parochial to an extent that some farmers have not benefited from the extension services at all.

Inadequate access to extension services is serving as a barrier towards climate change adaptation in these districts. Similar findings were reported by Mugambiwa (2018) in Mutoko rural district that inadequate access to extension services has a negative effect on the farmers ability to adapt to climate change. This is because access to agricultural extension services contributes to the smallholder farmers' knowledge of climate change, its impacts and the need for adaptation (Zvamasiya et al. 2017). In the light of this, the inadequacy of information about climate change adaption which serve as another barrier in Zimbabwe's rural communities stems from the lack of adequate and broad-based extension services that enhance training and awareness which resultantly informs adaptation. In Bikita district, Nyahunda and Tirivangasi (2019) established that farmers bemoaned the lack of commitment by extension officers unlike before where they used to conduct field visits and provide improved climatic information as well as technical assistance. Mavhura (2020) further argues that farmers with access to extension services are likely to develop a positive attitude and are willing to take contingent actions to reduce its impacts. In Chivi south and Umzingwane districts, small holder farmers lamented that extension officers appear to have parochial knowledge about climate change. This can be attributed to lack of adequate training about climate change (Nyahunda et al. 2019). Nevertheless, it should be highlighted that, extension services have a positive influence on behavioral patterns that can foster adaptation measures. At this juncture, it is important to infer that the more the Zimbabwean government clings to its climate policies without implementation, the more the daunting circumstances of rural farmers remain unattended.

Outbreak of Health Emergencies

As the researchers traversed in gathering data to find answers to the objective of this study, it emerged that the outbreak of pandemics such as malaria and Corona Virus Disease (COVID-19) is stalling the adaptation efforts of rural people. Matebeleland south province where Umzingwane district is located has been reeling with the surge of malaria disease. Also, in the Chiredzi district in Masvingo province, Zengenene et al. (2020) allude that malaria prevalence is always recurrent. As such, rural farmers' meagre resources have been channeled towards meeting health care costs among other exigencies (Tapera 2019). The outbreak of the COVID-19 as a global pandemic exacerbated the situation in Zimbabwe like in many countries around the globe. Response mechanisms adopted by the Zimbabwean government in tandem with the guidelines provided by the World Health Organization (WHO) resulted in the pronouncement of the nationwide lockdown on the 26th of March 2020 to curb the transmission of the virus (Mhlanga and Ndhlovu 2020). The lockdown measures prescribed citizens to be confined to their homes only to leave to procure basic commodities including medications or as essential workers. On the same note, businesses, schools, and borders were closed (Dzobo et al. 2020). The most daunting factor about the pronouncement of the nationwide lockdown is that, it disrupted most livelihoods particularly those in the informal sector where most rural people are involved as part of their livelihood diversification strategies to withstand the impact of climate change.

To add on, the most poignant factor is that the lockdown measures were decreed without safety nets in place for the poor neither the availability of disaster relief packages to the already vulnerable populations by the government. As such, the outbreak of the COVID-19 pandemic serves as a double blow for rural farmers that have been reeling with climate change impacts for some time. What should be underscored is that adaptation efforts employed by most rural people to withstand the impacts of climate change through a cocktail of strategies were shattered, disrupted and disfigured by the outbreak of the COVID-19 pandemic. The eruption of the COVID-19 pandemic juxtaposed to the resurgence of malaria disease is disruptive and could potentially lead to food security and stunted livelihoods in most rural communities.

This has a boomerang effect on the ability of rural people to adapt to the impacts posed by climate change such as drought. It is also important to infer that its only when people are healthy, with resources and with the liberty to embark on their livelihood activities that they can adapt to risks dovetailed by climate change. This is not the situation in the wake of the COVID-19 pandemic where gatherings that are the hallmark of social capital are prohibited and migration which is a common adaptation strategy is not feasible amidst the lockdown restrictions. Again, poverty levels among rural farmers are being widened under the confluence of climate change impacts and COVID-19 pandemic where most farmers are compelled to dispose their meagre resources to withstand the pressure of hunger and other loses. Lastly, the outbreak of health emergencies such as the COVID-19 pandemic stands to reverse the gains of adaptation made by rural people. To worsen the situation, the government is now focusing on devising contingent measures to mitigate the impacts of the disease and associated risks and climate change risks are no longer a priority despite them being visible in rural communities.

Conclusion

This book chapter provided a synopsis of barriers towards effective climate change management in Zimbabwe's rural communities to guide policy developments and interventions dedicated to ameliorate the identified barriers and others that were not captured in this study. As contemplated in the themes of this chapter, barriers can be circumvented or subjugated through the development and implementation of broad-based policy regimes that addresses the plights of the disadvantaged farming communities. To extrapolate from this, rural people can only triumph over the barriers to effective climate change adaptation when they are rescued from the jaws of poverty. This is because most challenges that inhibit adaptive capacity for rural people are hinged on poverty therefore other challenges evolve from the conundrums of poverty. As such, Zimbabwe still needs strong institutions that support climate change adaptation and mitigation. The presence of these institutions should be complemented by the recognition of the ability to adapt to climate change for citizens as the responsibility of the government and its subsidiary organs. This initiative should not remain in the board rooms or demonstrated on paper but it must be translated into practical interventions that addresses the felt needs of rural farmers. On the same note, there is need to improve the country's disaster preparedness planning, rescue and recovery systems where rural communities are beneficiaries of disaster proof mechanisms. Efforts to foster effective adaptation to climate change should mainstream the best practices of rural people hinged on indigenous knowledge and social capital. This is because these practices can be easily defined and accessed by every rural household regardless of socioeconomic status. Lastly, gender equality is essential to enhance adaptive capacity especially for women that are highly encumbered by climate change impacts than men. Cultural and traditional patterns that insubordinate women and exclude them from decision making processes need to be extinguished in Zimbabwe's rural communities for women to be able to adapt and remain resilient in the wake of climate change impacts.

Abstract

Global Circulation Models (GCMs) are used to forecast climate change in Southern Africa, and the evidence shows that the region is going to warm up by up to 2° by the year 2050. Namibia is one of the driest countries in Southern Africa and is at a high risk of becoming much drier than current situation by 57%.

Very few studies have been carried out in Southern Africa to show actual impacts of climate change. Practical applicability of GCMs at a local spatial scale remains limited due to the coarse nature of the models. Hence, improvement of the GCMs must begin with better understanding of the local microclimates and how they respond to regional circulation patterns. In many regions of Southern Africa, the lack of potential tools to access old climatic records precludes the estimation of climate trends beyond 100 years. In spite of these impediments, there are areas with excellent tree species such as *Dichrostachys cinerea* that are able to be used as climatic archives for specific time periods. In this chapter, the study shows that the combination of tree ring chronologies and precipitation records is a powerful methodology in climate modeling in the southern hemisphere and reveals nuances that show climate change. The evaluation of data from tree rings coupled with precipitation trends reveals signals that show that climate has indeed been changing over the past ten decades and will have a negative impact on livelihoods. These data can now be used in predictive models that can be used to project future scenarios and assist policy makers and planners to see how climate will evolve in the next 50–60 years.

Introduction

Current scientific, observational, and anecdotal data show that climate change is now a well-observed phenomenon in most parts of the world (IPCC 2007, 2015; Shikangalah and Mapani 2019). Traditional livelihoods of subsistence farming, food security, water security, and cultural organizational patterns are likely to be, and some are already impacted by effects of Climate change. Thus, climate change will be a major problem in the near future, impacting water resources, agricultural and food systems in Southern Africa, particularly Namibia (Adhikari et al. 2015). In Namibia, there is an increasing trend observed in flooding, droughts, and evapotranspiration (Zeidler et al. 2010). The shortening of the crop growing season, rising average summer and winter temperatures, is among some of the evidence of climate change impacts in Namibia (Mapaure 2016). Temperature in Namibia has been increasing at three times the global mean, and the increase in temperature prediction for 2100 for Namibia ranges from 2 °C to 6 °C, particularly in the central regions (Reid et al. 2007).

These impacts will with time increasingly limit water supply, development activities, and consequently will affect all cross-sections of society (Ohlsson and Turton 1999; Showers 2002; Gumbo 2003; Wang et al. 2009). A number of authors have predicted that a quarter of the world's population will experience severe water scarcity within the first quarter of the next century and approximately a billion people in arid regions will face absolute water scarcity by 2025 (Seckler et al. 1999; Ruth et al. 2007). Water demand in urban areas is constantly on the upswing in Africa, Namibia, included (Mapani 2005; Shikangalah and Mapani 2019). The water demand is anticipated to rise by 50% between 2010 and 2030 (Lafforgue 2016).

Trees are excellent archives of environmental site conditions that affect their biological processes (Breitenmoser et al. 2014) and this information is reflected in their growth ring histories. Growth rings provide information about the history of the area in which the trees are resident, including other information such as tree age, fire events, droughts, attacks by pests, logging, and severe storms (Xing et al. 2012; Feliksik and Wilczyński 2009). Growth rings in trees are influenced by climate conditions and they show distinct episodes of moist and dry periods for over time (Novak et al. 2013; Palmer et al. 2018; Shikangalah et al. 2020). Dendrochronology can be used to reconstruct and draw conclusions about rainfall patterns over regional, hemispheric, or even global scales (Zhang 2015; NASA 2008). Tree growth rings are a valuable proxy for climate change studies on both local and regional scales (Nock et al. 2016; Novak et al. 2013; Steenkamp et al. 2008). Data from growth rings records is valuable for providing information that may not be available in areas where climate records never existed in the past. Hence, they aid the understanding of ecosystem dynamics and to predict changes in the ecological surroundings. This information is especially important in arid and semi-arid environments such as Namibia, where sound land management is crucial due to the climate-related vulnerability of such environments and the frequent lack of observational data. This holds particularly true for Namibia as the country is the most arid in Southern Africa and second only in aridity to the Sahara Desert in North Africa (Food and Agriculture Organization (FAO) 2005; Turpie et al. 2010). More than 90% of Namibia's landmass is classified as semi-arid, arid, or hyper-arid, and the country is characterized by sporadic rainfall and high evaporation rates (Mendelsohn et al. 2002; Shanyengana et al. 2004; Barnard 2012). This chapter is aimed at assessing the responsiveness of *D. cinerea* to different climatic environments and thus be used as a proxy for climate change.

Evidence for Climatic Variation from Dendrochronological Studies

In this study, we selected sites that had a degree of variation in both precipitation and temperature. This climatic gradient revealed how the species responded to different amounts of rainfall and temperatures. The study sites are located at Lake Otjikoto (19° 11′ 41″ S; 17° 32′ 59″E); Farm Onyoka located on the Waterberg Plateau Park (20° 25′ 0″ S; 17° 13′ 0″ E), and Farm Kuzikus (23° 20′ 0″ S; 18° 21′ 59″E) located south of Windhoek (Fig. 1). The annual precipitation for the study sites is 550 mm to 600 mm for Lake Otjikoto, 450–500 mm for Onyoka, and less than 300 mm for Kuzikus. These sites also vary in temperature as follows: an average annual temperature of 25 °C for Lake Otjikoto, 30 °C for Waterberg Plateau Park, and 31 °C for Kuzikus (Mendelsohn et al. 2002). Lake Otjikoto has better soils of loamy to clay with a good water holding capacity as opposed to the deep sandy Kalahari soils (Kříbek et al. 2018; Mendelsohn et al. 2002; Rodgers et al. 2017).

Samples and Data Processing

The precipitation data for 1970–2014 were obtained from Namibian official Meteorological Service in Windhoek. The growth rings of *Dichrostachys cinerea* were used, a native species to Namibia which is a fast-growing species that has become an undesirable encroacher and is particularly a problem in areas where there has been overgrazing (Orwa et al. 2009; Chepape et al. 2011; O'Connor et al. 2014). The population of *D. cinerea* decreases significantly from Lake Otjikoto site where the trees are abundant, to Kuzikus where the trees are very few (Fig. 1).

Wood samples of *Dichrostachys cinerea* were collected from randomly selected trees from three sites namely Lake Otjikoto, Waterberg, and Kuzikus (Fig. 1), with a total of 32 samples of *D. cinerea*. For each tree, one sample disc was taken at a height of about 1.0 m and air dried. The rings were identified using a combination of techniques for correction and validation of ring growth, that is, binocular microscope; WinDENDRO software, which automatically counts and dates each marginal parenchyma; and COFECHA program (Holmes 1983), which is commonly used in dendrochronology to ensure quality and measurement accuracy in growth ring segments

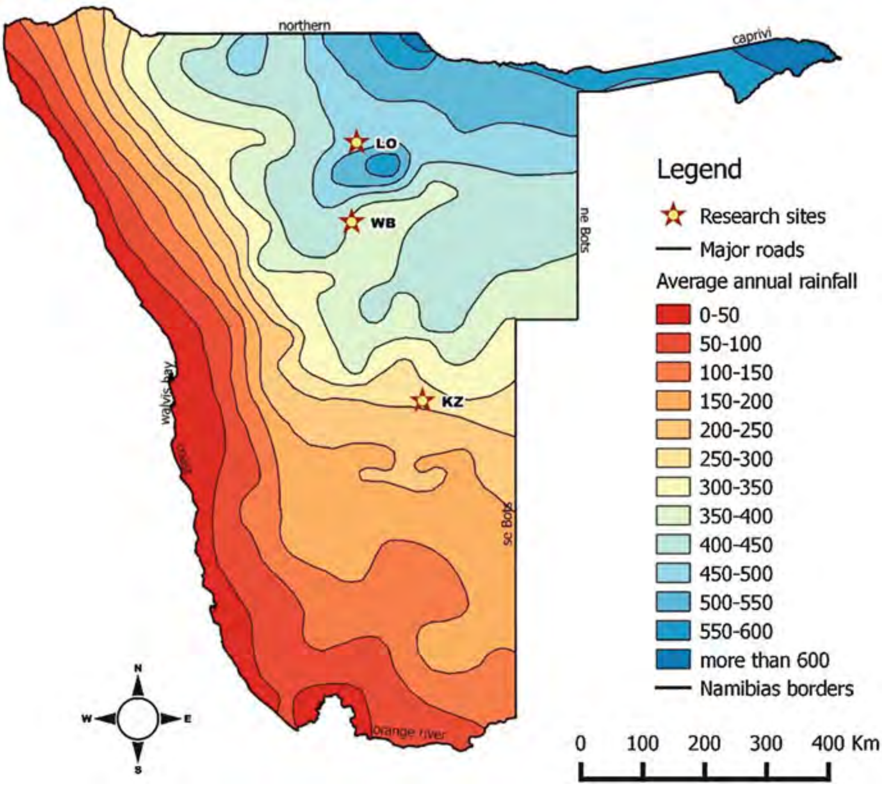

Fig. 1 The three study sites Lake Otjikoto (LO), Waterberg (WB), and Kuzikus (KZ) are shown along the rainfall gradient in Namibia

(Grissino-Mayer 2001). To make sure that all the rings were correctly detected and dated by WinDENDRO software, at least four different paths radiating from the pith were created and analyzed (Grudd 2006; Heinrich et al. 2009; Shikangalah et al. 2020).

To explore the influence of temporal climatic variability on growth rings, the use of response and correlation functions from tree-ring chronologies and monthly climatic data was employed after the methods of Zang and Biondi (2013). Using the dplR package (Bunn 2008) of R 3.4.4 (R Core Team 2018), the *dcc* function in TreeClim Package in R was used. The *dcc* function builds upon and extends the functionality of program DENDROCLIM2002 (Biondi and Waikul 2004; Zang and Biondi 2013, 2015). A total of 32 samples were subject to spline detrending (50% frequency) and then averaged to a chronology using Tukey's biweight robust mean. The timeframe used is only for the wet period (November of previous year–April of current year) is used between 1977 and 2015.

Precipitation as Reflected in Tree Rings

Rainfall in Namibia is unequally distributed, even in years when the country receives good rains, not all areas experience the same precipitation levels. Figure 2 shows the annual rainfall at the three study sites for the years 1970–2014. The rainfall distribution at the three sites follows the national trend where precipitation decreases from north-east to south west (Fig. 1). Figure 2 shows rainfall variability over four decades at the three study sites. At Lake Otjikoto, the annual rainfall was above the average (558 mm) for the years 1972–1974, 1976–1978, 1997, 2001, 2006, 2007–2008, and 2011–2012. At Waterberg, the following seasons had above average (471 mm) precipitation, 1973–1974, 1983–1984, 1987–1988, 2001–2001, and 2013–2014 seasons. Kuzikus has the least number of years with above average rainfall (281 mm), namely, 1973–1974, 1997, and 2006–2007. In decadal terms, the decade 1970–1979 had more rainfall than the 1980–1989 at Otjikoto, whereas the decade 1990–1999 had less rainfall than the 1970–1979 but higher rainfall than the

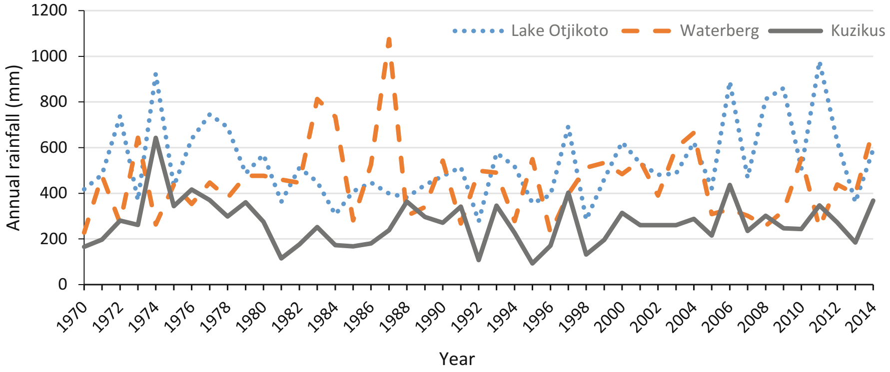

Fig. 2 Annual precipitation variation over the last four decades for Lake Otjikoto, Waterberg, and Kuzikus

1980–1989 decade. However, the 1990–1999 decade at Otjikoto had a much higher variance than the previous two decades. This feature was much more enhanced in the 2000–2009 decade, where the variability was extreme. For Waterberg, the most variable decade in terms of precipitation was the 1980–1989 decade, followed by the 2000–2009. In the 2000–2009 decade, there was much less rainfall at Waterberg compared with the three previous decades. Kuzikus lies in a semi-arid zone, and precipitation variability is the norm. Kuzikus shows a highly variable precipitation signature over all the four decades.

In Fig. 3a, the growth of *D. cinerea* at Kuzikus (annual rainfall of 250–300 mm/a) shows a positive correlation with rainfall except in years when flooding occurred. At Waterberg (Fig. 3b) and Lake Otjikoto (Fig. 3c), the correlation is also positive. In

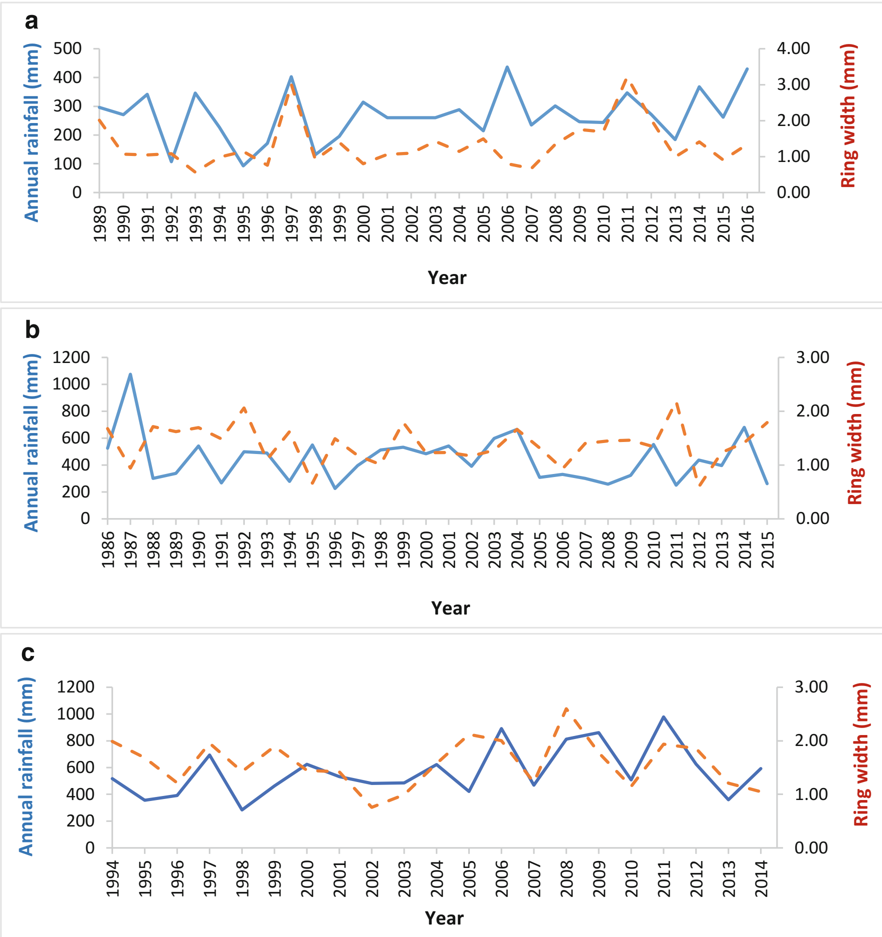

Fig. 3 The relationship between ring widths and annual rainfall *Dichrostachys cinerea* at (**a**) Kuzikus (300 mm), (**b**) Waterberg (450 mm), and (**c**) Lake Otjikoto (600 mm), based on average growth ring of 4 trees per site

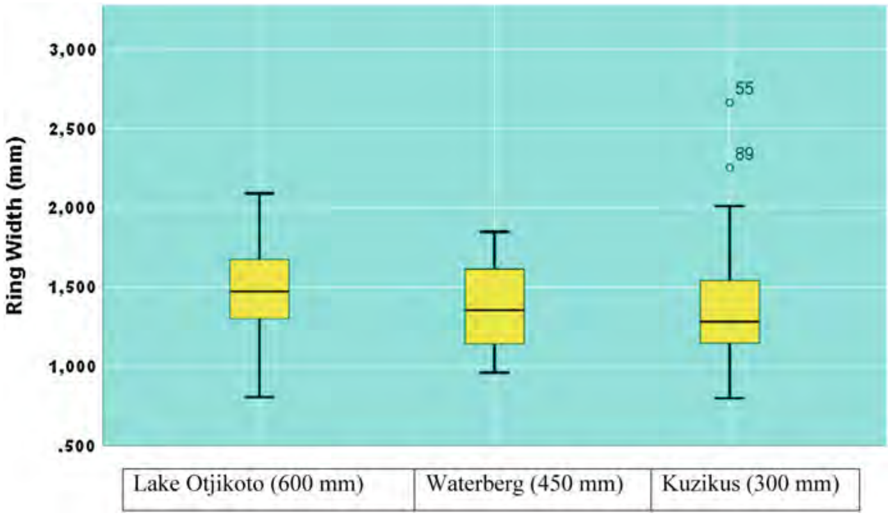

Fig. 4 Summary of all data from Fig. 3 for the three study sites. The median ring width for Otjikoto is much higher than for both Waterberg and Kuzikus

years when annual rainfall was received over a short period of time, resulting in runoff, the correlation is weak, for example, 2006 and 2016 at Kuzikus, and 1987 and 1995 at Waterberg. Figure 4 summarizes the comparisons in ring width growth across the precipitation gradient. *Dichrostachys cinerea* ring width growth correlates with the amount of precipitation, though the median ring widths did not significantly differ among sites.

Growth Ring Responses to Climatic Variation

Using bootstrapped correlation function analysis (R Core Team 2018), the darker bars in Fig. 5 indicate a coefficient significant at $p < 0.05$, and the lines represent the 95% confidence interval. Figure 5 shows that the response coefficients of temperature, precipitation, and aridity at Lake Otjikoto and Kuzikus sites. The results shows that at Lake Otjikoto, the temperature, moisture availability, and overall aridity have positive but weak influence on growth rings in some months, mainly November and December (temperature), February (temperature and rainfall), and all three variables during March and April months (Fig. 5a). On contrary at Kuzikus, the influence of moisture availability is still positive but to a lesser extent than at Lake Otjikoto (Fig. 5b). The temperature has a significant negative influence in growth rings in December (darker bar, Response Coefficients (r) $= -0.13$).

Figure 6 shows the autocorrelation lags of growth ring width with precipitation soil moisture. For Kuzikus, *D. cinerea* in the period 2000–2009 shows a negative correlation, whereas at Waterberg shows an intermediate response to precipitation soil moisture with growth ring width. The growth ring soil-moisture correlations at

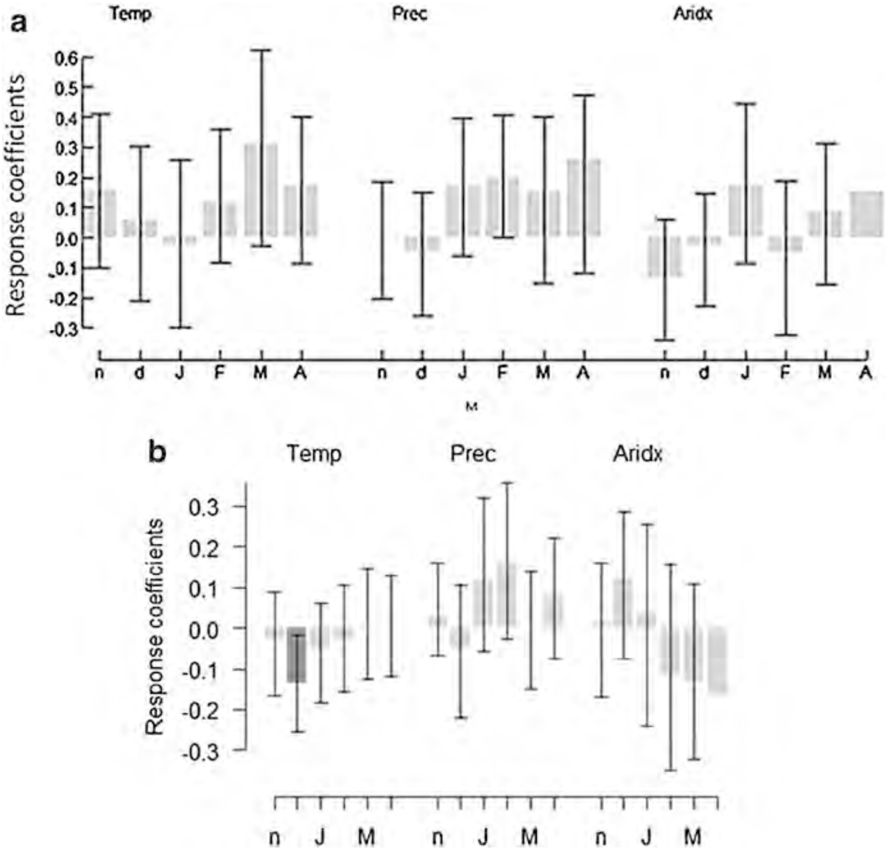

Fig. 5 (**a**) Lake Otjikoto site: *D. cinerea* growth ring responsiveness to temperature, precipitation, and aridity (climatic factors affecting tree growth the most). (**b**) Kuzikus site: *D. cinerea* growth ring responsiveness to temperature, precipitation, and aridity (climatic factors affecting tree growth the most)

Kuzikus where temperatures are high are much weaker compared to the correlations at Lake Otjikoto where rainfall is much higher. Lake Otjikoto shows a very strong positive correlation, way above the normality curve.

Lessons Learnt from Arid and Semi-arid Savannas

Evidence from precipitation (Fig. 2) and tree growth rings has shown that *D. cinerea* is sympathetic to precipitation soil moisture (Figs. 3, 4, and 5). This relationship is cardinal in the use of tree ring chronologies as proxies to climate variability. Trees are good archives of biomass systematic addition due to their physiological response to water stress that affects growth rings (McCarrol and Loader 2004). Additionally the stomatal conductance is controlled by the relative availability of edaphic

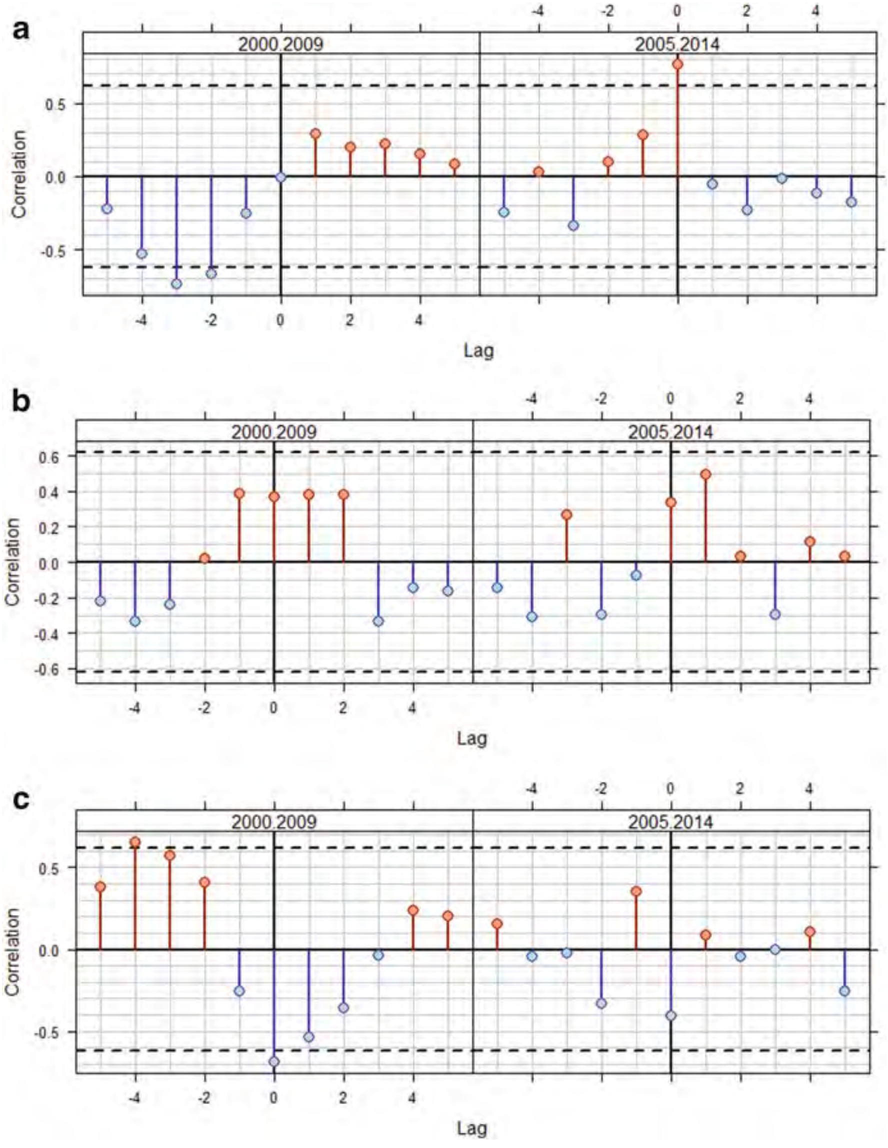

Fig. 6 Auto correlation lags (1–4) of rainfall with tree ring growth data. Kuzikus in (**a**) is a much drier and is the opposite of the wetter Otjikoto pattern in (**c**)

moisture (precipitation) and external leaf water vapor deficit (humidity) (Woodborne et al. 2015). In Namibia, the wet (rain) season used to start at the beginning of November four decades ago; and there has been a slow but gradual and systematic shift to mid-December in the past decade (Shikangalah and Mapani 2019). Such information is available in precipitation and tree ring growth records (Shikangalah et al. 2020). Work in Southern Africa has now proven beyond doubt that dendrochronology works as good as in the northern hemisphere for certain species of trees (Gourlay 1995; February 2000; Fichtler et al. 2004; Trouet et al. 2006; Woodborne et al. 2015; Shikangalah et al. 2020). Woodborne et al. (2015) reconstructed a 1000 year carbon isotope rainfall proxy record from the South African *Adansonia digitata*.

The key significance of soil moisture supply for the tree growth and its apparent influence is indicated in Fig. 4, where the Lake Otjikoto site with a higher mean annual precipitation shows a much higher ring width growth than at the other two sites. The data illustrate that *D. cinerea* growing in areas with high amounts of rainfall grows wider rings when all other climatic factors are taken together (Fig. 4). The patterns observed in rainfall (Fig. 2) are reflected in the autocorrelation diagrams (Fig. 6) which is a reflection of the microclimate effects on tree growth ring at each particular location. This suggests that *D. cinerea* growth rings can be used as a proxy for climatic variations wherever it is present. This finding is echoed by Kwak et al. (2016) who showed that soil moisture or groundwater near flowing streams influenced tree ring width growth and the size of the rings was proportional to the amount of moisture received.

The results show that in the years when floods occurred (Fig. 3), tree ring width did not correspond to the amount of rainfall received. This fact was attributed to runoff effects, where certain species do not add significant biomass under flooded conditions (e.g., Schulman 1945; Astrade and Bégin 1997; Kwak et al. 2016). Thus, there is an optimum maximum soil moisture threshold for *D. cinerea*.

Southern African species have been for a long time considered as not good at adding biomass systematically on an annual basis. However, tree chronologies for *D. cinerea* and *S. mellifera* were established by Shikangalah et al. (2020). Watkins et al. (2018) showed that tree ring sensitivity to climatic variables is dominated by precipitation. It is abundantly clear that for Southern Africa, Namibia, in particular, tree ring studies are excellent proxies for climate variability studies as they act as natural archives that record site conditions and precipitation effects.

The responsiveness of *D. cinerea* to precipitation, air temperature, and the overall aridity was also examined (Fig. 5). Overall, the response coefficients suggest contrast response of growth rings to climatic conditions at the two sites, with exception of rainfall and aridity in January and February. The low responses are mostly experienced at Kuzikus, while most of the positive responses are experienced at Lake Otjikoto. The response function also showed a precipitation response to a less significant correlation during February to April when the temperatures are cooler after some rainfall. The response coefficients are indicative periods on which the growth rings are quite small, suggesting that *D. cinerea* trees have a very narrow range of responsiveness in which they can grow, therefore supporting the evidence that they add the least amount of biomass in areas of less rainfall such as at Farm Kuzikus (Fig. 4). Due to the lack of darker bars which show a high significant response, these results demonstrate that growth rings are also influenced by other variables such as type of soil, groundwater, and vegetation.

Conclusions

Growth rings in *D. cinerea* correlate to the amount of precipitation uptake by the species. Dichrostachys *cinerea* is dependent on rainfall for its survival, it has colonized wetter sites (Lake Otjikoto and Waterberg) more than it does in drier sites (e.g., Kuzikus). Therefore, it is much more important for farmers in high rainfall areas to anticipate more encroachment by *D. cinerea* and take necessary interventions to control or manage it. With regard to the usefulness of the species as proxy for modeling climatic conditions, it is concluded that *D. cinerea* is more responsive to climatic variables as it has proportionally responded to the amount of rainfall with ring growth and temperature. At Lake Otjikoto, growth rings are enhanced by both precipitation and temperature, whereas at Kuzikus, only the precipitation improves growth rings, the temperature effects the growth rings negatively. The findings from this chapter suggest that *D. cinerea* can be used as a proxy for precipitation shifts with time over relatively short periods, for instance, of 30- to 50-year histories, and where older trees can be found, it can be used to reconstruct climatic changes over several hundred years.

118 Just Societal Transformation: Perspectives of Pastoralists in the Lower Omo Valley in Ethiopia

Sabine Troeger

Contents

Abstract

Pastoralists' livelihoods in Africa are highly endangered by adverse forces – the climate change being one among those. Against this background, climate change adaptation is conceptualized as strategic agency in the field of risk-laden livelihood environments, that is, agency in the face of risky options and non-calculable uncertainties.

The chapter conceptualizes pastoralists' livelihoods exposed to a four-fold hierarchy of environmental risks and forces defining the actors' arena of strategic decision making: From the global scale of ever extending impacts by the climate change imperative, to the national scale of government policies in terms of decentralization, challenging people to govern and define their communal

efforts in terms of climate change adaptation, and down to the regional scale, which in the presented case is dominated by a large-scale investment, the Kuraz Sugar Development Project, which again confronts local actors with adverse forces toward villagization and eviction from pasture grounds. Right at the end of this hierarchy and in accordance with discourses on "climate services," the end-users and local actors, the pastoralists, are confronted with and offered a product that they can input into their decision making: cattle feed from the residues of the irrigated sugar cane. The question remains whether substantive aspects of processes turning into true environmental and social justice in terms of recognition, procedures, and distribution will be paid attention to.

Transformation Toward Sustainability in Terms of Social Justice: Two Perspectives in Ultimate Dependence

The notion of transformation is increasingly promoted in scientific and likewise popular discourses as a solution to unsustainable practices. Transformations toward sustainability are needed to address many of earth's profound environmental and social challenges. In transformational adaptation literature the distinction between incremental adjustments and transformational responses is to be found. As defined by the IPCC-Report 2018: "Global Warming of 1.5 °C," incremental transformation refers to some means and instruments of "adaptation that maintains the essence and integrity of a system or process at a given scale," while "transformational adaptation implies 'changes of fundamental attributes of a socio-ecological system." A transformative response to obviously unsustainable circumstances of life, be these ecologically or socially based, will require engaging with the root causes of inequality and likewise environmental degradation, which necessitates some transformational adaptation in the indicated sense. Furthermore, actions taken to shift socio-ecological systems toward more sustainable pathways can have substantial social impacts and may exclude members of communities from decisive processes.

The named perspective emphasizes the importance of contesting dominant social and political structures, rather than accommodating change to address the root causes of unsustainable systems and catalyze genuinely alternative futures. Transformations toward sustainability can only be taken as a success in case social justice is considered a central concern. In consequence, all actions taken to shift toward environmental sustainability can have both positive and negative social implications for different groups relative to the status quo, which means attention is needed to both understanding and realizing social justice during sustainability transformation (Temper et al. 2018). Following this notion three dimensions of justice are to be differentiated: (a) recognitional justice in acknowledgment of and respect for preexisting governance arrangements as well as the distinct rights, worldviews, knowledge, needs, livelihoods, histories, and cultures of different groups in decisions; (b) procedural justice with reference to the level of participation and inclusiveness of decision making and the quality of governance processes, and c) distributional justice, which can be defined as fairness in the distribution of benefits and harms of decisions and actions to different groups across space and time (Bennett et al. 2018).

Following the vision to turn scientific information from climate monitoring, research and modeling into operationally available information and services that would help societies to cope with climate variability and change, the World Meteorological Organization (WMO) launched the process for developing the Global Framework for Climate Services (GFCS) at the World Climate Conference (WCC) in September 2009. This conference recognized ongoing discourses on the unambiguous importance and relevance of climate services, which were considered essential to adaptation to environmental and climate variability and change (European Commission 2014). Climate services are to be seen as one essential contribution and element of transformations toward sustainability. But at the same time the perspective of climate justice identifies climate services as the source of a double inequality with a distribution of risk and responsibility (Adger et al. 2006, 2009). Climate services will mitigate the impacts of climate-related stresses, while the end-users' perspective is a key in tailoring the service measures (climate-services.org).

Against the background of these generalizing recognitions with relation to societal transformation in terms of environmental justice the chapter aims to explore the implications of present day environmental dynamics, the climate change intertwined with market and governance perspectives exemplified in their concretized meaning for pastoralism and pastoralist livelihoods in the Lower Omo Valley right in the south of Ethiopia: The Lower Omo Valley, until 2011 one of the most peripheral and likewise politically neglected regions of Ethiopia, has turned into a hotspot of societal transformation geared by natural, social, economic, and cultural forces. Home to 16 ethnic agro-pastoralist societies (recognized UNESCO World Cultural Heritage in 1980), formerly well adapted to the fragile semiarid environment of the lowlands, the Lower Omo Valley is nowadays highly impacted by irrevocable and fundamental changes in livelihood constellations caused by forces in a four-fold global to local scale gearing toward some ultimate and irrevocable societal transformation, that is, processes, which hold a strong grip on those ethnicities calling the Lower Omo Valley their home in terms of fundamentally re-defining the constituents of livelihood systems as of at present. With reference to the initial perspective of the chapter the argument will pose the question in how far and to which degree processes of transformation to be observed in the Lower Omo Valley are to be taken as sustainable, which includes the perspective of justice with reference to the addressed ethnicities, the pastoral communities in their distinct and unique representation.

Grounded on actor oriented and constructivist reasoning the chapter subsequently relates to the perspective of human agency in the face of risky environments. Following Appadurai's concept of spatiality (1990), when he coins five terms with the suffix "-scape" indicating the ambiguity and fluidity of social phenomena, the chapter interprets agency by people in the context of their "social constructions" of their environments. The argument relates to the idea of "riskscapes" as defined by Mueller-Mahn and Everts (2018). Riskscapes are intertwined with social practices. The focus on practices posits that understanding human activity is key to any deeper knowledge of events and states. Schatzki (2002) emphasizes the fact that any practice involves various people and is always part of a larger set of socially ordered actions, highlighting the dynamic nature of social practices, how they change and how they relate to spatial and temporal dynamics. The argument follows Schatzki (2012:14), when he says, "a practice (. . .) is an open ended, specially temporally dispersed nexus of doings and sayings." Based on this recognition the concept of "riskscapes" refers to temporal-spatial phenomena that relate risk, space, and practice. Riskscapes link the material dimension of physical threats, like for example the climate change, the discursive dimension of how people perceive, communicate and envision risks, and the dimension of agency, that is, how people produce risks and manage to live with them. In consequence, risks are not to be taken "objectively given" phenomena, but are shaped and constantly modified through practices, which are socially embedded. Thus, observations in the field and with representatives of the communities in focus are to be understood in terms of agency in recognition of people's perceptions, interpretations, and evaluations of their environments.

The chapter elaborates on four perspectives of given environmental – natural as well as social and sociopolitical – constellations and livelihood frameworks in scales in the Lower Omo Valley. The argument will draw the attention to two comprehensive conclusions of these observations and assessments in the field, to subsequently link these with regional forces in terms of villagization and sedentarization policies, which are taken as "dispositives" as understood by Foucault (1977). In line with this understanding, present and pressing development perspectives are outlined, which highly challenge and tackle the field of environmental justice. Concluding, the argument will revise the field and discursive findings with relation to the four analytical scales and suggest some rounding up picture of the observed societal processes in terms of a transformation answering the claim to social justice.

Figure I titled "Societal Transformation" illustrates the above referred to analytical concept in scales:

The Climate Change Imperative as Perceived and Acted upon by Pastoral Communities: The Global Scale

Data from the field leave no room for doubt about the severity of ongoing and in the course of time further enforced climate change impacts in the Ethiopian Lowlands (Troeger et al. 2012). The Lower Omo Valley, located in the southern part of these lowlands, is highly exposed to a climate change pattern characterized by considerably shortened *Belg* rains as part of the customary rainfall pattern. These were formerly expected to be starting end of February or early March and lasting until end of May or beginning of June. The eastern and southern regions of Ethiopia, demarcated by the Rift Valley, are highly dependent on this specific rainfall pattern for their annual agricultural production as well as their migratory routes with their livestock, which in this case is cattle, whereas the goats and sheep, the smaller ruminants, remain with the women, the wives, children, and elderly people. They will feed on the pastures and bush-vegetation in the vicinity of the homesteads, which are rhythmically shifted within a radius of some kilometers but remain in line with the pastoralist livelihood system more or less concentrated on some an ethnically defined neighborhood.

At the time of the field assessment the pastoralists discussed the spatial and quantitative changes of temperature, precipitation and floods. To their perception, all of these un-contradictorily stated deviations and irregularities in rainfall started around the year 1989 and since then have shown a gradual decline in precipitation. More severe changes were perceived to have started after 1998 and culminated for the first time in the year 2011, when large parts of the Horn of Africa were struck by one of the worst droughts ever recorded in 60 years, which translated into a severe food crisis. In July 2011, the United Nations declared a famine, but already as early as January 2011, considerable heads of livestock had died, as reported by the people. The drought that started in 2011, whether it was caused by global climate change factors or the effect of a very harsh La Niña event as suggested by IRIN News (15 July 2011), took place in the wake of 4–5 years of more or less failed *Belg* rains, as summarized to be a general trend by the diagram below:

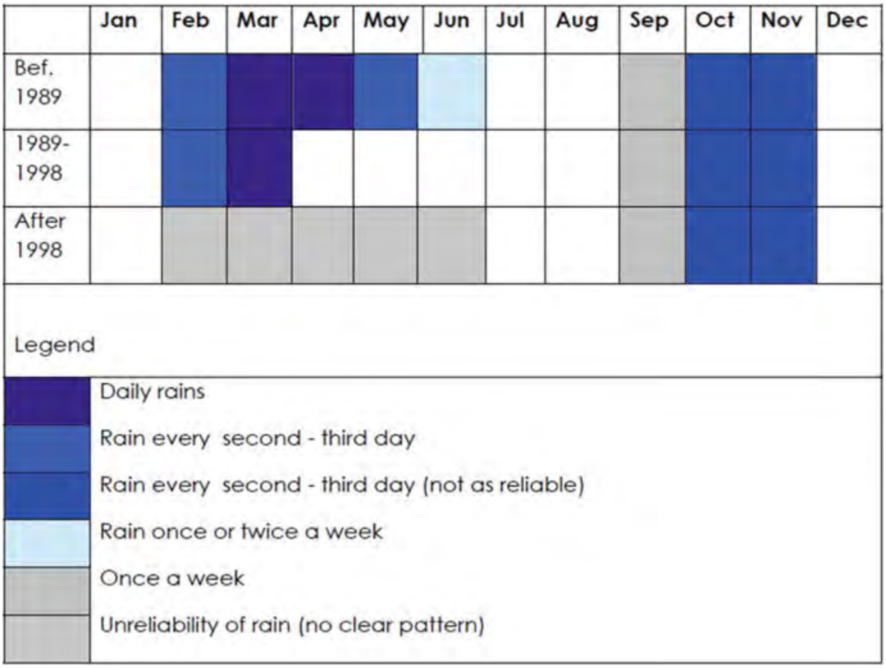

Figure II: The Climate Change pattern as perceived and acted upon by the people. (Source: Troeger et al. 2012)

"*Everything that is happening now, is beyond our capacity*" was the unisonous statement of the people, be these young or old, when talking to them in the field. The conclusion drawn by Moro, at that time Nyangatom women leader, summarizes the research findings (Troeger et al. 2012) and unambiguously indicates a livelihood configuration highly at risk, going hand in hand with a dissolution of beforehand sustainable codes of conduct, namely the indigenously established "culture of sharing," when people deliberately and spontaneously shared food and further agricultural produce and items (Troeger 2016b & 2018).

A concordant climate change pattern showed the precipitation and subsequent constellations of food crises in the past year, the year 2019, which can be taken as an indication of the further continuing decline in and unreliability of rainfall:

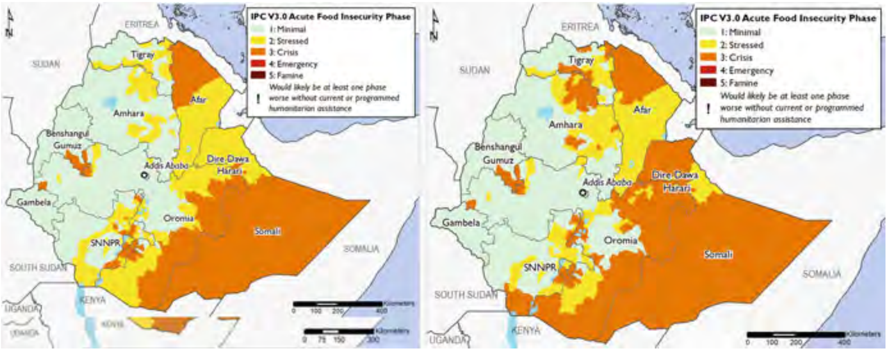

Figure III: Patterns of food Insecurity in the wake of deficit precipitation in the Lowlands – the year 2019. (Source: with permission by Famine Early Warning Systems Network (FEWS.net))

Moving back to the initial question of people and pastoralists in confrontation with processes of environmental risk and transformation, pastoralists in the Lower Omo Valley see themselves and are to be taken as threatened beyond their formerly established coping potential. According to their reports the young herders could not follow their seasonal migratory pattern among other things. There were reports about young herders, who stayed away from their culturally manifested neighborhood for several seasons in succession. People were worried about these environmental tendencies and complained that, as the weather got drier and it became increasingly difficult to survive, neighborhoods fell apart, people abandoned their traditions and were forced to accept other lifestyles (Troeger et al. 2012).

The "Committee": A Pathway Toward Climate Change Adaptation and Mitigation? – The National Scale

Turning to the national level, the argument moves on from the following observation:

> Following the agenda of the government, the claim of "development" has always been and is as well with the new policies guided by the present Prime Minister Abiy Ahmed the directive of the rulers of the state. Governments' interventions labeled NRM, natural resource management, combine hegemony and governmentality projects to conform citizens into its governmental state ideology. While local governments continue to be representatives of the controlling apparatus of the political elite rather than representatives of interests of their constituents (Ayele 2011), they will follow the "development narrative." Party loyalty is demonstrated by adopting agricultural ideas promoted by the state, which is indicated by Lefort (2012), who suggests that so-called model farmers are rather party agents instead of famers with high agricultural competence.

Based on this insight the political role of "committees," coinciding with the claim for decentralization all over Africa and together with the mainstreaming of participatory approaches in development practice, is to be questioned. Do communities experience a shift in policies to advocate local actors and resource users and play a more active role in natural resource management (NRM), which in many cases today is to be understood as climate change adaptation (CCA)? Decentralization in general describes the process by which bundles of entrustments, like regulatory and executive powers, responsibility and authority in decision-making, are transferred to local agents, which again calls for new institutions and processes of institution building, that is, the committees. The following argument digs deeper into this perspective of local policies and into the perspective of "handing over the stick," the guiding principle of the participatory approach in development practice PRA and of governance in local contexts. And at this point, the question of environmental justice becomes vital as the impact of decentralization is to be measured with respect to recognitional, procedural, and distributional just and fair outcomes relating to actors and activities on the local scale.

The targeted processes of decentralization come about in the shape of "committees," that is, institutional settings, which have mushroomed up in various development contexts all over Africa. Activities of the "Western" ideal of democracy in the shape of committees focus in general environments of obvious global change, which force local actors to unanimously and fundamentally adapt to the irreversible changes in nature. Informed by this perspective, the committees mirror the principal idea of equal representation and equal voice. Per definition has the ideal of "participation" developed to be the counter-balance to the sociopolitical institution of "committees," which again claims to "give people a voice." In consequence, the notion of "voice" unambiguously links the concepts of "committee" and "participation" with the need for "communication," true communication, which enables intersubjectivity via a mutual exchange of people's perceptions, interpretations, and valuations, in short: social constructions. In summary, committees are taken to be the platform for participation in realization of the demand for "communication" regarding "giving people a voice."

Corresponding with Government policies in promotion of sustainable and decentralized community development in Ethiopia, a "committee" has been established with the Nyangatom community. The Nyangatom are one of the 16 ethnicities in regional focus. Their committee was explicitly established to safeguard and control the recently established scheme of rangeland enclosures in support of climate change adaptation needs in terms of referred to propagated improved land use techniques. Rangeland enclosures, enclosed by bush thorn fences, are manifestations of private landownership, which excludes members of the community from participating in the advantages of the protected grazing areas behind the fences. In consequence, parts of the former "commons" are claimed by the powerful representatives of the communities. The committee was first installed in order to govern the new scheme on local grounds and resist against the powerful take over by some community members. But very soon after it was appropriated by Government employees, by "experts" from Addis Ababa.

In contradiction to the outlined and to our "Western European" eyes normalized and customized ideal of democracy the established committee meets societal constellations on the ground, which had known and were based on some means and ways of mutual consensus finding by their own constitution. The Nyangatom, one of the unique pastoralist ethnic groups of Ethiopia's south, situated in the Lower Omo Valley, numbering about 10,000 people, has like its neighboring pastoralist communities, ever since been guided by an "age-group system." The system is constituted by five age groups: children, youths, herders of 25–50 years, the political class of the "elephants" aged 50–65 years, and the very old and wise men in the role of spiritual guides, as explained by two community guides:

> The elders used to manage the grazing land by telling the herders to shift from pasture to pasture. They sent young herders to check the condition of the grass, and then they decided on the migration paths. If someone was seen taking his animals to the forbidden areas, he would be punished. But punishment is not constant. It will vary from people to people and it depends on the severity of the action. But it as well respects the livelihood constellation of the trespasser and defines the punishment in accordance. (Soya Kurupa, man – 14 March 2015, approx. 42 years) (Troeger 2018)

> The cultural management has no written rules and regulations, because once the elders pass the decision, no one will disobey. It is a management, where everyone has to obey. We have grown up with it, so we like it very much. (Moru Lomarle, woman – 12 March 2015, approx. 55 years) (Troeger 2018)

Interpreting village-level ethnographic data from the named pastoralist livelihood scenery, the case of the Nyangatom, the chapter supports the following thesis: The formula of "transformative adaptation," as propagated by, for example, the 5th IPCC assessment report 2014 and likewise by the report on "Global Warming of 1.5 °C" (see above) with some successful climate change adaptation in view, and subsequently multifold suggested by initiatives hailing processes of societal transformation, does not necessarily gear toward a change in the name of a more resilient and sustainable development. Field data reflect on interpretations and perceptions by the pastoralists involved relating to this transformative impetus. They indicate "disagreement in the shadows" as defined by Rancière (1998), and a disruption of processes of communication and mutual cooperation. With this portrayal Rancière indicates some community constellations, which do not allow for open resistance but only offer some hidden away and not openly articulated opposition (ibid.).

Listening to the people, to "the people's voice," reveals the true process lines of the committee meetings and offers the chance to get closer to the meaning of "governance" and "participation" facilitated by processes of communication in given frameworks of the committee. Perceptions and interpretations are singled out in line with the perspectives of: "structural forces and governance," "modes of participation," and "articulation of social correctness."

> I myself had the idea of establishing rules to govern our problems with the drought and the use of the pastures, but then I heard that the Woreda people are coming to establish the rules and regulations. And there were some people from Addis Ababa, who gave us some papers,

> which listed the rules. They asked the people to add on it, and of course, everything was clear, and nobody added anything on top of the by-laws, and the committee was selected from different age-groups. (Lobowa, approx. 42 years – 14 March 2015) (Troeger 2016b & 2018)

Quite in line with the general articulation of the "development narrative" in Ethiopia, obviously no participation, which could indicate true "governance," had been sought. The community member claims initially own, self-determined ideas about necessary regulations, but he had no chance to promote these tentative frameworks of governance. No "freedom to articulate one's own voice" is given in this process of communication. No recognitional nor procedural justice is given to him and his ideas. He is neither respected in his worldviews, knowledge, and needs, nor is there any true chance for true participation offered to him. The message from the district and national governance representatives turns out to be an unambiguous top-down message, which has to be "swallowed" by the people on the ground, by those, who in future would be the ones to realize these handed over regulations. Structural forces govern the information instead of true communication processes. No communication in the ideal sense is realized, which is even more emphasized by the following statements:

> Us elders, we were unsure whether to accept the new rules, but the Woreda people made us accept the idea of bye-laws. (Dida Lolibes, man – 11 March 2015, approx. 64 years) (Troeger 2018)

> The leaders from the Woreda and the people from Addis made us discuss the question of the punishment for not following the rules. So, the discussions were led by the experts, and they were the ones to give a speech on the positive side of the new governance system and make the community accept the idea. Even me, I accepted it. (Ariapa Lokitibo, man – 14 March 2015, approx. 38 years) (Troeger 2018)

By listening to the people's voice it becomes obvious that the modern idea of committees will not match with the culturally established and believed in articulation of authority and representation. The idea puts the indigenous identity at risk. The articulated obedience toward culturally manifested rules represents customary regulations and a sense of belonging and identity. Especially the emphasis on a fair, socially reflected and balanced execution of established rules and regulations contrasts the perception of today's realization of power and authority. The obvious notion of "disagreement" indicates a situation, when meant to be partners in communication do not necessarily contradict each other openly but disagree in the shadow of claimed consensual modes of governance. On the surface, this consensual governance has reduced political conflict and disagreement (Swyngedouw 2011), but in reality, the partners in communication have not reached a common ground of understanding. "Disagreement in the shadow" should be taken to the open and made understandable to all. The new challenges and arrangements with relation to the range enclosures and in consequence processes of commodification of the 'commons' are to be discussed and reflected on mutually and in an atmosphere of mutual freedom of articulation. But this disposition cannot and will not be found in a situation, when the inherited and traditional authority of the "elephant" age group is confronted with some authority of the government in regional and national contexts.

The so-called "participatory" processes in the pastoralist communities does not only confront the people on the ground with readymade answers and new regulatory frameworks but excludes some members of the community completely from the wished for democratic process. They are put at risk. Thus, neither some "equal grounds of understanding" nor any "freedom to articulate one's perceptions" and evaluations of the given social needs in terms of a fair and transparent handling of the new "structural forces" in the shape of the climate change imperative is sought for:

> My neighbors in our settlement did not participate in the discussions. According to what I now know they are not happy with the decisions because they did not get any clarification on this matter like we did from the Woreda and the people from Addis. (Ariapa Lokitibo, man – 14 March 2015, approx. 38 years)

The example of the Nyangatom pastoralists in south Ethiopia unambiguously highlights given processes of communication to be by far not manifested in the open and freed from structural power. Communication in the committees is dominated by "experts," that is, the agents of the government following the "development narrative" as outlined above. The actors on the ground resisted the officially outlined principles and practices of climate change adaptation "in the shadow": "We should take disagreement to mean a determined kind of speech situation: one in which one of the interlocutors at once understands and does not understand what the other is saying. Disagreement is not the conflict between one who says white and the other says black. It is the conflict between one who says white and another who also says white but does not understand the same thing by it or does not understand that the other is saying the same thing in the name of whiteness" (Rancière 1998).

Essentially, this argument proposes that governing climate change has been characterized not only by disagreement, but climate change communication in this case is to be understood as subcutaneous resistance, voiced quietly and under cover, stating in the end some ultimate failure in communication. With reference to the differences in an articulation of social justice as defined above the committees in today's shape are not to be understood as windows of opportunity toward more environmental justice and sustainability in societal transformation. Mouffe (2013) links to the reflections of Rancière (1998) and Swyngedouw (2011) referred to above, when she states: "We have to relinquish the claim that the processes of democratization should consist in the global implementation of the Western liberal democratic model . . . the kind of individualism dominant in Western societies is alien to many other cultures, whose traditions are informed by different values. Democracy, understood as 'rule by the people', can . . . take other forms – for instance, forms in which the value of community is more meaningful than the idea of individual liberty."

The argument summarizes observations in the field accompanied and highlighted by the voices of the local agents stated above and objects to any claim of social justice granted to these agents, the pastoralists. The process of decentralization is not to be taken as any granted path toward true communication with effective recognition of all community members on equalized grounds. Accordingly, the challenge to reach some just and in this way sustainable societal transformation is not responded to in any meaningful terms of governance.

Large-Scale Investment, Irrigation, and Villagization: Opening the "Ground" to the State – The Regional Scale

Turning toward the regional scale, the argument links to the frequently quoted statement by the late Prime Minister of Ethiopia, Meles Zenawi, the sociopolitical meaning of which is to be considered one of the most crucial turning points toward the situation of societal transformation as of today: "I promise you that, even though this area is known as backward in terms of civilization, it will become an example of rapid development" (Meles Zenawi speaking at the Pastoral Day Festival in Jinka, South Omo Zone, 25 January 2011).

The first "state" representation in the Lower Omo Valley times back to the 1960s, when programs of sedentarization and the establishment of the Omo National Park (1966) and the Mago National Park (1979) led to increased resource pressure for the agro-pastoralist ethnic groups, traditionally inhabiting this area and using its resources for pastures for their livestock and especially the river banks for river retreat agriculture. Soon after, that is, in the 1980s, the then Ethiopian military regime released the Omo Basin Development Plan and in this context initiated the construction of the Gibe III hydro dam north of and at the entrance of the Lower Omo Valley, the construction of which was started in 2008 and the filling of which was completed in 2016. Today, the Gibe III dam is to be taken as the most influential structural incentive of those transformative forces and risks, which have defined and continue to define life and the livelihood systems in the Lower Omo Valley.

Relating to Meles Zenawi's argument, commercial investment processes were predicted and initiated, which turned Ethiopia and especially the pastoralist lowlands of the country into a hotspot of what commonly is called the "land grab." By emptying Ethiopia's pastoral lowlands for large-scale investors, in the case of the Lower Omo Valley the Kuraz Sugar Development Project (KSDP), the ground was opened for police and military, for the "state," giving protection to these investors. The establishment of the large-scale investment was sidelined and backed by the implementation of new agricultural technologies in settling and sedentarizing pastoralists in relocation sites by providing them with agricultural extension packages in terms of chemical fertilizer schemes, improved seeds, which the pastoralists had to pay for, and small parcels of irrigated land (Regessa et al. 2019). The government deliberately claimed the culturally inherited pastoralist land, the "commons," for investments, as it was considered "underutilized" and "unproductive," as the pastoralists were interpretated not "civilized" enough to make appropriate use of it. This villagization program, officially known as *Mender Masebaseb*, meant some fundamental transformation to the pastoralists – they were supposed to become and be sedentary and give up or at least considerably reduce the basis of their livelihood system, their seasonal extensive cattle drives and migrations.

The Lower Omo Valley, South Omo, in historical times was and up to now is to be taken as an environment of latent and open social conflicts, conflicts on various levels and with reference to diverse agents and contesting parties. The 16 agro-pastoralist ethnic groups find themselves in partly violent competition on grazing grounds and heads of cattle. These conflicts have largely been analyzed by anthropologists like David Turton (1985) and Jon Abbink et al. (2014). Nowadays, since 2011, since the valley has turned into a region of high national interest, the local manifestation of the Government-owned Kuraz Sugar Development Project has opened new grounds for conflicts including human rights violations. About 90,000 people in the Lower Omo valley had been depending on flood-retreat farming for sorghum cultivation along the Omo (Turton 2010). In the more southerly parts of the Lower Omo the areas flooded by the river were larger, while the people on the surrounding plains were even more reliant on flood retreat farming than their neighbors in the north, as these practice rain-fed agriculture. Since the end of the Omo floods in 2015, most groups in the northern part of the Lower Omo Valley have become entirely dependent on rain-fed cultivation for crop-production, which leaves them highly vulnerable to climate change induced droughts, or solely dependent on corporation-controlled irrigation systems (Stevenson and Buffavand 2018). Furthermore, reductions in the river flows downstream of the sugarcane plantations are taken to reduce the availability of water – moisture in the soil – with damaging effects on the pastures for the pastoralists' livestock, especially cattle and sheep, while goats are browsers and can partly feed on bush vegetation. Land clearance for sugar plantations has additionally restricted wildlife in vital habitats and cut people's access to subsistence opportunities (Buffavand 2016).

KSDP operates on about 100,000 ha production sites of sugar cane, the formerly pastoralist "commons," irrigated by water from the Gibe III hydrodam. In conjunction with the dam, a system of canals has been built to distribute water to the Omo-Kuraz Plantation, within which selected plots of land have been assigned for use by "settler pastoralists" (Pictures I).

Picture I The example of one of the two irrigation canals along both sides of River Omo (source: with permission by Omo Turkana Research Network (OTuRN 2016)

At full capacity the Kuraz production sites would realize, this the initial projections, a quarter of Ethiopia's sugar and ethanol production, more than any other sugar production site in the country (ESC 2014). The sugar cane is, or will in near future be processed in up to five sugar factories lined along river Omo and situated in pastoralist territories. What is happening in the Lower Omo Valley combines elements of different types of displacement. The scheme was planned and executed by the current regime in Ethiopia in collaboration with an Italian engineering firm and international financiers. In 2012, the South Omo Zone Agriculture Bureau promoted a "Villagization Plan," which described how and when in the course of the coming year the people would be moved into new villages (FDRE 2012). In the plan the benefits of villagization are described as follows: "growing new crops, such as sugarcane on irrigated fields would improve food security; providing people with schooling and medical services would improve their health; settling in planned villages would reduce conflicts that result from "mobility in search of water and pasture". . . . "In the case of land that relies on rain (for cultivation) 2 hectares would be appointed to each settler pastoralist, whereas those settling on irrigable land would be appointed 0.5 hectares each" (FDRE 2012).

In contradiction to these positively connoted outlooks, findings from the field by E. G. J. Stevenson and L. Buffavand (2018) indicate that crop yields were and will be by far not sufficient to feed the pastoralist settlers, let alone to produce a surplus for sale. ". . .villagization was actually experienced by the Bodi settlers as undermining food security and diminishing well-being. It was experienced as heat, as disruption of routines, as a loss of control over livelihoods, as being treated like children rather than adults, and as abstracting work from ordinary sociality" (ibid). In congruence with these findings the study on "Social-ecological change in the Omo-Turkana basin: A synthesis of current developments" by almost the entire group of researchers active in the Omo-Turkana basin (Hobold et al. 2019) recapitulates their findings in a sense of comparative winners – the migrant laborers – and losers – the indigenous peoples (including both agro-pastoralists and pastoralists, but with more borne by agro-pastoralists currently): "Important SES-wide impacts will result from changes in regulating, provisioning, and cultural ecosystem services, including potential environmental degradation; loss of biological and cultural diversity; heightened competition and conflict over natural resources; and the potential for increased dependence on food aid" (ibid.). The other major actors – agro-industry investors, and the governments of Ethiopia and Kenya – they classify as in an equivocal position, with potential for large gains, but also exposure to substantial risks – a position, which is highly contradicted by one of the authors – Benedikt Kamski – at another place. In his argument titled "Omo investors won't scrub away Kuraz's sugary stain" (Kamski 2019) he states: "ESC (Ethiopian Sugar Corporation) rushed into the multi-billion dollar project, largely neglecting critical feasibility and impact assessments" (ibid). The author stresses the urge ESC is experiencing when the capital-intensive transformation of the region failed to bear fruit for its indigenous communities, which in turn creates new conflict dynamics. He concludes: "If economic interests alone guide investment decisions, official visions for inclusive pastoralist development – as recently reiterated by Deputy Prime Minister Demeke

Mekonnen – will require additional effort and financial commitment by the government, and a big question mark remains over whether this will materialize” (ibid.).

Climate Services, Pathways Toward Processes of Beneficial Societal Transformation? – The Local Scale

As indicated above, the chapter will now and finally turn toward and highlight some projected initiative in terms of climate services towards a promotion of livelihood security and environmental justice in favor of the indigenous inhabitants of the Lower Omo Valley, the pastoralist societies. The reasoning of this perspective responds to the again and additionally outlined and named below livelihood risk and conflict scenarios taken to be highly virulent and tangible.

Upon the time and again scheduled and rescheduled completion of the Kuraz Sugar Development Project (KSDP) the overall about 800,000 ha pastoral land will be reduced by 100,000 ha. The sugar production was from the very beginning meant as vehicle of state governed development and progress. But, in spite of the major cutbacks in size and processing capacity, has the KSDP highly impacted on the livelihood system of the pastoralists (Kamski 2019; The Oakland Institute 2013). River Omo is nowadays framed by about 15-m broad irrigation canals, which hinder traditional use of water by the pastoralists for animals and river bench agricultural cultivation. As the pastoralists had to give way to the sugar plantations, they were called to re-settle in newly established permanent villages – the “villagization program” driven by Government policies. In the course of the thus induced transformation processes, many pastoral households are nowadays facing a livelihood situation of food-insecurity. In need of watering their livestock the pastoralist herders are nowadays forced to virtually beat their animals through a dark subway underneath the bottom of the irrigation canals, the so-called underfly. As the floor of these subways is moody and slippery, herders complain about injured cattle with broken legs. Lacking mostly veterinary services in the pastoral setting of life herders will eventually feel forced to kill their injured animal (Pictures I and II).

Additionally, and along with the establishment of the sugar plantations some extensive labor force was needed. Up to today, about 30,000 migrant laborers have arrived from the Ethiopian Highlands. Moreover, re-settlers from the highly populated areas of, for example, the Konso in South Ethiopia have taken advantage of the labor demand in the sugar project. The number of migrant laborers is expected to reach some hundreds of thousands, when all production sites and the five sugar factories will be fully operational (Kamski 2016).

Against the depicted situational setting, resource-based conflicts and at times violent encounters are and in future will be the “order of the day.” In the course of resource – land and water – scarcity, the agro-pastoralists ethnicities find themselves squeezed by natural factors (climate change) and the sugar cane development project. Hence, some growing resentment and animosity toward the dominance of the sugar project and some resistance against the migrant population are poisoning today’s encounters between the diverse interest groups. The pastoralists feel treated

Picture II One of the 'underflies', the only paths for the pastoralist herders to drive their livestock for watering (source: with permission by Omo Turkana Research Network (OTuRN 2016)

unjustly and surely suffer from a lack of recognitional as well as distributional justice.

Moreover, resource scarcity has increased the intensity and frequency of interethnic conflicts among the agro-pastoral ethnicities. If not solved, the current tensions and violent confrontations are likely to engulf the entire South Omo regional entity – one of Government's perspective development corridors in Ethiopia.

In summary, food and livelihood security of the agro-pastoralists in the Lower Omo Valley have become highly vulnerable. This relates on the one hand to the considerable impact of climate change in the course of which the *Belg* Rains fail several seasons in succession as outlined above but likewise to the reduction of freely accessible pasture land in the course of the establishment of the sugar production sites and thus the reduced option in shifting cultivation in comparison to former times. The anchor element of this setting is "feed for the cattle," the central economic and likewise sociocultural value in pastoralist livelihoods. With relation to this socioeconomic "anchor element" in question, the agricultural value chain of the produce sugar cane moves into focus. This value chain is centered to be the protagonist of conflict mediation and resolution in its function to smoothen livelihood stress and vulnerabilities. It is meant to be the manifestation of climate services applicable in given contexts.

In the course of the following argument some design shaping a rather realistic feature of climate services was outlined in 2019, but seemingly has not been realized up to now. As pointed out above the following discussion will in consequence be somehow speculative – but all the same realistic. The envisioned scheme of climate services targets the given lay of conflicts between the indigenous pastoralist communities and the Ethiopian Sugar Corporation (ESC) by one central element: by cut-off residues, bagasse, and molasses from the sugar cane, by-products from the sugar production – to be turned into cattle feed. A project like this would be conceptualized as "contract research," with high emphasis on the value chain development of the sugar cane, but likewise with explicit focus on various social perspectives on conflict resolution, discharging into a process of integrative societal transformation (Picture III).

Guided by the promoted Government politics in terms of “ethnic reconciliation” the project could operate on value chain development and open access to cattle feed for the pastoralist ethnicities. New environments of coexistence among the interest groups in question on equalized grounds were to be defined and processes of integrative societal transformation to be eased.

It can be foreseen that climate services as outlined above bear dangers in terms of some processes of fatal societal transformation, as will be outlined as follows: Indigenous pastoralist societal organization does by its concepts of live and livelihood constituents not incorporate the idea of feeding and, even much less, fattening cattle, whereas the government program of villagization claims the idea of sedentism of the pastoralists in South Omo, which necessarily implies the need for some ways and means of stationary sources of income for the then non-migratory population. In consequence enforced societal transformation will demand considerable conceptional architecture and research endeavor in order to accompany and facilitate these pathways into newly to be designed livelihood systems and outcomes. But, this

Picture III A herder with his favorite ox (source: with permission by Julia Pfitzner) should be noted: these at first sight completely new and seemingly culturally non-acceptable pathways are not to be taken as any purely unrealistic illusion! Already ten years ago and in the face of the above illustrated severe climate change induced droughts, had Nyangatom cattle herders started to sell cattle – at that time under disguise and hidden away from their fathers and elders (Troeger et al. 2012). Very obviously, processes of societal transformation were on the way – already at the beginning of the decade, to be enforced and accelerated by today's bundle of urges. Already at that time some members of the pastoral communities, especially the young men and women, were ready for processes of societal transformation. They were for example ready to abandon their culturally manifested and strict rule to not slaughter cattle except for religious reasons. The perspective of cattle feed would newly and additionally demand some readiness for societal transformation on the side of the pastoralists. The pastoralist cultural setting does by traditionally fixed rules not allow for any sale and ownership in capitalist terms, which would necessarily be one of the terms of sale and storage of cattle feed. – And at this point the question whether the climate service initiative in the outlined way would do good or harm must stay unanswered.

Conclusion

Concluding and turning back to the initially highlighted challenge envisioning societal transformation in terms of environmental justice realized with and for the inhabitants of the Lower Omo Valley in Ethiopia the chapter summarizes the argument in succession of the four environmental scales of analysis.

Very obviously do the forces on the global scale, the climate change imperative, threaten the livelihood system of pastoralism and the individual inhabitants of the pastoral lowlands in a way, which does not open any window of chance for a positive change. The pastoralists cannot but react on this threat by leaving the area with the cattle herd for seasons in succession with almost no way of return. In consequence of the given risky environment the people abandon their culturally inherited customs like the "culture of sharing" and try to survive as individual households and families, which is to be taken as a, if not fatal then at least highly damaging and un-just momentum of societal transformation.

The offer or challenge of decentralization and handing societal concerns, that is, governance, over to the people on the ground in the shape of committees does not offer any true chance of sustainable transformation. As the "state" governed committees do not open any room for recognitional and likewise procedural justice, and do neither acknowledge preexisting governance arrangements as well as worldviews, knowledges, or cultures nor safeguard feasible and acceptable ways of participation and decision making, these two dimensions of justice in societal transformation are not realized in any operational way. The process is to be taken as unsustainable.

Human rights focused critics of the Omo-Gibe basin, namely the Oakland Institute (2013), describe the effects of the upstream hydropower reservoir Gibe III and the land clearing for the Kuraz Sugar Development Project, that is, the forces at the regional scale, as a tragedy that has caused hunger and conflict. Again, and with relation to these forces, no justice in terms of recognition and installment procedures was and is granted to the people, the pastoralists on the ground, and as well constellations at this scale are to be taken as unsustainable.

Finally, the local scale in vision, the chapter turns against a too euphoric interpretation of the perspective of "transformations" in terms of climate services. Cattle feed from the residues of the sugar cane might offer some chance, maybe the only chance, for some partial loss compensation. But surely the more substantive aspects of a sustainable, which means a just handling of given situational settings, would need attention in the face of the claim for environmental and social justice:

- Which distributional effects will societal transformations have within the pastoralist societies? Who of the members of the pastoralist communities will be in the lead and govern the processes of feed storage, distribution and sale, and how will these subsequent leading social positions be legitimized?
- How will questions of societal justice, participation, and the distributive effects of climate change be addressed in social debates?
- Which changes in modes of governance and participation could be essential for any promising transformative processes?

Abstract

The impacts of global warming on rainfall in West Africa were examined using a numerical framework for 5 monsoon years (2001, 2007, 2008, 2010, and 2011). Rainfall characteristics over the three climatic zones, Guinea coast, Savannah, and Sahel, were analyzed. The potential changes associated with global warming were assessed by the pseudo-global warming (PGW) downscaling method. Multiple PGW runs were conducted using climate perturbation from the 40-member ensemble of the Community Earth System Model version 1 (CESM1) coupled with Community Atmospheric Model version 5.2 (CAM5.2) component large ensemble project. The model output was compared with Tropical Rainfall Measuring Mission and Global Precipitation Climatology Project rainfall alongside surface temperature from the European Center for Medium-Range Weather Forecast Reanalysis. Results show that the estimated rainfall amount from the future climate in the 2070s increases slightly compared with the current climate. The total rainfall amount simulated for the current climate is 16% and 63% less than that of the PGW runs and observations, respectively. Also found is an increase (decrease) in heavy (light and moderate) rainfall amount in the PGW runs. These results are, however, contingent on the global circulation model (GCM), which provides the boundary conditions of the regional climate model. CESM1.0-CAM5.2, the GCM employed in this study, tends to provide a greater surface temperature change of about 4 °C. This projected temperature change consequently caused the increase in the simulated precipitation in the PGW experiments, thus highlighting the advantage of using the PGW method to estimate the likely difference between the present and future climate with reduced large-scale model differences and computational resources. The findings of this study are, however, useful to inform decision-making in climate-related activities and guide the design of climate change adaptation projects for the West African region.

Introduction

West African monsoon (WAM) prevails during the West African rainy season and provides a large amount of rainfall, over 75% (Hagos and Cook 2007), in most parts of the region. Activities of the WAM vary across intraseasonal, interseasonal, and interannual time scale. This temporal variability is expected to intensify as a result of human-induced climate change which can thereafter cause serious consequences for health and human well-being, agriculture and food security, as well as water resources and hydrological cycles (Houghton et al. 2001; IPCC 2018).

Scientific researches have made tremendous efforts to improve the understanding of climate change and its causes, and these efforts are being advanced further to better understand the current and future potential impacts (CNR 2010; IPCC 2018). Climate models have proved useful to assess the current state of the climate and to project future climate conditions under various scenarios (NOAA 2019). Fully coupled global circulation models (GCMs) are useful tools for performing global simulations. These state-of-the-art models can be employed to investigate climate change associated with increase in greenhouse gas concentrations caused by anthropogenic activities. However, the coarse nature of GCM's horizontal resolution limits their ability to reproduce local climates, which are directly related to the inability of the model to properly resolve orographic features (IPCC 2007). Other methods such as statistical downscaling (Schmidli et al. 2006), dynamical downscaling (CORDEX, Giorgi et al. 2009), and direct simulation by high-resolution GCM (Wild et al. 1995) are gaining more application to project climate conditions at a regional scale. Therefore, to better represent climate phenomena of interest, in our case the West African monsoon, extremely high horizontal resolution is required. For example, a grid point interval of less than several kilometers or rather at a convection-permitting scale, usually less than 4 km (Prein et al. 2013), is more appropriate for simulating the complex interactions related to orography and local climate, which directly impact the monsoon system of the region.

Because the monsoon rainfall can vary at different time scales, long-term dynamical downscaling, such as the CORDEX, or ensemble projects are necessary to determine the impacts of global warming on the monsoon variability. Long-term simulations at several tens of kilometers or even convection-permitting grid is, however, rather difficult to obtain because of insufficient computational resources and high cost of the use of available resources. Considering the current constraint, to avoid huge computations as regards simulating a longer year-to-year variability, short period numerical experiments are done using the pseudo-global warming method.

The pseudo-global warming (PGW) approach (Liu et al. 2017) is a dynamic downscaling method that permits regional climate change projections with the use of a regional climate model. The PGW method employs initial and lateral boundary conditions that combine 6-hourly reanalysis data and the climate change signals, which are the monthly averaged differences between the current and future climate projections produced by a GCM. The method expects the boundary condition mean state to have similar climatology to those of the GCM future climate projections, but the daily evolution is similar to that of current years. The PGW technique provides the possibility of having a direct comparison between the present year and the PGW year in the context of the interannual variation with the addition of future climatology.

The objective of this research is to investigate the impacts of global warming on rainfall in West Africa during the monsoon period. We employed the PGW method to directly compare future rainfall amount with that of the current. The remaining part of the study is structured as follows: section "Model Domain, Data, and Methods" describes the study area and numerical experiment setup as well as the observation and reanalysis data used. Results and discussion are presented in section "Results and Discussion" and the conclusion is drawn in section "Conclusion."

Model Domain, Data, and Methods

Model Domain and Numerical Experiment Setup

The WRF model version 3.8.1 model is used to perform the regional climate simulations over a 20-km horizontal resolution and 50 model levels. Similar to the studies of Gbode et al. (2019a, b), the domain covers the West African region (0°–20° N, 20° W–20° E; see Fig. 1), including parts of the Atlantic Ocean, that provides the most moisture carried into the region by the low-level monsoon flow.

Five years were selectively simulated and analyzed to account for interannual variability. The considered years represent wet (2008 and 2010), dry (2001 and 2011), and normal (2007) WAM years. The characteristics of the chosen years are determined by the departure of the total annual rainfall amount from long-term mean total annual rainfall over the entire West African domain (not shown for brevity).

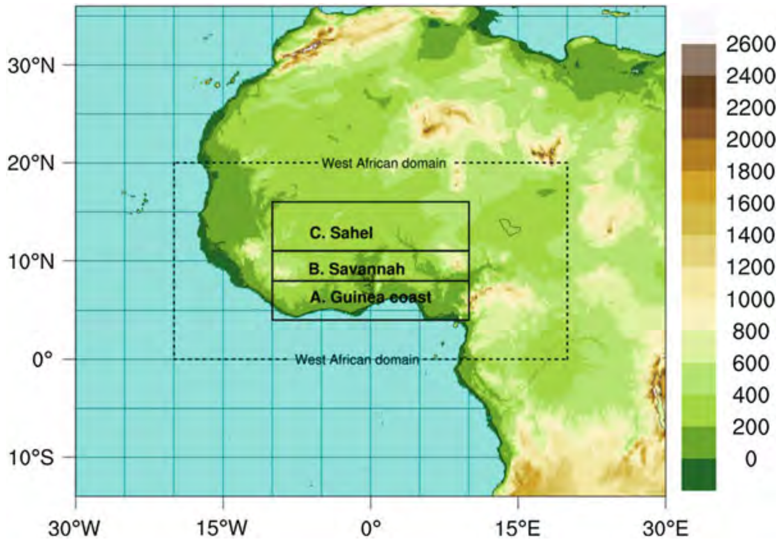

Fig. 1 WRF model domain showing elevation in meters and highlights of the West African (0°–20° N, 20° W–20° E) region and the three climatic zones: (**a**) Guinea coast, (**b**) Savannah, and (**c**) Sahel. (Source: Gbode et al. 2019b)

The numerical study includes three experiments each for current climate and PGW simulations. These experiments combine different WRF model physics: two microphysics (MP), Goddard (GD) and Weather Research and Forecasting (WRF) model single-moment 5-class (WSM5); three planetary boundary layers (PBL), Mellor-Yamada-Janjić (MYJ), Mellor-Yamada-Nakanishi-Niino (MYNN) Level 2.5, and Yonsei University (YSU); and three cumulus convection (CU), Bett-Miller-Janjić (BMJ), new Tiedtke (nTDK), and new simplified Arakawa Schubert (nSAS) parameterization schemes. The choice of the selected combinations is based on results from a preliminary study (Gbode et al. 2019a).

The first experiment was a retrospective simulation aimed at reproducing the variability and mean state of the current climate within the model domain of ~20 km. The simulation contains the selected years, each extending from February to December, but the period March 1 to October 31 was analyzed. The present climate runs are hindcast runs driven by 6-hourly ERA-Interim (ERAI, Dee et al. 2011) atmospheric data with soil (moisture and temperature) initialization from the National Centers for Environmental Prediction Final Reanalysis (NCEP-FNL 2000) (Eq. 1). The NCEP FNL soil data was used to be consistent with the unified Noah land surface model, which was kept constant, as described in Gbode et al. (2019a).

$$WRF_{\text{Input1}} = ERAInterim_{\text{Atmosphere}} + FNL_{\text{Soil}} \tag{1}$$

The second simulation closely follows the pseudo-global warming (PGW) approach used in previous studies (e.g., Liu et al. 2017). Though the approach doesn't account for extreme events, it, however, allows direct comparison between the current and future climate. The simulations of each of the selected years were forced with ERA-Interim, FNL reanalysis, plus climate perturbation (see Eq. 2) derived from the Community Earth System Model version 1 (CESMv1) with the Community Atmospheric Model version 5.2 (CAMv5.2) of the Large Ensemble Community Project (LENS) (Kay et al. 2015):

$$\begin{aligned} WRF_{\text{Input2}} = {} & ERAInterim_{\text{Atmosphere}} + FNL_{\text{Soil}} \\ & + \overline{\Delta CESM1\_CAM5.2_{RCP8.5}}^{\text{monthly}} \end{aligned} \tag{2}$$

where $\overline{\Delta CESM1\_CAM5.2_{RCP8.5}}^{\text{monthly}}$ (see Eq. 3) is the monthly 30-year LENS 40-member ensemble-mean change signal of the business as usual representative concentration pathway (RCP8.5), a comparatively high greenhouse gas emission pathway (Riahi et al. 2011):

$$\begin{aligned} \overline{\Delta CESM1\_CAM5.2_{RCP8.5}}^{\text{monthly}} = {} & \overline{CESM1\_CAM5.2_{2071-2100}} \\ & - \overline{CESM1\_CAM5.2_{1976-2005}} \end{aligned} \tag{3}$$

The perturbed physical fields include horizontal wind, temperature, and relative humidity. First, the climate change signals are obtained at monthly average resolution, and then these are interpolated to analysis times and the model grid

Table 1 Model greenhouse gas concentration to reflect the midyear value of the current (1976–2005) and future (2071–2100) simulations (IPCC 2007, 2014)

Greenhouse gas	Current	Future (RCP8.5)
Carbon dioxide (CO_2)	379 ppmv	801 ppmv
Methane (CH_4)	1774 ppbv	3564 ppbv
Nitrous oxide (N_2O)	319 ppbv	414 ppbv
Chlorofluorocarbons-11 (CFC-11)	251 ppt	86 ppt
Chlorofluorocarbons-12 (CFC-12)	538 ppt	211 ppt

when adding them to the analyses. The LENS CESMv1-CAMv5.2 is approximately 1° latitude/longitude with CAMv5.2 as its atmospheric component. CESMv1-CAMv5.2 is a 40-member ensemble of the LENS of fully coupled CESMv1 simulations for the current (historical) and future (RCP8.5) periods 1976–2005 and 2071–2100, respectively. Each member is subjected to the same radiative forcing scenario but begins from a slightly different initial atmospheric state created by randomly perturbing temperatures at the level of round-off error (Kay et al. 2015). The ensemble average is used to remove interannual variability from the climate change signal.

Before running the PGW simulations, the WRF model was recompiled to reflect the expected mean greenhouse gas concentration levels of the midyear of the last climate epoch of the twenty-first century (i.e., 2086) for the representative concentration pathway 8.5 (see Table 1; IPCC 2007, 2014). RCP8.5, a greenhouse gas concentration (not emissions) trajectory, is one of the four RCPs IPCC adopted in its fifth Assessment Report (AR5). The RCP 8.5 is categorized based on possible radiative forcing value of 8.5 W/m^2, which assumes that emissions will continue to rise throughout the twenty-first century (Meinshausen et al. 2011).

Datasets

The absence of a richly dense network of conventional rain gauges and synoptic weather stations limits the model validation to satellite rainfall products (SRPs) and reanalysis datasets. For rainfall, Tropical Rainfall Measuring Mission (TRMM) (Huffman et al. 2007) and GPCP (Huffman et al. 2016) are used. Though the satellite-derived rainfall contains differences consequent to their observation platforms and different algorithms used in producing them, they, however, conserve the mean rainfall features (Sylla et al. 2013). The Global Precipitation Climatology Project 1° Daily (GPCP 1dd) is a reliable SRP produced from optimized merged estimates computed from microwave, infrared, and sounder data observed by the international constellation of precipitation-related satellites and precipitation gauge analysis (Huffman et al. 2016). Also, the daily TRMM 3B42 version 7 is another reliable source for merged high-quality precipitation estimates (Huffman et al. 2007). The model rainfall is compared with both GPCP and TRMM and its surface air temperature against reanalysis data from the European Center for Medium-Range Weather Forecast Reanalysis (ERAI).

Results and Discussion

Temperature Characteristics

Figure 2 shows the mean surface air temperature averaged during the period JJAS for ERAI reanalysis and model outputs (i.e., present and future runs). In this panel, Fig. 2a, b shows the current and future runs from CESM, Fig. 2c depicts ERAI, Fig. 2d, f shows the present climate runs, Fig. 2g, i shows the PGW runs, and Fig. 2j, l depicts the difference between PGW and present climate during JJAS. The boxplot below Fig. 2c shows the statistics of the 2-meter temperature from March to October over the area within latitudes 5–15°N and longitudes 10°W−10°E.

The reanalysis shows observed temperature range between 20 °C and 36 °C with a steep gradient in the Sahel. This gradient is associated with the Saharan heat low defined by the mean position of the intertropical discontinuity (ITD) and low-pressure center, mostly in August when the monsoon is fully developed (Nicholson 2013). Also, surface air temperature over complex orographic terrains is cooler relative to the desert and nearby land areas. During the twentieth century (Fig. 2a), CESM simulates similar distribution as observed but cooler temperatures over complex terrains, mostly over the Cameroon Mountains and Fouta Djallon highlands. In the future runs (Fig. 2b), the model simulates warmer conditions over the complex terrains and even higher temperatures of about 40 °C over the Sahel. The present runs from the WRF model (Fig. 2d, f) also agree with the reanalyzed temperature gradient but with some biases mostly in the Sahara desert region. Simulated air temperature in the PGW runs, generally, shows warming across the entire domain and ocean (Fig. 2g–i). The maximum value exceeds 40 °C over the desert area. Relative to the present climate, the PGW runs are 5 °C warmer. In GD-MYJ-BMJ8.5 and WSM5-YSU-nSAS8.5, there is a uniform warming of 4 °C from the coast upward to about 15°N latitude followed by a northward steep gradient. A similar warming pattern is found in WSM5-MYNN-nTDK8.5 but restricted only to about 10°N. Over the ocean, the magnitude of warming is lesser perhaps due to its high heat retention capacity.

The box-percentile plot below Fig. 2c presents the distribution of temperature values during the period March to October for the area enclosed within latitudes 5°–15°N and longitudes 10°W–10°E. The values of ERAI range between 25° C and 31 °C with the mean being 27.9 °C. The distribution of the current climate simulation ranges from 24 °C to 31.5 °C. Relative to the WRF simulations, CESM simulates lower temperatures during the current and future runs. Results of the PGW runs show a wider range of temperature (28–36 °C) and a significant shift in the mean. The average difference in the mean between the PGW and current is approximately 4 °C. The warming is generally found in all three simulations.

Further analysis of the probability distribution shows that the surface air temperature averaged over 0–20°N and 20°W–20°E varies from 24 °C to 31 °C and from 27 °C to 35.3 °C for the current and future climate, respectively, with two density maxima that are related to stronger peaks in some months (Fig. 3). These density maxima could be associated with pre-monsoon, when the temperatures are

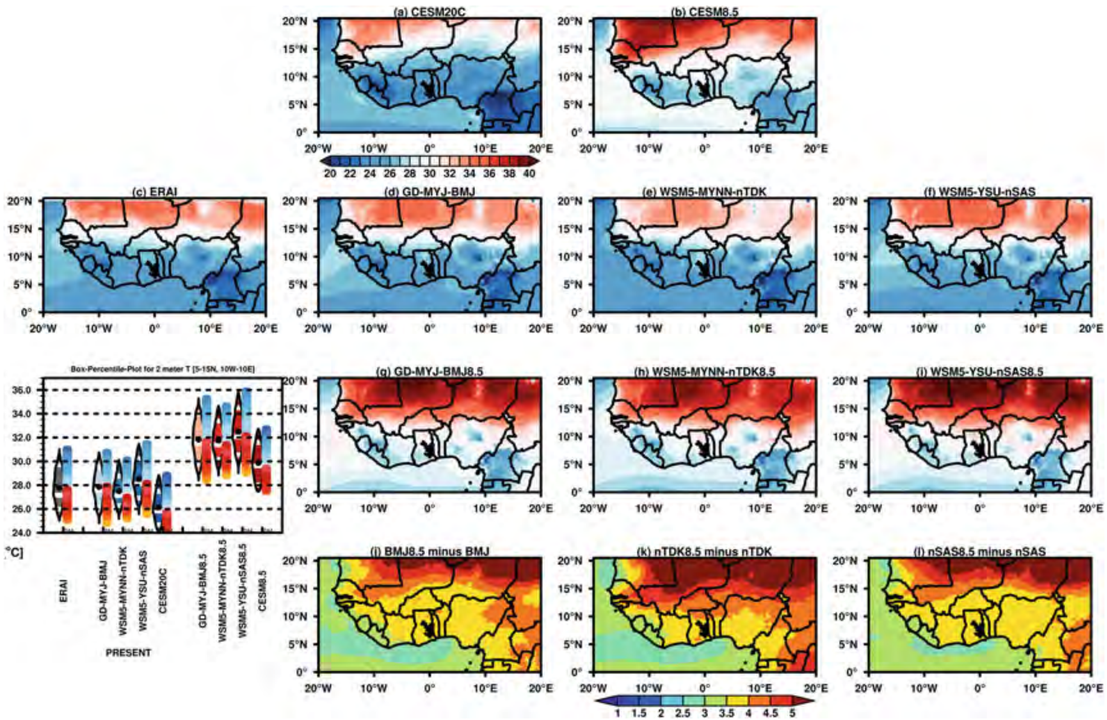

Fig. 2 Average surface air temperature during the period JJAS for ERAI reanalysis and model outputs (i.e., present and future runs). Panels (**a**) and (**b**) show the current (twentieth century) and future (2071–2100) runs from CESM, (**c**) depicts ERAI, (**d**–**f**) *show* the present climate runs, (**g**–**i**) show the PGW runs, and (**j**–**l**) depict the difference between PGW and present climate during JJAS. The boxplot below **c** shows the statistics of the 2-m temperature from March to October over the area within latitudes 5–15°N and longitudes 10°W–10°E. Values in the WRF model plots are averages derived from the selected five years (i.e., 2001, 2007, 2008, 2010, and 2011)

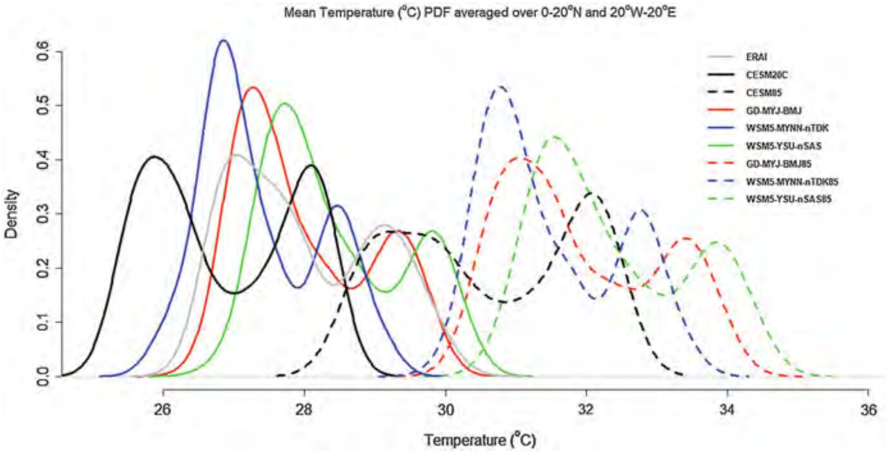

Fig. 3 Probability density function of observed and simulated daily mean temperature averaged over 0–20°N and 20°W–20°E domain. ERAI and WRF outputs are derived from the average of the selected five years, while CESM20C and CESM85 are derived for the period 1976–2005 (continuous lines) and 2071–2100 (dash lines), respectively

usually high as a result of clear sky conditions that allow more insolation to reach the surface, and post-monsoon periods, when the temperatures are usually low as a result of frequent convective activities that bring about cloudy conditions which prevent incoming radiation from reaching the surface. The observed density (gray line, i.e., ERAI) corresponding to the low (high) temperature maxima is higher (lower). CEMS simulates lower temperatures compared with ERAI and WRF current and PGW runs. This underscores the benefit of having a high-resolution regional climate simulation. The three model experiments also reproduced the observed distribution with varying densities. For example, the density of low temperature values in WSM5-MYNN-nTDK is higher compared with that of GD-MYJ-BMJ and WSM5-YSU-nSAS. During the last climate regime of the twenty-first century (2071–2100), both GCM and RCMs simulate a significant increase in temperature. Temperatures in the WRF runs are expected to increase more compared with the GCM. The upper bound shift in temperature could reach 3–4 °C.

Precipitation Characteristics

The observed average daily precipitation amount and the modeled values for present and future simulations during the period June–September (JJAS) are presented in Fig. 4. Also, the bottom boxplot of Fig. 4 shows the statistics of the daily precipitation distribution from March to October over the area bounded by latitudes 5–15°N and longitudes 10°W–10°E. GPCP and TRMM (in Fig. 4a, b) show average daily rainfall values reaching 14 and 16 mm day^{-1}, respectively. Both observed products agree in terms of producing maximum values over complex orographic terrains and

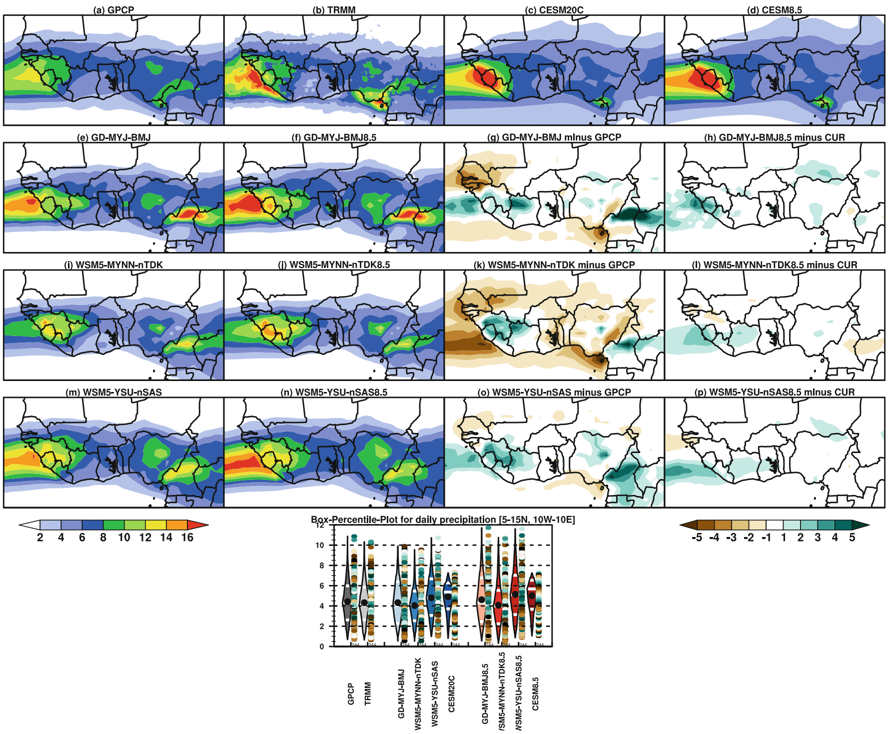

Fig. 4 Spatial distribution of average daily rainfall (mm day^{-1}) for the period JJAS. Values of (**a**) GPCP, (**b**) TRMM, and (**e**, **f**, **i**, **j**, **m**, and **n**) WRF runs are derived from the average of the five simulated years, while (**c** and **d**) CESM values are derived from the considered 30-year current and future periods. Differences between (**g**, **k**, and **o**) GPCP and WRF current and (**h**, **l**, and **p**) PGW and current runs are also presented in the figure. The bottom boxplot shows the statistics of the daily precipitation distribution from March to October over the area of latitudes 5–15 °N and longitudes 10 °W–10 °E

minimum in other land areas. CESM simulates values of 16 mm day^{-1} in the twentieth century and RCP8.5 (Fig. 4c, d) in agreement with TRMM, but the GCM, however, shows deficiencies in reproducing the observed maximum over complex terrains of Jos Plateau and the southeast orientation pattern over the Cameroon Mountains; this points out the limitations of the GCM to reproduce certain features due to its coarse horizontal resolution that makes it difficult to properly capture atmospheric phenomena at smaller horizontal scales than its grid.

Consistent in observations and WRF simulations is the band of maximum daily average rainfall sitting, on average, along latitude 10°N. Also, the RCM runs agree with observations as they simulate the climatological precipitation maxima over complex orographic terrains of Cameroon Mountains, Jos Plateau, and Fouta Djallon highlands with extension toward the western coast of West Africa. In the present year simulations, GD-MYJ-BMJ also reproduces the magnitude of 16 mm day^{-1} over the Cameroon Mountain and the west coast of the monsoon region (Fig. 4e). For

WSM5-MYNN-nTDK and WSM5-YSU-nSAS (Fig. 4i, m) runs, the simulated magnitude could be 15 mm day^{-1} or less. The PGW runs show an increase in daily precipitation relative to the present climate runs, most especially over complex orographic terrains and over the west coast of West Africa. While the simulated values of GD-MYJ-BMJ8.5 and WSM5-YSU-nSAS8.5 could be greater than 17 mm day^{-1}, that of WSM5-MYNN-nTDK8.5 only simulates maximum of 15 mm day^{-1} (Fig. 4f, j, and n).

Although the models agree with the observation patterns, there exist some systematic errors. The degree of these errors is quantitatively assessed, firstly, by taking the difference between current runs and GPCP (Fig. 4g, k, and o). The results show wetness of about 5 mm day^{-1} over complex terrain and other land areas. In contrast, dryness (less than −5 mm day^{-1}) is simulated over the western Sahel and along the southern coast of the monsoon region as well as ocean areas. Secondly, the degree of error is quantitatively assessed by computing the difference between PGW and current climate runs which shows general wetness of less than 4 mm day^{-1} around the western part of the region and small extent of 2 mm day^{-1} dryness in other land areas (Fig. 4h, l, and p). Further, to examine the effect of warming on precipitation, the statistics of observations and model results are presented at the bottom of Fig. 4 (boxplot). Results show that the maximum observed and modeled daily precipitation in the considered area (5°–15°N and 10°W–10°E) is about 11 and 12 mm day^{-1} for PGW runs. In CESM, the values are less than 8 mm day^{-1}. The mean value for GPCP and TRMM is slightly above 4 mm day^{-1}. For the current climate runs, GD-MYJ-BMJ agrees with the observed mean values, while WSM5-MYNN-nTDK simulates exactly 4 mm day^{-1}. WSM5-YSU-nSAS produces higher magnitudes of daily precipitation and an increase in the mean (i.e., 5 mm day^{-1}). The impacts of warming are evident through an increase in the mean and maximum value of PGW runs. This response is most obvious in GD-MYJ-BMJ8.5 and WSM5-YSU-nSAS8.5, where there is a slight increase in the mean (~0.2 mm day^{-1}) and maximum daily rainfall (>12 mm day^{-1}). In WSM5-MYNN-nTDK, there is an increase in the maximum daily precipitation values but no significant change in the mean distribution.

The precipitation changes (shown in Fig. 2) between GPCP and current runs are averagely found to be −5, 0.6, and −50% in the Guinea coast, Savannah, and Sahel, respectively. Also, differences between TRMM and current runs may reach maximum values of −19, −7, and −52% for the corresponding climatic zones. Some of the models underestimate the observed average daily rainfall, mostly in TRMM. Between the current and PGW runs, the average percentage difference is generally small and ranges between −2% and 16% over the entire monsoon region. In general, the average percentage difference is greater mostly in the Sahel. This suggests the possibility of experiencing greater impacts on rainfall regimes in the Sahel as a result of global warming. Relative to Sahel, a less impact is felt in the Guinea coast, where there are heterogeneous surfaces and features, and a mild influence in Savannah (Table 2).

Furthermore, the probability distribution analysis of the average daily rainfall amount reveals varying densities over the 5–15°N latitudes and 10°W–10°E

Table 2 Average percentage difference (%) of total rainfall amount observed and modeled during the period March to October for the five years over each climatic zone. GPCP and TRMM (upper row) are subtracted from the current model runs (lower rows) to compute the percentage difference. In the same manner, the current runs are subtracted from the PGW runs

	GPCP			TRMM			PRESENT		
Climatic zone	BMJ	nTDK	nSAS	BMJ	nTDK	nSAS	BMJ8.5	nTDK8.5	nSAS8.5
Guinea coast	–12	–10	7	–3	−18	−19	3	–1	8
Savannah	1	–6	7	–3	−6	−12	3	4	6
Sahel	–47	−59	−45	−50	−44	−63	16	−2	9

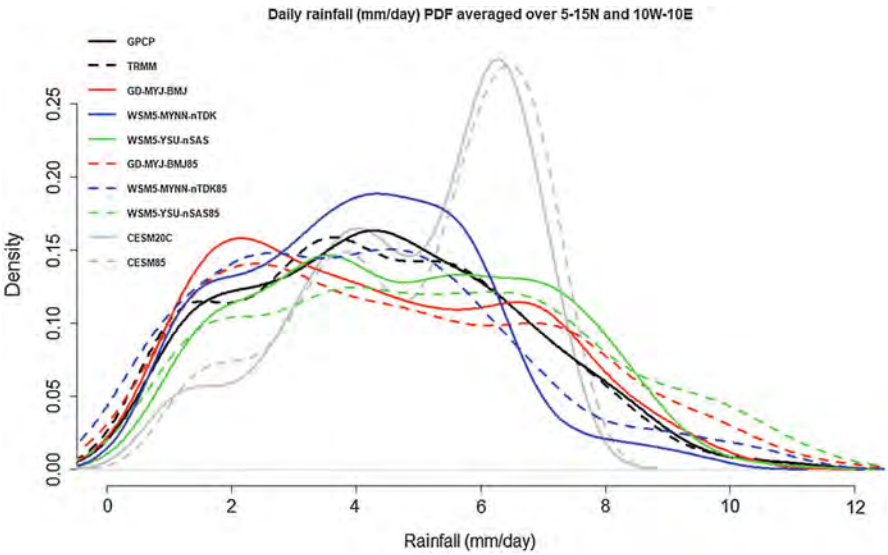

Fig. 5 Probability density function of observed and simulated daily mean rainfall averaged over the 5–15°N and 10°W–10°E domain. GPCP, TRMM, and WRF outputs are derived from the average of the selected five years, while CESM20C and CESM85 are derived for the periods 1976–2005 and 2071–2100, respectively

longitudes (as shown in Fig. 5). The rainfall distribution between GPCP and TRMM is similar with little differences. Both the current and future climate runs of CESM possess a high density of rainfall of about 6 mm day^{-1}. Also, a slight rainfall increase of greater than 6 mm day^{-1} is simulated in CESM future runs relative to the current runs. Whereas values of less than 6 mm day^{-1}, however, occur more in the GCM's current runs. The distribution in the WRF simulations is similar to that of the observations, thus highlighting the benefit of having high-resolution regional climate simulations. Generally, the WRF model simulates occurrences of increased heavy and light rainfall in the PGW runs. Also, the PGW run simulates lesser frequencies of moderate rains. WSM5-YSU-nSAS PGW runs simulate higher average daily rainfall intensity relative to WSM5-MYNN-nTDK and GD-MYJ-BMJ, respectively. This combination, however, simulates lower densities of moderate average daily rainfall.

To further investigate the characteristics of daily rainfall over the region, the rainfall is disintegrated into different categories, light (1–2 mm day^{-1}), moderate (≥2–10 mm day^{-1}), and heavy (≥10 mm day^{-1}), based on the probability density function presented in Fig. 5. Rainfall between 1 and 2 mm provides percentage of rainfall within the range of 7.7–8.7% for the period March to October (not shown for brevity) and decreases by 0.8–1% in the RCM. Category of rainfall within 2–10 mm provides 54–67% of rainfall and shows not only a decrease in the frequency of rains but also a decrease in the percentage (i.e., 3–6%) in the future. Heavy rainfall (i.e. 10 mm and above) contributes between 24–31.4% and 30–37.9% rainfall amount in the current and future climate, respectively, in WRF simulations. This type of rainfall is expected to increase by 3–6.5% in the future. For CESM, the percentage of 42.2% and 49.4% is simulated in the current and future climate, respectively. The GCM simulates this feature only in the complex terrain of Cameroon Mountains and the west coast of the monsoon region.

Though the results of this study are based on the GCM, which provides the boundary conditions for the RCM, it provides useful insights to inform decision-making in climate-related sectors of the economy such as agriculture, water resources, hydropower generation, and other climate-dependent activities. Likewise, the findings are useful to guide the design of climate change adaptation projects that will ensure a climate-resilient and sustainable development. The PGW approach used, however, doesn't account for extreme events. Hence, the need for longer-term simulations in future studies to assess extreme events and their associated impacts.

Conclusion

This study examined the impacts of global warming on precipitation amount during the West African monsoon season using the PGW method. Three experiments that combine microphysics, convection, and planetary boundary layer parameterization schemes were also conducted for both current and PGW climate runs. Model runs were performed for selected wet (2008–2010), dry (2001–2011), and normal (2007) monsoon years in the region at 20-km horizontal resolution. Also, the precipitation characteristics over the three climatic zones; Guinea coast, Savannah, and Sahel, were analyzed. The current and PGW climate runs showed good agreement with the observed precipitation by reproducing the spatial distribution pattern over complex orographic terrains. The estimated rainfall amount in the 2070s from the PGW runs increased slightly compared with the current climate runs. In all climatic zones, the total precipitation amount simulated by the current climate is less than 16% and 63% relative to the PGW runs and the observations, respectively. However, the difference between current climate runs and observations is higher relative to that of PGW runs. GD-MYJ-BMJ runs have good agreement with observations in terms of simulating the characteristics of wet, dry, and normal monsoon years, which is defined by total precipitation amount. WSM5-MYNN-nTDK is more consistent in defining the precipitation characteristic in Savannah and Sahel, while WSM5-YSU-nSAS rarely agrees in any two of the climatic zones. Also found is an increase in heavy rainfall amount and a decrease in both light and moderate rainfall amount.

Though the results of this study are based on the GCM, which provides the boundary conditions for the RCM, it provides useful insights to guide policymakers to make informed decisions on issues concerning climate-related sectors of the economy such as agriculture, water resources, hydropower generation, and other climate-dependent activities. Besides, the findings are useful to guide the design of climate change adaptation projects that will ensure a climate-resilient and sustainable development. The PGW approach used, however, doesn't account for extreme events, hence, the need for longer simulations in future studies.

Acknowledgments The German Federal Ministry of Education and Research (BMBF) primarily funded this research through the Doctoral Research Programme-West African Climate System (DRP-WACS) hosted at the Federal University of Technology Akure (FUTA), Ondo State, Nigeria. Many thanks to NCAR's MMM Laboratory for supporting the research work. Abstract

Climate change strongly affects the health of sub-Saharan African populations. Effective adaptation strategies are required in order to enhance their limited adaptive capacities. The DFG-funded Research Unit (RU) “Climate change and health in sub-Saharan Africa” unites nine research institutions from Burkina Faso, Kenya, Germany, and Switzerland that will design, implement, and evaluate four different adaptation projects in these two African countries from 2020 until 2022.

First, the effectiveness of an agro-biodiversification and nutrition program will be established for the reduction of child undernutrition of climate-sensitive nutrients in rural Burkina Faso and Kenya. Two respective cluster-randomized controlled trials (cRCT) will be conducted, each consisting of 2 × 600 children. Second, another cRCT will be conducted among 2 × 300 households in rural Burkina Faso to investigate how sunlight-reflecting cool-roof coatings affect human health outcomes, including cardiovascular and heat-related outcomes. Further outcomes comprise indoor temperature, carbon footprint, and productivity. Third, an index-based weather insurance (IBWI) will be introduced in rural Burkina Faso. The effects of IBWI on childhood nutritional status, dietary behavior, and healthcare seeking will be determined in 2 × 20 villages. Fourth, microbial larviciding has been evaluated as a promising environmental control for malaria vectors in Burkina Faso. Here, the interactions between climatic factors and the effectiveness of the intervention will be tested using spatiotemporal models.

Introduction: Proposed Adaptation Strategies for Climate Change Impacts in Two Exemplar Regions of Sub-Saharan Africa

Climate change constitutes one of the biggest threats and opportunities to global health (Costello et al. 2009; Watts et al. 2015). The World Health Organization (WHO) estimates that between 2030 and 2050, climate change will cause approximately 250,000 additional deaths/year, with an increasing trend (WHO 2014). Indeed, global warming, weather instability, and weather extremes have emerged as major risk factors for global health acting on their own or modifying the effect of the wide array of the immediate and intermediate determinants of health. The recent report by the International Panel on Climate Change (IPCC) has concluded that climate change is expected to exacerbate a wide range of health problems, including undernutrition, vector-borne diseases, and noncommunicable diseases (IPCC 2017; Woodward et al. 2014). The report further points to the heat-mediated productivity losses, not least in agricultural production in low-income settings (Kjellstrom et al. 2017). While the causes, impacts, and mitigation efforts of climate change truly act globally, efficient and effective adaptation strategies require local solutions. This is particularly true for sub-Saharan Africa, where climate change impacts on health are felt strongest because the populations there exhibit the least adaptive capacity.

Autonomous and planned adaptations will be necessary to meet the challenges of common smallholder subsistence systems in sub-Saharan Africa (IAASTD 2009). Small-scale subsistence farmers are defined as rural households with agricultural-based access (max. 2 ha) to essential resources for survival (Grace et al. 2012). Proposed adaptation strategies generally refer to risk management or production enhancement, and include:

- Altering the timing or the location of cropping activities and the diversification of agriculture (Constanzo and Bàrberi 2013)
- Increasing the access to financial and technological resources that facilitate adaptation to climate change (Bizikova et al. 2009)
- Risk protection by index-based weather insurance (IBWI) as one option of market-based risk management mechanisms (Leblois and Quirion 2013)
- Novel methods of vector control to overcome drug resistance, changes in vector-biting behavior, and altered vector species (Tusting et al. 2013)

Herein, four specific adaptation strategies are described that will be designed, implemented, and evaluated over the next 3 years (2020–2022) within the framework of the Research Unit (RU) "Climate Change and Health in sub-Saharan Africa," funded by the German Research Foundation (DFG). The RU builds on previous collaborations and existing research infrastructure within the Health and Demographic Surveillance Systems (HDSS) in Nouna (Burkina Faso) and Kisumu (Kenya). The locations and the characteristics of the two HDSS sites are presented in Fig. 1 and Table 1, respectively.

According to the gross domestic product (GDP) per capita, Burkina Faso is one of the poorest countries in the world, whereas Kenya ranks among the lower-middle-income countries (World Bank 2018). The HDSS sites Nouna and Kisumu have been established in the early 1990s; the Kisumu area is more densely populated than the Nouna site. Climate-wise, these two HDSS locations differ: Nouna experiences one rainy season per year with excessive rainfalls in August and high temperatures during the dry season; Kisumu has two rainy seasons and experiences lower

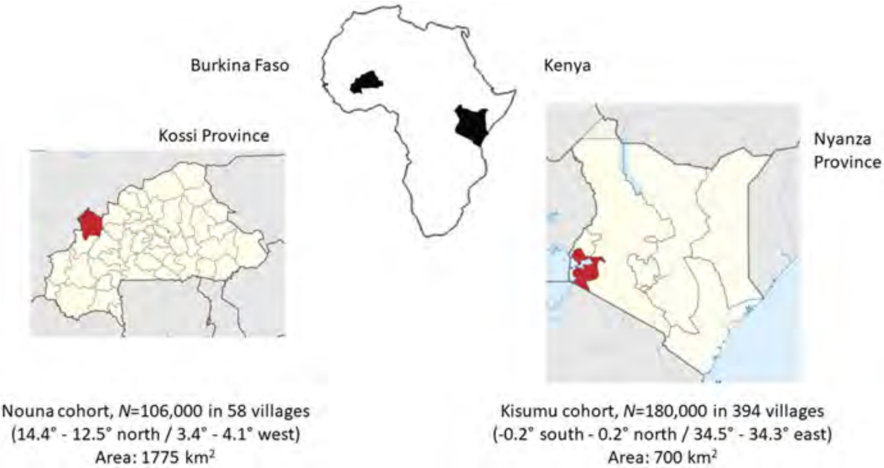

Fig. 1 The Health and Demographic Surveillance sites in Burkina Faso and Kenya

temperatures in the highlands. The inhabitants of both regions live on small-scale subsistence farming, which is complemented by fishing in the Kenyan areas close to Lake Victoria. The typical diets in both regions are based on starchy staples and legumes. According to the Living Standards Measurement Study (LSMS) by the World Bank, the share of livelihoods from subsistence farming in both areas ranges between 70% and 90% (World Bank 2017). The proportion of children with acute and chronic undernutrition tends to be higher in Kisumu than in Nouna. Both areas are holo-endemic for malaria transmission with similar prevalence among children. HIV incidence in Kisumu is three-times higher than in Nouna.

Strategy 1: Agro-Biodiversification and Nutrition Intervention in Rural Burkina Faso and Rural Kenya

Background

Climate change impacts food security through direct and indirect pathways (Myers et al. 2017), and presumably affects the spread of malaria in sub-Saharan Africa (Caminade et al. 2014; Dasgupta 2018). Increased greenhouse gas emissions, particularly CO_2, reduce the contents of iron, zinc, and protein in major staple foods in this region (Myers et al. 2014; Smith and Myers 2018). This development will likely slow down the reduction of macro- and micronutrient undernutrition in the most vulnerable population group of children aged <5 years and their mothers (Smith and Myers 2018). As an integral part of a food-systems approach, agricultural bio-diversification seems to be a promising tool to achieve resilience against increased atmospheric CO_2, improved dietary diversity, and thus, adequate micronutrient supplies and protein utilization (Constanzo and Bàrberi 2013; Olney et al. 2015). Still, the success of

Table 1 Characteristics of the Nouna and the Kisumu Health and Demographic Surveillance (HDSS) areas

Characteristics	Nouna, Burkina Faso	Kisumu, Kenya
National GDP per capita in 2017	670 US$	1508 US$
Health care facilities	1 district hospital with surgical unit, 13 basic health facilities	36 health facilities: 1 district hospital, 2 private hospitals, 11 health centers, and 22 dispensaries
Geographic position	North-west (Boucle de Mouhoun)	West (Nyanza Province)
	Land-locked	Partly located at Lake Victoria
	Rural and semi-urban	Rural
Surveillance area	1775 km^2	700 km^2
Altitude	260 m above sea level	1070 m above sea level
Population under surveillance	115,000 individuals	220,000 individuals
	14,548 households	54,869 households
	58 villages	385 villages
Starting of HDSS	1992	1990
Age structure of HDSS	17% <5 years of age	13% <5 years of age
Weather/ climate	Rainy season: June till October	Long rains: March till May
	Mean annual rainfall: 800 mm	Short rains: October till December
	Daily min T: 20–28 °C	Mean annual rainfall: 1200–1500 mm
	Daily max T: 29–37 °C	T between 17 °C and 35 °C
Major crops in subsistence agriculture	Millet, sorghum, maize, peanuts, rice, and sesame	Maize, beans, sweet potatoes, sorghum, rice, cassava
Nutritional status of children <5 years	21% stunting	30% stunting
	14% underweight	20% underweight
	10% wasting	6% wasting
	~80% anemia	~50% anemia
Malaria in children <5 years	Malaria is hyper- to holoendemic, peaking at the end of the rainy season	Malaria is holoendemic with transmission throughout the year
	Prevalence: 30–50%	Prevalence: 30–50%
HIV/AIDS	HIV rate: 0.26/1000 pyrs	HIV rate: 3.09/1000 pyrs
	Prevention of Mother-To-Child Transmission (PMTCT) according to WHO guidelines (coverage 50–80%)	PMTCT using Nevirapine, Lamivudine, Zidovudine

such adaptation strategies depends on the local food supply chains (Sibhatu et al. 2015) and remains to be established for sub-Saharan Africa. In addition, a healthy nutritional status through agricultural bio-diversification may also reduce the risk of clinical malaria among young children living in endemic regions (Danquah et al. 2009). Yet, expanding the agricultural land cover bears the adverse potential of generating breeding sites for malaria vectors, thereby fueling parasite transmission (Janko et al. 2018).

This project addresses the potential of a household, agricultural bio-diversification, and nutrition program to improve the nutritional status and to reduce episodes of clinical malaria among young children and their mothers living in two subsistence and malaria-endemic areas of rural sub-Saharan Africa. The specific research objectives are:

(i) To establish the baseline cross-sectional associations of self-sufficient food supply and dietary habits with the status of climate-sensitive nutrients (protein, iron, zinc) among children at the age of supplementary feed introduction (6–24 months) and their mothers in rural Burkina Faso and rural Kenya.
(ii) To establish the effects of the agricultural bio-diversification and nutrition program on dietary habits, anthropometric measures of protein-energy under-nutrition, micronutrient status, and the risk of clinical malaria among young children and their mothers.
(iii) To quantify the relative contributions of additional household greenspace and improved childhood nutritional status through this agricultural and nutrition intervention to malaria risk in children.

Procedures

This project will start in January 2020 and involves the scientific evaluation of an integrated agriculture and nutrition program focusing on agricultural bio-diversification to improve the status of climate-sensitive nutrients among children aged 6–59 months. For this purpose, this study will adopt a program that was successfully implemented and evaluated in other parts of rural Burkina Faso (Olney et al. 2015). The conceptual framework of this intervention program relies on three impact pathways that are depicted in Fig. 2:

- Increased production of climate-resilient horticultural crops and diversification of crops for increased consumption of these foods.
- Increased output of foods to increase income.
- Increased knowledge related to the importance of agricultural diversification (= use more indigenous plants) for the resilience of local crops and thus, food and nutrient security for healthy families, thereby increasing the adoption of optimal practices.

More specifically, the study will conduct two cluster-randomized controlled trials (cRCT), enrolling 600 households at each site with children at the age of supplementary feed introduction (6–24 months) at baseline. These households will be randomized to the control group or the intervention group. The intervention will comprise an agriculture component and a nutrition part. The agriculture component will foster agro-diversification using horticultural crops in home gardens, based on

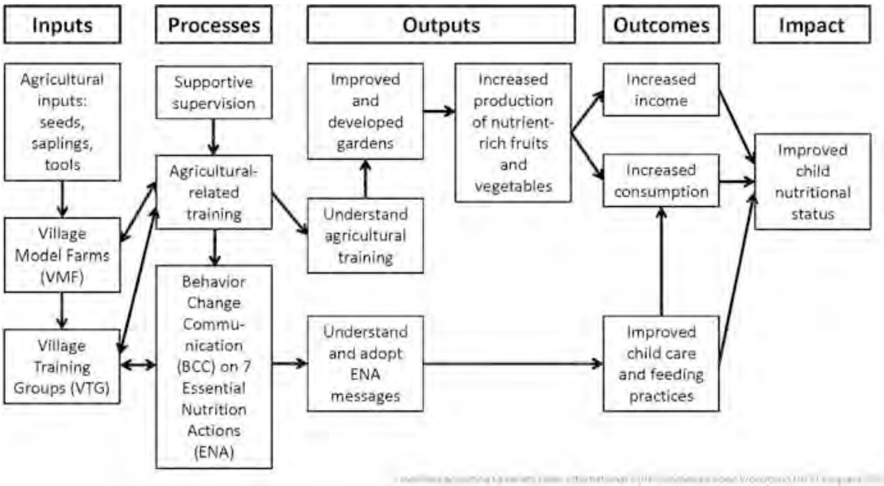

Fig. 2 Impact pathways of the integrated agricultural bio-diversification and nutrition program, modified according to Hellen Keller International's Homestead Food Production Program 2013

village model gardens and specific trainings. The nutrition component comprises regular sessions on Behavior Change Communication focusing on the seven Essential Nutrition Action (ENA) messages by the World Health Organization. After an observation period of at least 12 months, height-for-age z-scores among the enrolled children (30–48 months) will be assessed as the primary nutrition and health-outcome. Secondary outcomes include weight-for-age z-score, weight-for-height z-score, iron and zinc status, incl. hemoglobin concentrations (Hb), species richness in home gardens, dietary behavior, and associated costs. The data will be analyzed on an intention-to-treat basis by random effects linear models and accounting for the cluster design. The formative research of this project has started in September 2019; the recruitment of households with young children is envisioned for the middle of 2020; and follow-up shall be completed in the first quarter of 2023.

Strategy 2: Cool Roofs to Improve Human Health, Environmental and Economic Outcomes in Rural Burkina Faso

Background

Increasing mean global temperature and extreme heat are adversely affecting people's health. Projections show that warming of 4 °C in 2100 relative to preindustrial levels in sub-Saharan Africa will result in an increase of monthly summer temperatures by 4–6 °C above present-day temperatures (Schellnhuber and Hare 2013). Even if warming is limited to within 2 °C by 2050, adaptation costs in Africa are expected to rise to USD 35 billion/year, while warming in the range of 3.5–4 °C, as projected under current emissions, will elevate adaptation costs dramatically to USD

50 billion/year (AMCEN, UNEP, and Climate Analytics 2013). These costs highlight the need for early action.

Millions of homes in resource-poor countries are built with low-cost materials, such as corrugated metal roofing sheets, that expose occupants to high temperatures. Owing to their high expense and electricity use, technologies such as air conditioners are ill-suited in resource-poor settings to alleviate the discomfort from heat. In sub-Saharan Africa, where climate change effects on health and well-being are most severe, adaptive technologies do not yet meet the needs of populations to ease the burden from heat.

Advances in housing technologies can passively reduce indoor temperatures through increased solar reflectance and catalyzed thermal emittance (Singh et al. 2010; Howden-Chapman et al. 2007). Cool roof coatings in the form of a liquid applied membrane (LAM) are a promising, low-cost intervention to reduce indoor temperatures that may prove suitable for immediate wide-spread use across new and existing building stocks. Cool roofs that reflect direct sunlight can stay cooler than roofs that absorb sunlight. Solar reflectance (the ability to reflect the visible wavelengths of sunlight, reducing heat transfer to the surface) and thermal emittance (the ability to radiate absorbed solar energy) are the two main mechanisms through which cool roofs reduce indoor heat (Levinson et al. 2002). In clear skies, up to 95% of solar radiation is absorbed by a typical roof surface; cool roofs can substantially reduce this fraction (Dabaieh et al. 2015).

LAMs are sprayed or painted on the roof surfaces and seem to be the most suitable cool roof technology for existing homes in Nouna, Burkina Faso, because they can effectively coat surfaces with undulations or complex roofing structures such as mud bricks or corrugated tin. Different LAM types have different Solar Reflectance Indices (SRIs), which indicate the level of solar reflectivity. LAM substances can also be easily transported and are created on site.

Furthermore, LAM roofs have minimal upfront costs, zero maintenance costs, and possible co-benefits of carbon emission reduction and air quality improvements. Despite the potential for alleviating the burden of heat on the poorest households, the effect estimates on environmental and human health outcomes of cool roofs in sub-Saharan Africa remain unknown. The study site is therefore located in northwest Burkina Faso – characterized by hot dry seasons with temperatures exceeding 40 °C and a wet rainy season.

The long-term research goal is to identify viable passive housing adaptation technologies with proven health and environmental benefits to reduce the burden of heat stress in communities affected by heat in Africa. The specific objectives of this study are to:

(i) Establish the cultural acceptability of different types of LAM-based cool roofs in Nouna, Burkina Faso
(ii) Establish the effect of the cool roof on the primary endpoint heart rate as an indicator of physiological stress
(iii) Determine the effects of the cool roof on a range of secondary endpoints, including indoor temperature, indoor humidity, cardiovascular morbidity and mortality, household energy consumption, and socioeconomic outcomes

Procedures

Within the RU, this project will start in January 2020 to test a cool-roof coating on mud-brick and tin roofs in Burkina Faso. The project will collect health, environmental, and economic outcome measures, with the primary outcomes being health-related, including heart rate and core body temperature.

First, a formative qualitative study will be conducted to establish the cultural acceptability of the cool roofs. Several versions of the cool roof are possible, with different appearances and different technical properties. For the successful execution of this trial and for long-term impact, it will be important to understand how best to introduce and apply the cool roof in a community and in individual homes and which color and surface material to offer. The trial will start with a formative qualitative study to elicit the local meaning of climate adaptation using the cool roof as well as perceptions of and preferences for particular cool roof colors and surface materials. Second, a cool roof mechanism study will be conducted. Before embarking on a large-scale cluster randomized controlled trial, a small-scale study of mechanisms in eight households will be conducted, which will serve two purposes. First, it will provide pilot data to optimally design the trial processes given the real-life constraints of working in rural Burkina Faso. Second, it will provide fundamental quantitative insights into the physical mechanisms of the cool roof. Most importantly, the third part will comprise a cluster-randomized controlled effectiveness trial. To date, the effects of cool roofs has not been tested in randomized controlled trials, even though such rigorous causal tests are highly feasible. In addition, there have been no studies of cool roof effectiveness in sub-Saharan Africa, the subcontinent where both the effects of climate change will be most severe and the current capacity to adapt to climate change is most limited. Thus this study will be the first cool roof cluster-randomized controlled trial (cRCT) to establish the effects of the technology on critical heat, health, and socioeconomic outcomes in 600 households. The target primary and secondary endpoints include home temperature and humidity, heart rate, core body temperature, hydration status, thermal comfort, cognition, blood pressure, and clinic and hospital utilization.

Strategy 3: Index-Based Weather Insurance in Rural Burkina Faso

Background

Emerging evidence highlights the role of climate change in the rise of climate variability and extremes around the globe (Kotir 2011). In turn, increased climate variability and extremes negatively affect the overall stability of global food systems through the decrease in food production (Rosenzweig et al. 2001). Climate change-induced production disruptions increase rural small-holder farmers' vulnerability to undernutrition and poverty (Herrera et al. 2018). This is especially true in sub-Saharan Africa (SSA), where rural households depend mainly on rain-fed subsistence farming and consume around 70% of what they produce (Belesova et al. 2018).

A plethora of adaptation strategies (such as crop diversification, savings, credit, informal risk-sharing arrangements at the community level) has been proposed to address the risk that climate change poses to food production (Dercon et al. 2014). Index-based weather insurance (IBWI) emerges as a promising solution vis à vis traditional crop insurance which suffers from high operational costs and premium because the indemnity payment requires strenuous verification of production losses on each farm. The verification process can be challenging in settings where farms are small and scattered, as is the case in smallholder subsistence farming in rural SSA (Leblois and Quirion 2013). In contrast, IBWI ameliorates the high operational costs and the cumbersome indemnity verification process by making indemnity payments conditional upon an objective and independently measurable weather index (e.g., rainfall or temperature index) (Skees 2008). Payment to the insured is triggered when the index falls below or above a pre-agreed threshold (Carter et al. 2014). IBWI is by no means the panacea for handling all farm losses risk faced by small-scale farmers but stands as the option with the most significant potential of "getting the big risk out of the way" (Skees 2008).

Procedures

With specific regard to the field of research, IBWI is expected to produce health gains through two distinct impact pathways that are depicted in Fig. 3. First, IBWI will expectedly improve health by improving nutritional status thanks to improved food security. Second, households who enjoy IBWI protection are anticipated to experience a lower need for saving and hence to have more disposable income for other expenses, including health service utilization, a fundamental element to maintain and restore one's health. There exist approximately 18 IBWI schemes in SSA. The majority of

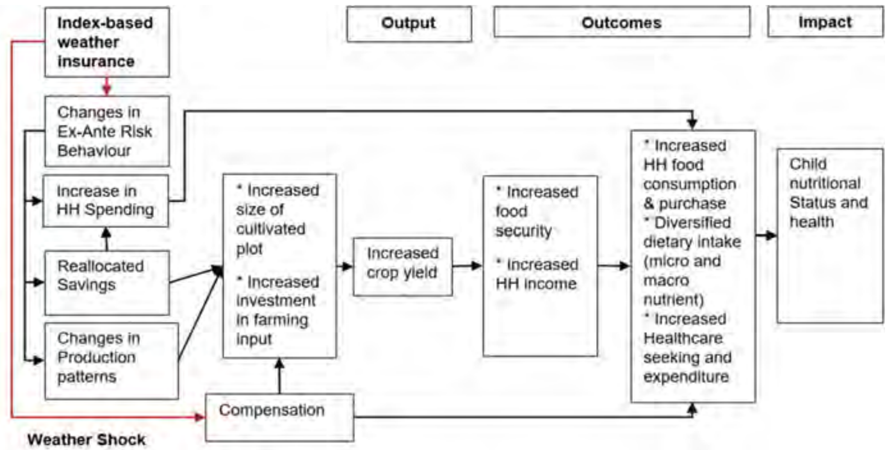

Fig. 3 Impact pathways of index-based weather insurance to improve health among smallholder subsistence farming families

these schemes are in operation, but face multiple challenges pertaining to the demand, index design, and institutional support (Hess and Hazell 2016).

So far, the literature on IBWI has concentrated on index design problems such as basis risk and farmer characteristics that influence demand and uptake of IBWI. Less is known about how the different stakeholders (national and global policy agents, first-line implementers, and beneficiaries) interact in the design and implementation of IBWI and how this interaction might affect the success and scalability of IBWI (Duru 2016). In particular, since the literature on IBWI has been dominated by development and agricultural economics, little attention has been paid to whether concerned stakeholders conceptualize the link between insurance and health, via the causal links outlined earlier. To bridge this knowledge gap during the RU lifetime (2020–2022), a political economy analysis (PEA) (Participants at the Bellagio Workshop on Political Economy of Global Health 2015) will be conducted to understand institutional interactions of the different stakeholders involved in the design and implementation of IBWI. The PEA will be grounded in document analysis and key informant interviews, to examine how structures, institutions, and agents work towards the implementation of IBWI in Burkina Faso and Kenya. In light of recent literature highlighting polycentric governance as a driving force of policy development in LMICs, the work will also address the role of international agencies in shaping the emergence of IWBI as a climate change adaptation strategy in SSA.

Strategy 4: Larviciding Against Malaria Vectors in Rural Burkina Faso

Background

Despite intense worldwide efforts, malaria is still the world's most important and deadly tropical mosquito-borne parasitic disease. It is responsible for an estimated 435,000 deaths and 219 million disease cases (WHO 2019). Variation in climatic parameters such as temperature, rainfall amount and patterns, and humidity are known to exert influence on malaria transmission through direct influence on the life cycle of vector mosquitoes and malaria parasites (Okuneye et al. 2019).

Climate change is likely to worsen the malarial situation in many areas where malaria transmission already takes place, while, at the same time, it might grant relief in few other regions (Murdock et al. 2016). Additionally, new areas that have been traditionally malaria free, such as regions in the cooler climate and at a higher altitude, will experience an increased risk for transmission. Climate change greatly impacts and alters the El Niño cycle that is known to be associated with increased risks of some diseases transmitted by mosquitoes, such as malaria, dengue, and Rift Valley fever (Mabaso and Ndlovu 2012). In dry climates, heavy rainfall can provide good breeding conditions for the mosquitoes, while droughts in wetter areas can facilitate the formation of more mosquito breeding sites. Climate change together with an increase in resistance of vectors against insecticides and observed changes in mosquito biting behavior poses a threat to the efficacy of traditional vector control measures such as impregnated nets and indoor residual spraying that are currently in place (Ashley et al. 2014; Killeen et al. 2016; Thomas and Read 2016). For securing and improving current achievements in malaria vector control in a changing climate, it is more important than ever to administer control efforts in an integrated fashion, adding additional approaches, without pulling out from the already implemented ones.

Several of these shortcomings in current malaria vector control can be addressed, to varying extent, by extending control efforts to vector larvae. Other than chemicals such as DDT that were used in previous control and eradication efforts, modern vector larvae control can rely on biological larvicides such as *Bacillus thuringiensis israelensis* (*Bti*). Those are environmentally safe, target species-specific in their mode of action, and show no resistances (Becker 2000). Within the last decade, there has been generated a large body of evidence, showing that *Bti*-based larviciding can bring down malaria vector populations by order of magnitude and significantly reduce malaria prevalence (Tusting et al. 2013; Dambach et al. 2019). One of the main advantages of larviciding is that the vector larvae cannot elude intervention, and they can be targeted where they are concentrated and easily detectable. Dambach et al. have already shown in 2016 that *Bti*-based larviciding can be provided at low cost, similar to or lower than those of LLINs (Dambach et al. 2016; Maheu-Giroux and Castro 2014). Future formulations of *Bti* with increased residual effect and the use of new substances such as insect growth regulators are likely to reduce intervention costs further.

Procedures

The way of how larviciding is carried out depends on the used larvicide. The most common approach is to perform larviciding during the period of highest malaria transmission, which follows the period of highest vector abundance, which, in most settings, is the rainy season. In the case of *Bti*, the mostly used larvicide formulation is dissolved in water and then brought out with knapsack sprayers onto the surface of potential mosquito breeding sites such as ponds, puddles, roadside ditches but equally to smaller features such as tire marks or hoof prints that are filled with water (Fig. 4). Within several hours up to 1-day posttreatment, the larval stages of mosquitoes will have died off, which can be confirmed by visual control. Due to *Bti's* organic structure and sedimentation, it loses efficacy after a few days and reapplication is required (Dambach et al. 2014). In tropical climate, this retreatment interval is shorter compared to higher latitudes, and larviciding has to be carried out again every 8–10 days. Hence, depending on the duration of the rainy season, and the ambient temperature, only a few up to more than ten treatment rounds might be needed to effectively control vector populations. Besides the implementation of a meticulously followed spraying calendar, it can be beneficial to monitor larviciding success as a part of quality control, in particular during the first time of carrying out. The first step of program quality control is performed by determining the larvae kill-off rate. As a next step,

Fig. 4 Project members are spraying a stagnant body of water in Burkina Faso, in which mosquitoes develop, with the biological insecticide *bti*. (© Dr. Peter Dambach, Heidelberg Institute of Global Health (HIGH), Universitaetsklinikum Heidelberg, Germany)

adult vector abundance is monitored through different types of traps and catchment techniques and compared to a pre-intervention baseline or an untreated reference area.

Conclusions

Herein, presented four viable and propagated adaptation strategies are presented to support populations in sub-Saharan Africa in their development of climate-resilience. These projects are united by their careful alignment of design research, early involvement of stakeholders and decision-makers, and scientific evaluation of health outcomes as well as economic returns. Global climate change mitigation efforts are certainly needed. Still, climate change impacts on health are already discernible in rural Burkina Faso and Kenya. These transformative projects will enhance the local adaptive capacities for combatting the major health problems undernutrition, cardiovascular heat-stress, and malaria in these regions.

Abstract

Climate change adaptation entails exploiting not only economically but also environmentally beneficial strategies by all stakeholders. However, the successful implementation of adaptation actions is also subject to the perception of climate change, usually influenced by knowledge, experiences, and sociocultural factors including gender relations, among the target group. This chapter analyzes the perception of climate change among rural households in Southwest Nigeria and ascertains the coping and adaptation strategies in use among the households. A total of 239 respondents were interviewed across the vegetative zones available in the study area. Findings revealed that 54.8% were involved in crop farming. About 51.0% and 45.6% practiced change in sowing date and harvest date, respectively. Respondents' perception had a significant relationship with adaptation measures such as change in harvest date ($\chi^2 = 56.753$, $p = 0.026$), planting improved varieties ($\chi^2 = 55.866$, $p = 0.031$), and mixed cropping ($\chi^2 = 55.433$, $p = 0.042$). Respondents had a favorable perception of climate change. The study concluded that although their perception of climate change was favorable and indicated their understanding of its negative effects on their livelihoods, it did not take cognizance of women's insecure access to production resources. It recommended the development of easily accessible weather forecasts to aid livelihood decisions and enlightenment on improved women's access to production resources and biodiversity protection.

Sustainable adaptation strategies · Perception · Rural livelihoods · Southwest Nigeria

Introduction

Rural livelihoods comprise a diversity of capabilities, assets, and activities that rural people, households, and communities require to earn and secure their living (FAO 2003). Climate change threatens and erodes these assets, thereby hampering income generation and perpetuating poverty (IPCC 2007). However, the successful implementation of climate change adaptation strategies, which are essential to adjusting and reducing its negative impacts on food security, is influenced by rural households' perception of climate change (Apurba and Haque 2017).

In developing countries, climate change is occurring in the midst of other developmental stressors, such as poverty, fluctuating oil prices, and land degradation. Adaptation strategies are aimed at lowering the vulnerability of natural and human systems to climate change so as not to frustrate food security and poverty reduction efforts (Bhatasara and Nyamwanza 2017). Due to its effect in slowing down economic growth, national governments have integrated climate change adaptation measures into their policy frameworks. At the local level, households adopt diverse strategies in their livelihoods to cope with climate change. They include change in planting date, livelihood diversification, borrowing, zero tillage, rationing, afforestation, planting improved crop varieties, and sale of assets, such as livestock (Akinbami et al. 2016; Abdulai et al. 2017). In the face of climate change, the survival of rural livelihoods is facilitated by adaptation strategies as they ensure

(i) Food security
(ii) A more reliable income flow for the welfare of households

However, as Agyei (2016) pointed out, the question of the sustainability of adaptation strategies must be answered before they are pursued. More important to the achievement of sustainable adaptation frameworks are the barriers to their implementation, including sociocultural barriers (Antwi-Agyei et al. 2014). Sociocultural barriers could stem from the values, beliefs, and norms of people. These factors shape their perception of climate change – a vital element that determines the adoption of sustainable adaptation strategies (Yaro 2006; Moser and Ekstrom 2010). Perceptions are gaining more recognition in climate change and adaptation studies because past experiences, observations, and future expectations of rural households may influence the choice of adaptation strategy employed to address climate change impacts (Maddison 2007).

Perceptions have been found to be one of the factors driving the choice of adaptation and mitigation strategies, thereby necessitating its integration in the design and development of climate-smart interventions for rural livelihoods, particularly agriculture (Grimberg et al. 2018). Five general classes of impediments to adaptation have been identified. They are financial, technological, cognitive, cultural, and institutional impediments. Local adaptive capacity recognizes not only the capitals and the resource-based components of adaptive capacity at local levels but also the intangible and dynamic factors such as perception (Jones et al. 2017). Rural livelihoods become more resilient when households are able to perceive first, the impacts of climate change, as well those of inappropriate adaptation measures (Alam et al. 2017). The study therefore aims to assess the perception of climate change among rural households in order to achieve sustainable climate adaptation.

Assessing perception of climate change among rural households will provide household-level data to aid the understanding of their resource exploitation behavior, capabilities, and challenges. In this way, local, context-specific sustainable adaption policies can be developed in order to address climate change issues and the interrelationship between livelihoods and gender concerns in rural areas. The study, therefore, aimed to ascertain the coping and adaptation strategies employed by rural households in their livelihoods and determine their perception of climate change.

Literature Review

Sustainable Climate Change Adaptation

Sustainable climate change adaptation entails the exploitation of available resources to meet present needs without jeopardizing the ability to meet future needs. It facilitates the pursuit of profitable livelihoods in a healthy environment. It, therefore, requires that rural households first become aware that climate change is real, understand the dynamic causes, and recognize available valuable adaptation strategies that are not only economically but also environmentally friendly before successful implementation can be achieved (Osumanu et al. 2017). If rural livelihoods are to recover from stresses and shocks while also sustaining their capabilities and assets without compromising the natural resource base, rural households must recognize that certain adaptation choices are capable of creating more harm than benefits in the long run (Bhatasara and Nyamwanza 2017).

The Concept of Perception in Climate Change Adaptation

Perception is formed from the combination of small bits of information about the environment and creating a duplicate internal representation. Perception refers to an individual's or group's unique way of viewing a phenomenon. It involves the processing of stimuli, memories, and experiences in the process of understanding. This highlights the three essential features of perception: (i) a sensory or cognition of the experience, (ii) personal experiences that help in interpreting and understanding a phenomenon, and (iii) comprehension that can lead to a response (Galotti 1994; McDonald 2012).

In relating perceptions to adaptation, studies (Asrat and Simane 2018; Zoundji et al. 2017; Ndamani and Watanabe 2015) have shown that as perception is dynamic, so is adaptation location-specific and influenced by key drivers such as socioeconomic, environmental, and institutional factors. Observations produce knowledge. Perceptions are interpretation of observations in connection to existing knowledge. Perceptions (of the effects of a chosen adaptation strategy) can combine with existing knowledge to produce adjusted or new action. However, before adaption action takes place, people must first perceive the reality of climate change and its impacts (Asrat and Simane 2018; Alam et al. 2017).

Description of the Study Areas and Methodology

Study Area

The study was conducted in the Southwest of Nigeria in 2018. Southwest Nigeria (also referred to as the Southwest geopolitical zone) has been experiencing intense dynamics of rapid socioeconomic development, land use, and population growth. It is made up of six states – Ekiti, Lagos, Ogun, Ondo, Osun, and Oyo. The area lies between longitude 2° 31′ and 6° 00′ East and latitude 6° 21′ and 8° 37′ North. It has a surface area of about 78,505 km^2, population of 17,455,052 people, and a population density of 353 persons/km^2 (NPC 2006). It is bound in the east by Edo and Delta states, in the north by Kwara and Kogi states, in the west by the Republic of Benin, and in the South by the Atlantic Ocean (Faleyimu et al. 2010).

The climate of Southwest Nigeria is tropical in nature and is characterized by wet and dry seasons (Faleyimu et al. 2010). The dry season is short, lasting generally from December to February. The average annual rainfall is 1,200–1,500 mm. The monthly mean temperature ranges from about 22.49 °C to 31.24 °C, while the average annual temperature is about 26.6 °C. Furthermore, temperature is relatively high during the dry season and low during the rainy season, especially between July and August (Oyinloye and Oloukoi 2013). The average annual relative humidity is about 76.05%. The relatively high rainfall usually precipitates widespread flooding in some parts of the region. However, the indiscriminate exploitation of the environment has contributed to recent flood events.

There are three main types of vegetation in the region – mangrove forest which is found mainly in Lagos state and some parts of Ogun and Ondo states; tropical rain forest which is found mainly in Ogun, Ondo, Ekiti, and some parts of Oyo state; and, lastly, guinea and derived savanna found mainly in Osun and some parts of Oyo and Ogun states. Most of the rivers are short, north-south coastal rivers. The major rivers include Ogbese, Ogun, Ogunpa, Oluwa, Ominla, Oni, and Owena (Oyinloye and Oloukoi 2013).

The predominant economic activities are farming, trading, and artisanship. The climate favors the propagation of crops like yam, cassava, rice, plantains, cocoa, kola nut, oil palm, and maize, among others. As a result, majority of the inhabitants are farmers who practice farming enterprises ranging from crop production, livestock breeding, forestry practices, fisheries and aquaculture to agricultural processing (NPC 2006).

Research Methods

Study Site Selection and Sampling Methods

Lagos, Ondo, and Oyo states were purposively selected to represent the vegetation zones in the study area – Lagos (mangrove and coastal swamp), Oyo (rainforest and derived savanna), and Ondo (rainforest and coastal). The research was conducted in Badagry, Epe, Akure North, Eseodo, Ifedore, Ilaje, and Ibarapa Central and Ibarapa North local government areas (LGAs). Five communities were randomly selected from each LGA to yield a total of 40 communities. A random selection of 6 households from each of the 40 communities gave 240 households. In-depth interview with 16 community key informants was carried out. Key informant selection and interviews were carried out in consultation with enumerators and community members.

Data Sources and Collection Methods

The study utilized both quantitative and qualitative data. These were gathered from household heads through interview schedule and questionnaire survey as well as interviews for key informants. Data on local coping and adaptation strategies employed by the households were obtained using the survey. Data on perception were obtained using Likert-type scale items. Interviews with key informants and overt observation provided information on nature of farming and other livelihood activities, local gender dimensions, climate change impacts in the communities, coping strategies employed, and underlying social challenges.

Data Analysis

Both descriptive and inferential statistics were used in analyzing the coping and adaptation strategies employed by the households and their perception of climate change. SPSS was used to analyze quantitative data. A chi-square analysis was carried out to determine if there was a relationship between the perception of the rural households and their choice of coping and adaptation strategies. The mean of the perception statements was used. Analysis of qualitative data was done in the context of interview themes.

Results and Discussion

While the study sought to elicit information from both male-headed and female-headed households in order to disaggregate data on gender basis, there was inadequate female-headed household sample size. Moreover, some of the women were unwilling to be interviewed due to their gender roles of cooking for the household and childcare. As a result, male-headed households made up most of the sample. Although 240 respondents were intended for the study, information was obtained from 239.

Primary Livelihoods of Rural Households

As is typical of rural communities, Southwest Nigeria is agrarian in nature. Many households are involved in agriculture for both family consumption and income generation. However, nonfarm livelihoods are nonetheless important. Some of these livelihoods are agro-allied in nature, e.g., processing and trading of farm produce. Table 1 displays the livelihoods of the rural households.

Many of the households were involved in crop farming as it was the primary livelihood source for 54.8% of the households. This was followed by trading/business as approved by 14.6% of the households. Fishing ranked third as 10.9% of the households claimed it was their primary source of livelihood. Both processing and artisanship ranked fourth because 6.3% each of the respondents claimed either was their main source of livelihood. Gathering of non-timber

Table 1 Primary livelihoods of respondents (N = 239)

Livelihood	No. replied	%
Animal husbandry	11	4.6
Trading/business	35	14.6
Processing	15	6.3
Fishing	26	10.9
Artisanship	15	6.3
Gathering of non-timber forest products	4	1.7
Hunting	2	0.8

forest products accounted for 1.7% of the respondents. Only 0.8% claimed hunting was their main source of livelihood.

Interviews with key informants and observations revealed that many of the households were smallholder farmers (average farm size >3.0 ha) involved mainly in maize, yam, cassava, plantain, oil palm, and cocoa. Farmers in the coastal areas were also involved in rice and coconut production. Animal husbandry, although widespread, was mainly for family consumption and for sale to maintain the welfare of the household during periods of hardship. Animals reared include goat, sheep, poultry, and, in some cases, pigs. Although fishing was the main source of livelihood in coastal areas, some households were involved in fish farming (aquaculture). Households involved in trading sold consumer goods which community members would have had to travel to more urbanized centers to buy.

Agriculture is the backbone of many rural economies, ensuring food security, employment, export earnings, and economic development. As Olajide et al. (2012) attested, it employs about 65% of the labor force in Nigeria, while contribution to GDP oscillates between 30% and 42%. However, as revealed by the study, it is worthy of note that the rural sector comprises a diversity of livelihoods and the players range from large and smallholder landlords, landless workers, fishing communities, nonagricultural entrepreneurs including artisans, public institutions, private firms, providers of inputs and services, farmers' organizations, and nongovernmental organizations. Building sustainable and resilient rural livelihoods will, therefore, require that this wide array of stakeholders be given recognition in development initiatives and plans (FAO 2003).

Climate Change Coping and Adaptation Strategies Employed in Rural Livelihoods

Rural households make adaptation choices to cope with the effect of climate change. Many factors influence the coping and adaptation choices adopted by rural households in the pursuit of their livelihoods. Whether these choices augur well for profitable livelihoods and a healthy environment is also another challenge addressed by factors such as their level of exposure and awareness, education, income, and cultural affiliation. Table 2 displays the adaptation choices employed by the households in order to ensure thriving enterprises.

Table 2 Coping and adaptation practices employed in rural livelihoods

No.	Types of coping and adaptation practices (N = 239)	No. replied	%
1	Change in sowing date	122	51.0
2	Change in harvest date	109	45.6
3	Mixed cropping	108	45.2
4	Purchasing extra feed for livestock (in dry season)	5	2.1
5	Planting of improved varieties	82	34.3
6	Afforestation	82	34.3
7	Community aid/support (money, labor, material)	18	7.5
8	Irrigation	78	32.6
9	Seasonal migration	42	17.6
10	Aid from government	33	13.8
11	Use of organic manure	70	29.3
12	Borrowing	35	14.6
13	Using media (TV, radio, mobile phone, etc.) forecasting	28	11.7
14	Sale of assets, e.g., livestock	49	20.5
15	Diversification of livelihoods	86	36.0
16	Construction of barriers and drainage channels	33	13.8
17	Increased watering of soil	28	11.7
18	Fuel conservation	26	10.9
19	Increased watering of livestock	21	8.8

Of all the coping and adaptation strategies, strategies 4, 12, and 13 cannot be regarded as sustainable. Low incomes are a peculiarity of rural areas, and purchasing extra feed for livestock in the dry season will only add to the pressure on their meager earnings. Rural households engage in sale of assets to obtain cash to offset pressing needs. More often than not, rural households lack the required collateral to secure loans from commercial banks. Consequently, they resorted to borrowing. These measures are maladaptive and unsustainable as they erode efforts at food security and poverty reduction. They borrowed from relatives, friends, and credit groups such as esusu (informal savings group for mutual access to credit) and farmers' groups. As buttressed by CARE (2011), these actions may appear to have immediate effect in managing crisis; they bear potential negative impacts on households' asset base, health, local biodiversity, and ecosystem. However, groups such as esusu and farmers' group can be veritable tools and platforms for improving welfare and achieving poverty reduction among rural households when provided operational resources and capacity.

About 51.0% and 45.6% of the respondents changed sowing and harvest dates, respectively, based on indigenous knowledge and personal observation of weather patterns and climate change impacts. This helped to minimize crop losses. Mixed cropping (45.2%), planting of improved varieties (34.3%), and afforestation (34.3%) were carried out to reduce risk. Mixed cropping serves as a buffer against weather fluctuation and an insurance against crop failure. Households involved in afforestation were those that had orange and kola nut trees. Tree planting was not widespread except for those that planted *Gmelina arborea*. These adaptation measures are encouraged by agricultural extension because they aid nutrient cycling, improved soil structure, and more reliable income stream. This result is in line with Asrat and Simane (2018) that adaptation strategies such as use of improved varieties and adjusting planting date were favored among farmers and also highlighted the role of extension in sustainable adaptation.

About 11.7% of them utilized weather forecasting services through electronic media in their livelihoods. The ISKA weather forecast service by GIZ is one of such platforms accessed through the mobile phone by respondents in Oyo state. This way, rural households are able to obtain climate information at affordable rates. Such platforms are useful in disaster risk management in developing early warning systems and preparedness of rural households (Antwi-Agyei et al. 2014). They promote the development of more resilient livelihoods.

Occasionally, support is mobilized for the household in form of money, labor, and materials by the community. This safety net is also badly affected by climate change impacts such as flooding, pest infestation and drought. Climate change makes it difficult to garner resources to help households in the community when there is a widespread effect (CARE 2011). Irrigation was employed by 32.6% and 17.6% resorted to seasonal migration. Usually, the irrigation practiced involved fetching water into watering cans from nearby streams to water farms during the dry season. This is because of the high cost of irrigation technology which smallholders cannot afford. Since agriculture in sub-Saharan Africa is basically rain-fed, poor access to irrigation limits production, impairing food production and income generation during dry season and drought. Moreover, the labor required to water the farms places extra strain on the time, energy, and health of household members. Members of rural households migrate in search of employment opportunities on a seasonal basis in order to augment income. However, increasing migration of men from rural areas in search of employment has caused the number of female-headed households to grow substantially (Omonona 2009; Gebre et al. 2019).

Households who obtained aid (such as money and implements) from government constituted 13.8%, while the use of organic manure was adopted by 29.3%. The use of organic manure is made easier where animals are being reared and crop residue can be utilized. Livelihood diversification (36.0%) was done to earn more income, especially into nonfarm or off-farm activities, such as artisanship (Loison 2015). This helps to increase income flow for the households. Construction of barriers and drainage channels was done in the coastal areas. Interview with key informants revealed that barriers were constructed usually by those involved in fish farming in the coastal areas to prevent their fish from being washed away by coastal flooding which could occur as a result of heavy rainfall.

Increased watering of plants prevents them from drying up or wilting which affects fruiting and, consequently, yield. Increased watering of livestock during hot weather reduces the incidence of heat stress among the animals so as not to affect their productivity. Fuel conservation reduces the rate of greenhouse gas emissions.

Table 2 also shows that respondents utilized more of coping and adaptation options that were affordable and easily accessible to them. The strategies include change in sowing and harvest dates, mixed cropping, afforestation, planting improved varieties, irrigation, and diversification of livelihoods. These strategies that come at little or no cost are favored by many rural households (Alam et al. 2017). For instance, household members assisted in fetching water from nearby streams to water farms.

Perception of Climate Change Among Rural Households

The belief system of rural households influences their adaptation choices and could either hinder or aid the implementation of sustainable adaptation strategies, especially at the local level. Like any other phenomenon, their understanding or opinion of climate change is shaped by their values, morals, and norms (culture), experiences, indigenous knowledge, education, exposure, opinion leaders in the community, and other factors. Table 3 reveals the opinions of the households as regards climate change.

Respondents agreed to statements 3, 4, 5, 8, 10, 14, and 15. They disagreed with statements 1, 7, 9, 11, 12, and 13. They were undecided about statement 2. Respondents agreed that the protection of biodiversity is impossible with climate change. This is one of the reasons that make rural households opt for unsustainable adaptation choices that jeopardize their livelihoods and environmental sustainability (Osumanu et al. 2017). They agreed that increasing temperatures caused a decrease in their productivity and planting improved varieties could help minimize crop losses. High temperatures, an indicator of global warming, could affect health and cause household members to spend less time on their livelihoods. Improved varieties can withstand harsh weather conditions and still give good yield. They agreed that accumulation of livelihood assets has become much more difficult with climate change. This is because climate change erodes their effort at income generation, food security, and poverty reduction.

They also agreed that local or indigenous knowledge is useful in reinforcing scientific climate information to make it more relevant to rural livelihoods. Local experiences employed in coping with climate change can be integrated with scientific climate knowledge to improve its acceptability and adoption. They agreed that women are vulnerable to climate change due to their insecure access to production resources. They agreed that rampant bush burning in preparation for land cultivation has a negative effect on the environment. This knowledge may be due to their contact with agricultural extension.

Households disagreed with the statement that there has been no change in climatic conditions in recent years. This implies that rural households are experiencing an alteration in weather conditions, evidenced by a dwindling of environmental resources such as water and fuel wood as stated by key informants. They disagreed that climate change does not affect the amount and quality of water, wood, and other natural resources. This is because with climate change, household members responsible for such roles, especially women and children, spend more time in search of water and fuel wood. Usually, they have to search deeper into forests (FAO 2008).

Table 3 Perception of climate change among rural households (N = 239)

S/N	Perception statement	SA F(%)	A F(%)	U F(%)	D F(%)	SD F(%)	Mean	Remark
1.	No change in climatic condition has been observed in the past 3 years (N)	30 (12.6)	18(7.5)	13 (5.5)	107 (44.8)	71 (29.7)	4.00	Disagree
2.	Men and women are equally vulnerable to climate change (N)	39 (16.3)	120 (50.2)	64 (26.7)	12(5.0)	4(1.7)	2.82	Undecided
3.	Protection of the environment and biodiversity is impossible in the face of climate change (N)	19 (7.9)	53 (22.2)	53 (22.2)	81 (33.9)	33 (13.8)	3.59	Agree
4.	Increasing temperatures tend to reduce the number of work hours and, consequently, productivity (P)	63 (26.4)	130 (54.4)	16 (6.7)	22(9.2)	8(3.3)	4.27	Agree
5.	Planting improved varieties can help boost yield (P)	62 (25.9)	133 (55.6)	23 (9.6)	13(5.4)	8(3.3)	4.24	Agree
6.	Climate change affects income generation of households (N)	68 (28.5)	106 (44.4)	36 (15.1)	20(8.4)	9(3.8)	4.21	Agree
7.	Climate change does not affect the amount and quality of available water, wood, fish, and other natural resources (N)	10 (4.2)	28 (11.7)	42 (17.6)	80 (33.5)	79 (33.1)	4.17	Disagree
8.	Accumulation of assets has become much more difficult with climate change (P)	74 (31.0)	63 (26.4)	60 (25.1)	30 (12.6)	12 (5.0)	4.08	Agree
9.	Climate information is not a priority in planning and decision-making in rural livelihoods (N)	6(2.5)	47 (19.7)	32 (13.5)	76 (31.8)	78 (32.6)	4.08	Disagree
10.	Local knowledge reinforces scientific climate knowledge and makes it more relevant to rural livelihoods (P)	62 (25.9)	88 (36.8)	48 (20.1)	32 (13.4)	9(3.8)	4.03	Agree
11.	Climate change has no effect on the health status of households (N)	19 (7.9)	17(7.2)	31 (13.0)	115 (48.1)	57 (23.8)	4.00	Disagree
12.	No change in climatic condition has been observed in recent years (N)	30 (12.6)	18(7.5)	13 (5.5)	107 (44.8)	71 (29.7)	4.00	Disagree

(continued)

Table 3 (continued)

S/N	Perception statement	SA F(%)	A F(%)	U F(%)	D F(%)	SD F(%)	Mean	Remark
13.	Climate change has not reduced the quantity and quality of food consumed by households (N)	21 (8.8)	53 (22.2)	23 (9.6)	65 (27.2)	77 (32.2)	3.88	Disagree
14.	Women are more vulnerable to climate change due to their insecure access to production resources (P)	33 (13.8)	96 (40.2)	49 (20.5)	96 (40.2)	33 (13.8)	3.66	Agree
15.	Rampant bush burning in preparation for land cultivation has a negative effect on the environment (P)	44 (18.4)	100 (41.8)	48 (20.1)	36 (15.1)	11 (4.6)	3.83	Agree

Grand mean, 3.92; N, negative statement; P, positive statement
S, strongly agree; A, agree; U, undecided; D, disagree; SD, strongly disagree

Respondents disagreed that climate information is not a priority for planning in livelihoods. This is because with relevant climate information, such as weather forecast, risks can be minimized. They disagreed that climate change has no effect on the health status of rural households. Also, they disagreed with the statement that climate change has not decreased the quantity and quality of food consumed by households. This implies that climate change has affected the food security of rural households. According to CARE (2011), climate change has made rural households resort to drastic and unsustainable measures such as food rationing and borrowing. Such conditions lead to hunger, undernourishment, and poor health status which can prevent them from achieving profitable livelihoods.

However, the respondents were undecided about statement 2 which stated that men and women were equally vulnerable to climate change (mean = 2.82). This is unlike statement 14 to which respondents agreed that insecure access to production resources contributed to women's vulnerability (mean = 3.66). This may stem from their culture which still makes it difficult for them to perceive gender gaps (Antwi-Agyei et al. 2014) due to conditions such as insecure access to production resources, poor level of education, etc. These stand as barriers to women empowerment and women contributing successfully to the welfare of their households in the face of climate change. Interviews revealed that women involved in agricultural production do not get a fair bargain either as hired labor or in the sales of their produce. According to CARE (2011), this can prevent them from fulfilling their responsibilities such as providing food for their families. Also, it can serve as a barrier to learning useful skills that can aid sustainable adaptation to climate change.

A grand mean of 3.92 implies that generally respondents have a positive perception of climate change. This means they recognize its limiting tendencies (Grimberg et al. 2018). It limits the potentials of their livelihoods in generating sufficient income and the achievement of food security. It serves as an impediment to the achievement of a vibrant rural sector which can contribute meaningfully to poverty eradication and national development. Interviews with key informants revealed extensive and effective contact with agricultural extension. Therefore, agricultural extension services can leverage on their positive perception to provide enlightenment for the protection of the ecosystem. This will discourage bush burning and loss of biodiversity through intensive hunting of unique plant and animal species. Agroforestry can also be encouraged as a viable option to building resilient livelihoods.

Relationship Between Perception and Coping Strategies of Respondents

A chi-square test of independence between respondents' perception of climate change and their choice of coping and adaptation strategies was carried out to determine if there is relationship between the two variables. The determinants of adaptive capacity among rural households are better assessed at household level to provide pragmatic and empirical evidence since adaptive capacity can vary dramatically between individuals, households, and communities (Osumanu et al. 2017). Table 4 shows the chi-square result of the relationship between perception and the coping and adaptation strategies of the households.

Table 4 shows that there was a significant relationship between respondents' perception of climate change and mixed cropping ($\chi^2 = 55.433$, $p = 0.042$). This implies that respondents' perception of climate change influences the choice of mixed cropping as an adaptation strategy. Thus, their perception encourages the use of mixed cropping as an adaptation option which may be the reason for about 45.2% of the households choosing this strategy. Moreover, mixed cropping comes at little or no cost to the households and minimizes risk of total crop failure.

There was a significant relationship between respondents' perception and planting of improved varieties ($\chi^2 = 55.866$, $p = 0.031$). This implies that their perception encouraged the choice of planting improved varieties which are less sensitive to climate change in order to improve their yield. This may be as a result of the impact of agricultural extension in the study area to give advice in order to build the resilience of livelihoods, especially agricultural production.

There was also a significant relationship between respondents' perception of climate change and change in harvest dates ($\boldsymbol{\chi}^2 = 56.753$, $p = 0.026$). Respondents' perception is, therefore, associated with the choice of harvest date which may be as a result of access to climate information or based on personal experiences. Planting new crop varieties, according to Alam et al. (2017), is an important strategy in climate change adaption among rural households. The authors also stated that

Table 4 Chi-square results – the role of perception in the choice of coping and adaptation strategies among rural households

Coping and strategies	χ^2	df	p-value
Mixed cropping	55.433	39	0.042[a]
Change in sowing date	36.787	38	0.525
Livelihood diversification	48.145	38	0.125
Sale of assets, e.g., livestock	47.561	38	0.138
Planting of improved varieties	55.866	38	0.031[a]
Irrigation	32.708	38	0.712
Afforestation	42.498	38	0.283
Seasonal migration	37.744	38	0.481
Change in harvest date	56.753	38	0.026[a]
Borrowing	50.915	38	0.078
Fuel conservation	42.140	38	0.296
Minimum tillage	43.473	38	0.250
Use of organic manure	38.650	38	0.440
Increased watering of soil	34.873	37	0.569
Increased watering of plants and livestock	40.807	37	0.307
Construction of barriers and drainage channels	31.591	37	0.720
Purchasing extra feed for livestock during dry season	34.155	36	0.557

[a]Significant at $p \leq 0.05$

perception and local knowledge contribute to the decision of choice of harvest date of crops to prevent yield loss occasioned by climate hazards.

The result shows that rural households would utilize innovative, available, and affordable sustainable adaptation strategies based on information that educates them on their benefits, thereby modifying or changing their perception. This is corroborated by Osumanu et al. (2017) that the determinants of local adaptive capacity, like household-level adaptive capacity, include their asset base, institutions and entitlements available in the community, the knowledge and information available to them, innovation, and flexible decision-making. These allow for the adoption of sustainable adaptation strategies that help build more resilient livelihoods.

Conclusion

Rural households employ diverse coping and adaptation strategies in response to climate change impacts on their livelihoods. Although their perception of climate change was favorable and indicated their understanding of its negative effects on their livelihoods, it did not take cognizance of women's insecure access to production resources. While some of the adaptation strategies, such as borrowing and sale of assets, are unsustainable, others, such as adjusting harvest and sowing dates, can be better facilitated by utilizing media to obtain weather forecasts in making planning decisions.

Government can partner with the communities and nongovernmental organizations (NGOs) in the development of early warning systems and easily accessible weather forecast in simple language. Effort should also be made in the establishment of irrigation technology in rural communities in order to reduce the drudgery of fetching water. This will boost food security and income generation among rural households. Government policies that will build the capacity of agricultural extension in providing information on crop choices and agroforestry activities should be implemented.

Women's access to production resources can be improved through policies that encourage greater gender inclusion in credit facilitation targeted at rural livelihoods. NGOs can target the erosion of institutional barriers to women empowerment by educating rural households on its implications for the rural economy and national development. Such training should also incorporate biodiversity protection. This is crucial to ending and reversing the effects of the dangers of harmful and ineffective practices on the environment. Agricultural extension can enlist the help of opinion leaders in the communities to drive the change in belief systems so as to promote the implementation of sustainable adaptation strategies.

Bioeconomy as Climate Action: How Ready Are African Countries?

122

Oluwaseun James Oguntuase and Oluwatosin Benedict Adu

Contents

Abstract

Bioeconomy is a new perspective for fighting climate change. Africa is warming faster than the global average, and climate change remains a major threat on the continent for coming decades. The development of sustainable bioeconomy is extremely important in Africa to accelerate mitigation and adaptation to climate change. However, this concept is not well diffused on the continent. The objective

W. Leal Filho et al. (eds.), *African Handbook of Climate Change Adaptation*,
https://doi.org/10.1007/978-3-030-45106-6_82

of this chapter is to present the current state of bioeconomy in Africa and the readiness of the member countries to adopt bioeconomy as climate action, with particular attention to the state of production determinants of a bioeconomy. The main factors and trends (both positive and negative), relating to building strategic capacity towards employing bioeconomy for climate action on the continent, are outlined. The findings and recommendations will assist both the academia and policymakers in Africa to integrate bioeconomy into their national and regional climate change mitigation and adaptation strategies and action plans.

Keywords

Climate change · Climate action · Bioeconomy · Production determinants · Africa

Introduction

Africa is one of the hotspots of vulnerability to the adverse impacts of human-induced climate change (IPCC 2014), with multiple biophysical, political, and socioeconomic stresses interacting to increase the continent's susceptibility and constrain its adaptive capacity (Connolly-Boutin and Smit 2016). Productivity in several African countries depend on natural resources, climate sensitive sectors such as agriculture, fisheries, forestry, and tourism, and climate-sensitive infrastructure such as houses, buildings, municipal services, and transportation networks. Endemic poverty, lack of awareness, and lack of access to knowledge also limit the continent's adaptive capacity to cope with climate change impacts (Fereja 2017; Ford et al. 2015). With increasing temperature, the Food and Agricultural Organization (2019) projected that there will be loss of 2–7% of GDP by 2100 in parts of sub-Sahara Africa, 2–4% and 0.4–1.3% in west and central Africa, and northern and southern Africa, respectively.

Bioeconomy is a set of economic activities, an alternative to our present fossil-dependent model, in which renewable biological resources are sustainably produced to replace fossil fuels in various forms of consumption and production, to produce products (goods and services) for final and intermediate consumption. As a new wave of economic system, bioeconomy combines, in a synergic way, both natural resources and technologies, with markets, people and policies to tackle societal challenges such as natural resource scarcity, fossil resource dependence, climate change, unprecedented waste generation, loss of biodiversity, and food and energy insecurity while achieving sustainable growth.

While the concept of bioeconomy emerged in the twentieth century, it was not until the twenty-first century that it gained wide attention of scientists and policy makers as a political-economic concept which proposes the replacement of fossil resources in order to combat climate change (Asada and Stern 2018). However, bioeconomy has not been adopted by several African countries (Oguntuase 2017).

Accordingly, the objectives of this chapter are to present the current state of bioeconomy in Africa, and the readiness of African countries to embrace bioeconomy as climate action. The chapter will also compare the readiness of African countries to embrace bioeconomy with that of countries having bioeconomy strategies.

Bioeconomy as Climate Action

Bioeconomy has been identified as an opportunity to achieve EU's climate change mitigation targets and reduce dependence on fossil-derived resources (Fehrenback et al. 2017). It also holds significant promise for solving the climate-related problems associated with fossil fuel use in heat, electricity, and transportation fuel production (Banerjee et al. 2018). Likewise, the use of bioenergy, devising smart strategies and value-chain pathways to lock the chain's greenhouse gases emissions, have been identified as a potential means of achieving the ambitious Paris climate target (Honegger and Reiner 2018).

Bang et al. (2009) estimated that industrial biotechnology, biofuels and bioenergy could reduce global greenhouse gas emissions by 1.0–2.5 billion tons of carbon dioxide (CO_2) per year by 2030. The reduction of GHG emissions and reduction in fossil depletion impact by biorefineries was also alluded to by Gnansounou et al. (2015). Similarly, Junqueira et al. (2017) showed that both first generation 1G (in the medium and long term) and second generation 2G ethanol can reduce climate change impacts by more than 80% when compared to gasoline, while Baral and Guha (2004) reported that growing short-rotation woody crops (SRWC) for use in cost-effective biomass-based technologies such as biomass-integrated gasifier/steam-injected gas turbine (BIG/STIG) is a cost-effective strategy to combat climate change.

In other studies, Jørgensen et al. (2015) reported that temporary carbon storage in biomaterials has a potential for contributing to avoid or postpone the crossing of critical climatic target level of 450 ppm; Shen et al. (2012) found that bio-based PET (polyethylene terephthalate) polymer has been found to have the lowest greenhouse gas (GHG) emissions, compared to recycled (partially) bio-based PET, recycled PET, and petrochemical PET; Singh and Strong (2016) demonstrated that biofertilizers improve the activity of methane-oxidizing methanotrophs, thereby enhancing methane oxidation and/or decreasing the production of methane – a most potent greenhouse gas.

Beyond climate change mitigation, there is a large potential for synergies between bioeconomy and climate change adaptation. Climate change is affecting all four dimensions of food security: food availability, food accessibility, food utilization, and food systems stability (FAO 2008), and bioeconomy offers opportunities for the agriculture sector to adapt. Bioeconomy will help improve food security and advance human development through the development of more efficient systems of agricultural production which can significantly increase the production of much healthier and more natural products, compared with the products obtained by intensive modern agriculture (Canja et al. 2017), support crop and animal diversification to produce a variety of foods suitable for health and nutrition (Bazgă and Diaconu 2013), thereby increasing the sustainability of the agricultural sector (Baidala 2016). Specifically, adoption of genetically modified (GM) technologies could help offset the detrimental effects of climate change (Ortiz-Bobea and Tack 2018) by helping to meet targeted yields, nutritional quality, and sustainable production to stabilize and increase food supplies, which is important against the background of increasing food demand in a warming resource-constrained world (Oliver 2014; Qaim and Kouser 2013).

Around 50% of harvest losses caused by environmental factors are down to drought, and it is expected that this proportion will continue to rise as a result of climate change (Linster et al. 2015), because drought stress tolerance of crops was a significant trigger for total yield in the last decades and its significance for yield is supposed to even increase in the future as a result of climate change (Lobell et al. 2014; D'Hondt et al. 2015). Genetically modified (GM) crops have been cultivated to be more resistant to drought and other biotic and abiotic stresses, increase yields by 6–30% on the same amount of land, help produce more crops per drop of water, help transition towards soil conserving farm practices such as low- and no-till systems, which are important for more efficient water use by better trapping soil moisture, and reduce greenhouse gas emissions associated with the application of fertilizers, fuel use, and plowing (ISAAA 2014; Parisi et al. 2016; Svitashev et al. 2016; Fedoroff et al. 2010).

Employing bioeconomy in the forest-based sector has been demonstrated as both climate change adaptation and mitigation methods. Lindner et al. (2017) submitted that while developing a forest-based bioeconomy with more intensive use of forest biomass can support climate change mitigation, active replacement of maladapted species will strengthen adaptive capacity. Kalnbalkite et al. (2017) submitted that products which are produced from wood take important place in the influence on climate change reduction, while Leskinen et al. (2018) found that for each ton of carbon (C) in wood products that substitute non-wood products, average emission are reduced by approximately 1.2 ton C. This corresponds to about 2.2 ton of CO_2 emissions reduction per ton of wood product, depending on the wood product and technology considered, and the method used to estimate emissions.

Buildings and construction related CO_2 emissions have continued to rise by around 1% per year since 2010, to account for 36% of global final energy use and 39% of energy-related carbon dioxide (CO2) emissions, when upstream power generation is included; these are significant causes of climate change (IEA 2017). Life cycle assessment (LCA) of the climate impact of buildings by Peñaloza and Falk (2016) showed that increasing the biobased material content in a building reduces its climate impact even if biogenic exchanges are assessed. A similar study by Pittau et al. (2018) expressed that storing carbon in biogenic construction products and building components can largely contribute to reducing carbon emissions. In another study, Lei et al. (2016) recommend the use of phase change materials (PCMs) in tropical climates to reduce building cooling load and improve energy performance.

Current State of Bioeconomy in Africa

Only South Africa has a defined bioeconomy strategy in the continent. Countries such as Ghana, Kenya, Mali, Mauritius, Mozambique, Namibia, Nigeria, Senegal, Tanzania, and Uganda have some bioeconomy-related activities as shown in Table 1.

Production Determinants in a Bioeconomy

The epistemological understanding of production factor as a durable input employed in production activities allows for naming of new variables influencing and employed in the production processes as determinants. Having in mind the essence of bioeconomy, which is transition to low carbon sustainable economy, and the

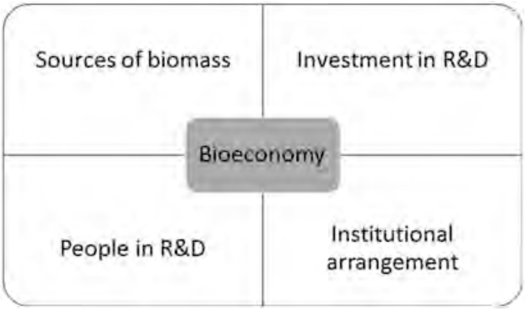

Fig. 1 Bioeconomy production determinants in line with classical view of production function

establishment that bioeconomy is a knowledge-based innovative economy (Lainez et al. 2018; Pyka and Prettner 2018), it needs to be stated that the primary production determinants of the bioeconomy extends beyond those in mainstream economic theory: land, labor, and capital.

This chapter adopts the common definition that bioeconomy is "the knowledge-based production and use of biological resources to provide products, processes and services in all economic sectors within the frame of a sustainable economic system" (German Bioeconomy Council 2013). It is situated in the context that bioeconomy is a knowledge-based economy whose four primary production determinants are the sources of biomass, investment in research and development (R&D), people in research and development, and institutional arrangement. The biomasses (biological resources) are acting as substitutes for other fossil resources. Investment in R&D focuses on the development and commercialization of products and processes within the bioeconomy system. The people in R&D encompass people employed within the bioeconomy system, who have obtained sufficient knowledge to add value across the bioeconomy value chain. Institutional arrangement is connected to the organization of the system which enables implementation of solutions that ensure competitiveness under dynamic changes (Maciejczak 2015; Talavyria et al. 2016) (Fig. 1).

Building a Bioeconomy Readiness Index

Some research findings reveal the need to measure countries' potentials for embracing bioeconomy as climate action. Bagla and Stead (2018) developed BioGreen, a method to assess the potential of bioeconomy in curbing significant climate change and its contribution to attaining Ireland's sustainability goals. Data from the JRC-SCAR Bioeconomy survey by the Bioeconomy Observatory showed that the need to combat climate change is one of the relevant reasons for the development of a bioeconomy in European countries (Langeveld 2015).

Mungaray-Moctezuma et al. (2015) developed the Knowledge Economy Index (KEI) which determined the necessary institutional characteristics of technology and human capital necessary for the knowledge-based economy in Argentina, Costa Rica, and Mexico from the perspective of bioeconomy as part of the economy. In another study, Henry et al. (2017) recognized the role of scientific and technological knowledge as a key driver in a bioeconomy and highlighted the need for every country and every region to identify possibilities and opportunities in order to set its own bioeconomy development agenda, consistent with its conditions, capacities, and needs.

The Organization for Economic Co-operation and Development (OECD 2002) aggregation method is a veritable method for building indices like the one for determining the readiness of a country or jurisdiction to embrace bioeconomy as climate action. The four-step approach to the aggregated indices OECD method as adopted by Schlör et al. (2017) are: (1) the selection of the variables, (2) transformation, (3) weighting, and (4) valuation.

Specific statistical indicators for determining the bioeconomy readiness of a country or jurisdiction are virtually nonexistent at present. The most significant quantifiable indicators representing the production determinants in terms of bioeconomy are shown in Table 2.

The proposed formula for calculating the bioeconomy readiness of a country or jurisdiction is:

$$f\ (\text{BIOMSS}, \text{INV RD}, \text{PPL RD}, \text{IAR})$$

where: BIOMASS = ***f*** (ARL, NBI, FOR)
INV RD = ***f*** (RDE, CSR, PCT, CPI, ALT, QRI, PROD)
PPL RD = ***f*** (ASE, RRD, TRD, QMC, UIC, SCT)
IAR = ***f*** (LAW, FIN, IFR, NCA).

The State of Bioeconomy Production Determinants in African and Selected Countries

Kenya leads African countries in the people in research and development category, performing better than Thailand and Bulgaria. Tunisia follows Kenya in this category and performed better than countries like Mexico, Costa Rica, Argentina, and South Africa, in that order. Mauritania, Lesotho, Liberia, Chad, and Congo are the worst performers as shown in Fig. 2.

An African country, Gambia, leads the biomass production determinant category. The remaining countries in the top ten are Malaysia, India, Costa Rica, Rwanda, Mexico, Sierra Leone, Malawi, Democratic Republic of Congo, and Tanzania. The poor performers are African countries – Algeria, Mauritania, Egypt, Chad, and Cabo Verde as shown in Fig. 3.

Scandinavian countries – Sweden and Finland – have invested in research and development more than other countries. South Africa is ahead of Bulgaria in investing in research and technology, while Kenya, Mauritius, Rwanda, and

Table 2 Possible indicators for measuring the bioeconomy readiness of a country or jurisdiction

Production determinant	Indicators	Explanation
Sources of biomass ***BIOMASS***	Arable land (% of country land area), ***ARL***	Includes land defined by the FAO as land under temporary crops (double-cropped areas are counted once), temporary meadows for mowing or for pasture, land under market or kitchen gardens, and land temporarily fallow
	National Biodiversity Index, ***NBI***	Richness in four terrestrial vertebrate classes and vascular plants with adjustments country size
	Forest land (% of country land area), ***FOR***	Forest area is land under natural or planted stands of trees of at least 5 m in situ, whether productive or not, and excludes tree stands in agricultural production systems
Investment in R&D ***INV RD***	Research and development expenditure (% of GDP), ***RDE***	Gloss domestic expenditures on research and development (R&D), expressed as a percent of GDP
	Company spending on R&D, ***CSR***	The extent companies invest in research and development
	Patents applications per million population, ***PCT***	Number of applications filed under the Patent Cooperation Treaty (PCT) per million population
	Capacity for innovation, ***CPI***	How do companies obtain technology; from exclusively from licensing or imitating foreign companies to conducting formal research and pioneering their own new products and processes
	Availability of latest technologies, ***ALT***	To what extent are the latest technologies available
	Quality of scientific research institutions, ***QRI***	Quality of scientific research institutions
	Production process sophistication, ***PROD***	Sophistication of production processes
People in R&D ***PPL RD***	Availability of scientists and engineers, ***ASE***	Availability of scientists and engineers in the country
	Researchers in R&D per million people, ***RRD***	The number of researchers engaged in Research &Development (R&D), expressed as per million
	Technicians in R&D per million people, ***TRD***	The number of technicians engaged in Research &Development (R&D), expressed as per million
	Quality of mathematics and science education, ***QMC***	In your country, how do you assess the quality of math and science education? [1 = extremely poor – among the worst in the world; 7 = excellent – among the best in the world]

(continued)

Table 2 (continued)

Production determinant	Indicators	Explanation
	University-industry collaboration in Research & Development, ***UIC***	The extent to which business and universities collaborate on research and development (R&D)
	Scientific and technical journal articles (2003–2016), ***SCT***	The number of scientific and engineering articles published in the following fields: physics, biology, chemistry, mathematics, clinical medicine, biomedical research, engineering and technology, and earth and space sciences
Institutional arrangement ***IAR***	Rule of law, ***LAW***	Measures countries' rule of law performance across eight factors: constraints on government powers, absence of corruption, open government, fundamental rights, order and security, regulatory enforcement, civil justice, and criminal justice
	Availability of financial services, ***FIN***	Provision of a wide variety of financial products and services to businesses
	Quality of overall infrastructure, ***IFR***	Quality of overall infrastructure
	Macroeconomic stability, ***ECON***	The extent to which a country's public sector can provide appropriate counter-cyclical measures and invest in projects that the private sector cannot finance

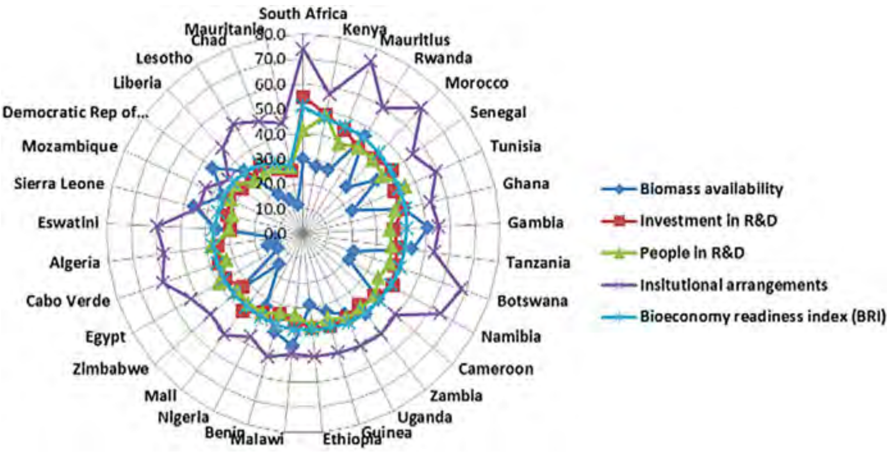

Fig. 2 State of bioeconomy production determinants in African countries

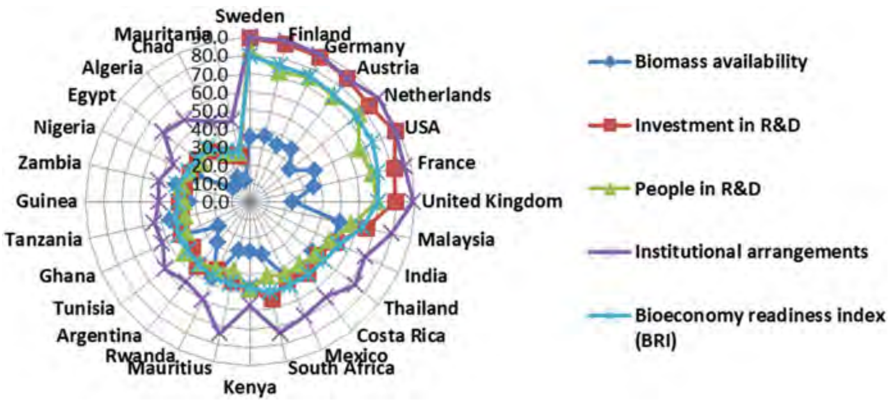

Fig. 3 State of bioeconomy production determinants in selected countries

Morocco perform better than Argentina. Mauritania has the least investment in research and development, followed by Chad, Lesotho, Liberia, and Congo.

African countries perform poorly under the institutional arrangements category. The continent's best performer, South Africa shares the same spot with Bulgaria, ahead of Argentina. Mauritania, Chad, Lesotho, and Liberia remain at the bottom of the log, just as in investment in research and development, people in research and development, and institutional arrangements production determinants.

Bioeconomy Readiness of African and Other Selected Countries

The top African countries in terms of readiness to adopt bioeconomy as climate action are South Africa, Kenya, Mauritius, Rwanda, and Morocco as shown in Fig. 4.

The bioeconomy readiness of African countries' compare to those of countries with bioeconomy strategies (Austria, Finland, France, Germany, Sweden, the United Kingdom, and the United States of America), and those with ongoing development strategies (Argentina, Bulgaria, Costa Rica, India, Mexico, The Netherlands, and Thailand) (Dietz et al. 2018; Sasson and Malpica 2017) as shown in Fig. 5.

Many African countries are endowed with relatively abundant natural biomass, yet they are poorly equipped to adopt bioeconomy for climate action, when compared with countries from America, Europe, and Asia. This is mainly due to the poor state of investment in R&D and dearth of people in R&D. Poor government spending on R&D, lack of patent applications, dearth of researchers and technicians in R&D, absence of latest technologies, poor industrial production process, poor university-industry collaboration, and poor institutional arrangements, especially rule of law and quality of infrastructure, are the key challenges to bioeconomy's development on the continent.

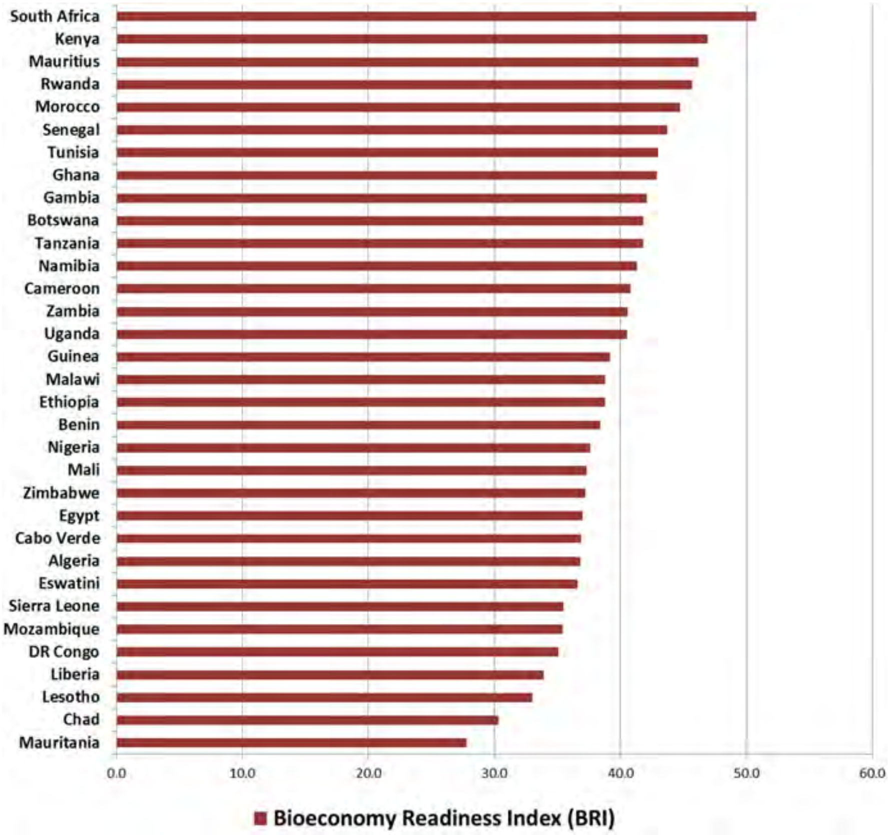

Fig. 4 African countries' bioeconomy readiness

Conclusions

This chapter presents the concept of bioeconomy as a knowledge economy with four production determinants: the sources of biomass, investment in research and development, people in research and development, and institutional arrangement. It introduces the bioeconomy readiness index (BRI) to determine the state of the production determinants of bioeconomy in African countries and other selected countries. Theoretically, countries with higher and better BRI will be better able to employ bioeconomy as climate action.

While there are bioeconomy-related activities in some African countries, it is significant to note that South Africa, the only country with defined bioeconomy strategy in Africa, has the best bioeconomy readiness index (BRI) on the continent. The possible policy implication of this is that formulating a dedicated national bioeconomy strategy, an integral part of national development agenda as applicable in South Africa, will help

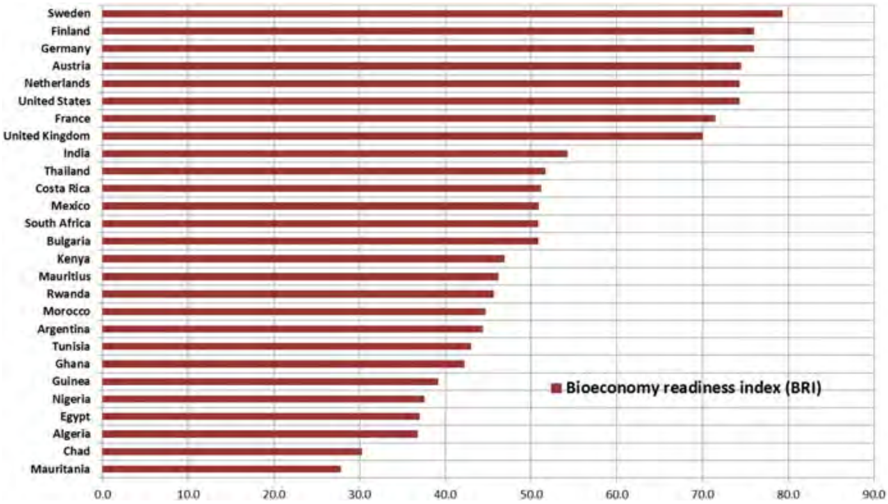

Fig. 5 Bioeconomy readiness of selected countries

improve the state of bioeconomy production determinants in Africa thereby increasing the continent's potential to employ bioeconomy as climate action.

Strategies to promote the bioeconomy in Africa must focus on targeted investments to support R&D activities; building efficient innovation system; improving the level of education, training, and skills of the populace; and supporting market development to enhance competiveness. Furthermore, African countries must improve general governance, the quality of their infrastructure, and the rule of law, to attract foreign investment in the bioeconomy sectors.

While this chapter shows important findings on the state of bioeconomy in Africa and the readiness of African countries to adopt bioeconomy as climate action, further studies are recommended in the specific areas of each production determinants to shape public policy decisions towards development of sustainable bioeconomy on the continent.

Incomplete datasets and nonavailability of comparable data remains major limitations in Africa underscores the urgent need to develop and sustain a data collection and management system on the continent to overcome the challenge of dearth of data in the bioeconomy system and related sectors. In the absence of quality data, it is difficult to formulate good strategies and scale up innovations for sustainable bioeconomy on the continent.

Flood, Livelihood Displacement, and Poverty in Nigeria: Plights of Flood Victims, 2012–2018

123

Joachim Chukwuma Okafor

Contents

Abstract

The impacts of flood on the Nigerian population over the years have been enormous. This is because the attendant associated risks such as destruction of lives and properties, livelihood displacement, and impoverishment of victims arising from increasing flood cases have constituted a threat to the citizens' survival and therefore inform the attention the menace has drawn among scholars, policy analyst. This chapter has as its primary aim, a critical assessment of the impacts of government responses over the plight of victims of flooding in Nigeria over the years under review. Thus, special attention is given in this chapter to the various barriers or challenges facing government response to the plight of flood victims in Nigeria. Finally, some valuable steps, which if taken will reduce these

barriers or challenges, are outlined. Though, the study adopted the use of secondary sources of data collection via content analysis, the experiences and knowledge gathered in this chapter will be strategically useful to people and organizations interested in the government of Nigeria's response to the plight of flood victims, barriers inhibiting the success of fund utilization in reducing the suffering and impoverishment of the flood victims, number of deaths, and population displaced as a result.

Keywords

Flood · Livelihood displacement · Poverty · Government responses · Flood victims

Introduction

Now in its sixth year, the threats the 2012 flood disaster along with the subsequent flood disasters that accompanied it posed on the livelihood of the victims in relation to the protracted impoverishment and displacement that these victims suffered while awaiting the government and private led humanitarian groups on relief materials have been the subject of debate among scholars, policy analysts, and climate change mitigation and adaptation experts (Nwodim 2016). The 2012 flood disaster in Nigeria that began in early July alone killed 363 people and displaced over 2.1 million people as of November 5, 2012 (Adekola and Lamond 2018).

According to the National Emergency Management Agency (NEMA), 30 out of the 36 states were affected by the floods. The floods were termed as the worst in Nigeria history in 40 years, and affected an estimated total of seven million people (Nkwunonwo 2016). The estimated damages and losses caused by the floods were worth 2.6 trillion naira (Cirella and Iyalomhe 2018). As rightly noted by Ndujihe (2018), flood disasters which followed the devastating 2012 event have the usual trend of submerging houses, deaths of people, population displacement, washing away of farmlands, and destruction of people sources of livelihood which have implications on the growing incident of impoverishment among affected Nigerian population. In fact, the 2018 flood disaster recorded in different states in Nigeria alone, especially from Bayelsa state, has been rated as the worst in the last 6 years (Akukwe et al. 2018).

In Nigeria, different factors have been deduced which account for the incessant cases of flood disaster in the country especially in states declared as the flashpoints for flood disaster (Nkwunonwo et al. 2016; Conversation 2017). First, climate change which causes global warming has been singled out as the basic factor that accounts for the increasing cases of flood disaster which has been shown to contribute to more extreme storms and rainfall. Another factor contributing to flooding in the country is that of the increasing rapid urban growth and poor drainage/culvert system planning. This chapter has as its objective the impacts of government response over these years on the plight of the flood victims. The assessment of the successive flood disasters from 2012 to 2018 on how it undermined livelihood, displaced population, destroyed farmlands, and foster impoverishment on the affected population. The rest of the chapter includes the introduction, definition of terms, method and sources of data collection and analysis, government response to the victims of floods in Nigeria, and protracted challenges facing the government in this regard.The reported cases of deaths, population displaced, damages and victims impoverished by flooding in Nigeria within the period under review. We draw conclusion with strategic recommendations.

Definition of Terms

The concepts of flood, livelihood displacement, poverty, government response, and victims of flood are pivotal in this discourse. Hence the definition of these terms will enhance a shared understanding of their usage in this discourse.

- *Flood*:
  This is the outpouring or overflowing of water usually through rainfall which covers dry space and causes devastations on the socioeconomic activities of the people. Flood can occur through outburst of dam which releases much water on the dry spaces. Recent flood disasters in Nigeria have brought about the deaths of Nigerians, the washing away or destruction of farmlands, submerging of houses which heralds population displacement. Flood can be defined as an overflow of large quantities of water onto a normally dry land. Flooding happens in many ways due to overflow of streams, rivers, lakes, or oceans or as a result of excessive rainfall. Flood or flooding also destroys crops and can wipe away trees and other important structures on land.
- *Livelihood displacement (LD)*:
  Livelihood implies various means through which individuals secures a living. Livelihood also involves individuals or people assets, capabilities, income, and activities required to secure a living. Livelihood displacement encompasses threats that disarticulate or disrupt the operations of livelihood. In Nigeria, like in any other parts of the world, floods or flooding has proved to be the potent threat to livelihood displacement or disruption. Natural disasters like earthquake, hurricane, and climate change could become threat to livelihood displacement. In Nigeria, the 2012 flood disaster and the successive disasters have washed away cash crops and farmlands, fish pond, poultry business economic activities where people derived their livelihood.
- *Poverty*:
  The displacement of people from their means of livelihood through flooding without the provision of relief material either from the government or private sector led humanitarian agencies to cushion the devastating impacts of the displacement could exarcerbated impoverishment among the victims of flooding. Poverty in this chapter means lack of capability or the capacity by the victims of flooding to provide for their basic necessities of life such as house, food, water, and healthcare, among others.

- *Government response (GR)*:
  This is taking to mean, assistance, and support in the forms of relief materials given to the flood victims with the intention to reduce their sufferings brought about by flood disaster. In Nigeria, National Emergency Management Agency (NEMA) oversees and supervises the delivery of these relief materials across the Nigeria. Each state in Nigeria, for administrative convenience, has their respective State Emergency Management Agency (SEMA). Part of government response to the plight of flood victims in Nigeria is the release of fund. In 2012, the government under President Good luck Jonathan released the sum of ₦17.6 billion for the support of flood victims. Under President Muhammadu Buhari, the federal government has earmarked ₦ 1.6 billion each for the following states in the wake of the 2018 flood disaster across these states. The benefiting states are: Ekiti, Osun, Akwa Ibom, Kebbi, Niger, Kwara, Ebonyi, Enugu, Abia, Oyo, Lagos, Plateau, Sokoto, Edo, and Bayelsa.
- *Flood victims (FV)*
  This is taking to mean individuals, groups, households, and communities that suffered from the devastating impacts of flood disaster. In Nigeria, there is victims support fund for flood disaster. Flood victims are person or persons whose houses were submerged by floods, farmland and livestock's destroyed, and source of livelihood is undermined or disrupted by flood disaster.

Method and Source of Data Collection and Analysis

This chapter adopted the documentary method of data collection that derived its base from the secondary sources of data gathering that include journal articles, newspapers, books, government publications, among others. The qualitative method of data analysis via content analysis was used to analyze the materials gathered from the secondary sources.

Reported Cases of Deaths, Population Displacement, Damages, and Victims Impoverished by Flooding in Nigeria, 2012–2018

From the year 2012 to 2018, the incident of flood disasters and its associated impacts on the victims of flood has been ernamours (Onwuka et al. 2015). Table 1 below covers the series of livelihood displaced, farmlands and cash crops washed away by flood, displaced people and livestock, impoverishment, and deaths, which occurred in Nigeria in some selected states. The logic behind the selection of these states was based on the declaration of the states as flashpoints or state vulnerable to flood disaster.

Table 1 Shows reported cases of deaths, population displacement, damages and victims impoverished by flooding in Nigeria, 2012–2018

S/ No.	State	Month & year	Reported cases of deaths, displacement, damages, and impoverishments of victims by floods	Remarks
1.	Enugu	March 2018	Flood destroyed buildings, killed a brick layer and 2 students at Uhuowerre community in Igbo Eze South L.G.A in the state	The flood incident destroyed farmlands of villagers with cash crops washed away by marauding flood
2.	Ogun	June 2018	Farmers in Idagba area of Ayetoro in Yewa L.G.A recorded loss of lives and fishes worth 100 million naira to flood. Twelve persons killed, 3,800 displaced, 200 homes destroyed in Abeokuta. Areas affected in the city include: Lafenwa, Ijaiye, Kuto, Oke Lantoro, Amolaso, Kobiti, and Ilawo	The people whose source of livelihood is tied to farming have been threatened and many became internally displaced in the process
3.	Delta	July 2018	Flood submerged 63 communities, destroyed 43 houses in Koko, Warri North, Araya, Isoko South L.G.A. Agbarhor Ughelli North and Oghara communities in the state	The flood was accompanied with heavy downpour and brainstorms
4.	Niger	July 2018	Twenty-three persons were reported dead while bridges, roads, and culverts linking villages were destroyed. Two persons were allegedly missing	The flood forced many villagers out of their homes, and economic activities were severely halted
5.	Kano	August 2018	Eight local government areas in the state were affected, and hardest hit was Kiru local government area which recorded the deaths of 3 persons	Indigenes/residents of these local areas are predominantly farmers. The flood halted their livelihoods, and their movement were restricted for days thereby undermining economic activities
6.	Bayelsa	October 2018	Seventy percent of the Bayelsan communities were submerged by flood. The hardest hit was communities in Sagbama L.G.A. Many persons were displaced. These communities include	The flood disaster led to closure of schools

(continued)

Table 1 (continued)

S/ No.	State	Month & year	Reported cases of deaths, displacement, damages, and impoverishments of victims by floods	Remarks
			Sampou, Kaiama, Bolou Orua, Toru Orua, etc.	
7.	Lagos	July 2017	Homes and buildings were submerged, movements along the roads became difficult in Lekki, Victoria Island, Ajah and other cities and towns in the state	This flood halted economic activities. Poor drainage system and inadequate urban planning were said to be force multipliers of the flood
8.	Benue	August 2017	An estimated 1,000 persons were displaced, 2,000 homes damaged and lives lost. The flood is peculiar to Benue state due to Benue river and serial heavy downpour as flashpoints state	Benue is known for consistent agricultural produce. Six Local government areas affected were Markudi, Agatu, Guma, Tarka, Logo, and Buruku
9.	Katsina	August 2017	According to the State Emergency Management Agency (SEMA), an estimated 1,000 houses were destroyed, many displaced from their homes and lives lost to flood in Inwala Jangebe village in Batagarawa, Kaita, Malumfashi, Mabai village of Kankara, and Kusada L. G.As	Majority affected by the flood were rural farmers. SEMA had distributed 2 trailers of cement and 600 bundles of roofing zinc to the flood victims across the L.G.As
10.	Imo	October 2017	The flood that occurred in Umuohii village in Oboama Autonomous community in Ezinihitte Mbaise destroyed buildings, farmlands, livestock, and economic trees	The heavy downpour that lasted for 2 days rendered 50 household homeless
11.	Oyo	June 2017	Over 3,000 houses were submerged as lives and properties were destroyed in Olodo, Oki, Akobo, Onipepeye, Kute, Eleyele, Ariyo, and Celestial Church Orogun along University of Ibadan-Ojo road in Ibadan metropolis by heavy downpour	The Oyo state government had promised to support the affected residents and repair roads, culverts, and drainages. Absence of these amenities widens the damages from flooding

(continued)

Table 1 (continued)

S/ No.	State	Month & year	Reported cases of deaths, displacement, damages, and impoverishments of victims by floods	Remarks
13.	Nassarawa	August 2016	Fifteen persons died, 36 houses submerged, and handful scores of people missing in the flood disaster in Mararaba, Gurku, Kabayi, and Ado communities in Karu L.G.A	Nassarawa state is among the flashpoint states warned by NEMA of impending flood disaster in the beginning of the year
14.	Yobe	August 2016	The SEMA estimated that about 300 houses were destroyed; farmlands and livestock were destroyed in Jakusko and Adaya communities by the flood disaster. Other villages affected by the flood include Ngelzarma, Jajere, Nangere, Buduwa, Nguru, Gashua, Damagum, Dapchi, etc.	Agrarian Yobe state is among the frontline states that Boko Haram had caused havoc; flood disasters intensified the sufferings of the people. Food, clothes, and building materials were provided to the victims by the state government
15	Sokoto	August 2016	Fifty houses were destroyed in Bachaka village in Gudu L.G.A by flood disaster caused by early morning downpour	No loss of lives was recorded but people farmlands and crops worth millions of naira were destroyed thereby aggravated the poverty of the locals
16	Bauchi	August 2016	Four persons died of flood disaster in Galamakira and Galam Baba communities in Ganjuwa L.G.A. Eight persons killed by flooding in Gulbuk community in Giade L.G.A	Lack of access to primary health care for those who sustained injuries during the emergency in these localities was glaring
17	Plateau	August 2016	All-night downpour destroyed 20 cows by herdsmen in Fobor-Angware and Maza, houses were destroyed, people in Jos East L.G.A. Roads linking communities were also washed away by the heavy flood	Twenty-nine other cows were discovered after the flood disaster. Farmers lost their sources of livelihood as many farmlands were destroyed by the flood
18	Kano	September 2015	Six persons were killed in Shanono, Dala, Tundu Wada, Gabasawa, and Takai L.G.As by flood and 1,600 persons representing families and properties	15.8 million naira was said to have earmarked for the purchase of relief materials for the support of the victims

(continued)

Table 1 (continued)

S/ No.	State	Month & year	Reported cases of deaths, displacement, damages, and impoverishments of victims by floods	Remarks
			worth millions were displaced by flood disaster	
19	Edo	September 2015	More than 35 communities were submerged by flood in Etsako East and Etsako Central L.G.A. An estimated 30,000 persons were displaced on the two divides, and farmlands with cash crops were destroyed by flooding. The affected communities were Udaba, Uneme, Usomegbe, Anegbette, Uneme-Ugwoyo, etc.	Victims of the flood were women and children who were in dire need of health-care facilities, foodstuff, shelter, etc.
20	Adamawa	September 2015	Seven communities in 5 local governments' areas were submerged by flood that includes Guluk, Shellenge, Lamurde, Demsa, and Numan. Borongo community was the hardest hit communities. People were displaced, and properties and farmlands were destroyed by flooding	Alleged to have caused by outburst flood water from Kiri-Dam and heavy downpour
21	Ebonyi	September 2014	Over 200 houses were submerged, families displaced by flood, and 2 persons killed as a result in Onuebonyi Inyimagu, Abakaliki, and Izzi local government area	The flood came as a result of a 3-day downpour which affected rice plantations plus other farms input. Ebonyi state is an agrarian state
22	Kaduna	September 2014	The flood claimed the life of a 7-year-old girl Theresa James at Anguwar Yelwa community in Chikun L.G.A. Other areas affected by the flood include Unguwar Rimi, Lere, Kachia, Kaduna North & South, Unguwar Dosa, Zaria council, etc.	The flood was said to have caused by 2-day heavy downpour
23	Oyo	June 2014	Ten persons were killed in Apete Ibadan when a makeshift bridge was collapsed by floodwater	Oyo state is among the flashpoints for high incident of flooding in Nigeria

(continued)

Table 1 (continued)

S/ No.	State	Month & year	Reported cases of deaths, displacement, damages, and impoverishments of victims by floods	Remarks
24	Anambra	November 2013	An estimated 1,000 people of the 2012 flood victims lost their voter's card in Ogbaru and Anambra East L.G.A	Anambra state is one of the states in the federation declared by NEMA as the national disaster in the country
25	Kano	August 2013	Five hundred persons were displaced by heavy downpour, 100 homes submerged, 4 person missing	Kano is the largest city in northern Nigeria where torrential rainfall is fairly common and residents in rural areas rely on agriculture for their livelihood
26	Yobe	August 2013	Over 300 houses were submerged and 1,000 persons displaced by from their homes. Areas affected in the state are Potiskum, Gashu'a, Nguru, Fika, Gaidam, Damagum, and Damaturu, the state capital	The flood also destroyed farmlands and crops
27	Cross River	July 2012	49,000 people were displaced by the flood. Over 212 communities, 1,800 houses, 82,361 farmlands, 13 lives lost, 13 suffered severe injuries, 18 markets, 15 churches, and 13 schools were destroyed	Agrarian communities whose farmlands and cash crops were destroyed became vulnerable. One among the states in Nigeria affected by the 2012 unprecedented flood experience
28	Plateau	July 2012	Thirty-nine persons were killed by the flood and 35 missing. An estimated 200 homes were destroyed by the flood, and 3,000 persons were displaced	Enlisted in the club of states severely affected by the 2012 flood disaster
29	Kogi	September 2012	An estimated 623,900 persons were displaced and 152,575 hectares of farmlands were destroyed by the flood	Flashpoints of states in Nigeria that are flood vulnerable
30.	Niger	October 2012	Over 117 communities submerged by flood, 663,000 persons were affected as the victims displaced from their homes. Farmlands destroyed and cash crops uprooted by the disaster	The victims and displaced persons in the various resettlements camps in the state appealed to the government to make their stay permanent. That is the degree of frustrations experienced by these flood victims

Source: Compiled by the Author

Government Responses to the Victims of Flooding and Challenges to Government Responses to the Plight of Flood Victims in Nigeria

In meeting with the increasing humanitarian needs of the flood victims, the National Emergency Management Agency (NEMA) was established via Act 12 as amended by Act 50 of 1999, to manage disasters in Nigeria. Therefore, from inception, NEMA has been tackling disaster-related issues through the establishment of concrete structures and measures, such measures as the education of the public in order to raise their level of awareness and reduce the effects of disasters in the country. In each of the 36 states including the Federal Capital Territory, there exists the State Emergency Management Agency (SEMA). From 2012 to 2018 involving the administration of President Good luck Jonathan and the current administration of President Muhammad Buhari, various emergency interventionist funds have been given to the states affected by the flood disasters. Under the former President Goodluck Jonathan, the sum of ₦17.6 billion naira was shared to states by the federal government to states hard hit by flooding. Following the rampaging floods of 2018, the federal government released ₦1.6 billion naira to 16 states that benefited from the intervention. The states are Ekiti, Osun, Akwa Ibom, Kebbi, Niger, Kwara, Ebonyi, Enugu, Abia, Oyo, Lagos, Plateau, Sokoto, Edo, and Bayelsa.

Despite federal government efforts in ameliorating the humanitarian needs of the flood victims, in 2018, the government pledged $8.2 million for relief efforts as well as declaring a state of emergency in four states, namely, Niger, Anambra, Kogi, and Delta States. NEMA set up five emergency operation centers to facilitate search and rescue operations and humanitarian support. Orji (2018) had revealed that the various efforts and program in rescue and support for the flood victims have faced huge practical challenges in reaching flood victims; however, these efforts have also reportedly been undermined by poor management, bad governance, and corruption. Other challenges derailing the government efforts in meeting with the humanitarian needs of the floods victims is failure on the part of successive government to plan and prepare for long-term solution to the crisis of flooding in the country. People mistrust on government ability to come to their rescue in the face of national disaster and inability of the Nigerian state to judiciously implement the provisions of disaster management plan. The widening gap in the interaction between the state (Federal Government) and various Civil Society Organisations (CSO) in the country have not been cordial.

Conclusion and Strategic Recommendations

We began the chapter with the position that the lives of the victims of floods in Nigeria from the illustrated cases in our Table 1 show that from 2012 to 2018, destruction of farmlands and cash crops, population displacement, deaths of many Nigerians and the wanton destruction of people livelihoods were devastating in Ngeria. With this, the following strategic recommendations are offered:

- Nigerian government should develop a long-term strategic plan toward the rescue, support, and release of humanitarian needs of the population. The culture of reactive from the federal government toward the plight of the floods victims should be discouraged.
- Fund so released for meeting the demands and needs of the floods victims should be monitored by the federal government to avoid rascality, misuse of funds, and diversion of the fund for personal aggrandizement of their members.
- There should be appropriate climate-related education in order to sensitize the population on risks associated with the floods.

Abstract

Evidence-based policies are recommended for the enhanced chances of efficacy in achieving policy goals. Achieving this in the policy development process may however require approaches that are not as simple especially in less developed countries, where the research-policy linkage is not commonly the case. This chapter provides a guide to a practical approach that could assist policy makers in similar societies based on the steps adopted in the development of the National Adaptation Strategy and Plan of Action on Climate Change (NASPA-CCN) for Nigeria. The NASPA–CCN has been acknowledged as among the models of climate change policy development that other countries could aim for. It is therefore positioned to offer lessons on policy development in a less developed country environment. The focus in this chapter however is not so much on the subject of climate change but the practical experiences and lessons learnt from the process involved in developing the NASPA-CCN providing lessons learned to mainstream climate change research evidence into policy.

Building Nigeria's Response to Climate Change (BNRCC) · Research · Community-based adaptation projects · Evidence-based policy development · Stakeholders · Perception · Resilience

Introduction

Climate change negatively impacts sustainable development across the world (World Bank 2019). Climate change slows the developmental progress made by many nations in the world. It is widely acknowledged that climate change is global and mainly caused by human activities, but the impacts are felt differently by different continents, regions, countries, communities, and sectors (NEST and Tegler 2011; IPCC 2013, 2014a, b, c; Gagliarducci et al. 2019). For instance, Africa's contribution to the major causes of climate change is marginal, but the continent is the hardest hit by climate change impacts (Tarfa et al. 2019; Niang et al. 2014). This is largely due to the vulnerability of the continent as well as her low adaptive capacity (Onyeneke et al. 2017). These characteristics present climate change adaptation as an important response strategy to countries in Africa especially sub-Saharan Africa. In responding to climate change in Africa, local adaptation strategies will not be sufficient, hence the need for planned adaptation to deal with climate risks (Tarfa et al. 2019). Planned adaptation strategies, which are often captured in countries adaptation action plans/programs, have been advocated all over the world. Unfortunately many action plans/programs adopted a top-down approach to their adaptation planning and are largely not informed by evidence. This is why many stakeholders advocate for evidence-informed adaptation policymaking and planning.

The impacts of climate change are evident in Nigeria and are likely to intensify in the future (BNRCC and Federal Ministry of Environment 2011; NEST and Woodley 2011) with the effects touching almost every facet of the national economy – communities, economic sectors, businesses, and governments across the country. Nigerian communities are responding to climate risks in their own ways with the limited resources available to them. The projected impacts of climate change in Nigeria are predicted to significantly worsen (Table 1).

Integrating climate change adaptation into development policies, plans, and projects is an effective approach to managing the risks and opportunities of climate change while enhancing sustainable development (BNRCC and Federal Ministry of Environment 2011). It is usually recommended that policies be evidenced based using the best available evidence to inform policy decisions (Nutley et al. 2009). This is because robust evidence is expected to provide an antidote to policy failures (Pawson 2002a, b). The main arguments for this are that evidenced-based policies have wider ownership, they stand better chances of being implemented, and they have brighter prospects of policy goals being achieved and sustained. This rather simple understanding has not been embraced in policy making, and evidence-based policies are the exception, rather than the norm. Evidence-based policymaking could be viewed as a process that rigorously and systematically employs robust and tested evidence in policy design, implementation, and evaluation (Sutcliffe and Court 2005). Head (2008) provided a nuanced description of the knowledge and evidence that characterize policy. According to Head (2008), these include political know-how, rigorous scientific and technical analysis, and practical and professional field experience.

Table 1 Projected trends of key climate change parameters for Nigeria by ecological zone

Climate variable	Mangrove zone	Rainforest	Tall grass (Savanna)	Short grass (Sahel)
Temperature	Increasing	Increasing	Increasing	Increasing
Rainfall volume	Increasing	Increasing	Decreasing	Decreasing
Rainfall variability	Increasing	Increasing	Increasing	Increasing
Extreme rainfall events – droughts	Likely	Likely	Increasing	Increasing
Extreme rainfall events – storms and floods	Increasing	Increasing	Likely	Likely
Sea level rise	Increasing	Not available	Not available	Not available

Scientific research seeks to generate knowledge. Commonly the lessons learnt are meant by researchers to contribute to public policies, and also of private interest to serve a wide diversity of goals. In all cases, there are stakeholders for whom scientific research can address the wide diversity of interests and perspectives by providing lesson learned. In addition, policy makers and managers in the public and private sectors recognize the need to be driven by knowledge. While this is the norm, in practice there is no consensus or unanimity of views of steps for the practical implementation of such research-driven policy development.

Nigeria has several policies related to climate change and environment. The process of developing these policies followed largely a top-down approach, where the federal government was mainly responsible for formulating the policies. Furthermore, climate change adaptation was not mainstreamed into these policies. This necessitated the need for a National Adaptation Strategy and Plan of Action on Climate Change for Nigeria, which used evidence from a bottom-up approach, to help address this situation.

The NASPA-CCN was a product of a Canadian International Development Agency (CIDA) supported Building Nigeria's Response to Climate Change (BNRCC) project implemented for four and half years in Nigeria. The BNRCC project included research, pilot projects, youth and communications activities and included a focus on gender in all project components. The research component included development of downscaling scenarios of future climate characteristics of Nigeria. Lessons learnt from all these components were used for climate change adaptation policy development which yielded the NASPA-CCN.

The BNRCC process of policy document development represents a classical and successful evidence-based approach. The objective of this chapter is to describe the steps followed in drawing lessons from these components of the BNRCC, steps adopted in synthesizing policy-relevant lessons from each component, and the perceptions about the process of developing the policy document. The NASPA-CCN was acknowledged prior to the COP18 in Doha by the UNFCCC as one model policy document that other countries could learn from (UNFCCC 2012).

Evidence-Based Policy

To understand evidence-based policy, the chapter first described what policy, public policy, and public policy making are and the how they link with evidence-based policy.

Public Policy

Policy is an effort to achieve desired outcomes by transforming the priorities and principles of governments into programs and courses of action. Thus, public policy can be viewed as a set of decisions by governments and other political actors to stimulate, modify, or frame a problem or issue that has significant impact in the political domain by policy makers or the wider public (Hassel 2015; Howlett and Cashore 2014). More precisely, public policy is seen as government actions, the reasons they do it and the differences attributable to such actions (Dye 1976).

Policy Making

As described above, policies are courses of actions which include goals and the resources to achieve them, regardless of how well or poorly formulated. Thus, policy making comprises both a technical and political process defining and matching the goals and means of different parties (Howlett and Cashore 2014). The public policy making process is concerned with provision of policy direction for the benefit of the public sector. This includes the identification, justification and formulation of relevant policies (Howlett and Cashore 2014).

Evidence-Based Policy Making

The practice of informing policy using evidence has become progressively popular. This popularity is driven further by the activities of policy communities such as within government departments, research organizations, multilateral organization, think-tanks, and initiatives which advocate for evidence-based policy making. Evidence-based policy can be defined as an approach that helps an individual or organization to make well informed decisions about policies, programs and projects based on scientific and empirical evidence, including impact studies, cost-benefit analyses, program evaluation, and academic research (Leuz 2018; Sutcliffe and Court 2005). Additionally, evidence-based policy is a set of methods which does not aim to directly affect the policy outcomes; rather it influences the processes through which policies are developed. Evidence-based policy proposes a thorough and systematic approach and extends the traditional concepts of research to acquire a comprehensive understanding.

Why Evidence-Based Policy Is Important

The importance of evidence-based policy is fairly apparent. The application of scientific knowledge and empirical evidence to policy decisions processes is sensible. The quest for Evidence-based policy is based on the premise that policy making should be informed by available evidence and should include rational analysis lead to better policies and regulations. Generally, policies based on evidence are considered to yield better results (Sutcliffe and Court 2005). Vital empirical evidences such as those generated from academic research can increase our understanding of the effects of policies. Furthermore, empirical evidences enforce discipline on policy making when they are theory-based which makes policy making less vulnerable to political pressures and capture (Cairney 2016; Leuz 2018). Also, given that research benefits from public funding, it is expected to significantly contribute to advance knowledge for the society.

In a report for the Australian Department of Industry, Innovation, Science, Research and Tertiary Education, Palangkaraya et al. (2012) summarized the importance of evidence-based policy. According to Palangkaraya et al. (2012), evidence-based policy accounts for which entity is affected, the magnitude of these effects, and the net benefit for the society. They state, for example, that a sound economic policy ought to take into consideration both financial effects (such as productivity and income) and nonfinancial effects (such as environmental and social impacts). Secondly, evidence-based policy also analyzes the counterfactual of a proposed policy, for example, the impact of a specific policy on third party entities' welfare and behaviors as a result of the proposed policy. Thirdly, evidence-based policy empowers policy makers to study and improve already existing policies and programs. Fourthly, evidence-based policy empowers an analyst to measure if the impacts of policies or programs are biased toward one subgroup (such as demographic, economic, or region). Finally, evidence-based policy is valuable to the public sector owing to a lack of appropriate price signal. Due to the profit maximization motive, the private sector typically assesses the efficacy of projects using metrics such as stock prices and revenue. However, the public sector essentially creates its own metrics of impact and value with the aim to maximize societal welfare. Importantly, rigorous research and evidence from credible and independent parties can help gain the trust of key stakeholders and the public.

The literature on evidence-based policy making is typically grouped into two: (1) theoretical arguments in favor/critical of evidence-based approach and (2) theoretical proposal to improve the evidence-based policy making process (O'Dwyer 2004). These two groups assume that the availability of evidence is desirable in the decision-making process. However, interpretation of the soundness of evidence is often times unclear; while the interpretation is universally acceptable at a particular point in time in the natural sciences, interpretation is beset with disagreement in the social sciences. The literature highlights factors that influence policy making, which also serve as opportunity to improve the policy making process. Overall, evidence-based policy making is supported by the literature.

Difference Between Evidence-Based Policy and Nonevidence-Based Policy

Evidence-based policy is closely related to non-evidence-based policy; however, there are major differences. There are basic assumptions of evidence-based policies in the literature: evidence-based policies is an important proposition, policy-makers should have access to evidence, properly interpreted evidence benefits policy development, evidence-based policies are superior to nonevidence-based policies (O'Dwyer 2004). Furthermore, there are different actors or parties considered in the literature on policy making; these parties include the policy makers, researchers, and practitioners. Other parties with limited roles include evaluators, participants and affected third parties (Lemke and Harris-Wai 2015). There are often no direct links between these parties, however, policy making benefits most with a closer link between the policy makers and researchers. The application of evidence is the major difference between evidence-based-policy and nonevidence-based policy. Importantly, it is relevant evidence that matters, not just any evidence. Lack of an evidence base for policy making implies that policies will be based on other factors (such as values and ideology of both researchers and policy makers, current public opinion, and political goals) (O'Dwyer 2004). The success of evidence-based policy is based on the availability of an evidence base generated through rigorous research relevant to policy (Sutcliffe and Court 2006). Availability of an evidence base is a necessary but not sufficient condition for sound policy making. The availability of an administrator vested with the role of assembling and providing clarity on the quality of research and generated evidence.

Development of Evidence-Based Policy

Different models have been used in the literature to explain the formulation and development of evidence-based policy. These models include, but are not limited to, knowledge drive model, problem-solving model, interactive model, political model, tactical model, and enlightenment model (for more details, see Almeida and Báscolo 2006; Daviter 2015; Trostle et al. 1999; Weiss 1979). These models can be applied jointly in analyzing the research-policy relation. It is also important to note that none of the models is sufficient to analyze the relationship, given the complexities inherent in the policy making process.

How Policy Makers Receive and Interpret the Outcomes of Specific Types of Research

The need for various types of evidence in policy making processes has increased among governments around the world. The typical forms of evidence with implication for public policy, according to (O'Dwyer 2004), include:

1. Descriptive evidence (such as employment statistics and trade deficits)
2. Analytical evidence (deals with establishment of causal relationships and explanations)
3. Evaluative evidence (deals with the effectiveness of existing policies and programs)
4. Policy analysis (relevance is based on the analyst's position in relation to power)

Sectoral Concentration of Evidence-Based Policy Making in Nigeria

Evidence-based policy making in Nigeria is largely practiced in the health sectors (Onwujekwe et al. 2015; Uneke et al. 2017, 2018, Uzochukwu et al. 2016). This situation is also observed in most developed countries (Parkhurst et al. 2018). The reason for the predominant practice of evidence-based policy making in the health sector (physical science) compared with social science fields can be explained by analytical approaches used for evidence collection. The evidence-based approach was pioneered by the medical field, with techniques such as randomized controlled trials, which are straightforward and easy to comprehend. Analytical methods in the social science field are seen to be prone to errors and biases (Bhattacherjee 2012; Ioannidis et al. 2017). Evidence from the physical sciences is generally more acceptable to policy makers than evidence from the social science in the event of excess information and ambiguity (Ioannidis et al. 2017).

The Frame: BNRCC

NASPA-CCN was a very practical example of evidence-based policy document. The methodology of the NASPA-CCN development specifies evidence driven process using scientific research and pilot project partners' inputs, with results mainstreamed into policy by first completing the Climate Change Adaptation Strategy Technical Report (CCASTR) and then using this information to develop the NASPA-CCN a key output of the BNRCC project.

The BNRCC project started 2007 had USD$5M of funding from CIDA and was managed jointly by ICF-Marbek and CUSO-VSO, along with the Nigerian Environmental Study Action Team (NEST) as the Nigerian implementing partner. The project ran from 2007 to 2011. The project was developed on the basis of the achievements of an earlier initiative, the Canada-Nigeria Climate Change Capacity Development Project implemented with funding from CIDA'S Climate Change Capacity Development Funding (CCCDF, 2001–2004). The overall goal of the BNRCC project was to "*enhance Nigeria's ability to achieve equitable, sustainable poverty reduction through more effective governance related to climate change in Nigeria*" (Marbek Resource Consultants and CUSO 2007). The BNRCC project objectives included "*building Nigerian capacity to meet international commitments and adapt to climate change through improved governance promoting gender equality, poverty reduction and more sustainable natural resource management*" (Marbek Resource Consultants and CUSO 2007). The expected impact is improved capacity of Nigerians to respond to the effects of climate change, reducing the negative impacts on the livelihoods of vulnerable men and women (Marbek Resource Consultants and CUSO 2007). The BNRCC project had four components which included the research, pilot projects, outreach/networking/communication, and policy components. It was implemented in fifteen (15) states of Nigeria (Fig. 1). All project components, except the policy component, had Advisory Groups. The Advisory Groups provided guidance and contributed to decision-making related to

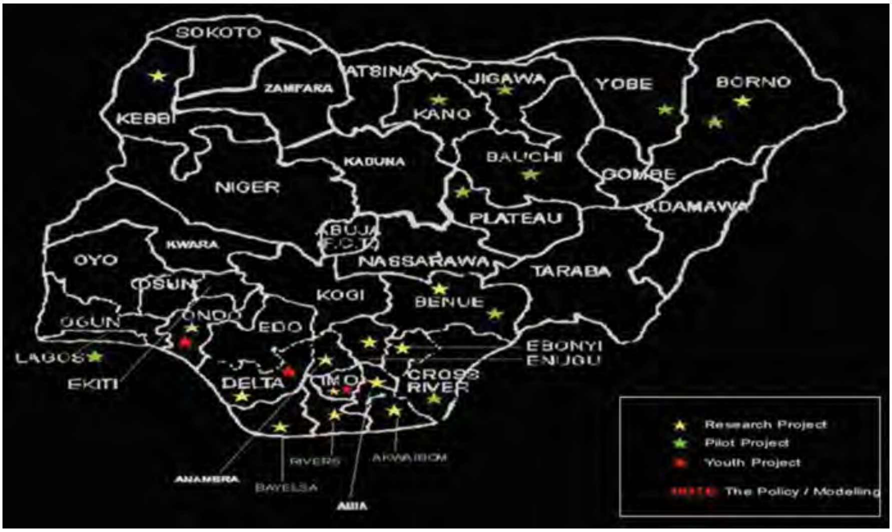

Fig. 1 Map of Nigeria showing states where BNRCC Projects are located

their specific components. The Advisory Groups did not directly participate in implementation of project activities. Each Advisory Group was composed of 5 members, representing a range of expertise and perspectives. The groups had balanced membership with regard to gender, geography, and categories of stakeholder. Each Advisory Group met regularly (approximately 3–4 times per year) during the most active phase of the component for which the Group provided advice.

Research Component

The research component had two categories of research carried out – socioeconomic research on climate change impacts, vulnerability, and adaptation; and climate scenario modeling. This component commissioned experts from diverse fields to carry out studies on socioeconomic aspects of climate change across Nigeria to generate evidence from the field. According to NEST (2011), the commissioned socioeconomic projects included:

1. Adaptation to Climate Change and Variability by Farming Households in the Niger Delta Region, Nigeria
2. Assessment of Impacts, Vulnerability, Adaptive Capacity and Adaptation to Climate Change in the Niger Delta Region, Nigeria
3. Gender Dimensions and Indigenous Knowledge for Adaptation to Climate Change in
   (a) Southeast Nigeria

The socioeconomic research projects collected gender disaggregated data and conducted gender analysis of the data collected. Gender was also considered in the composition of the socioeconomic research projects teams. The consideration of gender in all activities of the socioeconomic projects was informed by the fact that climate change impacts are not gender neutral. Climate change affects everyone, but the way and manner it affects men, women, youths, the aged, and people with disability differ significantly. This will also inform the kind of adaptation strategies needed for different groups. Experts, who are academics from universities across Nigeria, with prerequisite knowledge of climate change were selected and commissioned after a nationwide call for expressions of interest.

Also, the Climate System Analysis Group (CSAG), Department of Environmental and Geographical Science, University of Cape Town, Rondebosch, South Africa was commissioned to generate climate scenario models and predict the future impacts of climate change in Nigeria. This subcomponent was important and a major accomplishment of the project because the findings generated provided information on how Nigeria's climate has changed over time and what is expected in the future. Global Circulation Models (GCMs) are too coarse to predict local scale impacts on agriculture, health, natural resources, etc., in different ecological zones of Nigeria. The BNRCC downscaling improves resolution with 1971–2000 climate data from 40 Nigerian Meteorological Agency (NIMET) stations to fill the gap (Babatunde et al. 2011).

This component generated new knowledge and tools of analysis of climate change scenarios, vulnerabilities and impacts on men and women in key sectors and eco-regional zones as well as their local adaptation practices to climate change. Furthermore, it developed regional climate predictions for Nigeria's eco-regional zones, developed vulnerability analyses for adaptation applications, and identified traditional and new response guidelines, practices, strategies, and technologies for climate change adaptation.

Pilot Projects Component

The pilot projects reached 15 primary communities in 8 States from the coastal/rainforest, through the tall grass and short grass savannas to the Sahel ecological zones, covering Cross River, Benue, Plateau, Kano, Jigawa, Bauchi, Yobe, and Borno States. Knowledge generated from the pilot projects contributed greatly in developing the National Adaptation Strategy and Plan of Action on Climate Change for Nigeria (NASPA-CCN), a policy instrument now with the Federal Government. The Building Nigeria's Response to Climate Change project commissioned seven pilot projects partners across different ecological zones of the country to carry out community-based adaptation projects (NEST and Woodley 2011). According to NEST, Woodley (2011), the commissioned projects included:

1. Use of Agroforestry Strategies to Rehabilitate Sand Dunes and Improve Livelihoods of Rural Communities in the Nigerian Sahel
2. Strengthening Community-based Adaptation to Climate Change for Increased Food Security in Fragile Ecologies of Three Rural Communities in Bauchi and Jigawa States, Nigeria

3. Community-based Integrated Climate Change Adaptation Pilot Project in Two Communities of Plateau State
4. Promoting Climate Change Adaptation Best Practices in Communities in the Guinea and Sudan Savanna Regions of Nigeria
5. Alternative Livelihood Options as a Means to Promoting Community-based Adaptation to Climate Change in the Rainforest and Derived Savanna Zones of Nigeria
6. Alternative Livelihood Options as a Means to Promote Community-based Adaptation to Climate Change in two Coastal Communities in Akpabuyo Local Government Area of Cross River State
7. Alternative Livelihood Options as a Means to Promoting Community-based Adaptation to Climate Change in the Rainforest Zones of Nigeria

The pilot projects adopted a participatory, community-based adaptation, and demand-driven approach in its implementation (see NEST and Woodley 2012 for details). The pilot projects contributed in building resilience to climate change in Nigerian rural communities. Okali (2012) summarized how the pilot projects contributed to building resilience in rural communities. According to him, the pilot projects increased the buffer capacity of rural farming communities through promoting several livelihood diversification activities, training community members in project management, mainstreaming gender in all project activities, value addition of farm produce, introducing and promoting improved cookstoves, and promoting sustainable land management practices. The pilot projects also strengthened the capacity of rural communities for self-organization and enhanced their adaptive capacities (Okali 2012). In strengthening rural communities' capacity for self-organization, the projects adopted participatory approach in choosing and implementing adaptation interventions in the communities, formed project implementation committees (PIC) in the communities, formed and strengthened community-based organizations, included youths, men and women in projects' management and decision making, ensured that communities take full ownership of the projects to promote sustainability, and relied on local resources in project implementation and management (NEST and Woodley 2012). The project built adaptive capacities of rural communities through learning, creating awareness, knowledge and experience sharing, training, provision of peer education tools for knowledge transfer, creating a platform for different stakeholders to interact freely and provide feedback, and encouraging scaling up successful interventions beyond initial communities (NEST and Woodley 2012). For example, the water project in Kwaikong community in Plateau State (initial project community) was replicated in Kayarda community, and the Local Government Chairman of Langtang South donated about ₦500,000 to support the promotion of adaptation activities in his area (NEST and Woodley 2011). Some of the notable outcomes of the project included neighboring communities of all pilot project communities requesting early maturing varieties of crops tested and cultivated in initial project communities; and more farmers in some communities in the savanna area requesting more shallow wells for irrigation farming as a result of the success recorded in dry seasons after testing the shallow wells in the communities.

The NASPA-CCN

The main thrust of the NASPA-CCN is to "*minimize risks, improve local and national adaptive capacity and resilience, leverage new opportunities, and facilitate collaboration with the global community, all with a view to reducing Nigeria's vulnerability to the negative impacts of climate change*" (BNRCC and Federal Ministry of Environment 2011). This Plan of Action identified 13 priority sectors impacted by climate change in Nigeria. These sectors include agriculture (crops and livestock), freshwater resources, coastal water resources and fisheries, forests, biodiversity, health and sanitation, human settlements and housing, energy, transportation and communications, industry and commerce, disaster, migration and security, livelihoods, vulnerable groups, and education. The impacts of climate change on these sectors and the recommended adaptation strategies were drawn mainly from results of the pilot and research projects of the BNRCC.

Recognizing the role different stakeholders play in climate change adaptation (AECOM 2013), the NASPA-CCN allocates concrete responsibilities to all stakeholders including the federal government, state governments, local governments, civil society organizations, international development partners, communities and organized private sector with the government, the private sector, and civil society providing strong and visionary leadership. The federal government is expected to provide the overarching policy and legislative leadership, the states and the local governments lead in the regions and at the grassroots, the organized private sector explores business opportunities presented by climate change, while civil society organizations continue to act as catalysts at the adaptation frontline (BNRCC and Federal Ministry of Environment 2011). The process of developing the NASPA-CCN is described in details in the section that follows.

Process of Developing the NASPA-CCN

The NASPA-CCN led by four main partners including Building Nigeria's Response to Climate Change project of the Nigerian Environmental Study Action Team Ibadan, Heinrich Boll Foundation, NigeriaCAN (Nigeria Climate Action Network), and the Special Climate Change Unit (now the Department of Climate Change) of the Federal Ministry of Environment, was developed through an innovative process (see BNRCC and Federal Ministry of Environment 2011 for details). The development of the document involved all relevant stakeholders and experts in climate change space including communities, civil society groups, researchers, and specialists of different sectors. The Lead partners engaged with prominent stakeholders to set-up a multistakeholder process to develop the strategy document. A 25-member Multi-Stakeholder Forum whose membership was drawn from the government (local, state, and federal government officials), nongovernmental organizations, private sector operators, and researchers was formed to provide oversight (BNRCC and Federal Ministry of Environment 2011). The document largely used findings from the Building Nigeria's Response to Climate Change research and community-based adaptation projects.

The BNRCC project staff worked to develop a draft national strategy, drawing heavily on the knowledge gained through BNRCC's pilot projects and research. BNRCC engaged policy/research consultants to collect background research on existing climate change policy and advise on the development of sectoral adaptation strategies. BNRCC first commissioned experts of different sectors (agriculture, freshwater resources, coastal water resources and fisheries, forests, biodiversity, health and sanitation, human settlements and housing, energy, transportation and communications, industry and commerce, disaster, migration and security, livelihoods, vulnerable groups, and education) to produce the Climate Change Adaptation Strategy Technical Report (CCASTR) using inputs/finding from BNRCC's research and pilot projects and other relevant studies. The BNRCC team designed the table of contents of the report and presented and circulated it to the individual writers during different meetings and workshops. The team also designed three templates/tables for analyzing and synthesizing inputs from BNRCC's research and pilot projects and other relevant studies. These tables included Hazard-Impact-Vulnerability-Adaptation Matrix for all sectors in all ecozones in Nigeria; Policies, Programs, Adaptation Options Addressed, Implementing Agency and Cost Table; and Evaluation of Proposed Policies Table (see NEST and Tegler 2011 for details). These tables were populated by the commissioned writers/specialist of different sectors using findings that emerged from BNRCC's research and pilot projects and other relevant studies. The output of this process was a technical report called, Climate Change Adaptation Strategy Technical Report. The BNRCC team distilled the CCASTR text, produced the first draft of NASPA-CCN, and widely circulated the draft to stakeholders and experts for inputs (BNRCC and Federal Ministry of Environment 2011). Inputs received from stakeholders and experts were duly considered and incorporated in the document. The main focus of NASPA-CCN was priority policies, programs, plans, and actions.

Methodology

We conducted a survey across the country to determine stakeholders' perceptions about the NASPA-CCN and the process of producing it. The survey was carried out between October 2018 and May 2019. One hundred and twenty respondents drawn from federal ministries, departments, and agencies; state ministries, local governments; civil society organizations; academia (lecturers and postgraduate students); media; private sector operators; and communities participated in the survey. We presented the results of the survey in the result section.

Result

How Would You Rate the Process of Developing NASPA-CCN?

The rating of the process of developing NASPA-CCN is presented in Table 2. Majority (52.50%) of the respondents believed that the process was a very good one. The process followed a systematic manner in developing the document.

Multistakeholders forum composed of experts in their various organizations were established. A group of authors were also commissioned to write the Climate Change Adaptation Strategy Technical Report (CCASTR) using largely evidence from BNRCC's pilot and research projects. After writing the CCASTR, the BNRCC team distilled the NASPA-CCN from the CCASTR and several workshops and meetings were held to validate the document. This rating implies that the process of producing the NASPA-CCN is a largely accepted way of policymaking in Nigeria and countries with similar contexts.

What Do You Consider as the Key Success Factors of the NASPA-CCN Process?

Four key factors were identified and considered by stakeholders as the main contributors to the success of the NASPA-CCN as reported in Table 2. These include gender consideration in all activities that led to developing of NASPA-CCN, using evidence-based approach in developing the document – using concrete evidence from research and pilot projects, engaging/consulting relevant stakeholders in the process, and ensuring that all priority sectors affected by climate change were identified and considered in the process of developing the document. The evidence-based approach (reported by 90.00% of the respondents) applied in developing the document appeared to be most considered success factor (Table 3).

Table 2 Rating of the process of developing NASPA-CCN

Rating	Frequency	Percentage
Excellent	27	22.50
Very Good	63	52.50
Good	21	17.50
Fair	6	5.00
Bad	3	2.50
Total	**120**	**100.00**

Table 3 Key success factors of the NASPA-CCN process

Rating	Frequency	Percentage
Gender consideration	96	80.00
Using evidence from research and pilot projects in developing the document	108	90.00
Engaging/consulting relevant stakeholders in the process	105	87.50
Identification and consideration of all priority sectors affected by climate change	99	82.50

Limitations

This study was based on the knowledge and experience of the first three authors, who were part of the BNRCC team, CCASTR, and NASPA-CCN processes. Also, these authors were involved in preparing the first draft of NASPA-CCN. The chapter benefitted largely from the authors' knowledge and experience generated during implementation of the BNRCC project, CCASTR, and NASPA-CCN processes. The chapter rated stakeholders' perception about the process of producing the NASPA-CCN. Although many of the respondents interviewed were not involved in the NASPA-CCN process, they have read the NASPA-CCN and some other BNRCC reports, which informed their responses. However, our chapter did not focus broadly on the subject of climate change but the practical experiences and lessons learnt from the development of the NASPA-CCN which policy developers not just on climate change, but broader subject could learn in order to mainstream research lessons into policy.

Conclusion

The concept of evidence-based policy making does not necessarily imply good policy making. Biased evidence could lead to bad policy making decisions with damaging outcomes. Similarly, policies can be considered bad if their outcomes are ineffective, even if they utilize evidence-based. Evidence-based policy focuses mainly on the policy making process, however, good policy making not only considers the processes, but the policy outcomes (O'Dwyer 2004). Hence, it is recommended that evidence-based policy making should consider both processes and outcomes in order to be effective.

This chapter documented the experience and knowledge gained about the process of evidence-based policy making as well as adaptation to climate change impacts at the community level, acquired from implementing the BNRCC. The chapter also rated stakeholders' perception about the process of developing the NASPA-CCN – an evidence-based policy document driven by the BNRCC project. The process of developing the strategy document was generally rated to be very good. The project used concrete evidence from research and pilot projects, engaged/consulted all relevant stakeholders in the process, ensured that all priority sectors affected by climate change were identified and considered in the process of developing the document, and mainstreamed gender in the project and process. These factors played a significant role in the success of the BNRCC project and developing and delivering the NASPA-CCN. In particular, the BNRCC pilot projects contributed to building resilience of communities and sectors across the different ecological zones of Nigeria by improving the buffer capacity and capacities for self-organization and adaptive management.

Abstract

Reversing land degradation and achieving ecosystem restoration and management are routes to climate change adaptation and mitigation. The financial resources to achieve this are increasingly available. A major challenge is the absence of scalable mechanisms that can incentivize rapid change for rural communities at the decade-long time scale needed to respond to the climate emergency. Despite moves toward inclusive green finance (IGF), a major structural gap remains between the funding available and the unbankable small-scale producers who are stewards of ecosystems. This chapter reports on inclusive finance that can help fill this gap and incentivizes improved ecosystem stewardship, productivity, and wealth creation. A key feature is the concept of eco-credit to build ecosystem management and restorative behaviors into loan terms. Eco-credit provides an approach for overcoming income inequality within communities to enhance the community-level ecosystem governance and stewardship. The paper discusses the experience of implementing the Community Environment Conservation Fund (CECF) over a 8-year-period from 2012. The CECF addresses the unbankable 80% of community members who cannot access commercial loans, has c. 20,000 users in Uganda and pilots in Malawi, Kenya, and Tanzania. The model is contextualized alongside complementary mechanisms that can also incentivize improved ecosystem governance as well as engage and align communities, government, development partners, and the private sector. This complementary infrastructure includes commercial eco-credit as exemplified by the Climate Smart Lending Platform, and the community finance of the Village Savings and Loans Associations (VSLA) model upon which CECF builds. The paper describes the technologies and climate finance necessary for significant scale-up.

Climate change adaptation · Mitigation · East Africa · Ecosystems governance · Inclusive finance · Nature-based solutions · Technology · Land degradation neutrality · Forest landscape restoration · Incentive mechanism

Introduction

The objectives of this chapter are to (a) provide a background to the need for community-level inclusive finance to incentivize change adaptation and mitigation, (b) outline the concept of eco-credit, (c) describe an operational model of community eco-credit that shows promise to incentivize ecosystem management, climate change adaptation, and mitigation as well as disaster resilience building at the community level, and (d) place this model in a framework of complementary allied approaches. The paper also discusses the potential for scale-up and makes recommendations for future work. The paper is written by the innovators, designers, and implementers of the model over its 8-year development period (staff of the International Union for Conservation of Nature) and a group that have independently reviewed the approach (Ellis-Jones et al. 2018), and who are also designing the web-based and mobile-phone technology tools and models to support its scale-up (GreenFi Systems Ltd, a social enterprise). The paper's focus is ecosystem or landscape conservation, management, and restoration, but the model can include other environmentally positive actions.

The approach has been subject to a number of reviews including Kakuru and Masiga (2016), Ellis-Jones et al. (2018), World Bank (2017), Mott MacDonald (2018a, b), Roberts (2017), and Wild (2019). A limitation of the program was that the reviews indicated weaknesses in monitoring component with the absence of an impact monitoring protocol in the IUCN CECF Guidelines (IUCN 2013), particularly for assessing verified environmental and social impact. This monitoring protocol needs addressing in the main pilot location and warrants further research and development.

The Need for Green Community-Level Inclusive Finance to Meet the SDGs

Ecosystem Restoration and Management as a Route to Climate Adaptation and Mitigation

Land and ecosystem degradation is now considered to affect almost 25% of the world's land area causing a loss in ecosystem goods and services, costing an estimated US$6.3 trillion a year (WRI 2017), and is increasingly gaining attention in the development agenda. Similar analyses have been carried out for coastal ecosystems (Pendleton et al. 2012; Nichols et al. 2019). Approaches to addressing land and coastal degradation include land-degradation neutrality, forest landscape restoration, and ecosystem restoration as championed under the UNCCD, UNFCCC, and the

Convention on Biological Diversity (Achi target 15). These approaches are also embedded in the UN sustainable development goals (SDG), particularly under SDG 13, 14, and 15. Additionally, reversing land degradation and restoring ecosystems are seen as attractive nature-based solutions to climate change adaptation and mitigation. A recent study identifies and quantifies 20 conservation, restoration, and improved land management actions that increase carbon storage and/or avoid greenhouse gas emissions across global forests, wetlands, grasslands, and agricultural lands. They estimate that these 20 "natural climate solutions" (NCS) can provide 37% of cost-effective CO_2 mitigation needed through 2030 for a >66% chance of holding warming to below 2 °C. They suggest their analysis provides a robust basis for immediate global action to improve ecosystem stewardship as a major solution to climate change (N.B. the authors define a <2 °C "cost-effective" level of mitigation as a marginal abatement cost not greater than ~100 USD $MgCO_2^{-1}$ as of 2030) (Griscom et al. 2017).

This study is underscored by the recent IPCC report on land and climate change (IPCC 2019, 1543 pp.), which sets out in considerable depth of the linkages between people, land, and climate. It identifies the adaptation and mitigation response options, how these can be enabled and the required near-term actions. Specifically, it identifies that many land-related responses that contribute to climate change adaptation and mitigation can also combat land degradation and enhance food security. One of the key actions is sustainable land management which by reducing and reversing land degradation, at scales from individual farms to entire watersheds, can provide cost effective, immediate, and long-term benefits to communities with co-benefits for adaptation and mitigation. Enabling response options included in the report include; "*The appropriate design of policies, institutions and governance systems at all scales. These can be enabled by improving access to markets, securing land tenure, factoring environmental costs into food,* ***making payments for ecosystem services, and enhancing local and community collective action****. The effectiveness of decision-making and governance is enhanced by the* ***involvement of vulnerable local stakeholders****. . .. Near term actions are to* ***build individual and institutional capacity, accelerate knowledge transfer, enhance technology transfer and deployment****,* ***enable financial mechanisms****, implement early warning systems, undertake risk management and* ***address gaps in implementation and upscaling***" (extracted from IPCC 2019 our emphasis). According to the report these near-term actions can also bring social, ecological, economic, and development co-benefits that can contribute to poverty eradication and more resilient livelihoods for those who are vulnerable (IPCC 2019). The community eco-credit approach described here is designed to address many of these issues at the local level with a high level of community self-determination and engagement. Better ecosystem stewardship, which essentially (but not exclusively) means governance (including tenure and rights), will also support community stewards to adapt to climate change, through building resilience within interlinked social-ecological and socio-economic institutions at the community level. Resilience here means conserved and where necessary restored, well managed, and productive ecosystems, strong, fairly governed institutions, and integrated robust financial systems.

Increasing Availability of the Financial Resources for Ecosystem Restoration and Management

In addition to this, the financial resources to achieve ecosystem and land conservation and restoration at scale are now becoming available. Since 2006, when land degradation became a focal area, the Global Environment Facility has invested more than US$1 billion in sustainable land management practices (GEF 2019). Newer mechanisms such as the US$300 million Impact Investment Fund for Land Degradation Neutrality (UNCCD 2019) and the Green Climate Fund, which has received US$7.2 billion and which includes ecosystem restoration in its portfolio (World Bank 2019), are also supporting these efforts. However, efficiency, effectiveness, and very importantly equity remain critical questions, which must be addressed if public support is to be retained for this type of expenditure of public funds.

Urgency to Engage the Unbanked Rural Majority in Face of the Climate Emergency

Climate change is happening more rapidly than predicted (IPCC 2019), with deeper and more serious climate-related disasters of increasing frequency and severity. This engenders a greater sense of urgency with the need to help communities and broader society to adapt to climate change and restore the capacity of ecosystems to absorb carbon. While restoring land sounds an appealing solution, the reality is that many communities remain locked into a resource-poor existence unable to make the necessary investments in labor, time, and land to restore their ecosystems upon which they depend. It is also important to remember that vulnerability to climate impacts disproportionally affect marginalized members of many communities including women, youth, and elderly who are exposed to greater risks (Deering 2019).

The Need for Green Inclusive Finance to Incentivize Adaptation Actions of Rural Producers

In this chapter, we refer broadly to small-scale rural producers meaning female and male farmers (including pastoralists), fishers, and foresters that manage customarily or privately owned as well as the common pool land and sea resources. We prefer this term over smallholders or small-scale farmers as these terms imply livelihood options and tenure assumptions that may not hold true. In the literature, however, these latter terms are frequently used (e.g., Dalberg 2012, 2016; Verdone 2018) and are therefore are used here somewhat interchangeably.

Dalberg (2012), in their analysis of the financial needs of unbanked small-scale farmers, recognized that "*These smallholders also represent stewards of natural* *resources that are in need of sustainable management to prevent deforestation and degradation of ecosystems*" and further noted that "*Smallholder farming methods often turn to survival tactics that degrade the ecosystems farmers depend on. Constrained by low productivity and an inability to invest in their property, smallholders sometimes resort to shorter-term measures such as illegal logging, slash-and-burn agriculture, and intensive monoculture that impairs the viability of the ecosystems they depend on.*" Dalberg (2016) identifies this group to be 450–500 households million representing 2 billion people. Similarly, Verdone (2018) focusing on forest resources estimates that worldwide 1.5 billion smallholders depend on forest landscapes to produce food, meet their subsistence needs, and generate income. If small-scale fishers are added, this number is likely to increase. Dalberg 2016, considers that 80% are unbanked as they present too high credit risk for private sector investment (through credit or value chains). This represents a significant and largely unrecognized barrier to apply natural solutions to climate change especially via private sector investment (including impact funds). It is further noted that access to credit has been recognized, along with extension and information, to be the main drivers behind adaptation to climate change at the farm household level (Di Falco et al. 2011).

Given, therefore, that rural communities are severely cash constrained and that conservation often imposes opportunity costs, finding appropriate inclusive financial incentive mechanisms, including credit, for climate change adaptation and mitigation is critical. Approaches developed thus far include payments for ecosystem services (PES) and reducing emissions through deforestation and forest degradation (REDD). While huge investments have been made especially in REDD (and REDD +), progress has been slow (Clements 2010; Brockhaus et al. 2015; Börner et al. 2017; Ferraro 2017; Milbank et al. 2018; Andrews et al. 2020). An approach that has not been well explored is using inclusive finance and community savings and loan models to incentivize ecosystem management or restoration activities. We suggest this approach needs great attention and could also support the scale-up of both PES and REDD+.

Defining Inclusive Eco-credit

This chapter now sets out to define eco-credit and outlines an idealized theory of change which it incentivizes (Table 1). Eco-credit is here defined as "*credit that is conditional on ecological actions undertaken by the borrower as required under loan terms.*" The term was coined by the start-up company F_3Life (https://f3-life.com), the winner of the UN prize for climate change finance innovation in 2014 (UNDP 2014). Inclusive eco-credit can be further divided into two types – community and commercial and defined here. "Community eco-credit," which is the subject of this chapter, is defined as "*credit, managed at the community level, conditional on ecological actions undertaken by the community member borrower required under the loan terms.*" "Commercial eco-credit" is defined as "*credit issued by a commercial lender, conditional on ecological actions undertaken by the borrower required under loan terms.*" Eco-credit can be considered nested within

Table 1 Idealized theory of change for eco-credit groups and climate adaptation

1. Better managing and restoring ecosystems
Leads to:
2. Increased ecosystem productivity:
(a) Increases delivery of ecosystem services (e.g., water, cooling effects, soil building)
(b) Increased quantities of direct ecosystem products (food, fuel, shelter, fiber)
(c) Reductions in labor burden (particularly for women)
Leads to:
3. Improved inputs for household economy, income generation, and business
Leads to:
4. Greater household incomes
Leads to:
5. Household and community investment into:
(a) Education and health
(b) Further ecosystems management
(c) Potentially ecosystem sustainable value chains
Leads to:
6. Better development outcomes:
(a) Food, water, and shelter security
(b) Climate change adaptation and resilience
(c) Climate change mitigation
7. Meeting SDG objectives at community level (Fig. 1)

Inclusive Green Finance (IGF) defined by Schuite and Forcella (2015) as a financial sector that aims to support sustainable solutions, green products, and services to poor households and Micro, Small, and Medium-Sized Enterprises (MSMEs). IGF is an area that is receiving increasing policy attention, although mainstream financial institutions are only now beginning to take up the responsibility of climate change action (Alliance for Financial Inclusion 2019), and countries at the early stages of developing appropriate policy tools (Krogstrup and Oman 2019).

In considering the definitions of eco-credit, several points should be noted. Firstly, the contractual actions in the community model are collectively self-determined by the community as part of their ecosystem restoration and management plan and not imposed from outside. The plan is usually facilitated by an NGO (or an agricultural commodity company working with outgrowers (e.g., tea, coffee, and cocoa), and ideally follows best practice and is located within a framework of applicable law. With regard to this framework, it should be noted that the applicable law is not always appropriate and/or consistent and that, for many ecosystems, best practice has not been elaborated, and if elaborated may not be available at the community level. Thus, much additional work is needed in this area of practice. Secondly, credit programs can include both Islamic and interest-based financial models, and so have wide applicability. Thirdly, contractual actions that are undertaken do not have to be limited to ecosystem management or restoration, but can include other environmentally positive actions (e.g., adopting an energy saving stove), or indeed the same principle could be applied to other programs such as health and education (but without an environmental dimension would not be "eco"). Fourthly, this approach can work alongside social safety net financing (e.g., cash transfers) for the poorest community members and can potentially provide a route out of reliance on government assistance programs. Finally, the eco-credit approach could also be applied to mainstream finance provided through the banking sector, as identified by the International Monetary Fund (Krogstrup and Oman 2019) and applied by banks such as Barclays (undated) that offer credit discounts to home-owners adopting climate-beneficial technologies.

The underlying idealized theory of change (Table 1) is where access to credit at the community level helps to incentivizes behavioral responses to ecosystems management from unsustainable use to long-term stewardship and sustainable use patterns. These changes help develop virtuous cycles of increased ecosystem productivity and community development supporting most of the sustainable development goals (Fig. 1). It will also be important to understand how community credit can act as a behavioral driver that motivates individual and community courses of action. Behavioral determinants can be deeply ingrained and based upon factors like culture, habit, degree of ease, perceived barriers, social norms, or identity, and it will be also ideal to understand what elements of eco-credit might prevent or encourage the adoption of the ecosystem-positive behaviors.

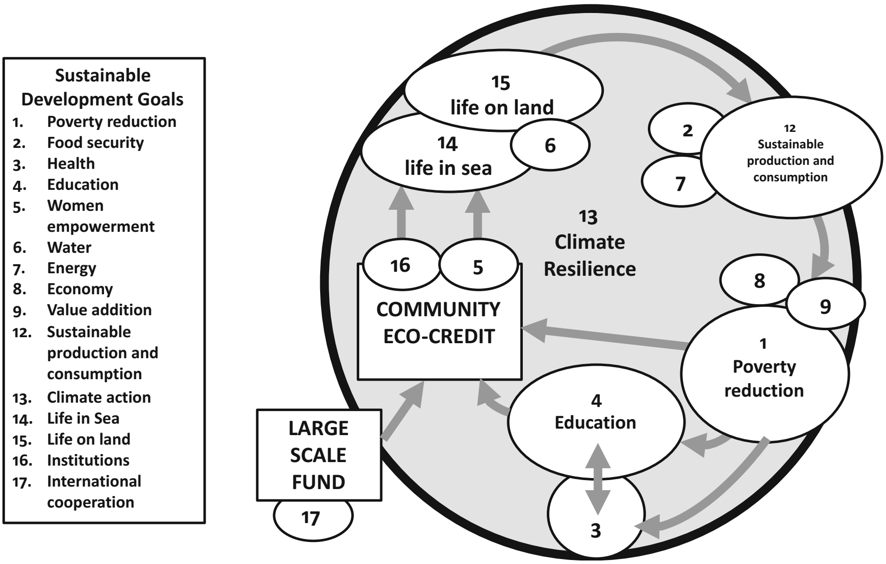

Fig. 1 Community eco-credit and the Sustainable Development Goals generating a virtuous climate resilient village economy. Development funding supports community eco-credit which supports improved ecosystem management leading to sustainable production and consumption which supports economic development, poverty reduction, and community-level investments in health and education

Community Environment Conservation Fund

Background to the Model

The CECF, a focus of this chapter, is an example of eco-credit and was initiated in 2012 in the Upper Aswa sub-catchment in the Northern Ugandan Districts of Lira, Alebtong, and Otuke. It was part of the International Union for Conservation of Nature (IUCN) project Building Drought Resilience through Land and Water Management (BDR). The project was implemented in the basins of the lower Tana River in Kenya and Upper Aswa River in Uganda. The project used IUCN's Resilience Framework – RESFRAM (Smith 2011) and was funded by the Austrian Development Cooperation. It aimed to improve the resilience of dry-land communities to the impacts of severe and frequent drought.

Settlers in the project area were formerly from agro-pastoralist communities, who had settled after over 20 years of disturbance from civil war. Baseline data collected in April 2012 indicated that the newly settled communities were over-exploiting their natural resources to meet immediate survival needs given the limited livelihood options available to them. At that time, the communities' reliance on natural resources was not, however, guided by any significant rules or set practices. Traditional management systems had been eroded during the war and new, statutory ones were only weakly enforced, if at all. As such, the unregulated exploitation of natural resources was leading to their significant degradation, and this degradation was in turn exposing those dependent on this livelihood approach to threats, such as climate change and disease. Wetlands and streams were being farmed right up to, and sometimes even into, the actual channel, and trees were being cut for charcoal, especially, the shea tree (*Vitellaria paradoxa*) which traditionally was protected due to its oil and other benefits. Such actions were increasing the potential for floods and the susceptibility to drought as a result of the reduced quality and quantity of water. Communities were caught up in a vicious cycle where they were both reliant upon, while also degrading, their natural resource base.

Implementing the IUCN Resilience Framework – RESFRAM

The IUCN RESFRAM approach promotes consideration of the following four components.

1. Diversity of the economy, livelihoods, and nature. Diverse markets or farming systems give women and men the alternatives they need to be adaptive. Enhancing and protecting biodiversity by maintaining, or recreating, natural diversity also ensures the availability of the ecosystem services needed to buffer climate impacts, such as storage of water in vegetated riverine habitats, and sustains life and productivity.
2. Sustainable infrastructure and technology – landscape management that recognizes, encourages, and combines the presence, development, and maintenance of

both engineered and "natural infrastructure," as well as adaptable, equitable, and sustainable technologies for their management, to reduce vulnerabilities. Infrastructure includes not only engineered responses, such as the sinking of boreholes, but also "natural infrastructure," such as healthy and functioning wetlands and floodplains that store water, lower flood peaks, or buffer surrounding lands from flooding.
3. Self-organization – a critical characteristic of resilient, highly adaptive communities is participatory governance, and self-empowerment.
4. Learning – ensuring that individuals (women and men) and institutions are availed, and can make use, of new skills and technologies as they become available helping them to make more effective use of information, and thus to develop effective adaptation strategies.

The IUCN team in Uganda examined different options to implement the resilience framework. One approach considered was to support what is often called alternative livelihood activities. In IUCN Uganda's experience, such alternatives have often been determined by external actors, been very unrealistic and, frequently, not in line with the differentiated livelihood priorities and aspirations of the women and men to whom they are promoted. Another approach considered, common in social safety net programs, was to directly pay people to carry out activities such as tree nurseries and soil conservation practices. This approach meant that extensive project delivery infrastructure would have been needed to deliver and monitor the work, which would not have been efficient nor sustainable. In addition, it would not have strengthened governance at the community level, a key feature of IUCN's work.

IUCN Uganda consequently developed its own approach that it called the CECF) (IUCN 2013). The CECF funding works by providing a grant for the establishment and capitalization of a community revolving credit fund to communities who have collectively agreed to develop and implement an environmental management plan. This means that environmental management work is promoted, undertaken, and monitored by whole communities, including different household compositions, to ensure receipt of the credit facility, but that the money itself can be borrowed and used for any purpose, for example, from paying school fees and hospital and doctors' bills to investments and other activities. In this way, the provision of the fund delivers improved environmental management because it enables improvements in livelihoods by removing barriers to accessing credit and not by prescribing specific actions. This is more effective than "traditional" conservation funds for alternative livelihoods because livelihood priorities are very dynamic and dependent on the status of a household at any point in time.

CECF Principles

The CECF was based on the Village Savings and Loans Association (VSLA) model (IUCN 2013), developed by CARE International and widely used in northern Uganda as an economic empowering mechanism for communities, and especially women, to access credit and build a resource base to tackle poverty (CARE 2017, 2019). Although derived from VSLA, the CECF model incorporated variations geared toward enhancing sustainable natural resources management (IUCN 2013). These have made it a unique tool to support climate change adaptation and to catalyze community-level implementation of the resilience framework. The CECF is based on seven key principles:

1. The Community Environment Conservation Fund should enhance natural resources management and governance within the area under consideration.
2. It should promote and be clear on individual and collective incentives and actions.
3. It should enhance self-determination. Conditions for using the fund should not be prescribed but should be acceptable enough to meet general conditions.
4. It should be an all-inclusive system that all categories of society (e.g., including women, younger, and elderly people, women-headed households, Indigenous Peoples) have an opportunity to participate in and make decisions on (conditions should be attainable by all members of society).
5. It should be transparent and highly accountable with both effective rewards and sanctions.
6. It should be linked to local governance systems; local government should provide legitimacy to the system by providing oversight.
7. It should be a revolving fund, sustainable over the long-term, and should be considered as a village social fund, and a permanent community-level asset, designed to attract and catalyze more support.

Self-determination is essential as this stimulates community collective action and ownership, therefore, community land-use plans are not determined by outsiders (Ostrom 1990). In this regard, the approach follows the first principle of the ecosystem approach that the ecosystem is a result of societal choices (Shepherd 2004; CBD 2019). The plans, however, needed to be compliant with local laws and wherever possible be supported by best practice. The project and government facilitators engaged with that process played the role of advising compliance with the legal framework and adopting best practice. It should be noted that the legal framework itself is often outdated, can be contradictory and does not always follow best practice. In the realm of managing complex ecosystems, best practice is itself evolving and sometimes contested.

CECF Results

In the intervening years from 2012 to the present (2020), the CECF has been implemented in three locations in Uganda, the Upper Aswa, the Rwizi River basin in the south-west and Mount Elgon, as well as at individual pilot sites in Malawi, Kenya, and Tanzania. The methodology has generated considerable interest as a scalable, replicable, adaptable, and cost-effective tool with the potential to build the financial, environmental, and social capital of participating communities who are

(i) dependent on natural resources for their livelihoods, and (ii) vulnerable to the impacts of climate change.

As mentioned, the approach has been subject to a number of reviews including Kakuru and Masiga (2016) (for Upper Asswa); Ellis-Jones et al. (2018) for Uganda and Kenya; a World Bank review (2017), and Mott MacDonald Reports (Mott MacDonald 2018a, b) for the Shire basin in Malawi; and Roberts (2017) and Wild (2019) for Pemba Island, Zanzibar, Tanzania.

In Malawi, the Ministry of Agriculture, Irrigation, and Water Development with World Bank support and technical assistance from Mott-Macdonald Ltd. have been using CECF to support watershed catchment management in the Shire River basin (Mott Macdonald 2018a, b). This component of the program was operational from 2016 to 2018 and supported the formation of 185 CECF funds. Early indications were positive and the CECF was instrumental in stimulating communities to take up actions in their village land-use plans. The project, however, has subsequently closed and the technical support is no longer in place – a follow-up is therefore recommended to assess how these are progressing and if they have survived the post-project cessation of technical support. In Pemba Island, the system has been tried for the first time with marine communities. Here GreenFi System Ltd. is supporting a Tanzanian NGO Mwambao Coastal Community Network to apply a modified approach with the members operating in groups of 30, with more specific environmental commitments, and using mobile phone technology for tracking. In this case, the background situation was examined in detail (Roberts 2017). A recent review indicated that the groups in the pilot community are progressing and the approach is appreciated at the community level (Wild 2019).

Of these reviews, the most exhaustive was Ellis-Jones et al. (2018) for Uganda (Lira, Mt. Elgon, Rwizi) and Kenya (Garissa and Tana River), and has been drawn upon to provide more detail. The overall purpose of that report was to assess the verifiable impact of the CECF approach to (i) inform design and implementation of systems which strengthen the CECF methodology in order to create a robust platform and credible basis for scale-up, and (ii) help build a richer story for IUCN to communicate the success and potential of the CECF methodology to potential funders.

The importance of a scalable methodology and credible financial, environmental, and social impact reporting is to (i) demonstrate return on investment for investors in a hybrid market-based/donor-funded model, (ii) show the cost-effectiveness of the CECF methodology in a crowded market-place for conservation concepts, and (iii) maybe most importantly, give IUCN management enhanced control over CECF implementation and performance such that the scaling is efficient and effective – and the methodology continues to be effective at scale. The review was constrained in terms of reporting impact by the lack of an impact monitoring protocol in the CECF Guidelines, particularly for assessing *verified* environmental and social impact. Financial data were available at project sites, however, but again there was no uniform methodology for loan tracking in the CECF Guidelines.

External Funding for CECF Groups

In terms of the review result, and most importantly, there appears to be a compelling case that community credit groups can be seeded with outside funds and, with the correct external mentoring, successfully manage this fund injection as a revolving credit facility. This is an important finding because the more established Village Savings and Loan Association (VSLA) methodology does not encourage group seeding with capital that has not been provided by the group members themselves, which has been a threat to the assumptions which underpin the CECF model. In discussing this with CARE, this contributes to the risk that group formation is principally for the purpose of receiving funds, a problem that is frequently encountered (Pennoti, pers. comm.).

However, it is important that external support and mentoring is maintained for groups in the initial phases and until such times that groups can be graduated. In Mt. Elgon, apparently most groups are inactive, and this appears to be because CECF was used as an exit strategy from a project site. This demonstrates that the CECF methodology requires patience in nurturing and developing groups to a point where they are self-sufficient in managing themselves. Further experiments are needed to uncover how much supervision and for how long groups need this support in order to stabilize, and at what time they can be graduated and where both loan cycles and improved ecosystem governance can continue independently and with low or no external support.

Verifiable Financial, Environmental, and Social Performance

In the Ugandan project, (i) groups were relatively large (with approximately 200 borrowers per group, although not all group members used their borrowing rights), and (ii) loan size were relatively small (average size US$15 to 16.50). Loan size was likely a function of group size and fund caps, whereas loan size should ideally be informed by a credit needs analysis during project design, which in turn informs the fund cap. In Garissa, Kenya, average loan sizes were close to what would be expected for unbanked individuals (US$113 for individual loans), however the Garissa project was still at an experimental stage having recently transitioned from individual loans to "group loans," a move that itself needs further analysis.

Across key sites (Lira and Garissa), late repayments were relatively low (92% of loans repaid within 5 days of the due date). However, defaults were not tracked. This was partly because group enforcement was good, and loans were marked as repaid, even though they were repaid through the sale of a borrower's assets, which is technically a default.

It was found that groups are willing to accept environmental conditionality as a term for loan access, but it was unclear the extent to which they complied with these terms later. Nonverifiable forms of evidence suggest that compliance is good, with reports of riverbank and stream protection, tree protection and planting, and numerous ecosystem governance institutions forming, but a robust environmental monitoring methodology is needed to verify these perceptions. CECF environmental obligations are quite complex, and likely impose both a financial and cognitive burden on members, which may act differently across age and gender groups. It is unclear what impact simplification of CECF-access terms may have in terms of boosting compliance, but once robust monitoring mechanisms are in place this can be tested.

The VSLA methodology, upon which CECF draws, was established to create positive social impact. And over decades, the approach has proven its value. The CECF methodology is new by comparison to VSLA – and offers a different value proposition in terms of social impact: improved welfare through improved natural resource management (as well as access to credit). This makes demonstration of the CECF impact very important, and the review recommended that the CECF Guidelines should include a robust social impact monitoring methodology to demonstrate its proposition.

Gender equity was largely achieved in CECF as inferred from the financial data. This was a good achievement given that there is no clear protocol to achieve this in the CECF Guidelines. Best practices need to be codified to ensure they are replicated in scale-up. Anecdotal reports which are quite widespread that CECF helped reduce the domestic violence by allowing women to have an independent source of income needs further research and analysis.

CECF Conclusions

Overall, the CECF was seen to be successful and hold significant promise but requires higher early years' investments to achieve stability before groups are graduated. Ongoing support is likely to be necessary for groups to sustain action. As yet, how this is provided is not clear. Overall the CECF was seen in the review to be:

- Generally successful and popular with communities. There has, however, been one failure where the scheme was used as an exit strategy at Mount Elgon. With no follow-up support, it did not become rooted and the vast majority of groups did not survive long.
- Environmental monitoring, however, has not been strong, with general anecdotal reporting of environmental gains and no systematic collection of environmental data.
- The model has evolved in different ways in different locations (Rwizi and Garissa).

It has now been tested with agro-pastoralists, pastoralist, smallholder farmers, and coastal fishers, as well as part of catchment management, and using both interest-based and Islamic finance models in three sub-Saharan African countries and with some additional key elements is ready for scale-up.

Other Community-Level Financial Infrastructure for Climate Change Adaptation

In this chapter, we have identified how this work can be located within a comprehensive financial infrastructure of complementary approaches for ecosystem governance at the community level. These existing complementary approaches that could work very effectively together are set out below and illustrated in Fig. 2. The key components of the model financial infrastructure at the community level to promote stewardship are:

- Community eco-credit (e.g., Community Environment Conservation Fund, the focus of this chapter)
- Commercial eco-credit (e.g., Climate Smart Lending Platform)
- Savings groups (e.g., Village Savings and Loans Associations)
- Value chains that support ecosystems (e.g., sustainable agriculture, forestry, fisheries, and tourism)
- Government social safety nets (e.g., work programs or cash transfers) and internal community labor

The Climate Smart Lending Platform

The Climate Smart Lending Platform builds eco-credit into the loan terms of commercial microfinance lenders that typically address the credit needs of the better off 10–20% of community members within a specific community. (This rule of thumb depends on the extent to which households are embedded in paper-trailed supply chains. For example, a pastoralist might be richer than a small farmer on half an acre. But because the farmer is selling into a paper-trailed supply chain, she will be able to attract credit and the pastoralist may not.) The Climate Smart Lending Platform is, therefore, commercial eco-credit, and works with microfinance banks to incorporate climate-smart agricultural and land-management practices into loan terms. When a client signs a loan agreement, they also sign a land management agreement which requires the client to manage their land in a way which is designed to protect them and their farm from climate change-related events. This approach is designed to enhance credit-provider profitability by reducing credit default risk and increasing the client debt service coverage ratio. Additionally, it ensures farmers are building resilience to weather events associated with climate change (Climate Policy Initiative 2015; Partnership for Forests 2018). A successful proof of concept trial with 75 farmers was carried out in the Nyandarua county of Kenya, in 2015. It complements community eco-credit (e.g., the CECF) as it works with the better off members of the community. The two approaches have yet to be tested in the same location.

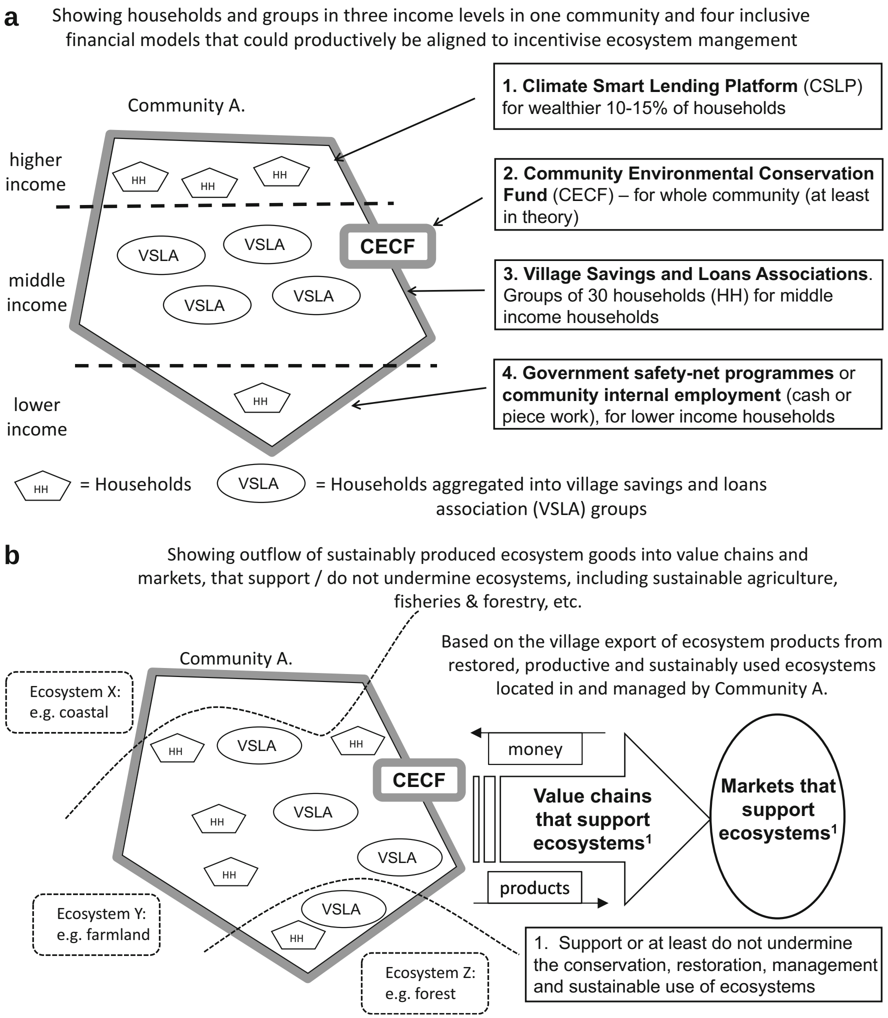

Fig. 2 (continued)

Village Savings and Loans Associations

CARE International, the leading proponent of savings-based social lending, created the Village Savings and Loans Associations (VSLA) model in Niger in 1991, and has since brought VSLA programming to many different regions and continents, adapting it to different contexts as its reach expands (CARE 2017). Thus, this is a tried, tested, and now massively scaled savings-led, community-based financial solution. CARE deliberately set out to scale it up in 2009, and has since expanded access to from an initial 1 million members in 2008 to 7.6 million across 51 countries

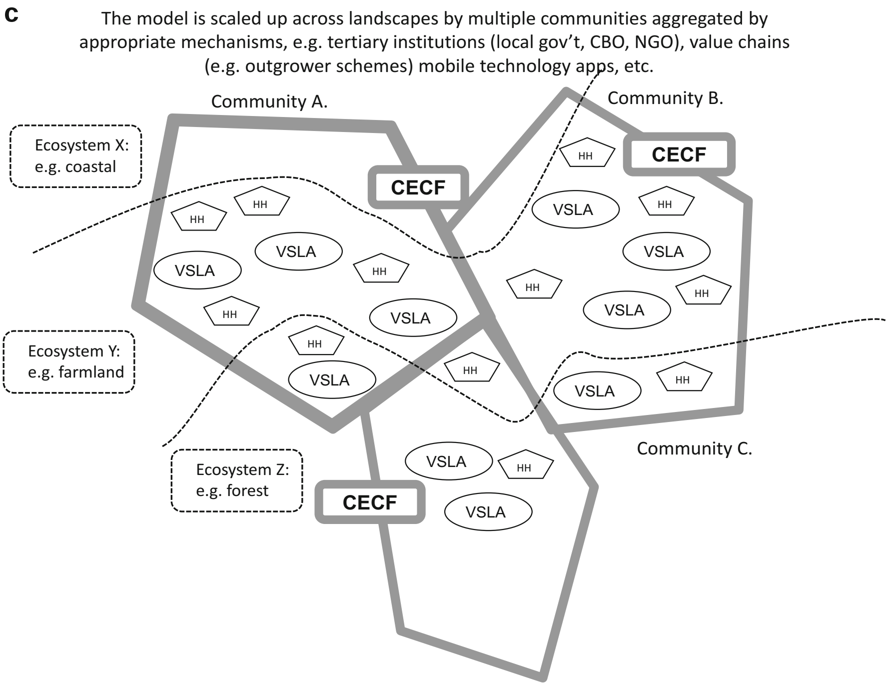

Fig. 2 A comprehensive and complementary inclusive of green financial infrastructure for ecosystem restoration at community level, showing (**a**) socio-economics, (**b**) value chains, and (**c**) landscape scale-up

today. These members represent 357,000 groups of predominantly rural, poor women collectively saving and investing over US$500 million per year (CARE 2019). CARE's investment in growing VSLAs and its broad-based industry engagement has allowed it to significantly multiply its impact; more than 26 other NGOs and several governments are implementing savings group programming at scale modeled on VSLA. This work has resulted in over 15.2 million VSLA members world-wide who are saving and investing in their respective communities (CARE 2017). 59% of CARE-trained VSLA members are in East Africa, 17% in West Africa, 13% in Southern Africa, 10% in Asia, and 1% in Latin America. There have been many studies on the impact of VSLA including randomized trials (e.g., Ksoll et al. 2016). These studies of VSLAs have found evidence of significant positive outcomes, including the number of meals consumed per day, household expenditure, and the number of rooms per dwelling. This effect is linked to an increase in savings and credit obtained through the VSLAs, which has increased agricultural investments and income from small businesses (Ksoll et al. 2016). While some attempts at greening VSLA have been made (Wild et al. 2008), the model has primarily focused on the social and financial double bottom line (Pennotti, pers. comm.). The VSLA financial infrastructure is now widespread and deeply embedded at community level and presents a huge foundation for scaling eco-credit if environmental actions can be integrated into group actions. To take one example, the northern Zanzibar Island of Pemba has over 90 VSLA trainers organized through a formerly CARE supported local NGO Pemba Savings and Credit Association (PESACA) (Wild 2019) could support the evolution of eco-credit. The VSLA model was the basis for the CECF innovation.

Sustainable Value Chains

The restoration and better management of ecosystems and the increased ecosystem productivity it brings will of itself enhance community livelihoods. However, the more that these are linked in with value chains that support and do not undermine these ecosystems from which they derive products, the greater the livelihood and income generation benefits will be generated. Further, the increase in community incomes is likely to increase the pace of scale-up and improve the chance of engaging the private sector in climate change adaptation. Many agricultural, forestry, fisheries and tourism-based value chains could fit into this category. The advantage of the eco-credit approach is that it is very scalable, overcoming the geographical scale limit of individual value chains. If tea, coffee, shea nut, sustainable forestry and agriculture companies all took a community eco-credit approach, they would not only green their value chains, but collectively would have significant climate change adaptation impact over wide areas. The recommendation is, therefore, that these commodity companies adopt a community eco-credit approach to support their communities of outgrowers with setting up and capitalizing community eco-credit funds. In addition to securing their produce value chains through sustainable land management, the commodity companies would enhance their social license to operate. Following the lead of the major land-based commodities, this could be replicated among the less organized agriculture, forestry and fisheries-based value chains.

Social Safety Net Funding and Internal Employment

A common feature in many societies are payments to vulnerable households via government social safety net systems. This is a broad topic and the purpose of highlighting it here is that (a) if these safety nets were aligned with ecosystem management and restoration and (b) if VSLA and CECF are recognized as potential routes out from the need of social safety nets, then funding would align for greater impact. The internal use of employment and piece work within communities is also common, where better off community members employ less well-off community members in activities such as digging land, collecting water, and firewood (Whiteside 2000). We expect internal employment to be an integral feature of community financial infrastructure that we outline supporting profitable climate adaptation activities, however, this requires further research.

Scaling Up Community Eco-credit

As eco-credit is relevant to most rural communities in the global south, and it has a very significant scale potential to assist communities to adapt to and mitigate climate change. We briefly outline here two elements that will be important for scale-up: (a) technology platforms and (b) large-scale funding, for example, a blended finance fund.

Technology: Mobile Phone and Web-Based Applications

For community eco-credit systems to scale-up effectively, technological solutions will be required. Indeed the 20,000 member strong CECF in Northern Uganda has probably reached the maximum scale possible on an analog system alone. Technology allows scale-up as it reduces the costs of the credit transactions, allows detailed monitoring of both financial and environmental performance, and allows organizations both using and providing grant finance to have real-time reporting on the use and impacts of their funding. These technology systems should include the following key elements:

- Core banking systems
- Environmental monitoring and verification
- Additional elements that will be developed in time
  - Upload community land-use and action plans
  - Boundary and way marking
  - Baseline ecological conditions
  - Baseline social conditions
  - Loan use and effectiveness – enterprise tracking
  - Extension and information via training modules and push SMS
  - Impact at social level – attribution to education and health outcomes

Establishing Large-Scale Funding

A barrier to the significant scale-up of community eco-credit is the capitalization of community eco-credit funds (e.g., CECF and similar). It is estimated that the resources required for each independent community-level eco-fund is in the range of US$1,500 to US$10,000 depending on the socio-economic baseline. There are good reasons to develop dedicated funding mechanisms to capitalize the community-level eco-funds.

IUCN, CARE International, and GreenFi Systems Ltd. developed a concept for a US$1-2 billion fund which was submitted to the 2019 and 2020 calls for the Global Innovation Lab for Climate Finance. The concept, called MaliVerde MaliBulu – meaning green wealth/blue wealth, was among the finalists, indicating that the creation of a specific fund vehicle could potentially gain traction (IUCN 2019).

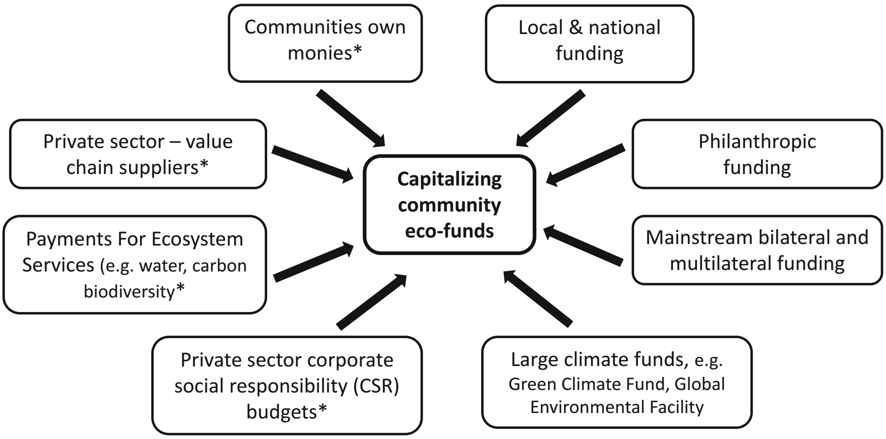

Fig. 3 Potential sources for capitalizing community eco-funds most of which could be channeled through a blended finance vehicle (*denotes private sector)

The goal of the fund was to establish a US$2 billion, 10-year fund to capitalize community eco-credit groups, with the aim of restoring the ecological function and carbon sequestration over large areas of land and seascape. If such a fund was successfully established, then community-level; eco-funds could be replicated in different geographies and targeting specific resources and livelihoods (pastoralism, agriculture, fishing, etc.). If US$2 billion, for example, were deployed into a fund or funds, it was considered that this would scale by 300% in 10 years, and 6,000% in 30 years, meaning 150 million small-scale producers in a decade, and (feasibly) a large proportion of unbankable small-scale producers globally would have access to capital and be contributing to nationally determined contributions (NDCs) to the climate emergency. As it is primarily focused on unbankable community members, the fund would need to adopt a blended finance mechanism, with development partners and aid agencies and large-scale climate financing providing a substantial grant element. The private sector would come in progressively as the groups became either part of an existing value chain (tea and other commodities), or established by a project finance model where the development finance absorbed the risk but the established funds being paid for by the private sector entity. The potential sources of resources and co-resources to establish the community eco-funds can be seen in Fig. 3.

Discussion

Scale Relevance of Community Eco-credit

Dalberg (2012, 2016) identifies that only 10–20% of the 450 million smallholder farm households (representing 2 billion people) receive commercial loans mostly through short-term trade finance, through export-based commodity value chain actors (e.g., tea, coffee, etc.). The authors outline the importance of this group not only to delivering food security (SDG 2) but also as ecosystem stewards (SDG 14 and 15).

> *Donors consider the world's 450 million smallholders a linchpin in poverty-reduction strategies because more than two billion of the world's poorest live in households that depend on agriculture for their livelihood. These smallholders* ***also represent stewards of natural resources that are in need of sustainable management to prevent deforestation and degradation of ecosystems*** (our emphasis). (Dalberg 2012)

The authors identify the opportunities of working with this group but point to a further set of challenges:

- Smallholder production (<2 ha) is low quality with poor market linkages and little finance. Unmet global smallholder finance is estimated at US$450 billion.
- Agricultural "social lenders" satisfy less than **2%** of the demand.
- The vast majority of smallholders are **nonaggregate**d only about 10% of smallholders currently belong to producer organizations.

The authors also note the contribution of VSLA as to informal finance (Dalberg 2016).

In a similar analysis, Verdone (2018), focusing on forest resources, also identified the often-overlooked economic potential of what is possibly the world's largest private sector. He reported estimates that "*more than 1.5 billion smallholders throughout the world depend on forest landscapes to produce food, fuel, timber and non-wood forest products to meet their subsistence needs and generate cash income. Despite the large number of smallholders and the large collective scale of their production, policy makers have overlooked smallholders' role as a powerful economic engine*" (Verdone 2018). If small-scale fishers are added, this number is likely to increase. This group constitutes the largest private sector although they are typically not considered so within the government policy of a number of countries. The Dalberg (2012) report identifies five primary growth pathways for deploying investment to address the current vacuum in smallholder finance:

(i) Replicate and scale existing financing models, such as the model proven by social lenders
(ii) Innovate new financial products beyond short-term export trade finance
(iii) Finance out-grower schemes of multinational buyers in captive value chains
(iv) Finance through alternate points of aggregation in the value chain
(v) Finance directly to farmers

Advantage of Community Eco-credit

We consider that the community eco-credit model could become a widespread additional tool in the financial toolbox that could influence several of these growth pathways because:

1. It incentivizes the stewardship of ecosystems and natural resources and supports the increased productivity of and income from these ecosystems and natural resources. This structure support changes in behavior leading to better ecosystem and livelihood outcomes for communities.

2. It aggregates farmers based on ecosystem/natural resources type and not primarily on value chains (although value chains do flow out of this ecosystem-first approach).
3. It is based on rights holders looking for partners – not capital looking for resources and labor (see below).
4. It provides, through grants to communities, the ability for smallholders to take loans and build up credit history.
5. By linking eco-credit group capitalization, it would also incentivize the greening of local business development.

Community eco-credit therefore provides one route for unbankable community members to develop a credit score, such that eventually, and with appropriate duty of care, they can bear a commercial loan, necessary to finance, for example, more expensive climate mitigation or adaptation technologies.

Aggregation for Ecosystem Management

In the eco-credit model, aggregation is via community institutions, not to meet the needs of a value chain of a commercial entity, but to better organize effective ecosystem restoration and management, and enhance ecosystem productivity. It comes from a different basis identified as "*investing in locally controlled ecosystems (e.g., forestry)*" (Elson 2012), representing a paradigm shift – away from capital seeking ecosystems and needing labor – toward local rights-holders managing ecosystems and seeking capital. It recognizes the need to distinguish and blend two types of investment:

- Asset investment (conventional investment in which the nominal value of underlying capital is expected to increase or at least not fall)
- Enabling investment (in which capital is foregone to build the self-sufficiency and attractiveness of the business in question)

Conclusion and Recommendations

The increasing recognition of the unfolding climate emergency has increased the urgency for public and private investment in ecosystem management and restoration as a key adaption and mitigation mechanism. Globally small-scale producers; fishers, foresters and farmers/pastoralists are the largest single group of stewards and primary investors in these ecosystems. Despite access to credit being a main driver behind adaptation to climate change at the farm household level (Di Falco et al. 2011), these groups are hardly served, and in fact are considered largely unbankable by the formal banking sector.

There is a great need therefore to find ways to fill this vacuum and bring inclusive finance for climate change adaptation to these communities. The CECF case study described here, using the concept of eco-credit, builds on the existing solidarity finance mechanisms which serve this group. It builds climate adaptation and ecosystem management actions into loan terms and incentivizes gender-responsive adaptation and mitigation at the community level, as well as supporting individuals and households. The CECF model has been tested in several locations in East and Southern Africa over 8 years and is ready for significant scale-up. Scale-up will be supported by the development of appropriate technology platforms and the development of a blended finance vehicle to capitalize and provide technical assistance to the eco-credit groups.

Other complementary mechanisms if used in the same location will significantly strengthen the CECF model. These complementary mechanisms include the commercial eco-credit of the Climate Smart Lending Platform, aligned VSLA groups, value-chains that do not undermine ecosystem, and where needed and aligned, social safety net funding. To fully take advantage of this model, we make the following recommendations:

- Scale-up and expand the operation and delivery of local autonomous community eco-credit funds.
- Make funding available to capitalize community eco-credit funds through the creation of large-scale blended finance vehicle (>US$2 billion) capitalizing this vehicle from multilateral and bilateral programs, carbon credits, private project finance, payments for ecosystem services, and corporate social responsibility.
- Support the development of value chains that support ecosystem restoration and sustainable-use that help communities conserve those ecosystems and support increased ecosystem productivity and poverty reduction.
- Commodity value chain companies with outgrower schemes (e.g., tea, coffee, cocoa, and timber) introduce eco-credit to their communities to enhance sustainable land and ecosystem management.
- Carry out further research into this model, individual, and behavioral responses and provide lessons and pathways for enhanced scale-up, including improved mechanisms for recording eco-compliance.
- The conservation community to provide more extensive and practical guidance in equitable sustainable management and conservation of ecosystems at the community level to enhance ecosystem productivity for local wealth generation.
- Explore the use of community eco-credit to support PES and REDD+ schemes.

Acknowledgments Appreciation goes to the Austrian Development Cooperation for funding the Building Drought Resilience project where CECF was developed.

Contents

Abstract

The objective of this study was to evaluate the pathways to enhance resilience to increased climate variability and directional change among pastoral households in Simanjiro District in Northern Tanzania. The study used household survey and rainfall and temperature data. Results indicate increasing temperature

and decreasing precipitation trends over the past four decades. Also, extreme climatic events, particularly drought, have become more frequent. Food and water insecurity are key factors causing an increased household vulnerability. Increased climate change-induced malaria prevalence poses additional health risks. Household adaptive strategies include livelihood diversification and migration. Local institutions are instrumental in enhancing climate change resilience at the local level. We conclude that livelihood diversification and migration are key pathways to enhancing households' climate change resilience.

Introduction

There is a strong consensus that temperatures, based on medium emissions scenarios, are likely to rise by more than 2 °C in most parts of Africa by the end of the century (Orlove 2019). Concomitantly, extreme events such as tropical cyclones, increasing rainfall intensity, and increased probability of drought are gradually becoming common (Kangalawe 2017; Pauline et al. 2017). Climate change impacts are already experienced in many locations (Pardoe et al. 2018). At a local level, these changes are manifested in many ways including shifts of rain seasons, erratic rains, extreme droughts and precipitation, strong winds, and higher temperatures (Berkhout 2012; Suckall et al. 2014). These changes have brought about adverse livelihood impacts such as reduced crop yields and changes in the crop calendar (Berkhout 2012; Mertz et al. 2009).

Climate change vulnerability is considered higher in developing countries due to particular socio-economic and ecological conditions that increase people's exposure to risk factors and reduce the adaptive capacities. Extreme events such as droughts and floods increase particularly rural livelihoods vulnerability because they rely more on climatic conditions (Sewando et al. 2016). Observed and projected changes in local climate conditions in Tanzania include precipitation variability increasing between 5% and 45% accompanied by a temperature rise of 2–4 °C (Trærup and Mertz 2011). The northern part of the country is reported to have undergone a shift in the onset of rainfall between 1980 and 2004 (Trærup and Mertz 2011). Associated with these changes are extreme events such as floods and a rise in human, crop, and animal diseases. Together, these changes adversely affect crop, mobility, and migration patterns among rural communities (Rodima-Taylor 2012).

The livestock sector in sub-Saharan Africa faces negative impacts of climate change (Suryabhagavan 2017). In Tanzania, livestock husbandry faces higher risks from these impacts associated with altered productivity in rangelands. Reduced productivity may adversely affect pastoral livelihoods and the economy of the entire livestock sector in the country. Apart from pastoral communities, the general population is likely to be negatively affected through high reliance on food products from grazing animals (Godber and Wall 2014).

Pastoral vulnerability will be further exacerbated by other livelihood stresses that characterize rural livelihoods. This includes high population growth in the context of a declining and highly dynamic resource base in Simanjiro District (Woodhouse and McCabe 2018; Lynn 2010). The combination of these effects with stressors ranging from short term drought and extreme precipitation events to long-term climatic shifts is likely to reduce further pastoralists' ability to sustain their current livelihoods system. The aim of this study was, therefore, to evaluate pathways to enhance resilience to increasing climate variability as well as directional climate change among pastoral households in Simanjiro District, Northern Tanzania. The study sought to answer four main questions: (a) What are the climate patterns and trends in the study area? (b) What is the status of household vulnerability to impacts of increasing climate variability and directional climate change? (c) What are the adaptive strategies employed by pastoralists in the study area in response to increasing climate variability and directional climate change? (d) What is the role of local institutions in enhancing the resilience of pastoral households to increasing climate variability and directional climate change?

Study Context and Methods

Covering an area of 20,591 km^2, Simanjiro District is located in Manyara Region of Northern Tanzania. The area's topography stretches from vast plains to scattered ridges and hill valleys. Climate is semi-arid with annual rainfall ranging between 650 and 700 mm. Rainfall is bimodal with short rains lasting from November to December and long rains from February to May. Temperatures range between 13 °C and 30 °C characterized by cold months from May to July and hot months between August and February (Homewood et al. 2009; Pittiglio et al. 2012). Livestock husbandry is common in drier areas while agro-pastoralism is predominantly practiced in wetter areas (Baird and Leslie 2013). The Maasai is the dominant ethnic group in the district, herding livestock of mainly indigenous stock (90%). Maize, beans, pigeon peas, wheat, and sunflower are the main crops grown for both commercial and consumption purposes (Baird and Leslie 2013).

The study used multiple data sources and data collection methods. Study wards were selected purposively based on the predominance of livestock production as the main occupation. Also, ward-specific factors such as livelihoods-ecological interlinkages were used to determine study wards. Household questionnaire surveys were conducted in eleven villages selected in four wards, namely, Endonyongijape, Emboreet, Loiborsiret, and Langai. Random sampling was used to select households targeting the household head. Key informants were selected using purposive sampling (Angelsen et al. 2012; Baird 2014). Household surveys were conducted between May and July 2014. Three aspects were used as measures of household vulnerability to climate change and respective adaptive strategies. These include food, water, and health. Food and water were assessed in terms of their availability (or lack thereof) and health situation was assessed in terms of the prevalence of climatically driven diseases. Adaptive strategies were assessed based on how households responded to cases of food and water scarcity as well as disease prevalence. Key informant interviews were conducted between February and March 2015. Household survey data ($n = 297$) and in-depth interviews ($n = 24$) were analyzed using descriptive statistical analysis. Monthly precipitation and temperature data were acquired from the Tanzania Meteorological Agency (TMA). Trend analysis was used to analyze climate data.

Conceptual Framework

This study adopted and operationalized the Sustainable Livelihood Framework (Chambers and Conway 1992) that has been widely used in socio-economic research on a range of topics falling within the poverty, livelihoods, and environment nexus (Reed et al. 2013). The framework offers useful analytical and empirical tools to order information and to understand the nature and interlinkages among livelihood aspects. The framework is built on four main components namely livelihood outcomes, livelihood assets, livelihood strategies, and the institutional context (Fig. 1). The institutional context is conceived as a crucial factor for sustainable livelihoods and for promoting local-level climate change resilience. For livelihood outcomes, the focus is on the household's vulnerability and

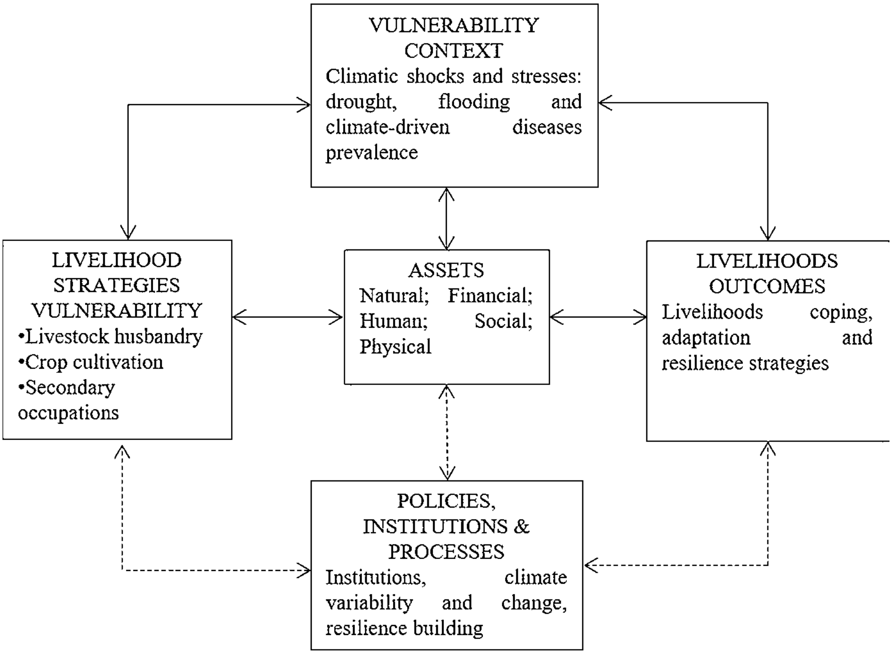

Fig. 1 Sustainable livelihoods framework. (Source: Adapted and modified from Chambers and Conway 1992)

responsive adaptation strategies. All four aspects are embedded in a vulnerability context as it is influenced by climate stressors and shocks.

The study was structured around local socio-ecological contexts that influence key livelihood strategies among study households. The policy environment and local resource management processes formed the institutional context. The vulnerability context is addressed by looking mainly at climate shocks adversely affecting household livelihoods, including drought, flooding, and diseases. These aspects are embedded in the four research questions of the study.

Results and Discussion

Local Climatic Trends

Temperature and rainfall trends are summarized in Figs. 2, 3, and 4. Fitted temperature values indicate an increment in average minimum temperatures of about 2 °C in the period from 1972 to 2013. Data show that the late 1970s to mid-1980s and early 1990s registered lower average minimum temperatures compared to the late 1980s and late 2000s, with relatively higher average minimum temperatures recorded. The average maximum temperature trend portrays a similar pattern with an overall increase in average maximum temperature of about 1.5 °C across the four-decade period based on the fitted line. However, the noted increment in average maximum temperature is statistically insignificant with 25% R-squared. The mid-1980s and late 1990s saw low average annual maximum temperatures. High average temperatures were recorded in the early and late 1980s as well as the first half of the 2000s. The R-squared value for the average minimum temperature indicates a statistically significant (72%) increase in minimum temperature over the 40 years.

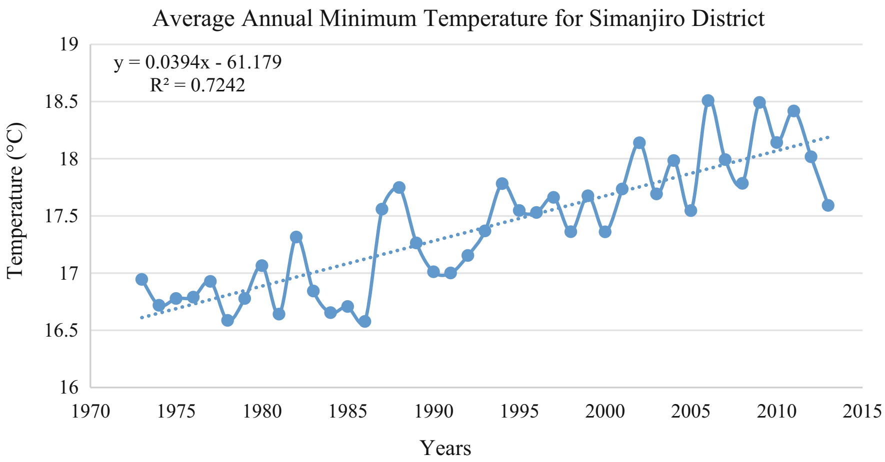

Fig. 2 Average annual minimum temperature for Simanjiro District. (Source: Ndesanjo 2017)

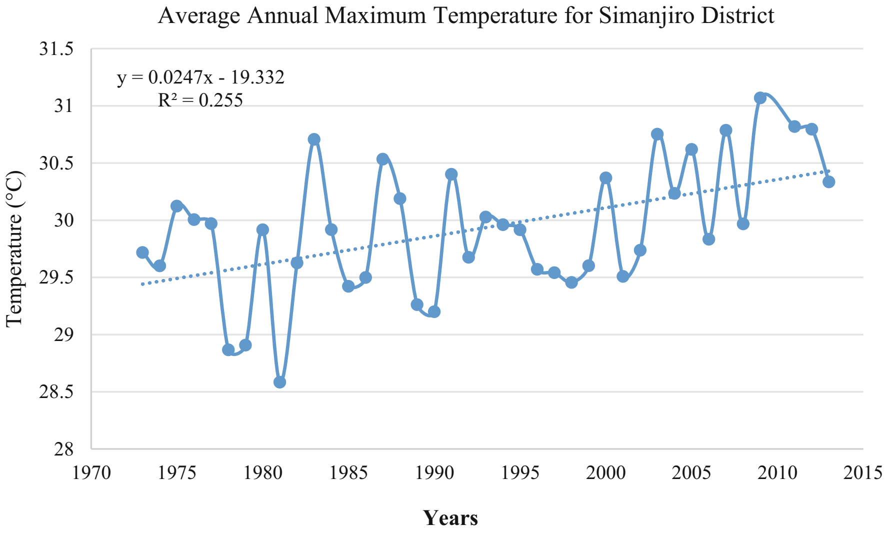

Fig. 3 Average annual maximum temperature for Simanjiro District. (Source: Ndesanjo 2017)

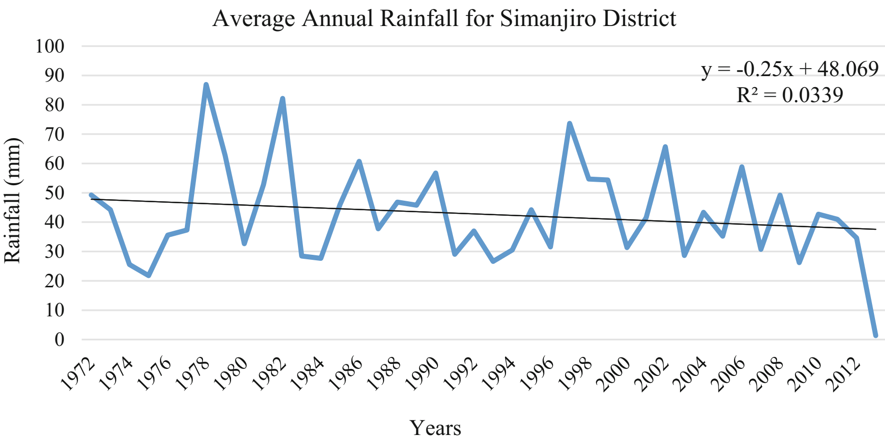

Fig. 4 Average annual rainfall for Simanjiro District. (Source: Ndesanjo 2017)

The rainfall trend indicates high average annual rainfall between the late 1970s and 1980s, late 1990, as well as early to mid-2000s compared to the mid-1970s, the first half of the 1980s and 2013 that saw a relatively low average rainfall. Overall, the 40-year data record in the study area reveals a decreasing but statistically insignificant trend in precipitation with an R-squared value of 3%.

Similar temperature and rainfall trends at both the country and continent levels have been noted in other studies such as that by Trærup and Mertz (2011) indicating temperature increase ranging between 2 and 4 °C combined with increasing precipitation variability on an increasing trend ranging from 5% to 45% in Tanzania. A study by (Pauline et al. 2017) indicates increasing extreme rainfall frequency. However, contrary to observations made in the two studies, the current study depicts a decreasing precipitation trend. Similar predictions were made by Paavola (2008) indicating decreasing precipitation up to 20% by 2100. The year 2013 saw extremely low rainfall, which may overly influence the predicted rainfall trend. However, no substantial difference was noted when omitting the year 2013 from the analysis.

Livelihood Profiles

The majority of surveyed households (86%) pursued an agro-pastoralist livelihood strategy. Other livelihood strategies were rare but include trade and wage employment by (3%) and (2%) of the households respectively. Off-farm labor and subsistence herding employ few households each at (2%). About 6% of households reported being engaged in a range of other livelihood occupations.

These results imply that apart from livestock husbandry as the main occupation in the study area, there is increasing adoption of crop farming suggesting a shift to agro-pastoralism as the main livelihood strategy. The increasing common combination of livestock and crop production reflects local communities' strategies to reduce the necessity to sell cattle to acquire food as well as a strategy to safeguard property (land) rights. Other drivers of increasing cultivation in the area include immigration by farming communities, drought, and livestock diseases, as well as government policies aiming to settle the Massai (Homewood et al. 2009). The relatively low percentage engaging in trading and wage employment may be attributed to cultural factors that discourage secondary economic activities. Hence, even when household members engage in secondary income activities, they usually invest the proceeds in livestock and farming (Homewood et al. 2009).

Household Vulnerability

The percentage frequency of common food items consumed is summarized in Fig. 5. Grain, legumes, meat, and milk contribute equally and constitute about 70% of food items consumed. Vegetables, bananas, and other food items are not commonly consumed.

Grain and milk have been widely documented as common foods in Maasai households (Hodgson 2011; Homewood 2004; McCabe et al. 2010). However, legumes are not common in Maasai pastoralists' diets. Discussions with household members during fieldwork indicate that the inclusion of legumes in their diets is an influence of other ethnic groups that have migrated to Simanjiro in recent years. Particularly, the *Waarusha's* (another Maa speaking ethinic group originating from neighboring Arusha) diet commonly contains legumes (mostly black beans locally known as *ngwara*). Although reported consumed with a high

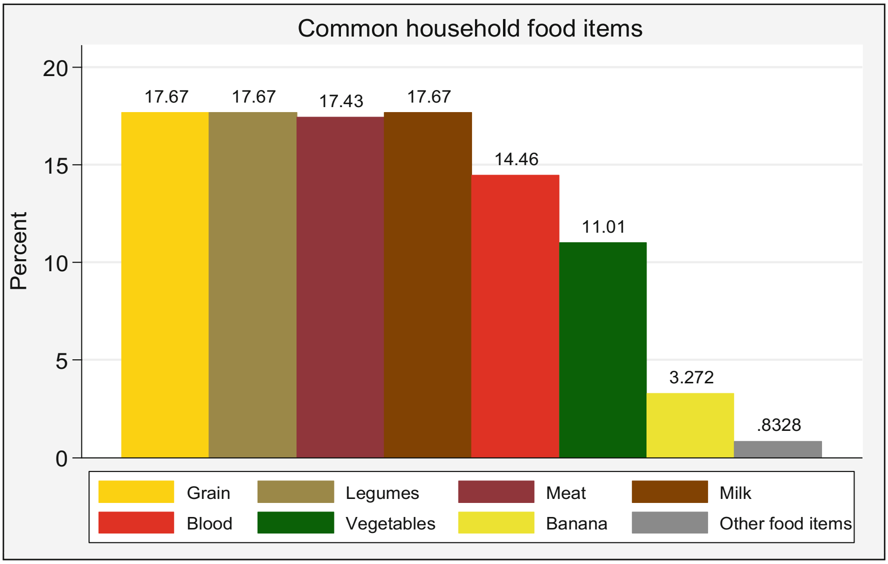

Fig. 5 Common food items consumed by households (numbers above the bars indicate percentage frequency). (Source: Ndesanjo 2017)

frequency, meat and blood are mainly consumed during special events and ceremonies, for instance, meat-eating feasts among Maasai warriors or initiation ceremonies. Besides, meat is a delicacy consumed at local weekly markets across Maasailand. Maasai rarely consume vegetables or bananas. The few records of these food items are most likely from non-Maasai households. Food consumption patterns depicted here indicate that livestock still is an important food source for most households either directly consumed or indirectly as a means to earn an income with which to meet other food requirements. However, as shown by Berkhout (2012) high dependence on livestock to supply household food requirements can increase climate change vulnerability in the long run.

Households were asked to rate food sufficiency during the previous 12 months and the results are presented in Fig. 6. There is no significant difference across the four wards in household food sufficiency ratings. About 63% reported that they had “somewhat sufficient” food while 29% reported a “somewhat insufficient” food supply during the past 12 months. Only 1% of the households reported a “very insufficient” food supply. Respondents were also asked about experienced incidents of household food insecurity and the exact months in which they occurred. The majority of households (78%) reported experiencing food insecurity between four and six months in the previous twelve months. The months in which food insecurity occurred are described in Fig. 6. These results point to food shortage incidents concentrating in the dry season lasting from August to December. This implies that food security is seasonal deterministic and that vulnerability will likely increase as a result of climate-induced exacerbation of drought in the dry season.

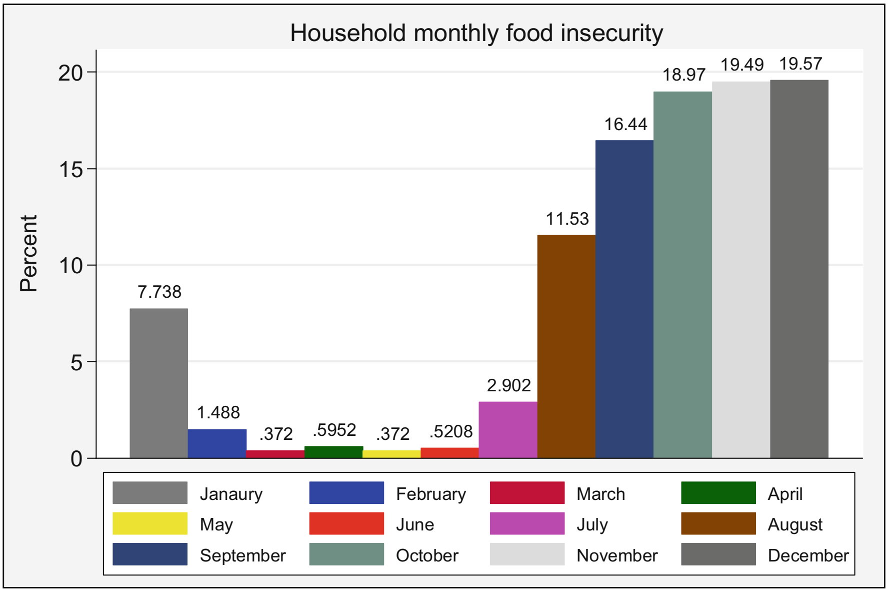

Fig. 6 Monthly household food insecurity incidents (numbers above the bars indicate percentage frequency). (Source: Ndesanjo 2017)

Water scarcity incidences and when such incidences occurred were recorded as a measure of household water security. About 98% of households rely on boreholes and dams as their main water source. Only 2% of households noted rain (harvesting) as a source of water for households. Households water sufficiency rating reveals that the majority of households (83%) considered water "somewhat available." Only 4% of households reported that water is "sufficiently available." About 13% considered "scarcely available." No significant difference was noted between wards. Duration wise, the majority of households (80%) reported experiencing water scarcity up to six of the previous twelve months. The months in which water scarcity incidents were experienced are presented in Fig. 7.

Several inferences can be made from these results. Firstly, most households have insufficient water available to meet year-round demand. Secondly, water scarcity coincides with the dry season indicating high seasonal household dependence on climate-sensitive water sources including rain-charged dams as well as groundwater. Thirdly, as many households rely on boreholes for their water requirements, financial constraints could affect their ability to access life-essential water.

In a study that examined the economic and environmental change in Niger, McKune and Silva (2013) linked erratic rainfall and increasing temperature to increasing threats to household water supply and the sustainability of their livelihoods overall. These authors also noted globalization as a driver of local vulnerability. Hence, in addition to the observed increase in the recorded measures of vulnerability, regional and global socio-economic stressors may have further local-level resource dynamic and vulnerability implications. In Tanzania and particularly

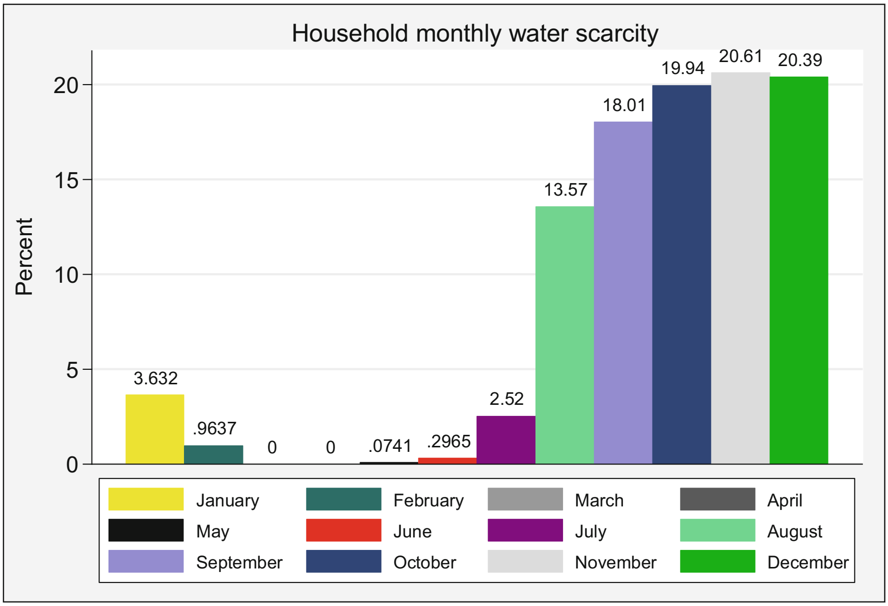

Fig. 7 Monthly household water scarcity incidents (numbers above the bars indicate percentage frequency). (Source: Ndesanjo 2017)

Simanjiro District, large scale foreign direct investments have been associated with pastoralists disenfranchisement potentially exacerbating their vulnerability to prevailing socio-ecological stresses and shocks (Hodgson 2011).

The prevalence of diseases was used as another measure of climate change impacts. About 69% of households reported malaria the most prevalent disease. Diarrhea, malnutrition, and "magical-related" illnesses such as curses were mentioned by only 2% of surveyed households. The majority of households (82%) indicated that illness affected them for up to five months. Only a few households (9%) reported illness affecting them up to six of the previous twelve months. Illness incidents were concentrated between February and July (Fig. 8).

Malaria prevalence is largely influenced by climatic conditions such as temperature and humidity which determine the procreation of its vectors which are mosquitoes (Irish Aid 2018). This likely explains the high frequency of malaria cases in the months of the wet season. The Maasai are known for their knowledge of herbs for traditional medicine (Kiringe 2006; Sindiga 1994). Hence, the high number of malaria cases despite this knowledge may imply an increasing trend of diseases that were previously uncommon in semi-arid areas like Simanjiro District and against which traditional ecological knowledge holds no remedies (van Lieshout et al. 2004).

Approximately, 63% of households use modern treatments as their main disease control mechanism, whereas about 34% opt for traditional treatment. However, both options were reportedly used interchangeably. The use of traditional treatments may,

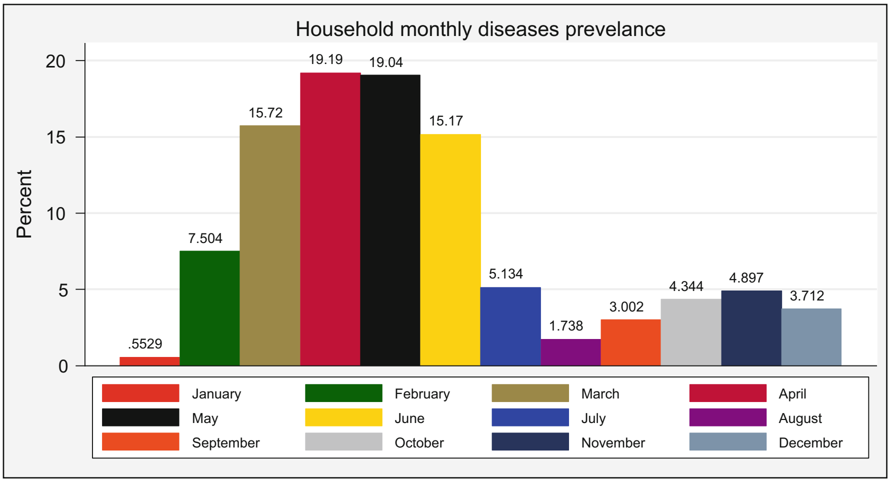

Fig. 8 Monthly household disease prevalence (numbers above the bars indicate percentage frequency). (Source: Ndesanjo 2017)

however, be under-reported here because mainly women seek this treatment including when children are ill and this may occur without the involvement of male household heads who were the respondents of this study. Modern treatments are likely to draw the attention of households' heads as this has financial implications that may require their consultation, whereas traditional medicine may be collected from the surrounding environment. Furthermore, traditional medicines are commonly used not only when a household member falls sick.

Climate Change Adaptive Strategies

This section addresses adaptive strategies employed by pastoralists in the study area in response to increasing climate variability and directional climate change. The majority of households (98%) indicated that they had food security enhancement strategies in place in the previous twelve months. About 72% of the households indicated that food reserves were the food security strategy employed. Seed banking was another food security strategy reported used, albeit by fewer households (22%). This implies that most households take the food security question seriously and prepare for shocks.

Households were also asked about alternative mechanisms employed when common food security mechanisms (food reserve and seed banks) failed following shocks such as livestock mortality and crop failure. About 58% reported that they resort to selling livestock while the rest (17%) mentioned liquefying household assets in response to shocks (Fig. 9).

These findings suggest that households' ability to purchase food is the most important food security strategy. A study by Miller et al. (2014) found that when

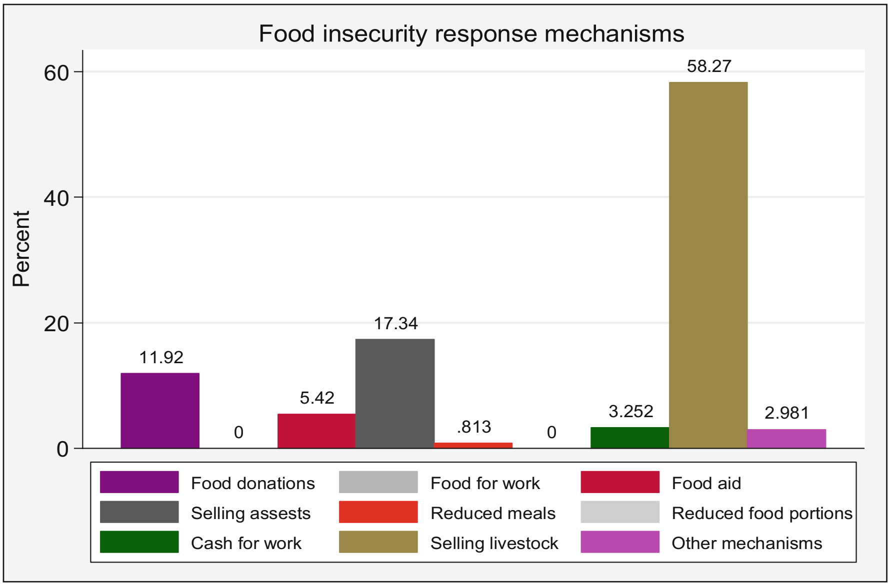

Fig. 9 Household food insecurity response mechanisms (numbers above the bars indicate percentage frequency). (Source: Ndesanjo 2017)

the situation is critical, pastoral households even purchase pasture access rights and other livestock feeds in addition to food for household members. Hence, the affordability of purchased food is critical for households to stay afloat during periods with severe food scarcity. This means that a reliable income source and asset base is crucial for household response to climate shocks as well as to directional climate change. Other studies have shown that the motivation for selling livestock in most pastoral households is to raise money with which to buy food (Pauline et al. 2017; Silvestri et al. 2012; Suckall et al. 2014).

Responses on strategies used to maintain water security indicate that about 60% of households have a water storage mechanism in place. Other strategies used to ensure water security are presented in Fig. 10. Households were further asked about the strategies used when they encounter acute water shortage especially when their regular strategies to secure water prove futile. About 42% reported that they substantially reduce their water usage. Others (40%) reported that the most ideal option is migrating temporarily to areas where water is accessible.

The predominance of water storage may arise from the fact that the studied wards are not serviced by piped water thus leaving water-storing as the main option. This result resonates with findings by (Trærup and Mertz 2011) in Northern Tanzania who found the absence of piped water to be the main determinant of water storage mechanisms. More importantly, the prevalence of water storage as an adaptation strategy may arise from the semi-arid condition of Simanjiro District most of the year, otherwise forcing people to cover relatively long distances on foot in search of water (Smith et al. 2000).

As water scarcity intensifies, the most prudent response mechanism is to reduce water consumption (Miller et al. 2014). This means limiting water use to cooking

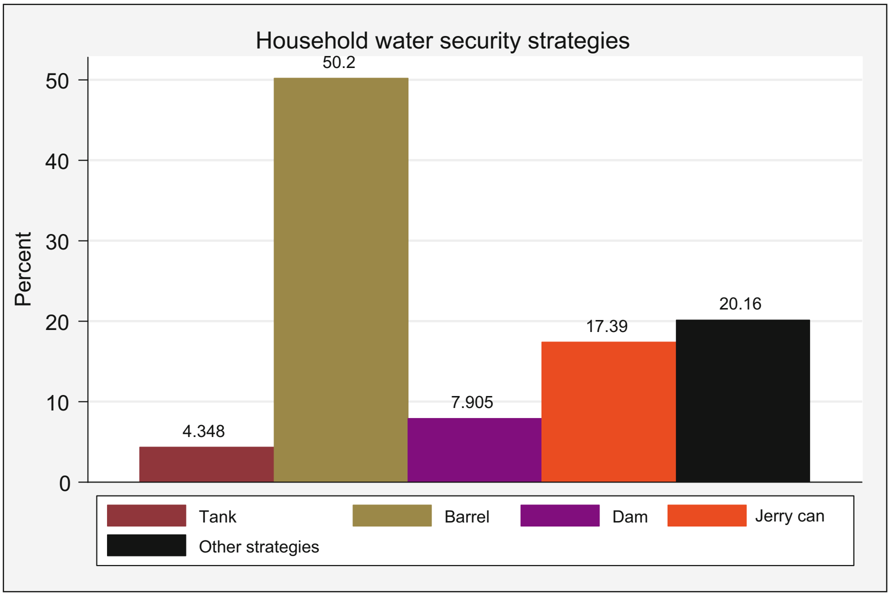

Fig. 10 Household water security strategies (numbers above the bars indicate percentage frequency). (Source: Ndesanjo 2017)

and minimal washing only. People often have to compete for water among themselves as well as with livestock for water during the dry season and the price of water from private boreholes often increases due to the high demand. Noticeably, water allocation in times of scarcity tends to favour livestock over people. Consequently, only those with sufficient financial resources will have access to water. As a result households are compelled to reduce their water use. These results deviate from those of Miller et al. (2014) who associated water scarcity in Simanjiro District with the replacement of customary arrangements with local government water resources management arrangements.

Water scarcity is a common determinant of migration among pastoral communities (Berkhout 2012; Brockhaus et al. 2013). However, only a small segment of household members temporarily migrates with herds to other areas in search of water. The migration of an entire household was very common before the *Ujamaa* socialism program in Tanzania in the 1970s (Hodgson 2004). Implementation of the program saw massive resettlement and sedentarization across Maasailand in Tanzania, which has substantially altered the migration patterns of pastoral communities in northern Tanzania.

Local Institutional Mechanisms and Climate Change Resilience

Information about the role of local institutional mechanisms in building climate change resilience was obtained from key informants ($n = 24$). One of the questions they were asked was to identify the nature of institutions that people approach for help in case of climatic shocks such as a drought. Based on responses, five categories of institutions were identified. All key informants interviewed ($n = 24$) indicated that that traditional leaders and the village government are the most common institutions approached for help. Local non-governmental organizations (NGOs) were another popular resort ($n = 23$). Civil society organizations (CSOs) ($n = 10$) and international NGOs ($n = 2$) were also mentioned as institutions that people approach for help.

The predominance of traditional leaders and the village government may be explained by the social organization of Massai societies and Tanzania's local government structure. Age is central for the social organization of Maasai society as duties and responsibilities are assigned according to age group (Ndagala 1991). Goldman and Riosmena (2013) describe that institutional frameworks among East African Maasai pastoralists are built on clan and age ties underpinned by decentralized leadership and traditional social networks. In the case of building resilience, local traditional leaders as the elders are in charge of resource control and allocation especially during periods of acute scarcity.

In Tanzania, the village council is the smallest local government unit overseeing day-to-day governance and development processes (Venugopal and Yilmaz 2010). This function makes the village government a must-go-to source for help whenever people encounter shocks that they are unable to handle. Similarly, interventions aimed at addressing local crises (including climate change) are channeled through village governments to people on the ground. Therefore, when people seek government support, the village government is the first place they would go. Thus, this institution is crucial in promoting local level resilience to climate and other socio-economic shocks.

Key informants identified several types of support provided by local institutions for building resilience (Fig. 11). Agricultural inputs form most of the support provided by traditional leadership ($n = 24$), village government ($n = 24$), and

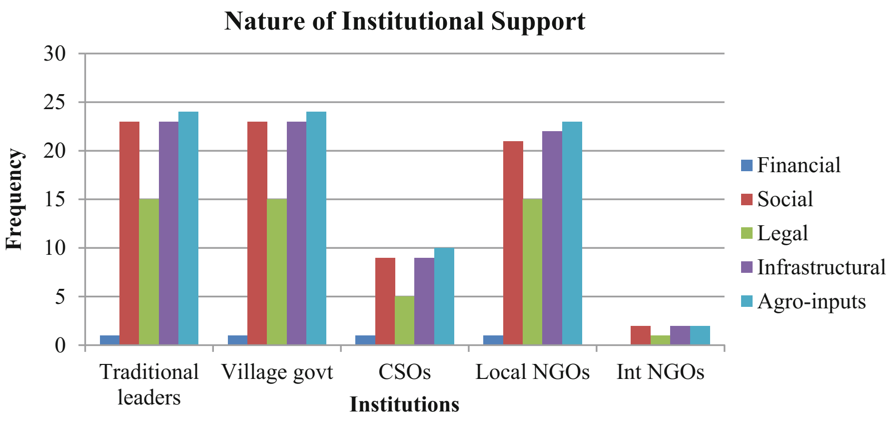

Fig. 11 Nature of support provided by local institutions. (Source: Ndesanjo 2017)

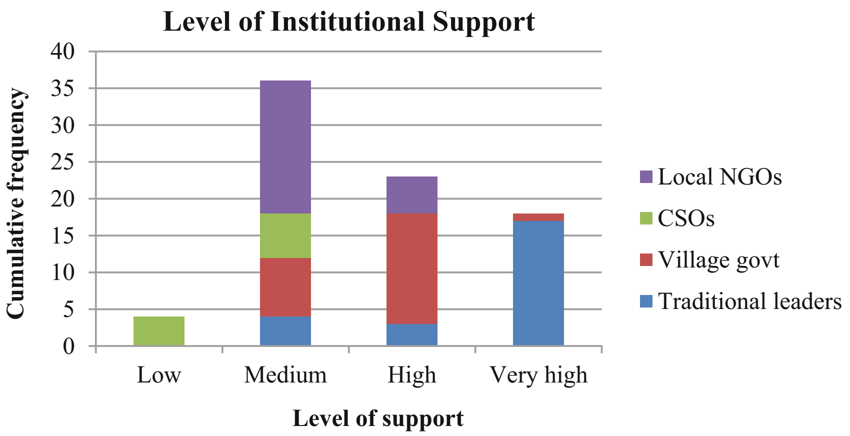

Fig. 12 Institutional support ranking. (Source: Ndesanjo 2017)

local nongovernmental organizations ($n = 23$). The same pattern was noted among civil society organizations ($n = 10$) and international nongovernmental organizations ($n = 2$). Other forms of support that were noted from the same institutions in order of their importance include infrastructural, social, legal, and financial support. Notably, unlike the rest of the institutions, financial support was not mentioned as provided by international nongovernmental organizations.

Institutional support in the form of agricultural inputs featured highest, possibly due to the dominant livelihood occupation, namely agro-pastoralism. This support was mainly in the form of extension services and disaster relief support when households succumb to shocks including mainly livestock mortality and crop failure due to drought. The role of local institutions in supporting local livelihoods and enhancing adaptability was noted in a study by Suckall et al. (2014) on community responses to climatic and socio-economic stresses in Zanzibar. The Zanzibar study found that local governments and cooperatives were instrumental in enhancing adaptive capacity not only through the provision of fishing and farming inputs but also providing market access assistance to local communities.

The level of support provided by institutions and their efficacy in promoting local resilience as ranked by key informants is presented in Fig. 12. Generally, most informants indicated that the level of support provided was medium. Traditional leaders were the highest-ranked local institution in terms of promoting local resilience followed by the village government. Local NGOs were ranked medium while civil society organizations were ranked lowest. Notably, international NGOs were not mentioned at all.

Traditional leaders affect the day-to-day life of pastoral communities particularly by leading people through extreme events such as drought. This explains the highly rated support of traditional leaders. The same applies to village governments. For example, findings by Miller et al. (2014) in Simanjiro-Tanzania indicate an increasing role of village committees in regulating resource use particularly water.

However, these results differ from observation by Berkhout (2012) who show that local government institutions are considered unable to support local communities' climate adaptation strategies. Noteworthy, civil society organizations and local NGOs were not rated favorably which may be explained by claims that most such organizations among Maasai pastoral communities are founded on the pretext of supporting local communities but in reality, serve personal interests of the founders (Hodgson 2011; Igoe 2003).

Limitations

The study has limitations. It adopted a cross-sectional household survey approach and is thus subject to data reliability challenges in terms of the magnitude of income, crop harvests, livestock births and deaths, and climate impacts with the possibility of strategic answers. Nondisclosure tendency among respondents especially with livestock wealth was encountered in the study. This could have affected the validity of the information provided by respondents despite taking some remedial measures such as deploying *Maa* speakers as field enumerators as well as triangulating the information with local informants such as village leaders, extension officers, and elders. The study also relied on recalled information by respondents, which is not always accurate.

Conclusions

This study sought to understand pathways to enhance the resilience of pastoral households in Simanjiro District-Northern Tanzania to increasing climate variability and directional climate change. A forty-year climatic trend analysis revealed changes in both temperature and precipitation in the study area. Also, extreme climatic events particularly droughts have become more common from the 1990s onwards. Drought is the main climate-induced shock to increasing household vulnerability in terms of food insecurity and water scarcity. Increasing prevalence of malaria during the wet season may also be attributed to climate variability and directional change and constitutes an increasing health risk to pastoral households. The main adaptive strategies employed by households include livestock and asset selling to address food needs and water storing accompanied by reduced usage. Local institutions and primarily traditional leaders and village governments were reported as fundamental in building local climate resilience.

The study concludes as follows. First, following observed climate trends in the study area, surveyed households are likely experiencing and responding more to local variability of the climate than permanent long-term shifts in the climate system. Second, country and regional level climate trends obscure local (district and village) level climate situations. Third, seasonal deterministic trends of food and water availability and/or scarcity as well as disease prevalence indicate the direct influence of local climate on household livelihoods. Fourth, diversifying livelihoods from agro-pastoralism and migrating to areas better endowed with resources such as water are important pathways to climate resilience. Finally, due to social proximity and mutual understanding between local communities and their local (traditional) leaders, these (leaders) play a crucial role in promoting local level resilience building.

It is recommended that creating mechanisms to monitor the local climate and regularly inform local communities is crucial to enable them to adjust their activities accordingly. Such an exercise should reflect the local context in terms of information dissemination and uptake as well as local livelihoods and seasonality. Also, a gradual and medium to long-term livelihood diversification initiative is a highly recommended policy strategy to increase resilience among pastoral communities as opposed to the current policy which condemns pastoralism as a backward and environmentally destructive activity. Finally, future research on local climate resilience should focus on evaluating livelihood diversification scenarios and assess trajectories. Equally, local knowledge systems and institutions should buttress policy-making and implementation to promote local resilience.

Abstract

Kenya is among the world's most vulnerable countries to climate change-related stresses and extreme events. According to FAO, over 75% of the country is classified as arid and semiarid with rainfall availability and amounts quite unevenly spread across the different parts of the country. The country has very skewed distribution of water sources with the western area being relatively well endowed with abundant water resources. The exponential growth in the country's population over the years, together with rapid environmental degradation and poor water resource development programs, have worsened the country's vulnerability to the effects of climate change. Ethnic conflicts over land resources are common-place in Kenya's rural areas where majority of the people live and the effects of extreme climate change events are likely to exacerbate resource-based conflicts. In this chapter we explore the extent of climate change-induced resource conflicts in three counties along rainfall availability gradient, namely, Kiambu County which experiences relatively high rainfall and also high urban population, Machakos County, which generally experiences modest rainfall availability, and Makueni County regarded to be one of the most arid and semiarid counties in the country. Data were collected in 2017 using a closed ended questionnaire. Between-subjects MANOVA design was used to examine relationship between independent and dependent variables. Qualitative results of the open-ended question reveal that climate change impacts can be diverse, particularly for vulnerable regions such as arid and semiarid regions such as Makueni County. In this county, respondents mentioned nine ways climate change had impacted communities, with the most frequently mentioned impact being increasing food insecurity followed by increasing water shortages. Machakos followed with seven impacts mentioned starting with increased water shortages followed by scarcity of pasture. In Kiambu County, only four impacts were mentioned with food insecurity being frequently mentioned among the list of impacts of climate change in the county. Results of the descriptive and inferential statistics reveal that resource-based conflicts vary along the hydrological gradient. In Machakos County, resource-based conflicts are perceived to have risen during the last 5 years (M = 3.92, SD = 0.66), followed by Makueni (M = 4.10, SD = 0.670). Kiambu residents do not consider resource-based conflicts to have risen during the last 5 year, (M = 2.50, SD = 1.38). Differences in severity of climate related conflicts are statistically significant, $F_{2, 76} = 12.78, p < 0.01$. Also, climate change is strongly perceived to be a factor in the rise of resource-based conflicts in Machakos County (M = 4.10, SD = 0.67). In Makueni County as well, climate change is perceived to be a significant contributor to resource-based conflicts (M = 3.98, SD = 1.70). These findings have relevance on county and national policies targeted to build capacity to cope with climate change induced resource-based conflicts among grassroot communities in Kenya.

Introduction and Background

Global climate change is one of the major socioeconomic and environmental challenges facing communities in the twenty-first century. The impacts of climate variability including extreme climate events are many, complex, and wide-ranging, and include among other human conflicts. In the African continent, the impacts of global climate change are exacerbated by environmental degradation, political instability, poor governance and corruption, rapid population growth, and urbanization, largely in form of informal settlements. Impacts on the agricultural sector, especially impacts on export crops such as coffee are feared to affect the economic production and growth in different regions. Reduction in acreage under cash crops has meant low income. For the last few decades, climate change has affected many regions of the world. According to Hussein et al. (1999), climate change exacerbates conflicts. The authors have argued here that human activities coupled with droughts of the 1970s and 1980s caused a lot of tensions in Africa. Communities got into conflict with each other as they competed over diminishing resources. This view gets support from Benjaminsen and Ba (2009). According to the duo, the conflicts between farmers and herders in the Niger Delta of Mali were escalated by the droughts mentioned. Herders grazed into the grain fields of cultivators leading to conflicts that at times became violent. Such conflicts are thought to have undermined the loyalty to the government. Governments have been accused of favoring one party at the expense of the other. In the case of Mali, the government was accused of favoring farmers and it was not taken kindly by herders. This resulted to frequent conflicts leading to stagnation in development. Peters and Mayhew (2019) have mentioned the increasing conflicts in Africa and the Arabic states while Price (2019) has given details of worrying trends in Afghanistan all coming from climate change conflicts. It is evident that climate change has scared the world with the scare being more real as years pass by.

In sub-Saharan Africa, climate variability threatens to reverse the decades of government investments to eradicate extreme poverty. Africa faces some of the worst forms of conflicts, and it is feared that climate change will further confound governments' investments for peaceful coexistence amongst communities and nations. While majority of the sub-Saharan African nations failed to achieve the Millennium Development Goals, it is feared that climate variability potentially poses a significant threat to the region's efforts to achieve the Sustainable Development Goals (SDGs). Most countries in SSA rely on rain-fed agriculture for livelihoods and incomes, thus extreme events such as the increasing and more prevalent and prolonged droughts with the continent's limited surface water resources complicates achieving some of the SDGs such as ending poverty in all its forms, ending hunger and achieving food security as well as ensuring healthy lives and economic growth among others. Sub-Saharan Africa has incidentally the most rapidly growing urban population posing real threat to water available for food production and other economic activities. In the huge arid and semiarid areas of SSA that are predominantly the home of pastoral communities, growing scarcity of pasture and water for livestock is likely to remain a huge driver of conflicts. Limited investments on technology and weak institutions and governance further comprise sources of vulnerability to Africa's development sectors which include climate change.

Kenya is among the world's most vulnerable countries to climate change-related stresses and extreme events. Seventy-five percent of Kenya's land mass is classified as arid and semiarid with rainfall availability and amounts quite unevenly spread across the different parts of the country. The country's western region is relatively well endowed with abundant water resources. The exponential growth in the country's population over the years, together with rapid environmental degradation and poor water resource development programs, have worsened the country's vulnerability to the effects of climate change. Ethnic conflicts over land resources are common-place in Kenya's rural areas where majority of the people live and the effects of extreme climate change events are likely to exacerbate resource-based conflicts. In this chapter we explore the extent of climate change-induced resource conflicts in three counties along rainfall availability gradient, namely, Kiambu County which experiences relatively high rainfall and also high urban population, Machakos County, which generally experiences modest rainfall availability, and Makueni County regarded to be one of the most arid and semiarid counties in the country.

Literature Review

Theoretical Review

This chapter draws on Strain Theory which posits that achievements of individuals and communities is pegged on goals and aspirations in life, and whenever these goals and aspirations are threatened, conflicts are bound to take place. The extreme climatic changes taking place in the world are threatening the ability to achieve the desires of different individuals and the society at large leading to tensions and conflicts. According to Agnew (2012), inability to achieve different objectives and goals lead to change in behavior. When climate changes occur, the economic status of people gets affected negatively. Increasing desertification has led to diminishing fodder for animals as well as lower production on the part of cultivators. The conflicts witnessed between farmers and herders in Tanzania attest to this. According to Benjaminsen et al. (2009), the conflicts whose source was climatic changes left a lasting mark. Enmity and killings resulted. The approach taken by Strain Theory is Malthusian. As the amount and quality of resources decline, competition between individuals as well as groups increases. Meierding (2013) contends that competition over resources result to violent clashes. In the African region, competition over pasture and water has been the main source of conflicts. Increasing desertification has also contributed to these conflicts. As cited elsewhere in this work, the conflicts have resulted to dire consequences including the loss of lives.

The Relative Deprivation Theory developed by Samuel Stouffer during World War II purports that people take action to acquire something that others possess and which they believe they too should have. According to Stouffer, opportunities, status, and desire for material gain at times lead to use of force. When resources become diminished or of lower quality, those who miss out feel disadvantaged in comparison to others. Those that are relatively deprived feel anger especially when they feel the privileged are not willing to share. Sunga (2014) contends that climate change creates conditions that make ethnic groups struggle for scarce resources. The author argues that those who fail to get the scarce resources are motivated to use violence which ends up in serious atrocities. The author views extreme climate change as a risk factor and a major cause of ethnic violence engulfing the developing countries. This argument raises serious concerns and calls for attention to the changing climate conditions across the world.

The Social Disorganization Theory has been used to explain the security implications of climate change. Due to climate change, communities have been on the move looking for less hostile weather to cultivate and herd animals. This has led to push and pull not only between man and man but also between man and wildlife. Communities become disorientated by climate change and this affects development. The energy and time that would have been devoted to economic progress is lost to look for better living conditions. Social cohesion and integration become compromised. Elsewhere in the African region, climate change has led to drought, landslides, desertification, pollution, sand storms, disease, hunger, and unusual weather (Folami and Folami 2013). In Northern Kenya, desertification has escalated with increase in sandstorms. Getting forage has become a hard task with conflicts over water increasing. The conflicts have at times led to deaths and fear. It is not uncommon for communities to attack their neighbors in the name of restocking when animals have been wiped out by drought.

Empirical Review

Climate change is arguably one of most serious environmental problems facing humans in the twenty-first century. The consequences of increasingly variable climate and extreme climate events are many and complex, among them resource-based conflicts. Climate-related resource-based conflicts are extremely varied from local, regional, to global contexts. Climate variability may directly and indirectly trigger diverse conflicts. Conflicts may be triggered for instance when communities migrate as a response to cope with impacts to different areas where they exert increased competition for resources in their new destinations. The impacts of climate change are particularly more profound in communities where people rely on their immediate environment for basic needs. In Nigeria, for instance, Folami and Folami (2013) have noted that climate change has resulted into extreme droughts triggering severe water scarcity.

Although impacts of extreme climate change events are felt most in the developing nations, developed nations too experience challenges of climate variability. In the United States, damages from tornadoes, floods, droughts, hurricanes, and wildfires during 2011 caused more than $200 billion in losses and over 1,000 deaths. Tornadoes, floods, droughts, hurricanes, and wildfires were all attributed to climate change (Scott and Andrade 2012). In South Africa, it is feared that grain production is likely to reduce due to climate change. According to Kuhlmann et al. (2012), climate change has had disastrous effects on pollination of flowering plants. Bees have been noted to shift to the more suitable areas to survive. In the same line, climate change has lowered grain production leading to starvation for the people. The increase of starvation, hunger, and want is a trigger for conflicts.

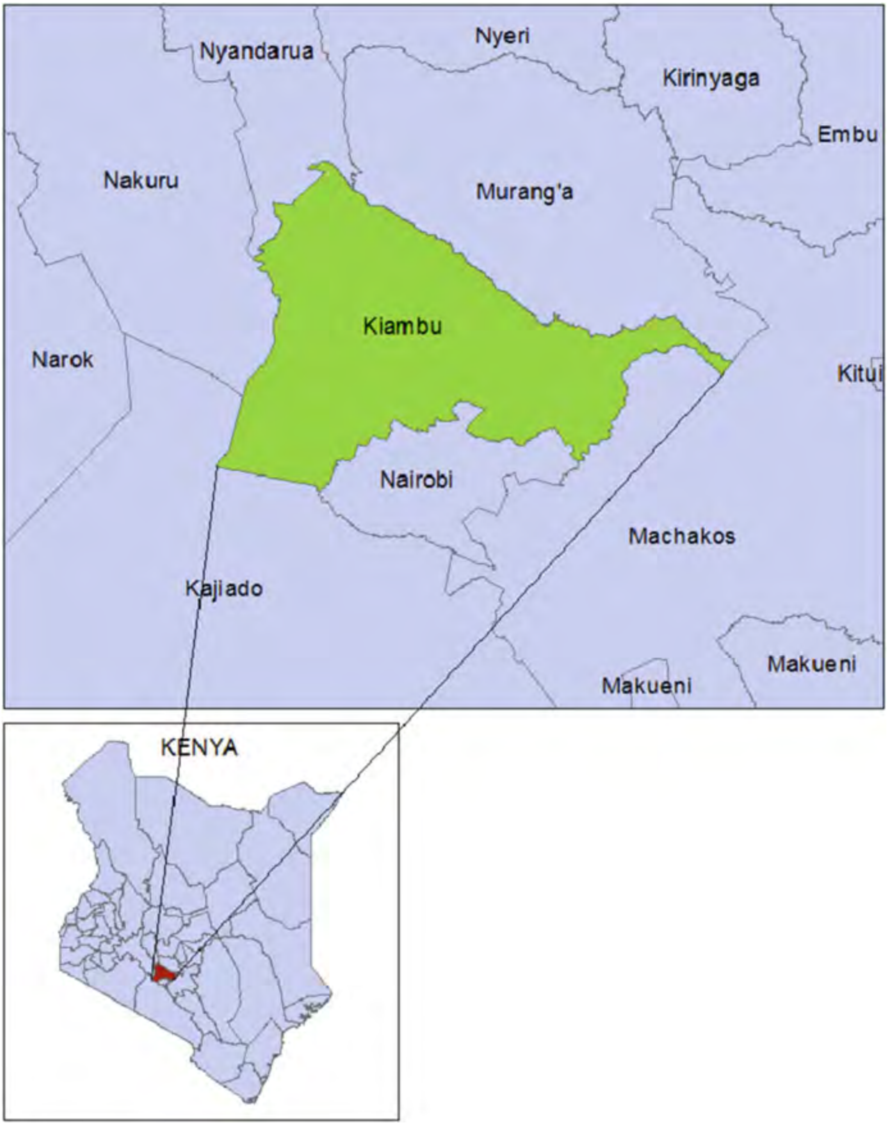
The past 10 years have witnessed conflict with nature resulting from improved technology and the fact that man is demanding more from nature. In developing countries, conflicts with wildlife have increased. Elsewhere, improved technology has enabled the powerful to clear large areas of land and exploit the natural resources at an alarming rate. Since climate change does not limit itself to a geographic region, the effects of change are felt far and wide. In sub-Saharan Africa, many communities live in economically poor and marginal regions. They therefore experience shortage of water and pasture the greater part of the year. Arable land is scarce (Serdeczny et al. 2017; Hadush 2018).

In Northern Kenya and upper Eastern region of the country, most people depend on those scarce resources for survival. Since rainfall determines the availability of water, pasture, milk, crop yields, and so on, its failure causes a lot of stress. Resources that people depend on get scarcer. Drying of shallow wells and earth dams lead to pressure that more often than not culminates into full blown fighting. Witsenburg and Adano (2009) have noted that in Marsabit region, conflicts over water and pastures have become a common phenomenon particularly during dry spells. Also, the authors have noted a rising competition between livestock and wildlife over pasture and water.

Research Methodology

The study used a cross-sectional survey design to collect and analyze data. Survey method has several benefits; it allows rapid collection, analysis, and reporting of research findings over relatively short period of time. Longitudinal design may, however, be needed to allow observations of conflict related to resources use over time and the mechanism driving the conflicts.

A Map of the Study Site



Brief Description of the Study Sites

Kiambu County

Kiambu County has warm weather with the warmest month being 18.7 °C and the coolest month registering 12 °C. The hottest months are January–March and September–October, while the coolest months are June and July. The rainfall aggregate for the county is 1000 mm annually. This is quite conducive for agriculture activities. Kiambu covers an area of 2,543.2 km^2. It has a population of 2,417,735 people according to Kenya National Bureau of Statistics (GoK 2019). The population density is 658.14 people per km^2. The population is predominantly Kikuyu community who comprise the most populous tribe in Kenya. Other ethnicities include Asian and Caucasian population working as businessmen or for various foreign missions. The county is cosmopolitan and hosts other communities such as Luhya, Luo, Maasai, Kamba, Meru, and Kalenjins, among others. The poverty index for the County is 21.3. The County relies mainly on agriculture and industries to sustain its economy.

Machakos County

Machakos County stretches from latitudes 0° 45′ south to 1° 31′ South and longitudes 36° 45′ east to 37° 45′ east. It is mainly semiarid with temperatures between 18 °C and 29 °C, July being the coldest month while October and March are the warmest. The average rainfall is between 500 mm and 1300 mm. The short rains are expected in October and December while the long rains are expected in March to May. Machakos County suffers from periodic drought between February–March and August–September. The County covers an area of 6208.2 km^2 and has an estimated population of 1,421,932 (GoK 2019). The population density is 240 persons per km^2 -and the poverty index is 59.6%. Kambas are the predominant tribe of Machakos County although other tribes live and work in the county. The county practices subsistence farming of maize and drought-resistant crops such as sorghum, millet fruits, and vegetables.

Makueni County

Makueni County is located within the former Eastern Province just like her neighbor Machakos. It lies between latitude 1° 35′ and 3° 00′ south and longitude 37° 10′ and 38° 30′ east. It is populated mainly by the Kamba community although many other communities live and work there. The County occupies 8,034.7 km^2 with a population of 987,653 people GoK (2019). Of the three counties under the study, it is more sparsely populated with population density of 120.9 per km^2, though still slightly higher than the national average. The climate of the County is generally dry. The county receives low inadequate rainfall of 600 mm with the average temperature being 23 °C to sustain any meaningful agriculture. The residents hence experience constant crop failures and are consequently in the list of counties in need of support of relief food. To sustain their livelihood, the residents harvest sand, degrading the few seasonal water sources existing. Makueni suffers from a poor road network in contrast to the other two counties under study.

Data Collection

Data was collected using closed ended questionnaires. There were eight Likert scale type of statements and participants were required to rank their responses, each statement on a scale of 1 = somewhat becoming less prevalent to 5 = becoming more prevalent. The sampler statement is "*conflicts related to scarcity of firewood, such as people illegally collecting/harvesting firewood in neighbors farms, quarrelling over collection of firewood*". Variable two measured participants' ranking to climate change as contributor to a list of similar statements related to conflicts to resource use according to scale 1 = does not contribute at all to 5 = contributes a lot. Additional sociodemographic data collected included gender of the respondent, education attainment, and age category. A total of 85 participants completed the questionnaires, comprising 30 from Makueni, 30 from Machakos, and 25 from Kiambu counties, respectively.

Data Analysis

Data was analyzed using cross-tabulation to compare percent frequency distribution by county. In addition, a one-way multivariate analysis of variance (MANOVA) between-subjects design was used to investigate the relationship between dependent variables and the independent variables, region, and gender.

Results and Discussions

Sociodemographic Characteristics of the Sample

Results of the sociodemographic characteristics of the sample are summarized in Table 1.

Table 1 Sociodemographic characteristics of the sample

Variable	Categories	Makueni (%)	Machakos (%)	Kiambu (%)
Age	18–29	**30**	**33.3**	**4.2**
	30–39	**26.7**	**23.3**	**33.3**
	40–59	**40.0**	**43.3**	**41.7**
	60 years or older	**3.3**	**0.0**	**20.8**
Education attainment	**Certificate**	**3.3**	**36.7**	**91.7**
	Diploma	**23.3**	**30.0**	**8.3**
	Postgraduate diploma	**16.7**	**6.7**	**0.0**
	Bachelor's degree	**40.0**	**23.3**	**0.0**
	Postgraduate degree (Master or PhD)	**16.7**	**3.3**	**0.0**

The frequency distribution in Table 1 shows that majority of respondent were in the category of age 40–59 years. Machakos had 40%, Makueni 43.3%, and Kiambu 41.7% in this category. Although the age bracket in this category was widespread in comparison to other categories, this category of respondents is made up of adults who have lived for a long time to experience changes brought about by climate change. Unlike those above 60 years who might suffer memory lapse, the 40–59 years group availed information which is quite vital. The 40–59 years category group has lived long enough to experience the changing climate patterns and conflicts over resources. It is surprising that while Kiambu had 20.8% of respondents being over 60 years, Makueni had only 3.3%, while Machakos had none. The lowest category in age had large numbers for Makueni (30%) and Machakos (33.3%), while Kiambu had only 4.2%.

The implication here is that climate change hardships might have lowered life expectancy in Makueni and Machakos. The higher percentage of those over 60 years in Kiambu is probably attributable to less climate change-related conflicts leading to longer life as a result of reduced stress. Alternatively, due to higher levels of development and probably having a more informed community, Kiambu County could be having people who are practicing more family planning hence a lower percentage of the young (age 18–29).

The findings in education achievement among respondents were quite amazing. It was surprising that the bulk of respondents in Kiambu had their highest education achievement being a certificate (91.7%) and diploma (8.3%). Makueni and Machakos which are not as highly developed had respondents with higher education and of degree and above at 56.7% and 26.3%, respectively. This is probably an indicator that due to conducive climate in Kiambu, people are actively involved in production in agriculture and industry and therefore do not pursue higher education despite having very good educational facilities as compared to its counter-parts. Probably in Makueni and Machakos, unreliable rainfall forced the community to seek high level of education in order to stand a better chance of employment to earn a living. The implication here is that climate change conflicts in both Makueni and Machakos have some positive contribution.

Perceptions of Impacts on Climate Change on Livelihoods

Respondents were asked what they perceived to be the impacts of climate change on peoples' livelihoods. Results are summarized in Figs. 1, 2, and 3. Climate change has had varied negative impacts on people's livelihoods with the more serious ones being water shortage and food insecurity though Kiambu County appears not affected by water shortage. The number of women affected by the adverse effects of climate is more than that of men probably because men venture into other income earning activities. It is possible that because of the arid nature of Makueni and Machakos, women feel the pinch more as they are the ones who must trek long distances looking for water and searching for food. While it is only five males who mentioned food insecurity in Makueni, the number of females is worrying as it

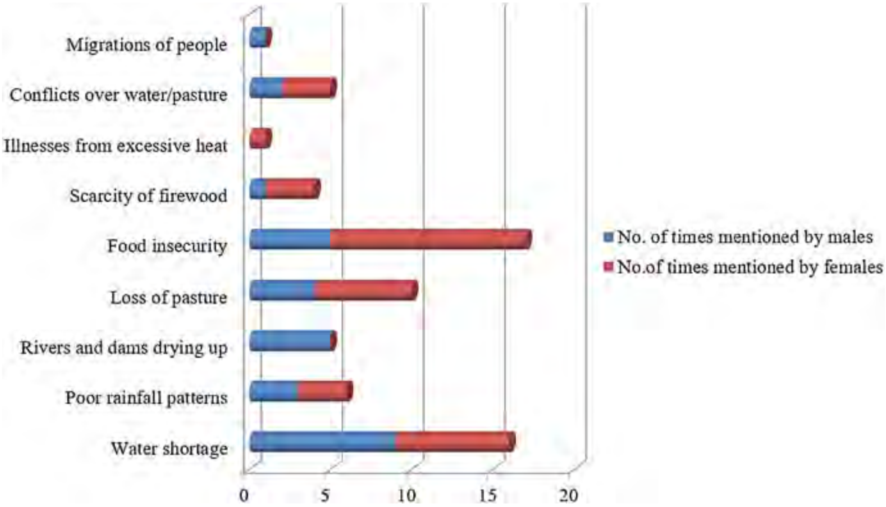


Fig. 1 Frequently mentioned impacts of climate change on livelihoods in Makueni County

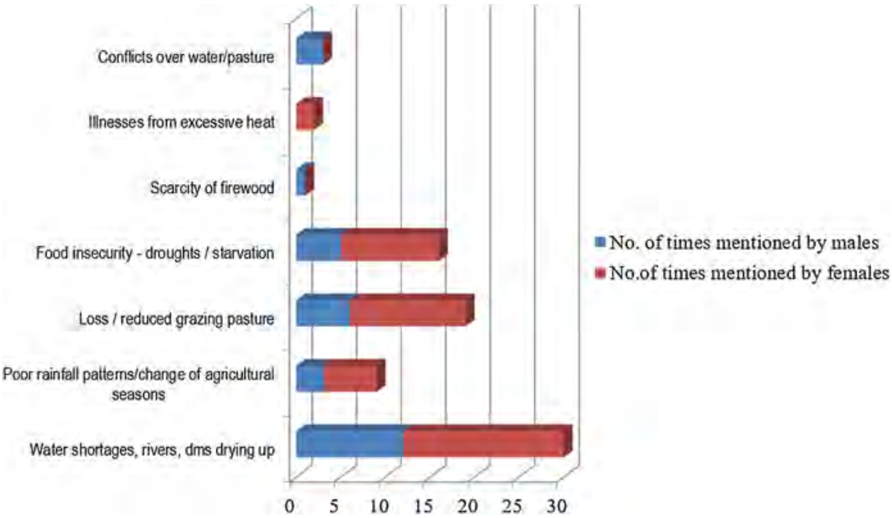

Fig. 2 Frequently mentioned impacts of climate change on livelihoods in Machakos County

stands at ten which is double that of men. In Machakos, it is surprising that while only three males mentioned that food security emanates from climate change, ten females which are more than triple the number had a similar feeling. The case of Kiambu County is different with nine males and eight females sharing a similar view. While women shoulder almost the entire burden of feeding the family in the arid counties of Makueni and Machakos with men leaving for urban centers to look for green pastures, feeding the family appears a shared burden in Kiambu.

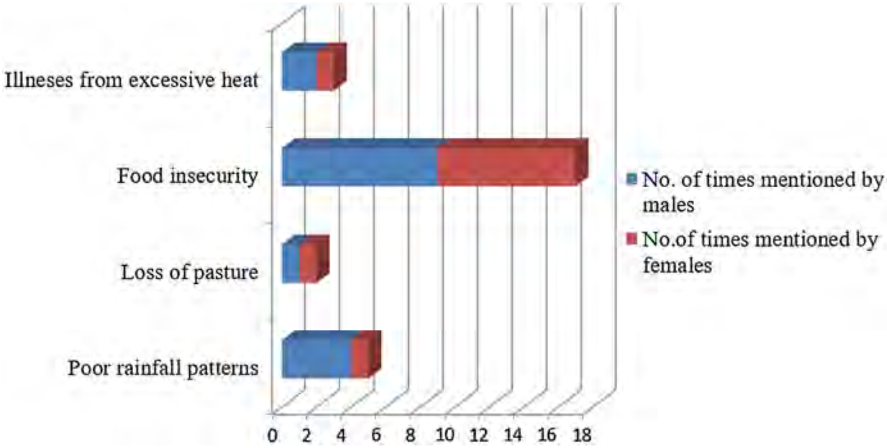

Fig. 3 Frequently mentioned impacts of climate change on livelihoods in Kiambu County

On water shortage, Makueni and Machakos feel the adverse effects of climate change. While nine males and seven females have lamented on water shortage in Makueni, a similar trend is seen in Machakos where 8 men mentioned water scarcity with the number of females almost doubling at 15. For the case of Machakos, it is surprising that more men than women lamented on water shortage. It is worth researching more on this area to establish why males would feel the pinch of water scarcity more than women. For the men reporting water shortage, it is possible that water vending is an income generating activity due to the biting water shortage in the semiarid zone. In Machakos, Kamba women and children are responsible for livestock feeding and fetching water.

Probably because of being in the highlands, Kiambu does not appear affected by water shortage. For Kiambu, having embraced the technology of water harvesting and having embraced water piping, there was no respondent who mentioned water shortage.

Wilting of plants and pasture is also felt more in Makueni and Machakos with the number of men and women being 4:6 and 6:13, respectively. In Kiambu, the numbers are a paltry 1:1.

Water shortage is an issue of major concern in Makueni and Machakos counties that needs quick response. Unless climate change is addressed quickly, lives will continue being threatened. It is surprising that even an area like Kiambu which is in the highlands has started experiencing food shortages occasioned by changing rain patterns due to climate change.

Citizens Perceptions of the Prevalence of Climate Change Induced Resource-Based Conflicts

Next was a Likert scale type of questions in which respondents were asked to rank prevalence of resource-based conflicts in the counties during the last 5 years.

There were eight Likert scale type of statements and participants were required to rank their responses each on a scale of 1 = somewhat becoming less prevalent to 5 = becoming more prevalent. The sampler statement is "*conflicts related to scarcity of firewood, such as people illegally collecting/harvesting firewood in neighbors farms, quarrelling over collection of firewood*". Respondents' responses are summarized in Table 2. Conflicts related to people illegally watering their animals in other people's water points were perceived to be becoming somewhat prevalent or more and more prevalent in Machakos at 73.4% while Kiambu had only 28% sharing this perception. Majority in Kiambu (68% of respondents) perceived that conflicts related to a person watering their animals in someone else's water point were becoming either less or somewhat less. It is also quite striking that conflicts related to scarcity of grazing pastures are quite high in Machakos and Makueni while Kiambu reflects a very different picture. The reason for this conflict could be that the community practices both types of farming. Arable farming covers the largest part leaving a small portion for herding/grazing, unlike Kiambu residents who use zero grazing. The kind of livestock farming is an indicator of increased conflict due to scarce grazing resources. These findings are consistent with those of other researchers (Ifejika Speranza 2010). Conflicts over resources such as grazing fields and food have been reported. Over 73% of respondents in both Makueni (73.3%) and Machakos (80%) perceived conflicts related to scarcity of grazing pastures becoming somewhat prevalent or more and more prevalent in comparison to Kiambu which had only 36% perceiving the same. While 40% of respondents in Kiambu perceived that conflicts related to scarcity of grazing pastures were becoming less and less, none of the respondents of either Makueni or Kiambu felt the same. It was also striking that while 66.7% of respondents in Kiambu felt that conflicts related to people illegally harvesting grazing materials were becoming less and less frequent or somewhat less frequent, only 6.6% of those in Machakos felt the same. Makueni posted 29.9% with similar feeling. Conflicts related to scarcity for food had even more interesting results. While none of respondents in Machakos perceived this becoming less and less, almost half of those in Kiambu (48%) perceived such conflicts becoming less and less prevalent. On the other hand, conflicts related to building materials were perceived to become less and less prevalent in both Makueni (30%) and Kiambu (40%) unlike Machakos 6.7%. Conflicts related to sand harvesting also appear to be quite interesting. While well over 80% of respondents in Makueni (80%) and Machakos (83.4%) perceived that conflicts related to sand harvesting were on the increase, only, 22.7% of respondents in Kiambu had a similar perception.

The probable reasons for these patterns could be the level of development of the different counties. Kiambu has posted different findings with both Makueni and Machakos probably because Kiambu is more developed. The infrastructure in Kiambu is more developed. With the good road network, transporting goods to the market is quite fast in comparison to Makueni and Machakos. Kiambu is also more cosmopolitan than both Makueni and Machakos. Although the population is predominantly Kikuyu, Kiambu is cosmopolitan and hosts other communities such as Luhya, Luo, Maasai, Kamba, Meru, and Kalenjins among others. Such people bring in new skills and enhance the growth of Kiambu. Other ethnicities include Asians and Caucasian population who are good businessmen. All these plus the fact that

Table 2 Citizens perceptions of the prevalence of resource-based conflicts

For each one, please indicate whether the nature of conflict is becoming: **More prevalent, Somewhat prevalent, Not sure, Somewhat less prevalent, Less and less prevalent**	County	Becoming less and less prevalent **1** (%)	Somewhat becoming less prevalent **2** (%)	Unsure **3** (%)	Somewhat becoming prevalent **4** (%)	Becoming more prevalent **5** (%)
A) Conflicts related to scarcity of firewood, such as people illegally collecting/harvesting firewood in neighbors' farms, quarrelling over collection of firewood	Makueni	13.3	13.3	3.3	26.7	43.3

C) Conflicts related to scarcity of water for livestock, such as people illegally watering their livestock in someone's water point	Makueni	23.3	20.0	6.7	16.7	33.3
	Machakos	3.3	10.0	13.3	26.7	46.7
	Kiambu	52.0	16.0	4.0	0.0	28.0
D) Conflicts related to scarcity of grazing pastures, such as animals straying into neighbors' farms/ plots in search for grazing pasture	Makueni	0.0	26.7	0.0	30.0	43.3
	Machakos	0.0	10.0	10.0	30.0	50.0
	Kiambu	40.0	20.0	4.0	24.0	12.0
E) Conflicts related to scarcity of grazing pastures, such as people illegally harvesting grazing materials in a neighbor's land/pasture	Makueni	13.3	16.6	10.0	16.7	43.3
	Machakos	3.3	3.3	16.7	33.3	43.3
	Kiambu	41.7	25.0	4.2	16.7	12.5
F) Conflicts related to scarcity for food, such as neighbors and other people illegally harvesting food resources in a neighbor's farm	Makueni	16.7	26.7	0.0	26.7	30.0
	Machakos	0.0	16.7	20.0	43.3	20.0
	Kiambu	48.0	20.0	4.0	12.0	16.0
G) Conflicts related to scarcity of building materials, such as people illegally harvesting thatch grass or building wood in a neighbor's farm	Makueni	30.0	6.7	10.0	33.3	20.0
	Machakos	6.7	40.0	16.7	20.0	16.7
	Kiambu	40.0	24.0	4.0	12.0	20.0
H) Conflicts over sand harvesting	Makueni	6.7	13.3	0.0	23.3	56.7
	Machakos	10.0	6.7	0.0	46.7	36.7
	Kiambu	59.1	4.5	13.6	0.0	22.7

Kiambu is a host to various foreign missions has ensured a higher income and better living standards. Another probable reason why findings for Kiambu differ significantly with those of Makueni and Machakos is climate. While Kiambu receives an aggregate rainfall of 1000 mm annually, both Makueni and Machakos receive less than 700 mm with Makueni receiving only 600 mm which is not adequate for a variety of crops. While Kiambu relies on major cash crops like tea and coffee and a variety of food-crops, Makueni and Machakos at times fail to harvest any food. Makueni is classified among the arid regions of Kenya.

The standard of living is higher in Kiambu as compared to Makueni and Machakos. While the poverty index is 21.75% in Kiambu, Makueni is ranked at 64.1%. People in Kiambu are relatively well off with many relying on other sources of energy other than firewood. The reliable rainfall and higher living standards might also have led to individuals having their private sources of pasture and water for their animals. Again, unlike the people of Makueni and Machakos who rely on sand harvesting and charcoal burning as a source of employment, Kiambu residents are busy in the farms, industries, or working in Nairobi which is their next-door neighbor. On the other hand, the poverty index in Ukambani indicates increase household firewood conflict and more climate effects as a result of cleared indigenous trees for charcoal burning to earn a living.

The potential implications of the above are that the simmering conflicts might soon result into full-blown conflict. With well over 80% of respondents in both Makueni and Machakos perceiving that climate-related conflicts are somewhat becoming prevalent and/or becoming more and more prevalent, an alarm is starting to ring. If climate does not improve and no interventions are put in place, signs of the region emulating war-torn countries like Sudan can be predicted.

Unlike in Makueni where major policies have been passed targeting mitigating climate change, the County government of Kiambu has bills and policies concerned with improved production. Kiambu being a major agricultural and livestock production area, a bill on Abattoirs has been passed. In April 2014, the Agricultural Department Strategic Plan was launched. Some drafts on Animal Disease Bill and Veterinary services are under discussion. Revolving funds have been set aside to improve agriculture. Machakos on its part has been seeking for partnerships and investors to help develop the County and save it from climate-induced problems. Watson and Hussein Kochore (2012) while referring to the drought situation in Northern Kenya have recommended that scholars of climate change must act with speed. In a similar vein, the situation in Makueni and Machakos requires urgent attention. These research findings corroborate Watson and Hussein Kochore (2012) findings expressed in their study of Northern Kenya where the authors reported prevalence of climate change related conflicts.

Citizens' Perceptions of Contribution of Climate-Change to Resource-Based Conflicts

Next was a Likert scale type of questions in which respondents were asked to rank climate change contribution to resource-based conflicts. Results are summarized in

Table 3. While an overwhelming 88% of Kiambu respondents perceived that climate change does not contribute a lot to conflicts related to firewood collection, a higher proportion in both Machakos and Makueni Counties shared a different opinion. Similar findings were witnessed in conflicts over water and grazing fields. While Kiambu saw almost no connection or too little between climate change and increased conflicts, with a 92%, Makueni and Kiambu were in sharp contrast with 6.7% and 33%, respectively. The figures for grazing pastures stood at 96% for Kiambu, 16.7% for Makueni, and only 10% for Machakos. The same figures were posted for illegal harvesting of grazing materials except for Machakos which had nil results. The feeling of Machakos was that there was a very strong correlation between climate change and grazing pastures related conflicts. An overwhelming 90% of those in Machakos said conflicts related to scarcity of grazing pastures were either somewhat increasing or were becoming more and more prevalent. In Makueni (70%) and Machakos (70%), there was a major perception that climate change is contributing to illegal harvesting of food in other people's farms. Only 4.3% of respondents in Kiambu felt the same with majority in Kiambu (95.6%) perceiving that climate change was either contributing nothing or too little to conflicts related to scarcity of food. Respondents in Kiambu saw almost no relation or a very slight relation between climate change and conflicts relating to building materials. The figure for Kiambu in this was 92%, while only 40% and 36.7% of Makueni and Kiambu, respectively, perceived the same. While each of Makueni and Machakos had more than 20% of respondents saying climate change was contributing more and more in conflicts related to building materials, Kiambu posted a nil result in that line. Perhaps more surprising are the findings from conflicts over sand harvesting. While Kiambu respondents (96%) perceived no or very slight connection between climate change and conflicts over sand harvesting, those in Makueni (73.3%) and Machakos (76.6%) perceived that conflicts over sand harvesting were either somewhat becoming prevalent or were becoming more and more prevalent.

Basing on what has been observed in the findings in the last 5 years; climate-related conflicts are something to worry about. There are more conflicts over resources in both Makueni and Machakos where climate is harsh as compared to Kiambu where climate conditions are friendlier. The implication here is that the climate change being experienced across the world is likely to lead to increased conflicts.

A one-way multivariate analysis of variance (MANOVA) between subjects, design was used to investigate whether the observed differences in participants' perceptions of prevalence of resource-based conflicts, perceptions of contributions of climate change to perceived resource-based conflicts, and perceived measures by the government to mitigate conflicts differed statistically across the three regions. The two dependent variables were: (i) composite indicator of perceived resource-based conflicts, (ii) composite indicator of perceived contribution of climate change to resource-based conflicts. The independent variable was the study region with three levels, Makueni, Machakos, and Kiambu. Results show that the differences in perceived resource-based conflicts are statistically significant $F_{2,\,76} = 12.78$, $p < 0.01$. Residents of Machakos county have a considerably higher perception that resource-based conflicts had risen during the last 5 years, $M = 3.90$, followed by

Table 3 Citizens perceptions of the prevalence of resource-based conflicts

Would say climate change is contributing a lot or not at all to the following conflicts?		Does not contribute at all **1** (%)	Somewhat less **2** (%)	Unsure **3** (%)	Somewhat contribute more **4** (%)	Contributes a lot **5** (%)
A) Conflicts related to scarcity of firewood, such as people illegally collecting/harvesting firewood in neighbors' farms, quarrelling over collection of firewood	Makueni	20.0	6.7	3.3	30.0	40.0

H) Conflicts over sand harvesting	Makueni	13.3	13.3	0.0	13.3	60.0
	Machakos	6.7	3.3	13.3	33.3	43.3
	Kiambu	92.0	4.0	4.0	0.0	0.0

Table 4 Relationship between citizens perceptions by region

Source	Dependent variable	Sum of squares	*Df*	Mean square	F	*Sig*
Region	Prevalence of climate change-induced resource-based conflicts	24.465	2	12.73	12.78	0.01
	Contribution of climate change to resource-based conflicts	114.41	2	57.21	44.07	0.01
Error	Prevalence of climate change-induced resource-based conflicts	75.72	76	1		
	Contribution of climate change to resource-based conflicts	98.65	76	1.30		
Total	Prevalence of climate-change-induced resource-based conflicts	1035.97	79			
	Contribution of climate change to resource-based conflicts	1094.45	79			

Makueni, M = 3.6, Kiambu residents do not consider resource-based conflicts to have been on the rise during the last 5 years, M = 2.4. Post-hoc tests using Turkey HSD revealed that the difference between perceptions from Kiambu differed statistically from those of Machakos, and also statistically from those from Makueni residents.

Results also show that the differences of perceptions in climate change as a contributor to the perceived rise in resource-based conflicts are statistically significant $F_{2,76} = 44.07, p < 0.01$. Residents from Machakos county have a considerably higher perception that climate change is contributing to the rise in resources-based conflicts in Machakos county, M = 4.0. Results show that Makueni follows with a relatively modest perception of climate change as a contributor to the perceived rise in resource-based conflicts, M = 3.99. Climate change is not regarded as a contributor to resource-based conflicts in Kiambu county, M = 1.2. Post-hoc tests using Turkey HSD revealed that the difference between perceptions from Kiambu differed statistically from those of Machakos, and also statistically from those from Makueni residents (Table 4).

Conclusion

This chapter explored the extent of climate change-induced resource conflicts along an hydrological gradient in three counties in Kenya, namely, Kiambu County which experiences relatively high rainfall and also high urban population, Machakos County, which generally experiences modest rainfall availability, and Makueni County regarded to be one of the most arid and semiarid counties in Kenya. Variability in the severity of climate change-induced resource-based conflicts was evident in counties along rainfall availability gradient. The impacts of climate change can be diverse, particularly for vulnerable regions such as arid and semiarid regions such as Makueni County. Respondents from Makueni County mentioned the highest number of climate-related impacts in the county, with the most frequently mentioned impact being increasing food insecurity followed by increasing water shortages. Machakos followed with respondents mentioning seven impacts that included increased water shortages and scarcity of pasture. In Kiambu County, only four impacts were mentioned with food insecurity being frequently mentioned among the list of impacts of climate change in the county. Results of the descriptive and inferential statistics reveal that resource-based conflicts vary along the hydrological gradient. Residents in Machakos County perceived resource-based conflicts to have risen quite significantly during the last 5 years, compared to perceptions from Makueni County. Kiambu residents did not consider resource-based conflicts to have risen during the last 5 years. Also, residents of Machakos County perceived climate change to be a factor in the rise of resource-based conflicts compared to perceptions from their counter parts from Makueni County. Although Makueni is the driest of the three counties, the publicity of the government's investments towards climate change mitigation and adaptation offers a possible explanation on the differences in survey results compared to residents' perceptions from Machakos County.

Suggestions for Further Research

Follow up research is needed to examine if survey results correlate with field observations in terms of reported climate change resource-based conflicts, different government and nongovernment agencies' investments and expenditures on climate change mitigation and adaptation, especially citizens participation in those projects. In addition, further studies are needed to investigate the self-reported food insecurity associated with climate change, the coping capacity under different resource, socio-economic and sociocultural settings, the consequences on malnutrition particularly on vulnerable population, and impacts on population health.

Water and Sanitation Infrastructure (AIAS) is the agency responsible for this project. The international consortium in charge of developing the CDP provided consultancy services to AIAS and the vulnerable cities of Beira and Matola. The assignment included not only capacity building but also institutional strengthening activities, as well as specific studies, mainly based on climate modelling (dynamic downscaling) and mapping exercises. Important results and conclusions were achieved, and further adaptation strategies to increase the resilience of the Mozambican urban water, sanitation, and drainage sector were proposed.

Adaptation · Urban water · Sanitation and drainage · Mozambique · Climate modelling · Adaptation options

Introduction

Mozambique is one of the top three among African countries most exposed to multiple weather-related hazards (GFDRR 2016). The country is located downstream of nine major international river basins, with extensive areas classified as arid or semiarid, and stretches of coastline on the path of tropical systems formed in the Indian Ocean. Vulnerable population, services, and assets are regularly exposed to floods and droughts, often severely. The devastating effects of Idai and Kenneth, the two intense tropical cyclones that in March and April 2019 struck central and northern provinces, will remain for a long time. According to the assessments published by the Government of Mozambique (GoM), a total of 2.8 million people were affected (GoM 2019a), with recovery and reconstruction works estimated at a total of US$ 3.2 billion (GoM 2019b). Before these events, the country was already facing high levels of food insecurity. Between September and December 2018, 1.78 million people suffered severe food insecurity in the country (GoM 2019b). Although the provinces most affected by these events tend to show higher levels of poverty compared to those least affected (Baez et al. 2018), natural disasters may challenge development of Mozambique as a whole.

Climate variability is already modifying the regional patterns of those extreme events. During the period 1960–2005, significant positive trends in temperature change were observed across most of the country and in all four seasons (INGC 2009). Rainy seasons commenced later, and dry spells lasted longer. As a result, over the past decades, the country has experienced increased droughts, flooding, and storms.

Climate scenarios vary across models depending on assumptions; however, most climate models suggest increases in mean annual temperatures, extended dry periods, more intense storms, and sea level rise (USAID 2012). As a result of climate change, the exposure to natural disaster risk in Mozambique will increase significantly over the coming 20 years and beyond (INGC 2009). Unless adaptations strategies are implemented, relative to baseline growth in 2003, gross domestic product could fall between 4% and 14% in the period 2040–2050 (WB 2010).

Moreover, given that Mozambique is such a poor country, under a "business as usual" scenario, climate change will impact even greater on the economy, driving the majority of the poor people into further poverty (Irish Aid 2018). There is a need to design effective mechanisms to address the risks and disasters associated with climate change by introducing inclusive and climate-resilient economic models that could increase income and generate social cohesion.

Climate change adaptation is being tackled by the GoM through different ongoing policies. As a "Least Developed Country" in the United Nations Framework Convention on Climate Change (UNFCCC), Mozambique published a National Adaptation Programme of Action (NAPA) in 2007. The NAPA outlined four specific actions, which aim to reduce the negative impacts of extreme hydrometeorological events through adaptation initiatives. Two of the program's prioritized strategies are reducing the impact on coastal zones and improving the management of water resources against climate change (MICOA 2007).

In 2012, the National Climate Change Strategy (NCCS) 2013–2025 was launched. Under the adaptation pillar of the strategy, several areas for intervention and consequent actions were identified. In terms of water resources, the strategy proposes, among other recommendations, improving rainwater drainage and sanitation systems (GoM 2012).

Mozambique ratified the Paris Agreement in 2017, and the country is defining the specific action for different goals proposed in the Intended Nationally Determined Contribution (INDC) submitted to UNFCCC in 2015 (MITADER 2015). The INDC reinforces NCCS objectives, to be implemented between 2020 and 2030. The first NDC is currently under development.

In addition, the National Disaster Risk Reduction Master Plan 2017–2030 is well-aligned with the adaptation priorities of the NCCS. The plan's main objective is to improve the resilience for population, livelihoods, health, and infrastructures, through an established culture of prevention, preparedness, response, and recovery (GoM 2017).

To carry out these climate policies, the GoM is drawing on both national resources and external aid. The country has attracted strong donor support for reconstruction and development over the last two decades and continues to obtain high volumes of international cooperation (Irish Aid 2018).

In this sense, the Cities and Climate Change Project (CCCP), developed in recent years with the aid of the World Bank, is one of the most important international cooperation initiatives undertaken in the country. The objectives of the CCCP include reducing disaster risks in urban areas and vulnerability associated with the impact of climate related. The project was approved in 2012 and finalized in 2019. Key analytical and infrastructure works to achieve the objectives were financed by the Bank. The CCCP had two components. Component 2, specifically aimed at increasing resilience in the cities of Maputo and Beira, was implemented by the Administration of Water and Sanitation Infrastructure (AIAS). AIAS was created in 2009, under the authority of the Ministry of Public Works and Housing, to manage urban water and sanitation investments, including drainage in small- and medium-sized cities.

In terms of the agreed priority actions and building on synergies within Component 2 of the CCCP, the Nordic Development Fund (NDF) approved parallel co-financing of this World Bank project. The Grant Agreement between NDF and the GoM was signed at the end of 2012 (NDF 2015). The NDF support, called "Capacity Development Programme (CDP)," was aimed at enabling AIAS (the national counterpart) and the municipal autonomous water and sanitation services of two selected cities (Beira and Matola), within their mandate, to act on climate variability.

The international consortium comprising of IDOM (leader), Nordic Consulting Group, Meteosim, and COBA was in charge of implementing the CDP. This 26-month technical assistance (September 2017–December 2019) project greatly benefited AIAS and other relevant stakeholders.

This chapter summarizes the activities and results of the Capacity Development Programme (CDP).

Institutional Strengthening

Resilience must be understood at country level involving all institutions and agencies together, in which stakeholders, decision-makers, officials, and other relevant stakeholders should understand the concept and how to put it into practice along with their specific tasks. This is the case in Mozambique, where an articulated vision of adaptation, disaster risk management, and resilience is still a challenge for national institutions (UNDP 2019).

The CDP has contributed to narrowing these gaps, with the completion of important activities.

In the first stage, a complete stakeholder mapping exercise was carried out (summarized in Table 1), including an assessment of the existing institutional influence on the decision-making processes in relation to resilience. It should be noted that a number of national agencies participate in the management of water cycle.

To develop skills in relation to resilience in AIAS, the institution needed access to available data and information on climate variability as well as coordination and cooperation with key institutions involved in climate change adaptation. The CDP facilitated inter-institutional linkages. Collaboration agreements were signed with the Ministry of Environment (MITADER), INGC, INAM, and INAHINA.

The two components or products specifically developed to improve AIAS managerial activities were an institutional website (www.aias.gov.mz) and a decision support system (DSS) based on a geographic information system (GIS) (Fig. 1). The new website serves as a platform to effectively publish the activities of the institution. The website also features internal management utilities, such as the possibility of remote access to information networks (intranet) and projects or shared resources. In terms of the GIS-DSS application developed, as a first step, the geo-referenced infrastructure database managed by AIAS was included and adapted. Following this, an analysis module of the vulnerability of receptors (population and assets) sensitive

Table 1 Key actors involved in water, sanitation, and hygiene (WASH) sector resilience (acronyms in Portuguese)

Institution/agency	Role/duties	Influence
National Directorate for Water Resources Management (DNGRH)	Water resources policies, regulations, and infrastructures	Medium
National Directorate for Water Supply and Sanitation (DNAAS)	Water supply, sanitation and drainage policies, regulations, and infrastructures in rural settlements	High
Water-Supply Asset Holding and Investment Fund (FIPAG)	Management of public investments in water systems for major urban areas	Medium
Administration of Water and Sanitation Infrastructure (AIAS)	Development of water and sanitation and drainage infrastructure in attributed secondary towns outside the FIPAG remit	High
Water Regulatory Authority (AURA, former CRA)	Urban water regulatory agency (tariffs approval, quality of service compliance)	Medium
Regional Water Administrations (ARAs)	There are four of them covering the country area (South, North, Center, Zambezi), assuming decentralized duties	Medium
Private agents	Contractors in public infrastructures and water systems for some urban areas	Low
Ministry of Health	Water supply quality standards	Low
National Directorate of Environment	Climate change policies. Focal point to UNFCCC	Very high
Natural Institute of Disaster Management (INGC)	Coordination of DRM policies and activities. Promote development in arid zones	Very high
National Institute of Meteorology (INAM)	Weather forecasts and seasonal outlooks. Alerts. Meteorological data register and exploitation	Medium
National Institute of Hydrography and Navigation (INAHINA)	Oceanography (marine weather), coastal protection, and navigation support	Low
Cities	Urban sanitation. Rural and urban water and sanitation	Low

Source: Authors, based on WB (2018)

to floods and droughts was designed. This tool also integrates geographic information provided by other institutional sources and a historical record of extreme events. The vulnerability module allows the different factors that determine the sensitivity and adaptive capacity of considered receptors to be classified/categorized. The DSS was designed using open-source GIS software. The objective of this tool was to provide support to AIAS in prioritizing new water and sanitation projects as well as operational and maintenance tasks, taking into account the climate risk component. Both products (website and GIS-DSS) were backed up with manuals on operation procedures.

Beira and Matola were the subjects of specific institutional strengthening activities. Both cities have their own water and sanitation services, which required strategic support in terms of organization and finance. In Beira, the Autonomous

Sanitation Service (SASB) was established by the municipality in 2008 and currently has its own staff. The Municipal Water and Sanitation

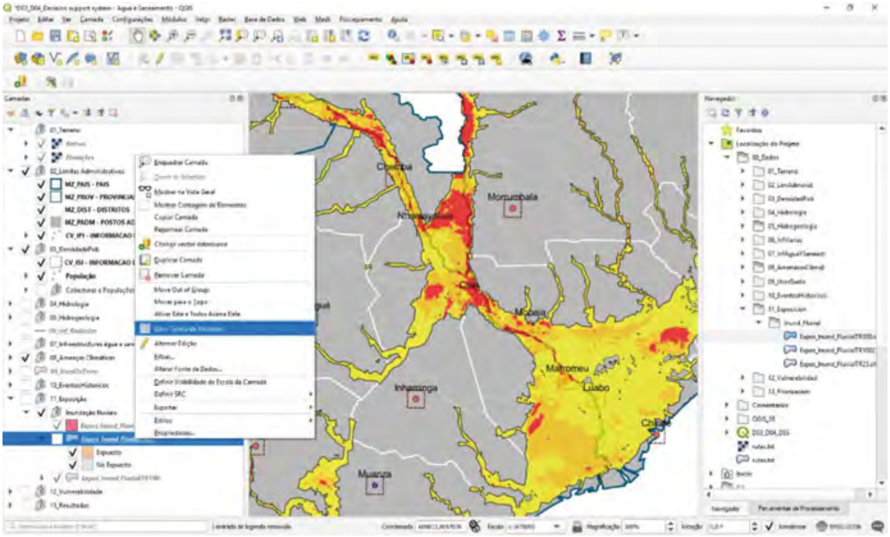

Fig. 1 GIS-based decision support system. (Source: Authors)

Entity (EMAS) of Matola was constituted in 2016 and is still under development with the objective of fully addressing its agreed responsibilities. An output of the CDP was adjusted business development plans for both SASB and EMAS, including resources and recommendations on diverse key items: rates, investments, resources, organizational chart, financial scenarios, accountability practices, additional sources of finance, or key performance indicators.

Institutional strengthening activities for AIAS, SASB, and EMAS followed a knowledge, attitude, and practice (KAP) approach. Under this methodology, the baseline study provided a good framework for defining capacity building activities and goals. One of the conclusions of the mapping exercise was that from the perspective of capacity development needs, there was limited knowledge among the Mozambican institutions interviewed about climate change phenomenon and its potential consequences. After defining the existing state of the intuitions, the technical needs identified set the basis for the design of a training program which was appropriate for each.

Capacity Building

One of the main targets of the CDP was to achieve the effective transfer of technical skills in relation to climate impact to the AIAS, municipalities, and other key stakeholders dealing with planning and management.

Water is the common denominator of the climate system (atmosphere, hydrosphere, cryosphere, land surface, and biosphere). Therefore, climate change affects water through a number of mechanisms (Bates et al. 2008) with a growing and significant impact on both the supply and demand of water, sanitation, and hygiene (WASH) delivery systems (Batchelor et al. 2011). These impacts as especially severe in African cities, with direct effects that affect people's health through waterborne diseases, damage to food, loss of income and the deterioration of sanitation, increased exposure to disease, and temporary reduction of access to health-care facilities (ActionAid 2006). Therefore, the WASH sector is highly vulnerable to potential climate effects.

Possible changes affecting WASH systems that could be expected in a changing climate can be grouped into four categories or drivers: (1) increased intensity of rainfall, (2) greater rainfall variability, (3) longer-term decline in rainfall, and (4) sea level rise. Table 2 presents the associated threats and potential impacts for each.

Most of these impacts are present in Mozambique. During the development of the CDP, workshops were held in in Maputo and Beira where these impacts were discussed (Table 5). It is worth noting that transboundary effects were repeatedly mentioned, as the country has to deal with the effects of practices carried out upstream in the shared basins. When towns and cities experience flooding from major rivers overtopping their banks, flood protection is considered in the context of the entire river basin, and this may include more than one state (ActionAid 2006). On the contrary, some possible positive effects associated with climate variability were identified during the workshops, such as the increased availability of water in the country's dams or the opportunity to develop new technologies in the country (sea water desalination for consumption).

In order to get a clearer picture of the future climate conditions in Mozambique and their related potential impacts on WASH systems, a specific climate modelling exercise was developed within the scope of the CDP. A good assessment of past and future climate conditions serves as input for the subsequent vulnerability analysis and risk assessment.

The climate in Mozambique varies depending on the location and the time of the year. This variability is due to the interaction of different factors, namely, the atmospheric systems and the topography of the country (INAM 2019). For the analysis, eight different climate regions were defined for the development of the CDP (Fig. 2, Table 3), considering certain uniformity in the aforementioned factors.

In terms of variability over time, the annual cycle has two seasons: the rainy season starts, approximately, in November and finishes in April, while the dry season starts in May and finishes in October. This variability is due to the shift of the Intertropical Convergence Zone (ITCZ), which is located very close to the country during the November-April period, and reaches the latitudes of Mozambique around January and February, when maximum precipitation is normal. Interannually, Mozambique is influenced by the El Niño–Southern Oscillation (ENSO), in which sea surface temperature (SST) positive anomalies in the Tropical Pacific Ocean are well correlated with dry conditions, especially in central and southern Mozambique. As concluded from the 5th IPCC report (Stocker et al. 2013), significant changes in

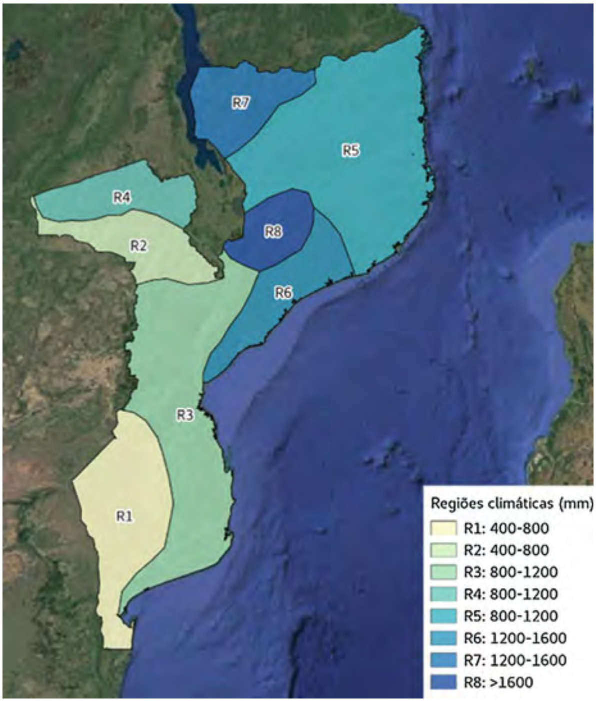

Fig. 2 Representation of climate regions in Mozambique. (Source: Authors)

ENSO are not conclusive, although there is a high confidence that ENSO will remain a dominant mode of natural variability in the twenty-first century.

Precipitation was selected as the meteorological variable most affected during flooding in the coastal cities of Mozambique. The intention of this study is to analyze the change of climatological patterns in this variable at national level and also at local level in Beira and Matola.

To assess historical changes in climate, consistent long-term meteorological observations were necessary. Since the weather station network in Mozambique is reduced (INGC 2009), with only one station per 29,000 km^2 and major geographical gaps in the provinces of Gaza and Tete, an alternative historical climatological database was necessary as a reference. Climate Forecast System Reanalysis (CFSR, Saha et al. 2010) was chosen as the most suitable gridded database without gaps in the historical climatology.

There are many climate scenarios as a result of running different models over long periods of time, developed by research institutes around the world, that can be used to assess the future climate. Global climate models (GCMs) are freely available through the Coupled Model Inter-comparison Project Phase 5 (CMIP5, Taylor et al. 2012), and regional climate models (RCMs) are available through the Coordinated Regional Climate Downscaling Experiment (CORDEX (http://www.cordex.org/)). However, due to their spatial resolution (around 100 km for CMIP5 models and 50 km for CORDEX models), they are still not capable of representing the local climate phenomena, potentially underestimating climate extremes, especially when

Table 2 Climate impacts on WASH systems

Driver	Associated threat	Potential impacts
Increased intensity of rainfall	Flash flooding	Direct damages/losses to facilities
		Ingress of groundwater into pipe networks, septic tanks, and pit latrines
		Peaks in diarrheal diseases
		Need of modifying design standards in sanitation and drainage infrastructures
	Greater peak runoff	Erosion (direct damages/losses)
		Transport of sediments and contaminants into water bodies and groundwater
Greater rainfall variability	Longer and/or more frequent meteorological droughts	Loss of quantity and quality of resources
		Low soil moisture (agricultural drought)
		Peaks in hygiene diseases
		Loss of efficiency of certain infrastructures (e.g., waste water treatment plants)
	Increased frequency of flooding	See “Flash flooding” above
Longer-term decline in rainfall	Reduction in river flows (hydrological drought)	Loss of capacity of surface water to dilute, attenuate, and remove pollution
		Increased algal growth in surface water and reservoirs
	Alteration of groundwater recharge rates	Loss of quantity and quality of resources
Sea level rise	Saline intrusion	Loss of quantity and quality of resources
	Coastal occupation	Direct damages/losses
	Erosion	Need of additional solutions on coastal protection

Source: Authors, based on Oates et al. (2014) and Charles et al. (2010)

topography is locally complex and land uses are varying depending on the location. Aligned with the data needs of the CDP, this study was focused on the generation and analysis of higher resolution climate change scenarios: 9 km resolution dataset for Mozambique in its entirety and 3 km resolution dataset for the city of Beira.

The new climate scenarios were generated based on a dynamic downscaling approach using the Weather Research and Forecast (WRF) model and its ARW solver (Advanced Research WRF), supported by the NCAR Mesoscale and Microscale Meteorology Laboratory. In contrast with other downscaling approaches, dynamic models like WRF solve the non-hydrostatic Euler equations governing atmospheric dynamics over a limited area at very high resolution. Indeed, the WRF model is able to solve atmospheric dynamics using multiple key parametrizations such as microphysics, radiation, cumulus, surface, and planetary boundary layer (PBL) and whose proper setup is of paramount importance to optimize the performance of the model. In this sense, several experiments were evaluated following a standardized methodology defined by Arasa et al. (2016), choosing the most convenient WRF options to minimize the error in the mean precipitation and the percentile 90th (P90) of daily precipitation, as

Table 3 Climate regions in Mozambique

Climate region	Description
R1	R1 comprises almost the whole provinces of Maputo and Gaza, in which topography is not complex and maximum altitude is around 500 m in the western part. The climatology is dry and hot and annual precipitation is normally below 600 mm/year
R2	R2 comprises the southern part of the Tete province, in which the topography is governed by the Zambezi river basin. The predominant climate is semiarid and hot and annual precipitation is normally below 800 mm/year
R3	R3 comprises Inhambane, Sofala, and Manica, whose topography is almost plain, except Manica with elevations between 600 and 1600 m. The climatology is close to tropical savanna and annual precipitation is around 1200 mm/year
R4	R4 comprises the northern part of the Tete province, in which the topography is mountainous, limited by the Cahora Bassa lake in the south. The elevations are over 2000 m at the northern boundary. The annual precipitation is over 1200 mm/year in spatial average and over 1600 mm/year in the higher areas
R5	R5 comprises Cabo Delgado, Nampula, the southeast of Nassa, and a coastal area of Zambézia. Orography is over 1000 m and annual precipitation is around 1200 mm/year
R6	R6 comprises the lower course of the Zambezi and Licungo rivers, which results in a plain topography. Precipitation is around 1200 mm/year in spatial average, although 1600 mm/year are reached in the north of the region
R7	R7 covers the northwest of Niassa and has a complex topography. The climatology is wet subtropical, and precipitations reach in average 1600 mm/year
R8	R8 is the wettest region and its topography is complex (Namuli mountains) whose highest points are the Mount Namuli (2700 m). The annual precipitation is 1600–1800 mm/year

proxy of extreme precipitation. The resultant optimized WRF configuration is shown in Table 4 (central and right columns).

The WRF model was used to downscale some GCMs from CMIP5 ensemble as well as CFSR. Due to computational limitations, the three most appropriate GCMs (among tens of models available) were chosen to be downscaled from CMIP5 ensemble, according to a comprehensive validation of GCM precipitation patterns over Mozambique area. As a result, MPI-ESM-MR (Giorgetta et al. 2013), IPSL-CM5A-MR (Dufresne et al. 2013), and CanESM2 (https://www.canada.ca/en/environment-climate-change/services/climate-change/science-research-data/modeling-projections-analysis/centre-modelling-analysis/models/second-generation-earth-system-model.html) were selected. The validation consisted of analyzing the performance of annual cycle bias as well as spatial correlation in Mozambique's annual precipitation cycle of each CMIP5 model against the GPCC precipitation dataset (Global Precipitation Climatology Center). (GPCC global dataset were used in order to keep the same grid scale between climate models and observations in the validation exercise.) The results of the GCM validation exercise are shown in Fig. 3, displaying the good performance of the selected models in the annual cycle as well as in the spatial distribution in the Mozambique area. All selected models show a Pearson correlation higher than 0.98 and a normalized root-mean-square error (NRMSE) lower than 20% in the annual precipitation cycle. In the same vein, spatial distribution of precipitation climatology for the three selected models is performing correctly showing spatial correlation with GPCC higher than 0.7 for an area covering Austral Africa.

The WRF model was run considering the three previously mentioned GCMs as inputs for two different 20-year periods of time: a historical/reference period 1986–2005 using CFSR and a future period (2026–2045) using the three CMIP5 models. These periods were chosen according to the design of climate simulations within CMIP5 initiative, which define the historical period between 1850 and 2005 and future period from 2006 to 2100 under the Representative Concentration Pathway (RCP) 8.5. This RCP8.5 is considered as a "business as usual" scenario reaching a radiative forcing of 8.5 W/m^2 at 2100. RCP8.5 is the most conservative scenario, since it predicts the most extreme global warming according to an increasing fossil burning and increase of greenhouse gases (GHG).

As part of WRF configuration, an optimal grid architecture is defined through three nested domains to downscale gradually the CMIP5 models (available at more than 100 km resolution); as shown in the left column of Table 4, the CMPI5 and CFSR models are used as input to the first domain D01 covering Austral Africa at a 27-km resolution. D02 is covering Mozambique at 9-km resolution, while D03 is covering the city of Beira at 3-km resolution.

The analysis of the WRF datasets is framed through the definition of a set of climate indicators, which represent the relevant climate aspects for the WASH sector, which are mean annual precipitation, annual precipitation cycle, dry spell (consecutive number of days with daily precipitation <1 mm), and intensity-duration-frequency curves. (IDF curves explain the relation between rainfall intensity

Table 4 WRF running domains and options selected which optimize monthly mean precipitation

	Parametrization	WRF option
D01: 27 km resolution (Austral Africa) D02: 9 km resolution (Mozambique) D03: 3 km resolution (Beira)	Radiation	CAM (Collins et al. 2004)
	Microphysics	WSM6 (Hong and Lim 2006)
	Cumulus	New-Tiedtke (Zhang et al. 2011)
	Surface	MM5 similarity (Monin and Obukhov 1954)
	PBL	YSU (Hong et al. 2006)

Source: Authors

(mm/h), rainfall duration (time rained at certain intensity), and rainfall frequency or return period (time span between two consecutive rain events).) Durations from 10 min to multiple days are considered as well as recurrences from 1 to 500 years return level. The change between future and historical periods in absolute (mm) and relative (percentage) values is analyzed.

Some of the obtained results are illustrated in Fig. 4, which show the change in percentage in the climatology of annual precipitation between future and reference periods for the three downscaled models for Mozambique, Beira, and Matola. IPSL-CM5A-MR and CanESM2 indicate an increase of mean precipitation between 5% and 20% in the norther part of the country (comprising R2, R4, R5, R6, R7, and R8, located mainly in Zambézia, Niassa, and Tete provinces) and also R1 in the inner southern part of the country, while MPI-ESM-MR shows insignificant changes for those regions. By contrast, a precipitation decrease is agreed with all three models in the R3, including the provinces of Gaza and Maputo. In the city of Matola, a decrease in precipitation of between 10% and 20% is expected. Similarly, in the city of Beira, the MPI-ESM-MR and CanESM2 forecast a decrease in the mean precipitation of between 10% and 20%, whereas IPSL-CM5A-MR forecasts a decrease lower than 10%.

In terms of the annual variability, no significant changes are concluded from the downscaled models, which indicates that the presence of a wet season between November and April and a dry season between May and October will remain in the future. This is in line with previous studies such as GoM (2012), in which it is concluded that climate projections show a diverging change in the wet season precipitation, although they show a decrease in the dry season. In addition, the strengthening of the subtropical anticyclones during winter may lead to a delay in the southward migration of the ITCZ. It may also lead to a southward shift of midlatitude cyclones. A combination of these dynamic changes and a reduction in moisture availability during winter could lead to a delay in the start of the rains over some areas (INGC 2009).

Looking at the IDF curves, an increase in the precipitation intensity for the same return period and a general duration for all the country are agreed for all three models. The detected change is much more significant for short durations, as it is shown in Fig. 5 for 10-year return period values for Matola and Beira. This also indicates that extreme precipitation phenomena are expected to be more frequent and with a shorter recurrence time. The most abrupt changes in precipitation intensity are expected to occur in R4, R7, and R8, which corresponds to the mountainous zones of the provinces of Tete, Niassa, and Zambezia. In the case of the city of Beira, a significant increase in the precipitation intensity is detected for all return periods and durations until 1 day, although the change is much more significant for the short durations.

In terms of the projection of dry spells, an increase between 20 and 30 days in the number of consecutive dry days is agreed among the three downscaled models in the provinces of Cabo Delgado, Nampula, and the coast of Inhambane. In these areas, the number of consecutive dry days is lower than 100 in the case of Cabo Delgado and Nampula and lower than 75 in the case of Inhambane. That supposes an increase in the number of consecutive dry days in areas in the north of the country, where this phenomenon is not so frequent.

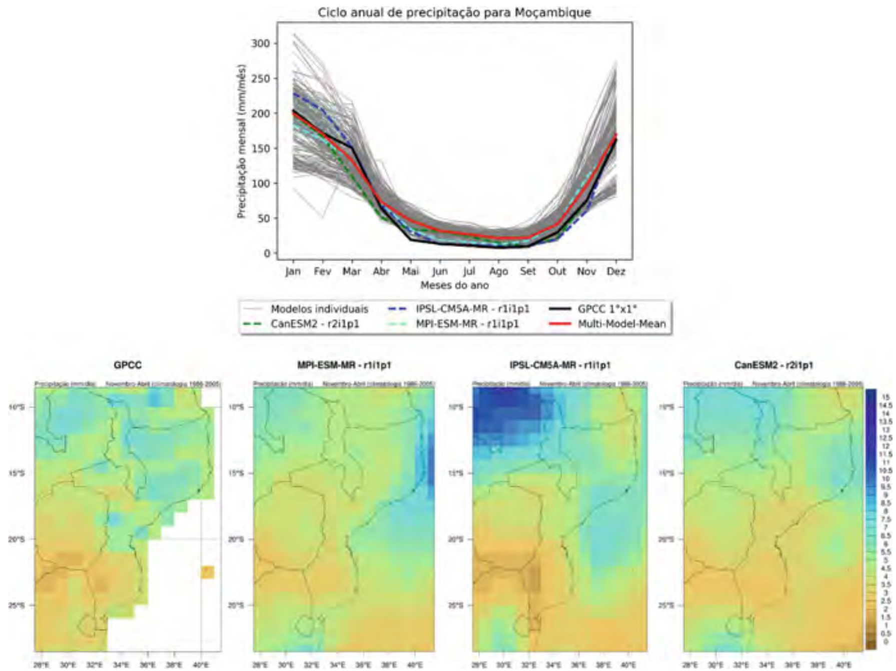

Fig. 3 GCM validation of annual cycle of precipitation in mm/day for 1986–2005 (top, solid dark line shows GPCC, while green, blue, and cyan dashed lines show CanESM2, MPI-ESM-MR, and IPSL-CM5A-MR, respectively). Mesoscale model: WRF. RCP8.5. (Source: Authors)

Considering that modifications in design standards can substantially reduce the impacts of climate change in Mozambique, even without additional resources (WB 2010), one of the main activities carried out using the results of the climate modelling as inputs was reviewing the existing regulations, technical standards and norms, and design criteria in water, sanitation, and flood control. This task had two objectives: to identify any possible inconsistencies or gaps and include the adaptation component. A total of six official documents were analyzed:

- Water Law (Law 16/91)
- Water Policy (August 2007)
- National Strategy for Water Resources Management (August 2007)
- National Water and Sanitation Strategy 2011–2025 (January 2012)

- Regulation of Public Systems of Water Distribution and Wastewater Drainage (Decree 30/2003)
- National Program for Water Supply and Rural Sanitation (Ministerial Diploma 258/2010)

Relevant modifications were only proposed for two of these documents. Regarding the Water Law, climate change has been incorporated into water resources management, enhancing the integral management of the basins as the best way to guarantee the adequate use of these resources and emphasizing the defense of the public water domain as a preventive measure to protect them. Regulation 30/2003 is the main technical standard in force for water and sanitation projects in Mozambique. An in-depth revision was carried out, in order to include a "climate factor" within the calculation of the precipitation design value for each one of the climate regions previously defined in the climate modelling exercise. Modifications to these regulations was then proposed and subsequently reviewed and approved by AIAS and DNAAS. The bureaucratic process until the official approval and publication in an official bulletin was not completed during the development of the CDP, as a wider institutional consensus was required.

The last technical activity completed within the scope of the CDP was aimed at streamlining the process of selecting and prioritizing adaptation measures that could effectively be applied in the Mozambican urban water, sanitation and drainage sector. The existing water and sanitation facilities were found to be suitable for most climates, perhaps with minor adaptation; however, the challenge is in selecting the technology to suit the predicted future climate (Charles et al. 2010). For this purpose, a specific decision tool was implemented. Based on a multivariate matrix, the tool has been designed to be an easy-to-use worksheet (Fig. 6) that allows consultation and presents the most appropriate adaptation options according to:

- Type of adaptation measure required: planning (9 different measures), infrastructure designing (29), operation and maintenance (8)
- Related threat: flash flooding, riverine flooding, sea level rise-coastal erosion, droughts, and average temperatures raising
- Geographic scope: local or regional
- Type of infrastructure: water and/or sanitation and/or drainage

All adaptation measures are described in specific fact sheets, including widely accepted selection criteria: vulnerability, urgency, synergy, no-regret, efficacy, feasibility, flexibility, and cost-benefit (UNFCCC 2011).

In order to effectively disseminate the results of the activities mentioned above and to foster the technical capacity of AIAS and other stakeholders, a series of thematic training workshops was programmed within the CDP project. Table 5 presents the main contents of each of these workshops held in Maputo and Beira.

The number of participant institutions in the different training activities carried out was significant. In addition to the technical staff and managers of AIAS, SASB, and EMAS, representatives of DNAAS, DINAB, INAM, INAHINA, INCG, the

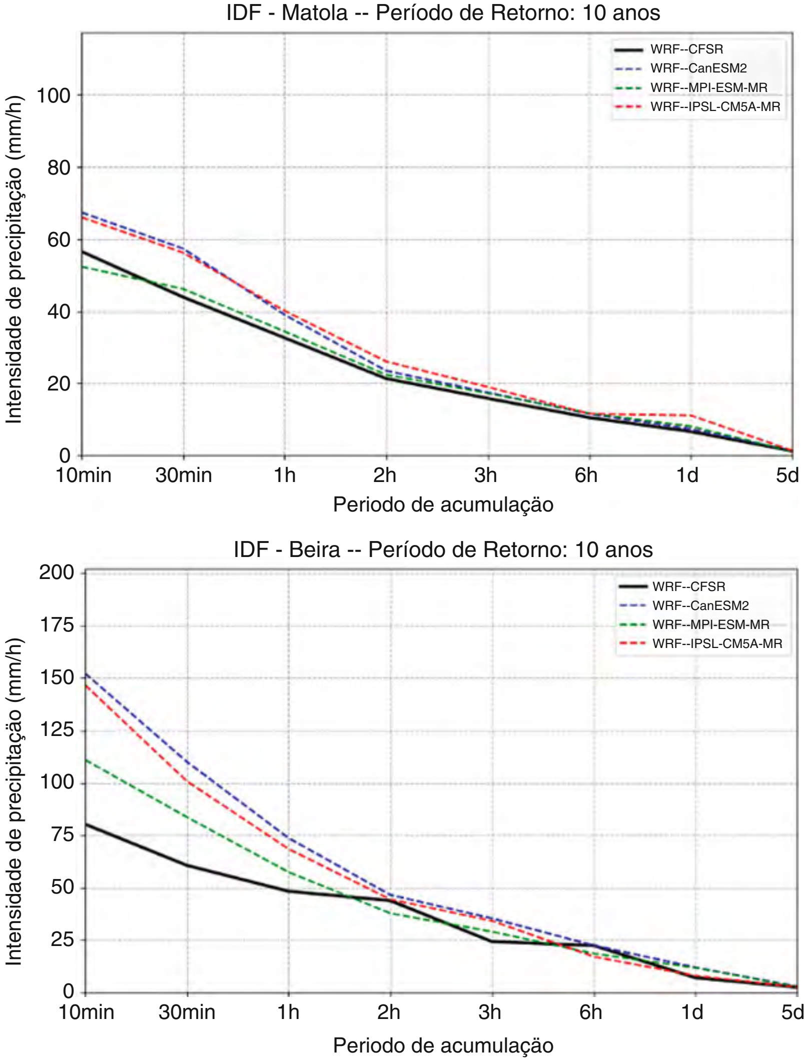

Fig. 5 Change (mm/h) in the precipitation intensity between reference period (WRF-CFSR) annual mean precipitation between reference (1986–2005) and future (2026–2045) in Matola (top) and Beira (bottom) MPI-ESM-MR (green shaded line), IPSL-CM5A-MR (red shaded line), and CanESM2 (blue shaded line). Mesoscale model: WRF. RCP8.5. (Source: Authors)

ARA Center, and municipal technical professionals from Quelimane and Nacala offered regular assistance as well. The feedback received from attendants after each workshop held was satisfactory, in terms of contents, scope, training materials, and complementary resources.

Fig. 6 Priority/decision-making tool for investments on urban water management. (Source: Authors)

Two study tours were organized in order to complete the capacity development program. The attendees were from AIAS, Beira, Matola, and other key stakeholders (ten participants each). The first trip was to Brazil, where two cities were visited. In the city of João Pessoa, some of the adaptations projects defined within the Action Plan as part of the Emerging and Sustainable Cities Initiative (ESCI) were seen. ESCI has been launched by Inter-American Development Bank in a number of Latin American and Caribbean cities, where IDOM has been actively collaborating, developing vulnerability and urban growth studies. In Rio de Janeiro, the delegation participated in the “Rio Water Week,” an important international event that served to give the group exposure to innovative initiatives and allowed them to make contact with other actors of the WASH sector. The second study tour was in Spain. The first stage of the trip included Seville, where with the collaboration of the public water and sanitation company (EMASESA), the regulatory framework of the city on drainage was shared and different infrastructures of interest (storm tanks, water and wastewater plants) were visited. In Madrid, the group was welcomed by municipal technical staff (the so-called Blue Department), who presented different projects related to sustainable urban drainage systems and held useful technical exchange sessions with Mozambican counterparts. The public company in charge of water and sanitation services in Madrid (Canal de Isabel II) also participated.

Finally, to improve the capabilities of the AIAS technical staff in the use of GIS tools, a hands-on training program “ad hoc” was organized. A specialist from the institution received specific training during the CDP project, including a 2-week internship in the GIS Division at IDOM’s headquarters in Madrid.

Resilient Urban Water Management Studies

African countries, in particular, face twofold challenge of managing climate change risk while at the same time, using sustainable approaches to extend the services provided, housing, and infrastructure (Campos et al. 2012). Adaptation is indeed an opportunity to promote social cohesion. In this sense, the cities of Beira and Matola are representative of other urban areas in the country.

Beira is a colonial city, established as a seaport to export raw materials from the African continent. Below the sea level, the city is located on a large estuary formed by the convergence of two large rivers (Pungwe and Buzi). It is also located in the path of the periodical tropical systems formed in the Indian Ocean. The city is exposed to frequent flooding which can be very disastrous when a cyclonic situation is combined with high tide. Certain coastal areas of the city suffer high rated of erosion. The main flood protection system to protect the city from coastal hazards was constructed decades ago and has deteriorated due to limited maintenance since its construction. This system is based on a network of open channels which divide the city and are controlled by floodgates. In some cases, they are connected to the retention basins. The city was barely affected by the Idai cyclone (GoM 2019b). Fortunately, given that landfall occurred at low tide, the city did not experience widespread coastal flooding. Therefore, it is more than obvious that actions must be taken to improve the resilience in the city. This problem has been addressed for

many years and various studies and projects have been carried out, funded mainly by international sources.

Matola is a city in the metropolitan area of Maputo. In the last few decades, its population has been growing exponentially due to the migratory flows both from rural areas and also from the capital city itself, since urban growth in Maputo is limited. Urban facilities do not meet the needs of this expanding residential occupancy. In particular, sanitation and drainage systems are insufficient and highly vulnerable to episodes of intense precipitation.

The CDP project has contributed to improving the urban sanitation and drainage systems of these two cities with the development of specific analysis. To achieve this, the municipal entities SASB and EMAS have been working together in agreement on the needs and action priorities of each urban area. The climate modeling that has been carried out will permit decision-makers to consider possible future impacts.

In Beira, all the completed works related to the improvement of the sanitation and drainage systems and the coast protection were firstly identified and analyzed. In the next stage, the impact of floods on the existing storm water and sanitation network in the urban and peri-urban areas of the city was assessed using climate scenarios and a combination of hydrological and hydraulic models, calibrated with existing data in order to simulate flooding scenarios. This work allowed a series of specific needs to be defined to promote and improve the system. Following a common approach with AIAS, a detailed study of the identified no-regret options was developed, improving the drainage system of a specific neighborhood in the city (Chota-Estoril). In addition, a comprehensive feasibility study (technical, economic-financial, environmental) was carried out.

The analysis and studies focusing on Matola were based on a detailed revision of the city sanitation and drainage master plan, considering the climate factor. A conclusion of this analysis is that the proposals included in the city's drainage master plan, issued in 2015, can be considered climate-proof. In addition, some improvements in technical aspects of the basic design of the sanitation and drainage system as well as some alternative solutions based on SUDS were proposed.

It may be possible to build on these activities through the projects and works, which would effectively address the needs of each urban area. In both cases, the business development plans mentioned earlier are an important component to guarantee the feasibility of the defined actions.

Conclusions

According to the evaluations given by both donor agencies (the Nordic Development Fund and the World Bank) and national counterparts (AIAS and the cities of Beira and Matola), the CDP has successfully contributed to mainstreaming climate adaptation in the Mozambican urban water, sanitation, and drainage sector.

The technical output of the CDP will serve an important input for the planning and design of resilient infrastructure. The capacity building activities have served to effectively transfer knowledge and good practices to AIAS, the city of Beira and the city of Matola, and other relevant stakeholders of the Mozambican WASH sector. To some extent, the support given during institutional strengthening will reinforce the sustainability of AIAS and other municipal entities as well as improving the success rate of their initiatives, although financial feasibility will require extensive structural reform and progress.

This type of assignment, combining institutional strengthening, capacity building and the provision of specific technical know-how, can be replicated in other African countries to promote climate resilience in other infrastructure sectors and activities.

Recommendations and Further Steps

Mozambique is a country under development. In addition to those growth prospects based on an improvement in the productive activity and the sustainable exploitation of country's natural resources, international cooperation is itself a key support in order to promote new urban infrastructures and/or improve the existing ones. Climate resilience holds an important role in this support, either as principal target or as a transversal component. As an example, it is worth mentioning two recently approved support programs. One of them aims to strengthen the capacities in disaster risk management at a country level (providing effective resources for developing the National Disaster Risk Reduction Master Plan 2017–2030), and the other is focused on improving Beira's coastal protection system. For both of them, the CDP contributions will be definitely useful.

The work along more than 2 years in close collaboration with numerous Mozambican institutions gave the chance of inspiring a few ideas, proposals, or even desires that may be taken as possible future areas of interest to develop.

The first suggestion refers to explore the possibility of carrying out an institutional reformulation of the national water sector as a whole. Concentrate attributions around a fewer number of public bodies without overlooking decentralizing objectives is clearly feasible. This would ease the decision-making process regarding key aspects, such as the integration of climate concerns on policies and developments. A "hydrographic basin" management approach – including transboundary negotiations and agreements – is highly recommended.

As can be found in many other regions around the world, it is been noted that urban planning in Mozambique still does not have the necessary power to manage the "cities growing" phenomena in a proper manner. This affects negatively and doubly those who are (socioeconomically) forced to find an urban habitat in unappropriated areas, exposed to natural threats. Adaptation plans are strategic instruments that may certainly contribute to urban resilience; based on spatial risk assessments, they indicate those spaces in which it is not appropriate to develop certain land uses or activities.

Regarding international agreements and commitments assumed by Mozambique to act in climate adaptation, coordinate action within WASH sector is mandatory in order to make articulate decisions, avoid redundancies, and hold an agile sharing of information. In this sense, the creation of a "sector-based committee," with own statutes and binding capacities, would be beneficial. In fact, this was a failed intent along CDP's enterprises, but it would be worthwhile took this idea up in the next future.

Abstract

Degradation of natural resources exacerbates a country's vulnerability to the effects of climate change. IPCC projections suggest that countries within the horn of Africa, which include Kenya, will suffer most from extreme climate change events, particularly more frequent and prolonged droughts. Women and children suffer disproportionately from the consequences of environmental degradation. Public participation is one of the strategies governments pursue to combat environmental degradation; however, there has been limited research to better understand students' environmental attitudes and pro-environmental behavior to better inform student-led participatory designs. Students comprise a significant proportion of the population in Kenya. This research conducted in 2018 at Nginda Ward, Embu County, comprised a survey of 121 students: 58 high school and 63 primary school students. The research investigated students' environmental knowledge, environmental attitudes, and pro-environmental behavior. Qualitative data were analyzed thematically. Multivariate statistics (MANOVA) were used to examine the relationship between the dependent variables and the participant's gender and level of schooling. From the results obtained, the top five most frequently mentioned *local* environmental problems by the students sampled included water pollution, deforestation, air pollution, scarcity of safe sources for water for domestic use, and soil erosion. Inferential statistical results revealed that there is a significant relationship between students' level of schooling and environmental attitudes, $F = 11.79$, (1, 120), $p < 0.01$. In addition, there is a significant relationship between students' level of schooling and environmental knowledge, *that is, perceived severity of environmental problems*, $F = 5.33$, (1, 120), $p < 0.05$. Research findings further revealed a significant relationship between gender and environmental knowledge, $F = 9.62$, (1, 120), $p < 0.01$. However, gender differences in pro-environmental behavior were not statistically significant. Also, differences between primary and high school students' pro-environmental behavior were insignificant.

Environmental degradation · Environmental attitudes · Pro-environmental behavior · Student-led participatory environmental conservation · Primary and high school students · Embu County · Kenya

Introduction

The sub-Saharan Africa (SSA) region is among the regions of the world experiencing severe environmental degradation and deterioration. Environmental degradation exacerbates the region's vulnerability to the effects of climate change. IPCC projections suggest the SSA particularly countries within the horn of Africa are most the parts of the world that will suffer most from extreme climate change events, particularly more frequent and prolonged droughts (IPCC 2014). While forest cover has improved remarkably in industrialized nations, the majority of the developing nations experienced severe deforestation during the last two decades. Other pervasive environmental problems in the SSA include species depletion and extinction, poor solid waste disposal, overpopulation, wide-spread soil erosion, desertification, and wide-spread pollution of surface water resources. There are many direct and indirect drivers of environmental degradation and changes in the SSA. These include rapid urbanization, overexploitation of land resources, wide-spread invasive alien terrestrial and aquatic alien species, and climate change.

There are many push-pull factors that drive urbanization in the SSA. This includes rural-urban migration driven by a mix of factors. The productivity of small-scale agriculture which was the main economic mainstay for majority of SSA residents have been declining dramatically due to poor land-husbandry practices, climate change, and environmental degradation forcing people to opt for urban life to pursue alternative economic opportunities (MEA 2005). Because of poor urban planning, pervasive urban poverty, and poor governance, urbanization in most of SSA towns and cities takes the form of proliferation of crowded information settlements. With poor solid waste management practices and limited or lack of sewerage, most urban wastewater, stormwater runoff ends in rivers and lakes untreated or partially treated, further polluting the region's dwindling surface water resources. Rising population further drives demands for firewood for cooking, the basic energy sources for cooking for the majority of the region's rising rural population. Deforestation in the SSA has been attributed to rising demands for farmlands, rising demand for grazing land, timber, as well as places for settlement.

Environmental degradation poses a threat to efforts by governments and donor agencies towards achieving many of the SDGs by 2030. Deforestation, for instance, worsens the scarcity of firewood, increasing the time women and girl children spent in the search of the commodity. The scarcity of water, firewood, and food is reducing time for productive work among women who are generally breadwinners among the families in the region. The loss of biodiversity threatens domestic and foreign tourism which employs thousands, further threatening the socioeconomic development and livelihood of millions (Shandra et al. 2008). Rising population drives increasing demands for fodder and fuel (MEA 2005). Arid and semiarid areas (ASALs) comprise a significant proportion of land for many of the countries with the SSA region. Thus, desertification has risen during the last decade as shortages of land forced millions of people to migrate to these ecologically fragile areas for settlement and cultivation. Consequently, desertification sets in due to over-cultivation and deforestation pose threats to biodiversity and livelihood of millions of people living in drylands. Extreme droughts associated with extreme climate change events have become commonplace in the ASAls in Kenya leading to massive livestock losses.

In Embu County, drivers of environmental degradation include the Kathangariri Tea Factory located in Nginda ward. According to some reports, the tea factory is estimated to consume 1,200,000 m^3 of wood fuel to process tea leaves per year. This fuelwood is purchased from the local community. Because many of the rural residents are poor, the majority are involved in the sale of firewood and charcoal for livelihoods. Rising trends in urban centers and towns in Embu County have further accelerated the use of wood since they use charcoals and wood fuel for cooking. It is estimated that biomass usage accounts for over 92.2% of energy sources in Embu County. All these degradations remain pervasive despite efforts by the national environmental management authority to educate people on the need to conserve the environment. A multi-institutional approach is necessary to combat environmental degradation. Young people comprise an important constituent in the fight against the degradation of natural resources; thus, understanding youth attitude, perception, and conservation behavior is crucial for current and future generation.

Kenya is among the world nations facing severe environmental degradation posing a huge threat to Kenya's socioeconomic development and growth. For instance, human encroachment in the country's water catchments, among them the Mau water catchment, has been blamed for the drying of springs and streams that feed river Mara. On the other hand, Mara River that waters the park is drastically reducing threatening livelihood in the park (Mango et al. 2011). Women and children suffer disproportionately from the consequences of environmental degradation. There has been a rise in efforts to mainstream environmental education. The number of nongovernmental organizations working to address environmental degradation has risen significantly over the last 10 years. Public participation is envisaged as a core strategy for combating environmental degradation; however, there has been limited research to better understand students' environmental attitudes and pro-environmental to better inform participatory environmental conservation models. Students compromise a significant proportion of the population in Kenya. The goal of this study was to primary and high school students' environmental knowledge, attitudes, and pro-environmental behavior.

Literature Review

Concept of Environmental Attitudes and Pro-environmental Behavior

Ajzen and Fishbein (1980) have attempted to provide theoretical explanations on the links between environmental attitudes and pro-environmental behavior. The researchers provided ways to overcome the challenges encountered by measuring attitude and behavior, which posed challenges to previous scholars. According to Ajzen and Fishbein, for one to measure the relationship between behavior and attitude, he/she must measure attitude toward a specific behavior. According to the authors, human beings adapt behavioral practices based upon the available information and not necessarily by unconscious drive or influential desires. Behavior is not determined by attitude directly, but rather attitude influences behavioral intention which leads to actions. Actions are influenced not only by attitude but also by social pressure. Behavioral outcomes are shaped or mediated by normative beliefs (Ajzen and Fishbein 1980).

This theory by Ajzen and Fishbein (1980) has been used in the analysis and explanation of factors leading to pro-environmental behavior. According to this theory, selfish competitive oriented people are less likely to behave proactively on environmental issues. Therefore, it is unlikely that selfish competitive integrated people consider environmental stewardship in their day-to-day decisions but rather are driven by greed to exploit resources for their gain. Thus, this theory sheds right on how to understand the pro-environmental behavior of different social groups within society.

Empirical Review

Several authors have argued that environmental degradation is a human behavior problem. Siefer et al. (2015) works on human-environment system knowledge framework attempted to demonstrate a correlation between attitudes and pro-environmental behavior among adults and graduate students in Chile. The authors posited that more knowledge of the environment translates to more awareness of problems associated with environmental degradation and thus change of attitude and pro-environmental behavior. The researchers discovered that the more aware individual was on global environmental problems created guilty upon him or her thus changing the behavior toward conservation. The authors also reported that environmental knowledge is the level of a personal feeling that his or her actions have led to degradation thus enhancing pro-conservation behavior. The authors did not find significant correlations between an individual's income and pro-environmental behavior, despite income level enhancing the individual's formal educational attainment.

Mifsud (2011) has examined the relationship between environmental knowledge, attitudes, and behavior, among Maltese Youth. The authors' findings suggested that Maltese Youth had enough global environmental knowledge but very little of the local environmental situation. This was found to harbor their change of behavior toward the local environment that was under degradation. Mifsud (2011) found that the use of radio, television, journal, and new paper was limited which could have portrayed the environmental situation on Maltese thus creating pro-environmental behavior. The authors' findings suggested that environmental knowledge enhances pro-environmental behavior.

There are several reasons why students may be more knowledgeable about the global environment than about the local environment. Mifsud (2011) attributed the predicament to the lack of textbooks on the Maltese environment. This situation may be exacerbated by market demands and forces that force book writers to publish books that sell, especially where there is a limited market for books, as is the case in Malta. The study further revealed the important interplay between media, family and friends, and local context and knowledge in influencing students' attitudes and pro-environmental behavior.

Measurement of environmentally relevant attitude and behavior is important for serious evaluation of environmental education programs. The clear environmental education program will only spring from proper measurement instruments that will take care of believing, attitude, values, and world view. This may depend on the pool of instruments used ranging from attitude measure, preservation, and utilization. It will allow persons to endorse environment protection and usage of natural resources. However, the author used one order; lack of measurement corresponding instrument will reduce attitude behavior consistency, which means the behavior is measured at a given level. On the other hand, the ecological situation at a given time will reduce attitude, making behavior measure either too easy or difficult. The socioeconomic status of parents was not measured; thus, little is known whether a household's socioeconomic status affects the social desirability of the youth.

Several other researchers have reported a relationship between education level and environmental attitude. According to Ugulu et al. (2013), pro-environmental behavior is influenced by many factors which include and not limited to norms, values, culture, education levels, gender customs, prevailing circumstances, and personal beliefs. Various theories that had been put forward to indicate how environmental attitude and pro-environmental attitude is influenced were put into consideration. The researchers reported gaps in the development of data collection tools to collect environmental attitudes and pro-environmental behavior data. The researcher found that female attitudes are higher than those of males, while the female student had a higher positive attitude than males (Gaye et al. 2005).

Environmental education is one way a country can prepare its youth to be responsible citizens of the environment. This will equip students to comprehend information on environmental issues; the more youth have a positive influence on conservation behavior. This is likely to enhance the required participation by students in environmental conservation and hence the positive behavioral change. Ugulu et al. (2013) has pointed out that science subjects tend to inspire desire and enlightenment amongst youth about environmental problems and knowledge on solving these problems. Ugulu et al. (2013) further argued that when youth lack knowledge on environmental issues, there is a corresponding lack of environmental stewardship. Education, therefore, seems to shape a critical positive conservation-related attitude and ecosystem conservation. Johnson-Pynn and Johnson (2010) have further examined explored environmental education among the East African Youth. The authors discovered that young people were aware of the many threats to local people and ecosystems in Tanzania and Uganda. A related study by Kioko and Kiringe (2010) on effects of education level on change of attitude and conservational behavior among Maasai Youth of Loitokitok District of southern Kenya reported that educational attainment influenced young people's actions toward the environment. The authors further reported that the gender of individuals influenced attitude toward conservation of environment and wildlife. To them, more males than females felt that wildlife and the environment should be conserved.

The level of schooling was found to enhance environmental knowledge and attitude toward wildlife and environmental conservation. Results from comparisons among formally educated youth and informally educated *moran* indicated statistical differences. High school students were higher than lower primary, while lower primary had higher attitudes than informally educated *moran*. Further, environmental clubs and visiting protected areas enhanced more coverage of wildlife and environmental topics.

The level of schooling enhanced the scope of understanding. On the other hand, the economic benefit increased levels of conservation because moran who benefited from tourism money had no problems with elephants using private land, while those who rely on crops had problems because of damage caused by elephants on their crop, and they had problems with them using private land. On the other hand, children whose parents were working in wildlife conservation had higher knowledge, awareness, and attitude than those whose parents were not working. Those who benefit from bursaries were for the idea that elephants should be protected. Females generally had a low attitude on conservation wildlife conservation because they associated the animals with danger. However, females showed more environmental concern than males. Based on the results of this study, the most prevalent method of practically engaging the Youth in environmental education appears to be participation in wildlife club activities. While all the schools had clubs, lack of funds limited club activities to gardening and tree planting within the school. Nevertheless, the clubs played an important role in environmental education. Membership increased the likelihood of students visiting protected areas such as Amboseli. However, Kioko and Kiringe's work (Kioko and Kiringe (2010) focused on the influence of the benefit of the conservation of wildlife on environmental education.

Materials and Methods

The research used a survey design to collect and analyze both qualitative and quantitative data. The sample constituted 121 primary and high school students. The researchers administered the surveys face to face with the help of teachers. All the responses were filled by the researcher according to the participants' answers. Additional data collected included the gender of the participant and also whether or not a participant had visited any conservation area.

Measurement variables are environmental attitudes, environmental knowledge and pro-environmental behavior. Students' environmental attitude was measured according to the level of agreement or disagreement on (9) statements from New Environmental Paradigm (NEP) scale (Dunlap 2000). Participants were required to rate their level of agreement/disagreement with each statement based on a scale of 5 = *strongly agree* to 1 = *strongly disagree* (overall score range, 9–45). The Cronbach's alpha value for the nine statements was 0.63. A high score means an individual had a higher agreement on items related to a particular statement. Students' environmental knowledge was measured using nine statements. Participants were required to rate their environmental knowledge according to a scale of 5 = completely agree to 1 = completely disagree. The Cronbach's alpha value for the nine statements were 0.72; a high score means a particular problem was perceived to be serious. Student's pro-environmental behavior (*self-reported willingness to support potential/ actual government's pro-environmental environmental conservation policies*) was measured using response to nine statements posed on willingness to support current or potential government conservation policies, based on a scale of 5 = *completely willing* to 1 = *not willing at all*. Cronbach's alpha for nine statements was 0.73.

Finally, students' participant pro-environmental behavior (*self-reported willingness to participate in community-organized conservation activities*) further measured using the response of nine statements posed on willingness to support community conservation activities, based on a scale of 5 = *completely willing* to 1 = *not willing at* all. The Cronbach's alpha value for the nine statements was 0.82.

Qualitative data were content analyzed and summarized the most frequently mentioned environmental problems by both primary and high school students. Quantitative data was analyzed using cross-tabulations to examine responses by primary and high school students. Inferential statistics, one-way MANOVA, was used to examine the relationship between environmental attitudes, environmental knowledge, and pro-environmental behavior and participant gender and schooling category.

Results and Discussion

Perceived Prevalent Environmental Problems

Study participants were asked to list what they perceived as the top three environmental problems in the local area. The lists of mentioned problems were entered in an Excel spreadsheet, and a tally was done to summarize the top five frequently mentioned environmental problems. Results obtained showed that the top five frequently mentioned environmental problems, in order of the most to least frequently mentioned problems included water pollution, deforestation, air pollution, scarcity of water, and soil erosion. Figure 1 summarizes the frequency of mention of the different environmental problems by category of the respondent (primary versus secondary). Water pollution was more frequently mentioned as a problem by the majority of high school students. Also, more high school than primary students perceived deforestation to be a priority environmental problem in the local area. Surprisingly, however, more primary than high school students perceived air pollution to be an environmental problem of concern. Also, more primary than high school students perceived soil erosion to be an environmental problem prevalent in the local area. However, water shortage was mostly mentioned many times by high school students compared to the number of times the same was mentioned by primary school students.

The pattern for different perceptions of prevalent environmental problems in the area is unclear. Deforestation is, however, a prevalent problem in the study area, and also the media in Kenya has sustained a campaign about deforestation as a priority environmental problem. Both student's daily experiences and also media publicity may explain the high mention of deforestation as a priority environmental problem.

Students Environmental Attitudes (NEP Questions)

Table 1 summarizes students' environmental attitudes according to the nine (NEP) statements posed. The majority of high school students (85%), compared to 63% of

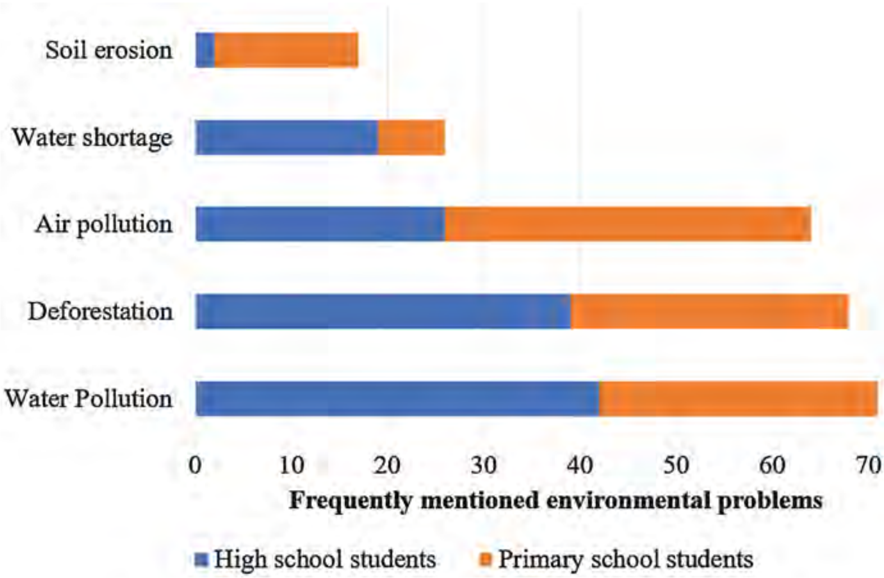

Fig. 1 Top five frequently mentioned environmental problems (N = 121). (Source: Survey data 2018

the primary students sampled, were strongly agreeable that the Earth has plenty of adequate natural resources if we just learn to develop them. The majority of the high school students (60%), compared to 58% of the sampled primary school students, were agreeable that "despite our special ability, humans are still subject to the law of nature." Most primary school students (59%), compared to 51% of the sampled high school students, were agreeable that with the statement that "plants and animals have as much right as humans to exist." Close to 60% of the high school students, compared to 46% of the primary school students sampled, were agreeable with the statement that "if things continue as they are present, we will soon experience a major environmental catastrophe." Only 14% of the high school students compared to 14% of the primary school students sampled were agreeable that "the Earth is like a spaceship with very limited room." Only 39% of the high school students sampled compared to 25% of the primary school students were agreeable with the statement that "we are approaching the limit of the number of people the Earth can support."

Environmental Knowledge: *Perceived Seriousness of the Environmental Problems*

Table 2 summarizes students' ratings related to the level of agreement/disagreement on the nine statements concerning the perceived seriousness of environmental problems. The majority of primary school students (66%) and 55% of high school students perceived that deforestation was a serious problem in the locality.

Table 1 Environmental attitudes of primary and high school students (NEP questions) (N = 121)

	Category	Strongly agree (%)	Somewhat agree (%)	Unsure (%)	Somewhat disagree (%)	Strongly disagree (%)
We are approaching the limit of the number of people the Earth can support	High school	39	12	3	29	17
	Primary school	25	4	9	27	36
When humans interfere with nature, it often produces disastrous	High school	55	20	6	10	8

	Primary school	21	11	14	9	45

Source: Survey data 2018

According to Kamweti (2009), Kenya is among the countries in Africa with the highest loss of vegetation cover, with 90% of the country's indigenous forests having been lost. Drivers of deforestation in Nginda Ward include Kathangariri Tea Factory which consumes an estimated 1,200,000 m^3 of wood fuel to process tea leaves per year.

60% of the high school students, compared to 48% of the primary school students, completely agree that pollution of streams and rivers is a serious problem in locality.

Majority of primary school students (59%) compared to 46% of high school students sampled agreed that soil erosion is a serious problem in locality. The findings are very consistent with the previous statement because where there is deforestation, soil erosion is becoming a prevalent phenomenon.

Half of the primary school students (50.0%), compared to 34% of high school students, completely agreed that siltation of streams and small dams is a serious problem in locality. Streams are very visible in the area being on the slopes of Mount Kenya. The coloration of the water, especially during the rainy season, was very visible.

Less than half of the high school students' (43%), compared to 41% of the primary school sampled, completely agreed that the spreading of towns and cities over more and more rural land is a serious problem in the locality. This perception may be probably a result students' awareness of the current trends of the rapid spread and growth of towns and urban centers in Embu County.

Less than half of the primary school students (45%), compared to 41% of high school students sampled, completely disagree that the degradation of local streams and rivers due to sand harvesting is a serious problem at the locality. Previous studies (Mango et al. 2011) have suggested a disconnect in which students were aware of global environmental problems confronting humanity today but not local issues. This is probably a manifestation of this problem at the study site.

Pro-environmental Behavior: *Self-Reported Willingness to Support the Government's Pro-environmental Conservation Policies*

Table 3 summarizes students' pro-environmental behavior measured according to respondent's self-reported willingness to support the government's environmental conservation policies on the nine statements posed.

Willingness to Support a Government's Ban on the Use of Plastic Bags

Plastic packaging of goods at shopping malls is a huge source of solid waste generation in cities and towns. In 2017, the Kenya government enforced a ban on plastic packaging. Participants were asked about their willingness to support the government ban on plastic packaging. Results showed that 84% of the primary school students were willing to support government ban compared to 66% of high school students.

Table 3 Pro-environmental behavior: *students' self-reported willingness to support potential government conservation pro-environmental policy* (N = 121)

	Category	Completely willing (%)	Partly willing (%)	Neither willing nor unwilling (%)	Not willing (%)	Completely unwilling (%)
Willingness to support a government's ban forbidding the use of plastic bags	High school	66	11	3	5	1

	Primary school	61	13	4	4	20

Source: Survey data (2018)

Willingness to Support a Government's Ban Forbidding Cutting Trees for Charcoal

Kenya has a policy that regulates charcoal burning. According to this policy, selling charcoal without a permit is prohibited. Although there are policies that require charcoal burning to obtain permits, this regulation is rarely enforced because the government lacks sufficient policing resources. Also, corruption in Kenya is pervasive further undermining the regulation of illegal charcoal burning. Participants were there asked if they were completely willing or unwilling to carry eco-friendly bags during their shopping. Results showed 57% of the high school students were completely willing to support the regulation compared to 43% of the primary school pupil.

Willingness to Support County Government's Policy Requiring Factories and Industries That Pollute Streams and Rivers Pay Charge Toward Cleaning Our Rivers and Streams

Kenya has a policy that regulates the quality of wastewater discharge into surface water bodies, streams, rivers, and lakes (GoK 2013). Polluter pay principle requires factories and other people caught discharging wastewater and other effluents in water sources to pay for the consequent cleaning. Participants were asked if they were willing to support county government's policy requiring factories and industries that pollute streams and rivers pay charge toward cleaning our rivers and streams. Results showed that 74% of primary school students and 72% of the high school students sampled were completely willing to support this hypothetical pro-environmental government policy.

Willingness to Support a Government Policy to Cancel the Licenses of Factories and Industries that Pollute Streams and Rivers

Factories and other industries are major sources of point sources of water pollution. Kenya has a policy that regulations point sources related sources of water pollution. Participants were there asked if they were completely willing or unwilling to carry eco-friendly bags during their shopping. Results showed that 61% of the primary school students were completely willing to support compared to 43% of the high school students. It is however not clear why a low percent of high school students showed willingness to support a government policy mentioned. Pollution of rivers and lakes by factories benefits only a few individuals by way of cutting costs of wastewater treatment, yet the majority of the citizens pay for those consequences in terms of illnesses.

Willing to Carry Eco-Friendly Bags During Shopping

The provision of packaging materials to customers in shopping malls is a huge source of solid waste generation. One method in reducing solid waste related to packaging provided by shopping malls is to provide incentives where people carry their eco-friendly bags when they go shopping. Participants were there asked if they were completely willing or unwilling to carry eco-friendly bags during their shopping. Results showed that 70% of the students were completely willing to carry eco-friendly bags during shopping, compared to 57% of the high school students.

Willingness to Support a Government Policy to *Charge* People Who Wash Clothes in Streams

Washing clothes in rivers and streams and lakes is a common practice in many rural settings in Kenya. Many forms of detergents used for laundry have high levels of phosphates and other chemicals that pollute water and potentially trigger local eutrophication problems in water sources. Participants were there asked about their willingness to support or not to support a hypothesized scenario in which county government enforced charges for people who wash clothes in streams in one measure to curb pollution associated with this practice. Results showed that 64% of the primary school students were completely willing to support the policy compared to 37% of the high school students. It's unclear why high school students would express low support toward a government policy that provides charges for people who wash their clothes in streams. Washing clothes in rivers and lakes contribute to localized eutrophication problems, undermining the quality of drinking water sources.

Willingness to Support a Government Policy to *Charge* People Who Wash Vehicles in Streams/Rivers

Washing vehicles in rivers and streams and lakes is a common practice in many rural settings in Kenya. Many forms of detergents used for laundry have high levels of phosphates and other chemicals that pollute water and potentially trigger local eutrophication problems in water sources. Participants were there asked about their willingness to support or not to support a hypothesized scenario in which county government enforced charges for people who wash clothes in streams in one measure to curb pollution associated with this practice. Results showed that 63% of the primary school pupil were completely willing to support the policy compared to just 48% of the high school students.

Willingness to Support a Government Policy to *Charge* People Who Pump Water from Rivers for Irrigation Without Permits

The abstraction of water from streams, rivers, swamps, and lakes to irrigate farm crops is a common practice. Although there are policies that require people irrigating crops to obtain water abstraction permits, this regulation is rarely enforced because the government lacks sufficient policing resources. Also, corruption in Kenya is pervasive further undermining the regulation of illegal abstraction of water from streams, rivers, lakes, and swamps for private irrigation gains. Participants were asked about their willingness to support or not to support a hypothesized scenario in which county governments enforced charges to all people found abstracting water for irrigation without permits. Results showed that 68% of the primary school students were willing to completely support compared to just 48% of the high school students.

Willingness to Support Policy to *Charge* Construction Companies Who Obtain Huge Amounts of Water for Construction from Streams Without Permits

Rapid urbanization has been a major source of extraction of water from both underground and surface resources. In many countries, the abstraction of huge amounts of water from streams and rivers competes with other forms of water uses such as water for livestock, small scale irrigation, and also domestic use. Even though governments may have policies that regulate regulate water abstraction, these bad practices might continue becuase governments lack sufficient resources to enforce compliance. Participants were asked about their willingness to support or not to support a hypothesized scenario in which county governments were to begin requiring construction companies to pay for the water they collect from streams, rivers, and boreholes. Results showed that 68% of the primary school students were completely willing to support compared to just (48%) of the high school students.

Pro-environmental Behavior: *Students' Self-Reported Willingness to Participate in Community-Organized Environmental Conservation Activities*

Table 4 summarizes results of students' pro-environmental behavior measured according to respondent's self-reported willingness to participate in the community-organized environmental conservation activities.

Majority of the primary school students, 80%, and 74% of high school students were willing to voluntarily participate if their communities organized to clean local water streams. Most primary school students (84%) and high school students (79%) were willing to volunteer in garbage collection activities to keep their neighborhood clean. The level of response indicates and probably suggests interests for better environmental hygiene.

Majority of the high school and primary school students (75%) expressed willingness to donate some seedlings to their neighbors if they needed to plant some trees in their yards/fields. Majority (80%) of the high school and 75% of primary school students were completely willing to voluntarily participate in tree planting activities in their neighborhoods. The high-percent willingness probably suggests students' perception of the need for action to combat deforestation in their own locality. The majority of the primary school students (84%) were willing to donate some seedlings to a public primary school near where they live to plant at the school if they had tree nursery. This was an indication of conservation behavior because tree seedling is sold for monetary gain, but these respondents were selflessly willing to donate. Social studies they learn in school may also have played a major role in shaping their thought-form.

The survey also revealed that 77% of the high school students were also willing to donate some seedling to primary school. Majority (83%) of primary school students and 80% of the primary school students were willing to attend the meeting organized to discuss solutions to the environmental problem affecting their community. The impact of environmental degradation affects everyone in the ward. However, more so women and children are affected more than others because of house chores like looking for firewood and fetching water. Gill and Kewlani (2010) have reported that as the problems of deforestation worsened in India, there was a corresponding increase in the amount of time that women spent looking for firewood. Deforestation further reduced working hours in the agricultural fields thus aggravating poverty and hunger within these communities in India.

Natural environment enhances psychological satisfaction, a key ingredient for healthy lives (Bermudez et al. 2015). On the other hand, environmental degradation, particularly deforestation, can trigger the removal of the girl child from school to assist in these home activities to help in search for the scarce firewood. This can lead

Table 4 Pro-environmental behavior: *self-reported willingness to participate in community-organized environmental conservation activities* (N = 121)

	Category	Completely willing (%)	Partly willing (%)	Neither willing nor unwilling (%)	Not willing (%)	Completely unwilling (%)
Willingness to volunteer to participate in a community organized to clean water streams near the place I stay	High school	74	6	11	0	9
	Primary school	80	14	2	0	4
Willingness to volunteer in a garbage collection activity to keep neighborhood clean	High school	79	11	5	3	3
	Primary school	84	11	2	0	4
Willingness to donate some seedlings to neighbors if they need to plant some trees in their yards/fields	High school	75	9	3	5	0
	Primary school	75	14	5	5	0
Willingness to donate some seedlings to a public primary school near where I live to plant at the school	High school	77	9	5	5	5
	Primary school	84	9	4	0	4
Willingness to volunteer to participate in a tree planting activity in my neighborhood	High school	80	6	8	3	3
	Primary school	75	9	5	22	9
Willingness to meetings organized to discuss solutions to environmental problems	High school	80	14	3	0	3
	Primary school	83	7	5	5	0

affecting my community						
Willingness to donate money toward youth environmental conservation activities such as wildlife clubs in schools	High school	59	23	8	5	6
	Primary school	55	23	5	9	7
Willingness to participate in community soil conservation activity in my neighborhood	High school	72	11	11	3	3
	Primary school	64	16	9	5	5
Willingness to donate money toward rural women groups involved in establishing tree nurseries	High school	63	14	5	8	11
	Primary school	84	5	4	4	4

Source: Survey data (2018)

to problems of gender parity in both high school and primary school enrollment. This can consequently perpetuate gender inequality in which women are unable to compete for jobs in the job market. Studies have shown that school wildlife and health clubs have positive environmental attitudes and pro-environmental behavior (Ajiboye and Silo 2008). Participants were asked to rank their willingness to donate money toward youth environmental conservation activities such as wildlife clubs in school. Results showed that barely over half of the high school students (59%) and 55% from primary were willing to donate money toward youth environmental conservation activities such as wildlife clubs in school.

Most soil conservation activities in rural areas rely on social capital for man power in undertaking various soil conservation activities. Social mobilization can take the form of men-to-men, women-to-women, but also youth mobilizing to dig trenches and holes among other soil conservation activities. Participants were asked to rank their willingness to participate in community soil conservation activities in my neighborhood. Majority (72%) of the high school and 64% of the primary school students were completely willing to voluntarily participate in soil conservation activities in their neighborhood. On the other hand, water was severely polluted by runoff during the rainy season. During recent years, there have been increasingly more rural women groups involved with raising tree nurseries both as a source of income and as alternative sources of seedlings to plant in their farms. Participants were asked to rank the willingness to support rural women groups involved in establishing tree nurseries. Results obtained showed the majority (84%) of the primary school students and 63% from primary were willing to donate money toward rural women groups involved in establishing tree nurseries. Primary school students also appear to have understood the importance of trees.

Relationship Between Environmental Attitudes, Environmental Knowledge, and Pro-environmental Behavior and Participant's Gender and Level of Schooling

A two-factor MANOVA was conducted to examine the relationship between environmental attitudes, environmental knowledge, and pro-environmental behavior and participant's gender and level of schooling. The dependent variables in the model were composite scores of environmental attitudes; environmental knowledge; and pro-environmental behavior-1 "participant's self-reported willingness to support potential a government pro-environmental policy" and pro-environmental behavior-2 "participant's self-reported willingness to participate in community-organized environmental conservation activities."

Results obtained revealed that there is a significant relationship between students' level of schooling and environmental attitudes, $F = 11.79$, (1, 120), $p < 0.01$ (mean for high school students = 3.78, $SD = 0.57$; mean for primary school students = 3.31, $SD = 0.90$. In addition, there is a significant relationship between students' level of schooling and environmental knowledge, $F = 5.33$, (1, 120), $p < 0.05$ (mean for high school students = 2.83, $SD = 0.96$; mean for primary school students = 2.43, $SD = 0.92$). These findings are consistent with those from previous research.

Research findings revealed a significant relationship between gender and environmental knowledge, *that is, perceived severity of environmental problems*, $F = 9.62$, (1, 120), $p < 0.01$ (mean for girls = 2.91, $SD = 0.97$; mean for boys = 2.39, $SD = 0.88$). However, gender differences and, also, differences between primary and high school students' pro-environmental behavior were insignificant. Also, none of the interaction effects was statistically significant.

Lessons Learned, Study Limitations, and Recommendations for Future Research

Four of the most prevalent environmental problems mentioned by the students, namely, water pollution, deforestation, scarcity of water, and soil erosion, are consistent with the literature on prevalent problems confronting Kenya's rural citizens. It is unclear what informed student's mention of air pollution, among the list of top environmental problems. This is probably informed by literacy gained from classes on prevalent environmental problems globally. Compared to water pollution, Kenya has had considerable media publicity and, also public attention during *barazas*, on deforestation and soil erosion as key threats to Kenya's environment and livelihoods. It is surprising, however, to find that students ranked water pollution as a top environmental problem.

This research is among the pioneer studies to use the NEP developed by Dunlap (Dunlap 2000). NEP scales have been used largely by researchers in western countries to measure environmental attitudes. Reliability tests revealed 9 out of the 15 NEW statements met the reliability threshold for a composite environmental attitude score. Further studies are needed to further explore the reliability of NEP scales for the measurement of environmental attitudes in Kenya. Measurements scales for environmental knowledge and pro-environmental behavior were adapted from literature. Further studies are needed to validate these scales in different parts of Kenya.

There are several limitations to this study. The target population is comprised of students largely drawn from one ethnic community. This potentially limits generalizations of study findings to different parts of the country. The study sample comprised of high school students were drawn from four, and primary school students were drawn from class seven. This study relied on a survey approach to gather data on self-reported environmental knowledge, environmental attitudes, and pro-environmental behavior. Future research needs to triangulate survey data with other techniques such as participant observation, to further verify correlations among variables. Potential opportunities for participant observations include targeting groups such as members of school health clubs and wildlife/environmental clubs to compare the extent of participation in and volunteerism toward community-organized environmental conservation activities.

This potentially limits generalizations of study findings to different schooling levels. There is, therefore, a need to examine primary versus high school students' environmental attitudes and pro-environmental behavior in other parts of Kenya and compare findings.

The study findings have implications on interventions, particularly by Embu County government and donor agencies working in the county, seeking to mobilize and engage participation by primary and high school students (school health clubs and wildlife/environmental clubs), in initiatives targeted to combat environmental degradation. Also, the country government use these findings to facilitate targeted environmental education to raise students' environmental attitudes and environmental knowledge to enhance conservation behavior.

Conclusion

Female students perceive environmental problems at the locality to be more severe, compared to their male counterparts. Nonetheless, gender differences in pro-environmental behavior are not statistically significant; also, between primary and high school students' pro-environmental behavior are significant. The study findings have implications on interventions by government and donor agencies seeking to mobilize student-led participatory efforts to promote environmental conservation and enhance rural communities' climate change adaptation efforts and resilience.

Abstract

As a Small Island Developing State (SIDS), Seychelles is quite vulnerable to the impacts of climate change, and adaptation is considered a national priority. Despite efforts to enhance its adaptive capacity, a number of barriers still hamper the adaptation process such as fragile institutions and inadequate governance to climate change, financial and human resource capacity constraints, and limited scientific knowledge and understanding of how climate change affects the country. A key barrier to climate change adaptation in the Seychelles is called "remote" or "legacy" barriers – linked to land use decisions made five decades ago during which wetlands were reclaimed for property development. Therefore, 80% of Seychelles' critical infrastructures are located on the coastline and are exposed to floods, erosion, and sea level rise. Additionally, the pros and cons of hard and soft adaptation interventions in the Seychelles ranging from rock armoring, retaining wall, groynes to ecosystem-based adaptation actions such as timber piling, beach nourishment, dune management, rainwater harvesting, and mangrove and coral restoration are assessed with recommendations on the way forward. In other words, this chapter provides some examples of actions and strategies that may assist the island nations to improve on adaptation actions. An example that addresses partly the financial constrain is the Seychelles' Conservation and Climate Adaptation Trust (SeyCCAT) that provide funding for medium- and large-scale project in the Seychelles since 2015.

Introduction: The Vulnerability of Small Island Developing States to Climate Change

Small Island Developing States (SIDS) are generally considered highly vulnerable to climate change, partly because they suffer from similar problems in relation to their landmasses, remoteness, and exposure to natural hazards (Scandurra et al. 2018). As far back as 1992, the United Nations Conference on Environment and Development (UNCED) was the first to recognize SIDS as a distinct group of fragile nations when it stated:

> SIDS, and islands supporting small communities are a special case both for environment and development. They are ecologically fragile and vulnerable. Their small size, limited resources, geographic dispersion and isolation from markets, place them at a disadvantage economically and prevent economies of scale. UNCED (1992)

As such, SIDS are generally considered highly vulnerable to climate change as sea level raise, and/or changes in precipitation patterns lead to various negative consequences such as reduction in agriculture yields and damages to infrastructure and to properties (Robinson 2015; Nurse et al. 2014).

For SIDS, the impacts of rising temperatures, sea level rise, variability of rainfall patterns, and more frequent extreme weather events reaffirm the varied climatic and non-climatic vulnerabilities encountered in Island States (IPCC 2018; Robinson 2015). Given that the Indian Ocean is warming at a faster rate than any other tropical ocean region (Roxy et al. 2014), sustainable exploitation of resources within the framework of the Blue Economy will be greatly affected in the absence of proactive adaptation measures. Whereas practitioners and scientists within the adaptation landscape define adaptation differently, we focus on the definition of adaptation as utilized by the Intergovernmental Panel on Climate Change (IPCC), as an "adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities" (IPCC 2007).

Reducing the vulnerabilities of SIDS and Seychelles in particular is important for the sustainable development of its Blue Economy, livelihoods, human security, and environmental protection. Such actions are both urgent and timely especially at a time when the world is paying attention to the implementation of the Sustainable Development Goals. According to Nurse et al. (2014), SIDS are already experiencing a range of climate-related impacts, including increased coastal flooding and saltwater intrusion. Although its location and landmass sometimes exacerbate its vulnerability to the impacts of climate change, proactive adaptation interventions have been designed, tested, and implemented across SIDS including those of the Indian Ocean Region. These adaptation actions include rock armoring, retaining wall, groynes to ecosystem-based adaptation actions such as timber piling, beach nourishment, dune management, rainwater harvesting, and mangrove and coral restoration (Guillotreau et al. 2012). These adaptation measures are necessary, for instance, for disaster risk reduction (DRR), economic development, as well as terrestrial, coastal, and marine biodiversity conservation especially in this era of the Sustainable Development Goals (Berrang-Ford et al. 2011).

Climatic and Non-climatic Induced Vulnerabilities in the Seychelles

The Republic of Seychelles, an East African archipelago made up of 115 islands in the Indian Ocean, is one of 58 SIDS around the world. Figure 1 outlines the position of the country. This SIDS suffers from climatic and non-climatic induced vulnerabilities ranging from variability in temperatures and rainfall to anthropogenic driven vulnerabilities that are linked to dependence on climate sensitive livelihoods and economic activities.

Temperature and rainfall variability: In the Seychelles, the annual average maximum temperatures between 1989 and 2018 was estimated at 30 °C while the minimum stood at 25 °C (Fig. 2a). Of importance to note is that the overall pattern between the maximum and minimum temperatures during the said period seems to be consistent. However, the diurnal graph (see Fig. 2b) that highlights the differences between the maximum and minimum temperatures shows a decreasing trend. This implies that the minimum temperatures are fast catching up with the maximum temperatures – an indication that the environment is getting warming over the

Fig. 1 Position of the Seychelles within the East African Region. Available online at https://www.google.com/search?q=map+of+seychelles+and+surrounding+countries

years. The implication of such a trend in temperature could be linked to the impacts on ecosystem good and services in the Seychelles such as the recurrent coral bleaching events, drought, flash flood, etc.

Furthermore, coral reefs, seagrass meadows, and mangroves in the Seychelles, for example, are supposed to establish a belt of coastal protection and ecosystem services along the shores. However, current manifestation of coastal vulnerabilities in the form of coastal erosion (see Table 1) reinforces the point that these protective ecosystems have been degrading fast. In the Seychelles, coral reefs have been altered over decades following mass mortality events. The most recent coral bleaching event in 2016 has caused coral mortality in the upper 15–20 m in average at least 70% at the Seychelles granite Islands (Wilson et al. 2012). As a result, overall reef growth is declining exposing the coasts of many Seychelles Islands to even more erosion with rising sea levels of the twenty-first century.

Rainfall patterns: Annual average figures on rainfall maximum and minimum between 1980 and 2018 in the Seychelles stood at 292 mm and 140 mm respectively (Fig. 3). An interpretation based on Fig. 3 indicate that there have been no major changes over time in terms of annual averages. In other words, the total amount of rainfall, particularly during the rainy seasons compensate for the total amount of less rainfall during the dry season. However, some incident of extreme rainfalls have been recorded in Seychelles with monthly figures equivalent to annual estimates. The most recent of such occurrence was during the last 2 weeks of May 2019 with flash flood that lasted for almost a week in some neighborhoods on Mahé Island (see Etongo 2019). According to same study, flash floods in the Seychelles is linked to

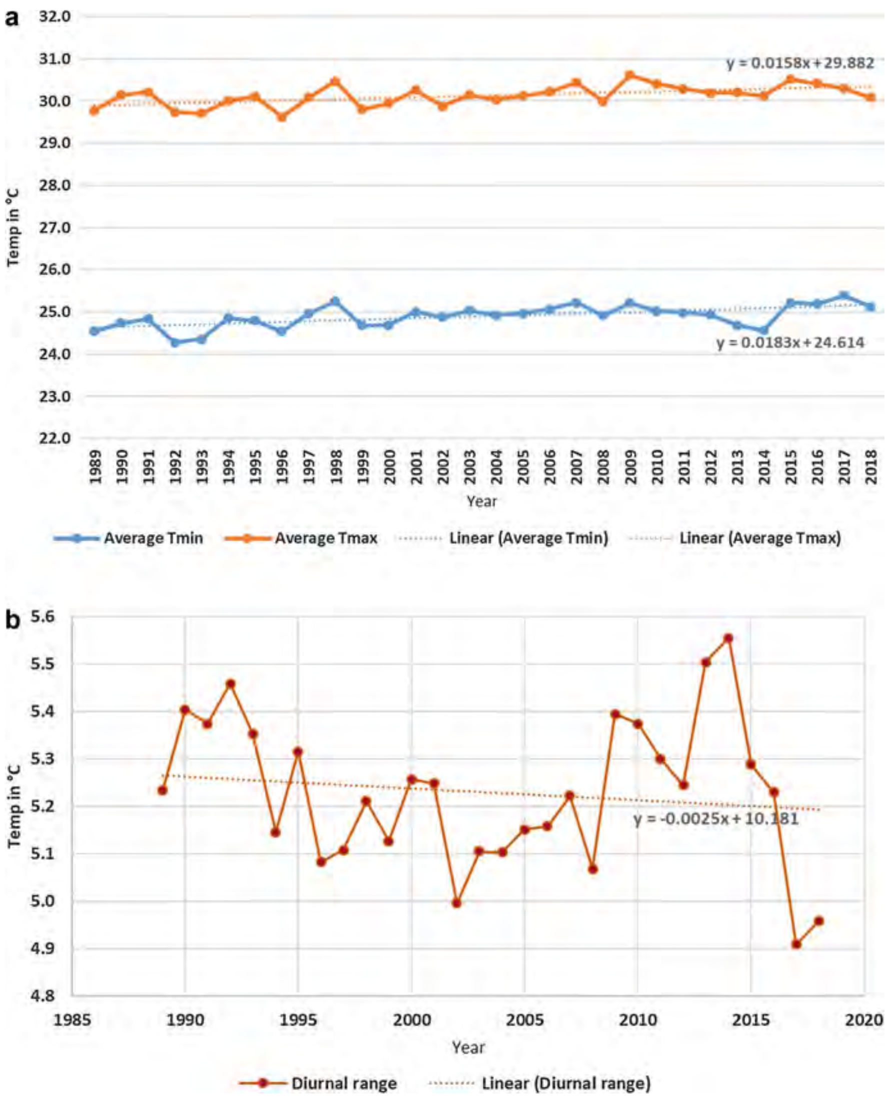

Fig. 2 (**a**) Average annual temperatures in the Seychelles between the years 1989 and 2018. (Source Seychelles Meteorological Authority). (**b**) Diurnal temperature ranges in the Seychelles between the years 1989 and 2018. (Source Seychelles Meteorological Authority)

legacy barriers to adaptation – the reclamation of wetlands for infrastructural development such as housing, resorts, roads, etc. An earlier study conducted in the Seychelles on climate change projection into 2021 indicated that the rainy seasons will be wetter and the dry seasons drier (Government of Seychelles 2009) – a clear manifestation of climate-induced vulnerability as shown in Table 1.

Table 1 Climatic and non-climatic induced vulnerability in the Seychelles

	Climate or climate-induced vulnerability	Non-climatic induced vulnerability	
1	Rainfall, precipitation, runoff	1	Economic, poverty
2	Monsoons, storms, winds	2	Social, cultural
3	Temperature (air and sea surface), heat, humidity	3	Human activities (general), recreational activities
4	Storm surge, coastal inundation, flood	4	Pollution, waste
5	Drought, dry conditions	5	Population growth, demographic changes
6	Sea level rise, tide, wave action	6	Food insecurity
7	Global warming	7	Lack of data/information gaps/ awareness
8	Water quality and/or availability, turbidity, siltation, sedimentation	8	Agricultural activities, soil (in) fertility
9	Soil/coastal erosion, landslide	9	Human settlement, housing
10	Resource/species/biodiversity loss	10	Deforestation
11	Diseases; air-, food-, water-borne	11	Over-exploitation of resources, overfishing
12	Coral bleaching/health	12	Environmental degradation
13	Ocean acidification	13	Land use changes
14	Ocean current	14	Size
15	Cloud cover	15	Location, insularity
		16	Cost of adaptation
		17	Elevation – low
		18	Dredging, land reclamation
		19	Ownership of land, complex tenure arrangements
		20	Lack of insurance
		21	Limited credit availability

The latest country's population estimate indicates that around 98.000 people live in the country (World Bank 2019). Similar to what is observed in other SIDS, Seychelles is currently facing unprecedented threats to its viability because of the impacts of climatic and non-climatic induced vulnerabilities. The development in the Seychelles has occurred predominantly on the coastline that are vulnerable to the impacts of climate change such as sea level rise, coastal inundation, beach erosion, etc. (Rice et al. 2019). The vulnerability of the Seychelles is illustrated by the fact that it has suffered from several disasters in the last four decades, some of which are driven by climate change, while others are non-climatic (see Table 1).

Additionally, new patterns of rainfall distribution have emerged in Seychelles amidst increasing coastal development, compared to the situation two decades ago (SMA 2019). The consequences are constant flash floods that last for several days in Mahé especially during the month of May 2019. Continuous rainfall for 2–3 days wasn't a major problem some four decades ago. However, the current situation is different given the level of coastal development that has taken place especially

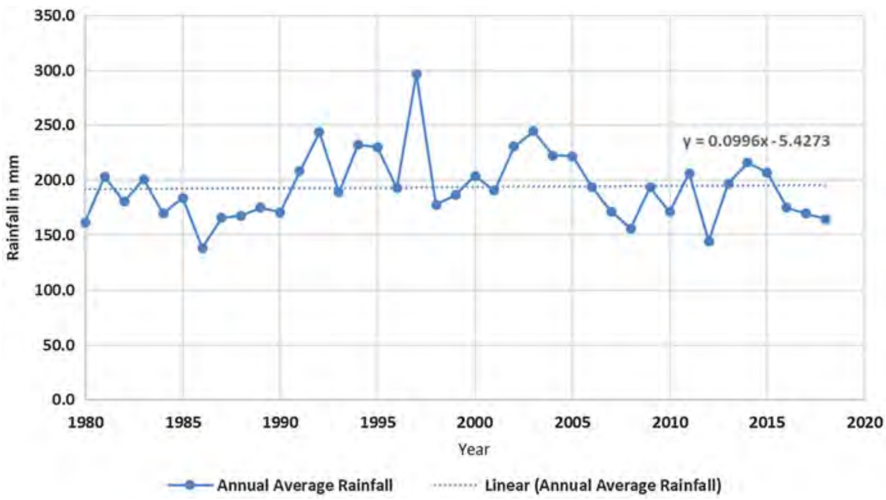

Fig. 3 Average annual rainfall in the Seychelles between the years 1980 and 2018. (Source Seychelles Meteorological Authority)

during the last decade on reclaimed wetlands whose water table is very close to the surface and may require several days for water to drain into the soil after rainfall (Etongo 2019: 45). Seychelles' vulnerability to the impacts of climate change has raised concern in four main areas, and they include sea level rise, changes in rainfall patterns, coastal flooding, and extreme weather events (Government of Seychelles 2013). Adaptation is considered a priority in Seychelles and in other SIDS as a strategy to mitigate both climatic and non-climatic driven vulnerabilities through the implementation of different adaptation actions. The next section of this chapter describes some of the adaptation interventions implemented in the Seychelles together with their pros and cons.

An Overview of Adaptation Measures in the Seychelles

A portfolio of approaches and interventions have been implemented in Seychelles, in order to adapt to the impacts of climate change. This section outlines some of them.

Hard Engineering Techniques

Hard engineering actions to adaptation in the Seychelles include highly visible, man-made structures, such as rock armoring, retaining walls, and groynes in order to protect especially the coastal and critical infrastructures such as roads, schools, hospitals, etc. (Rice et al. 2019). It is argued that hard adaptive measures involve capital-intensive, large, complex, inflexible technology, and infrastructure, whereas

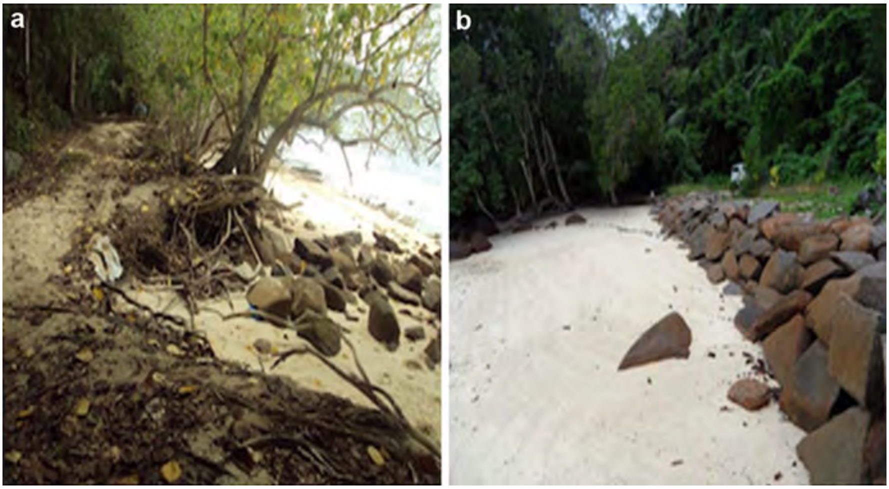

Fig. 4 Severe erosion at Anse Marie-Louise on Praslin Island highlighting coastal erosion (**a**) and the construction of rock armoring (**b**) to mitigate the impacts of coastal erosion (MEECC 2019)

soft adaptive measures prioritize natural capital, community control, simplicity, and appropriateness (Sovacool 2011). **Rock armoring** involves the placement of large rocks piled or placed at the foot of dunes in areas prone to erosion or in areas that have been severely eroded. A good example is the case of Anse Marie-Louise on Praslin Island (Fig. 4). Geo-textile fabric is usually placed behind and across the rock placements. The rocks absorb the wave energy and hold beach material. With time, the accretion of sand could result in the formation of new beaches (MEECC 2019).

The Seychelles' sea walls have been constructed of stone, timber piling, and rock armoring (Rice et al. 2019). **Sea walls** made of stone were mostly constructed during the colonial era, are low in height, and currently compromised by wave action and, therefore, rarely used today. Timber piling has been a more recently utilized strategy, and it incorporates EbA approaches such as dune restoration and replanting of native coastal vegetation. The success rate for this type of strategy is inconsistent. Most of the recent reclamation work on Mahé has been equipped with rock armoring and sea walls. Although these methods have proved to prevent coastal erosion, however, it is frequently considered an eyesore (Government of Seychelles 2017).

Soft Engineering Techniques

Soft engineering options are considered less expensive than hard engineering techniques. They are usually more long term with less impact on the environment. Examples of soft engineering adaptation actions implemented in the Seychelles include timber piling, beach nourishment, sand dune management, and the most recent being EbA. Due to their relevance, they are herewith described in turn:

Fig. 5 Timber piling for coastal protection on Praslin Island (World Bank and MEECC 2019)

Timber Piling

This method provides a physical barrier protecting unprotected dune-land from the direct hit of surging waves as has been implemented across the Seychelles. Geo-textile fabrics are placed behind and across the length of the wooden structures to complement the wooden pilings to trap sand that is washed up with the onshore transport of sediments by wave action (see Fig. 5). Backfilling with sand is implemented to allow the dune-land to recover more quickly than it would to further stabilize dune-land restoration and stabilize timber piling (World Bank and MEECC 2019).

Beach Nourishment

Beach replenishment or nourishment is a technique used in coastal defense management schemes. It involves importing sand off the beach and piling it on top of the existing sand, and this adaptation action has been implemented at different vulnerable beaches on Mahé Island in the Seychelles (Fig. 6). The imported sand, however, must be of a similar quality to the existing beach material so that it can integrate with the natural processes occurring there without causing any adverse effects (World Bank and MEECC 2019).

Sand Dune Management

Sand dune stabilization or sand dune management is used to prevent the loss of sediment on the beach. This method has been strengthened by coastal re-vegetation whereby selected coastal plants are planted to protect the dune-land vegetation and

Fig. 6 Beach nourishment project at the North East Point beach, Mahé Island (MEECC 2019)

stability (Fig. 7a). The construction of boardwalks (Fig. 7b) and bollards (Fig. 7c) has helped to stop the removal of sediments by anthropogenic activities especially across some hotspot areas on the North-East Point beach on Mahé Island.

Ecosystem-Based Adaptation

Ecosystem-based Adaptation (EbA) is a set of adaptation policies or measures that consider the role of ecosystem services to respond to the adverse impacts of climate change and can be used at multiple scales and in different sectors (Munang et al. 2013). EbA initiatives just like the Ecosystem-Based Adaptation to Climate Change in Seychelles that started in 2011 supported development aspirations and adaptation objectives through the sustainable management of biodiversity and ecosystems (Khan and Amelie 2014). This project uses nature-based methods through the application of technical solutions at specific watershed and costal sites such as reinforcing access to water, reprofiling of wetlands, and mangrove restoration (see Etongo 2019: 53). Coral reef restoration is another example of EbA projects that often entails the utilization of species resistant to bleaching and is considered a promising technology in Seychelles. There has also been wetland restoration work around Port Launay, Roche Caiman, and the freshwater marsh at North East Point. This work often entails the cleaning and replanting of mangrove areas.

The EbA project is considered a win-win for climate change and livelihoods because the forests and wetlands of Seychelles granitic islands play an important role

Fig. 7 Re-vegetation at *Anse à La Mouche* (**a**), constructed boardwalk at *Grand Anse* (**b**) and bollards (**c**) to protect dune-land from vehicles at *Anse Royale* (MEECC 2019)

in regulating stream flows and water quality. Forested land binds the soil, thereby decreasing soil erosion and increasing the capacity of soils to absorb and retain water. This allows water to penetrate deeper into the soil, allowing for less runoff and slower release. Wetlands and riparian vegetation also assist in reducing erosion while slowing water discharge over a longer period. The benefits include ameliorating the effects of climate change on water supplies by providing more regular stream flow during the lengthier dry season and, secondly, buffering against flooding following intense rainfall events. Similarly, mangroves and fringing coral reefs protect coastal land against coastal erosion, while coastal sand dunes and wetlands play an important role in controlling coastal flooding (UNEP 2017). All of these adaptation actions be it hard or soft that have been implemented in the Seychelles have their pros and cons as shown in Table 2.

Although some initiatives can potentially foster adaptation in the short term, there is a risk that they affect the environments', sectors', and people's long-term capacity and opportunities to cope with and manage the impacts of climate change (Magnan et al. 2016). Such a situation is considered as maladaptation. Climate change requires people to adjust ("adapt"), and the inability of persons and communities to adjust to environmental or economic instability is a part of maladaptation. Furthermore, people must be able to adapt not only to new hazards and changing resources, but also to new development initiatives, and to changes in access to and control over resources (Eriksen et al. 2015). It is therefore imperative to take stock of the adaptation actions that have taken place or are ongoing in the Seychelles given her vulnerability to the impacts of climate change.

Table 2 Summary of the pros and cons of adaptation actions in the Seychelles

Adaptation actions	Pros	Cons
	Hard engineering techniques	
Retaining wall and groynes	Protects coastal and critical infrastructure	Very expensive to set up and to maintain
Rock armoring	Rocks absorb the wave energy and hold beach material	Logistically difficult to organize
	Soft engineering techniques	
Timber piling	Physical barrier protecting unprotected dune-land	Timber may get used up over time
Beach nourishment	Replenishment technique helpful in coastal defense management	Requires constant importing of sand
Sand dune management	Prevent the loss of sediment on the beach	Requires careful maintenance
Ecosystem-based adaptation	Use the role of ecosystem services to respond to the adverse impacts of climate change	Needs to be combined with other techniques

Barriers to Climate Change Adaptation in the Seychelles

There are many barriers to climate change adaptation in the country. These are:

(i) Fragile institutions and inadequate governance related to climate change
(ii) Limited scientific knowledge and understanding of how climate change impacts the country
(iii) Financial constraints in supporting adaptation strategies
(iv) Human resource capacity (Etongo 2019: 55), here exemplified by limited staff trained on climate change adaptation methods

Khan and Amelie (2014) reaffirmed that a major institutional challenge to adaptation in the Seychelles is its effective integration into development planning. Aside from financial support provided by international agencies, national funding on adaptation actions is not only limited but poorly documented. This is also a trend seen elsewhere in Africa (Leal Filho et al. 2017). A recent report on climate change expenditures across government entities in Seychelles for 2018 stood at 597,953 SCR ($ 43,828.52) of which 20% of this figure correspond to adaptation and mitigation actions implemented by a single entity – the Public Utilities Corporation (CPEIR 2019: 12–13). Such low figures on adaptation for a country like Seychelles that consider it as national priority could partly be explained as estimates that do not match actual investments or lack of information from the private sector and difficulties in accounting for climate-related expenditures on adaptation.

Scientific knowledge and understanding on climate change adaptation in the Seychelles is another barrier partly due to fragmented knowledge on adaptation, little investment in research related to adaptation, and also difficulties encountered in the co-production of climate information for decision-making (Etongo 2019). Decision-makers from a wide variety of professional backgrounds increasingly find that their work intersects with the subject of climate change. The level of scientific expertise required to work on complex climate change adaptation problems is quite high, and most decision-makers in the Seychelles, other SIDS, and developing countries – such as city planners, resource managers, health officials, and farmers – lack a solid foundation on the science of climate change. When tasked with integrating climate information into their planning processes, decision-makers in the Seychelles and most developing countries faces two main challenges: (1) they find it difficult to know what climate information and data are best suited for a particular problem, and (2) they often perceive that climate information and data coming out of the scientific community is not usable in decisions (Briley et al. 2015).

A lack of appropriate knowledge and quality data further widens the adaptation deficit margin in Seychelles and other developing countries. This knowledge gap could be linked to the intensity of impacts that are usually beyond our range of understanding as was the case of heavy rainfall leading to flash floods that lasted for several days during the last 2 weeks of May 2019 on Mahé Island (see Etongo 2019). Furthermore, it could be the lack of technical knowledge, skills, tools, and technology and financial resources to effectively engage in proactive adaptation measures. For example, climate forecast in the Seychelles is largely based on comprehensive data collected from the airport, while such data are available in other parts of Mahé and the outer island but with lots of data gaps. Therefore, there is a growing need to improve on the early warning systems and strengthen information and decision support systems for the population in general for climate proofing in the Seychelles.

Social and cultural barriers can emerge in response to pre-existing perceptions of risk, beliefs, values, and preferences that underpin the ways individuals and societies experience, understand, and respond to climate change (Armah et al. 2015). Jones and Boyd (2011) found that socially and culturally embedded characteristics reinforce internal community structures to resist adaptation actions perceived as undesirable. Research also suggests that barriers vary according to place and culture may act as a mediating influence in resisting environmental change, particularly where change is perceived to threaten sense of belonging and place attachment (Armah et al. 2015). The role of informal institutions as barriers to adaptation in Seychelles is often ignored. Informal institutions are typically seen as the “invisible” norms that govern behavior, like customary practices or traditions and, are often embedded in a culture (Hodgson 2006). Parking of cars in the dune area across some hotspot areas on Mahé Island have led to the construction of bollards (see Fig. 7c). However, it’s not feasible to construct bollards across all of these hotspot areas, and cars could be seen parked in such places especially during the weekends.

Legacy barriers are another set of adaptation barriers that are common in the Seychelles and other developing countries. According to Moser and Ekstrom (2010), the spatial/jurisdictional and temporal origin of these barriers relative to the location of the actor are important. One of the legacy barrier in the Seychelles that put to test the nation’s capacity to adapt to climate change relate to land use planning in the past that affects drainage of rainwater (Etongo 2019). Majority of the development in Seychelles have occurred very close to the coastline either on reclaimed wetlands or at sites whose soil characteristics and/or water table is relatively high. Flash floods after heavy rainfall despite the availability of drainage systems is common in some neighborhoods in the Seychelles and is a barrier that is both remote and a legacy.

Options for Overcoming Adaptation Barriers in the Seychelles

Adaptation is a continuous process and not an outcome, and overcoming adaptation barriers could ensure proactive adaptation action that are capable of accommodating new information and or challenges linked to climate variability and change.

Climate change adaptation is not a stand-alone. Therefore, promoting synergies between adaptation and mitigation especially within the framework of EbA projects in the Seychelles has the potential of delivering a win-win solution for livelihoods and the environment. Adopting an integrated approach to community-based adaptation (CbA) and EbA have gained traction over recent years among scientist, policymakers, and development practitioners. Integrating CbA and EbA can also offer a cost-effective way to tackle climate change by capturing communities' knowledge and experience in dealing with climate variability and change. CbA is a bottom-up process that builds on local needs and capacities. It is based on human rights-based approaches that target the most vulnerable people and fully includes them in adaptation planning and implementation. It can also operate at scale, for example, through mainstreaming into government processes, but with communities remaining central to planning and action (IIED 2014). The Community Development Division in the Ministry of Local Government in the Seychelles could be used as an entry point into the various communities to improve adaptation through the integration of CbA and EbA actions.

In order to overcome the barriers that often arise during the co-production of climate information is to form direct partnerships with climate scientists to co-produce usable information for decision-making (Dilling and Lemos 2011). Collaboration between decision-makers and climate scientists offers an opportunity to leverage expertise from both parties to better serve problem-solving. Highly iterative interactions between decision-makers and scientists contribute to greater societal outcomes. The Seychelles National Climate Change Committee offers such platform for collaboration with the participation of a wide range of stakeholders from government, non-governmental organizations, research institutions, private sector, and community-based organization. However, this type of relationship requires a large investment of time, and the number of decision makers working on climate problems is much greater than the number of available partnering climate scientists (Bidwell et al. 2012).

Cross-sectoral and institutional collaboration is another option in overcoming most of the adaptation barriers that are institutionally driven. Collaboration across sectors will avoid the duplication of projects and improve on the efficient use of the limited financial resources nationally available for adaptation. Ford and Berrang-Ford (2014) are of the opinion that overcoming such barriers would require consistency, comparability, comprehensiveness, and coherency which they described as the 4Cs of adaptation tracking. The University of Seychelles offered a three-day short course in July 2019 on the topic mainstreaming climate change adaptation into development planning. This course provided a platform for different stakeholders to gain knowledge on mainstreaming adaptation into policy, across sectors and within projects. Additionally, the Global Climate Change Alliance (GCCA+) Seychelles have provided several trainings on climate change across different institutions in Seychelles during the last 2 years. The most recent was a training on early warning system that took place in the month of August 2019 at the Seychelles Meteorological Authority (SMA) office.

Furthermore, the very first climate change policy for the Seychelles and the Third National Communication to the UNFCC offers another opportunity to improve climate change adaptation in the country. A proactive climate policy should be coherent with other national development strategies. Some of these strategies are Seychelles Sustainable Development Strategy, National Communications in addition to Seychelles National Disaster Management Policy, and various legal mandates on environmental protection such as the Environmental Management Plan among others. Informal institutions that are rooted in culture or way of life might require new ways of doing things or a change in behavior in order to improve the adaptive capacity of Seychelles. A very good example in the Seychelles is the parking of cars in the dune area. Creating car parks in specific areas where land is available and convenient could partly address this problem. On the other hand, a wheel clamp policy could be implemented for those parking their cars in the dune area across different hotspots in the Seychelles. Institutional capacities, in particular measures of good governance such as participation, rule of law, accountability, transparency and responsiveness, etc., are the strongest predictors of national adaptation policy in the Seychelles and elsewhere (Berrang-Ford et al. 2014).

The role of local knowledge in adaptation to climate change is invaluable in reducing the vulnerabilities of communities to the impacts of climate change. However, there are concerns over its relevance for future adaptation amidst other challenges. Evidence from a study conducted in Tanzania suggests that local knowledge may contribute to adaptation to climate change in a number of ways especially when integrated with scientific knowledge (Naess 2013). Local knowledge especially among the fishing folks in the Seychelles is an important knowledge system that could be document. Local indicators of climate change impacts based on local knowledge have the potential to improve our understandings of how climate change affects the environment and the blue economy in the Seychelles. The fishing folks interact with the ocean space frequently and have accumulated local knowledge that could feed into early warning systems.

Finally, remote/legacy barriers are those barriers that are most difficult to address in the "here and now," as the locus of control is elsewhere and the origin of the barrier in the past. The three dominant types of such barriers include institutional ones such as the existing or missing governance structure and laws, economic and funding issues (such as the global economic crisis or state budget cuts), and attitudinal issues (the public's attitude, awareness and understanding of climate change, or longstanding personality conflicts). Since the year 2015 of its existence, Seychelles' Conservation and Climate Adaptation Trust (SeyCCAT) have provided financial support nationally for several research projects and small businesses in Seychelles related to climate change. Therefore, intervention in this case is remedial and compensatory by local actors: those who can and those who take it upon themselves "to break eggs" in order to make "omellette" – a view supported by Ekstrom and Moser (2014).

Conclusions

Several actions have been taken to improve climate change adaptation in Seychelles such as hard and soft engineering and policy options. These actions include policy development and revision, institutional setup, rock armoring, bollards, retaining walls, mangrove and coral restoration, rainwater harvesting, EbA approaches, human resource capacity development, research, education, and outreach. Despite such efforts to reduce the vulnerability of the Seychellois population to the impacts of climate change, several barriers hamper the adaptation process. Chief among these barriers include institutional and governance issues, scientific knowledge and understanding, financial issues, and human resource capacity. Adaptation actions are likely to be hindered by poor governance which in some cases is not limited to formal but also to informal institutions that are linked to cultural belief systems or a way of life. Parking of cars in the dune areas are "invisible" norms that govern behavior like customary practices or traditions often embedded in a culture.

Some proposed strategies to overcome these barriers include promoting synergies between adaptation and mitigation into sectorial policies and national development. Collaboration across institutions should be enhanced to avoid duplication of projects and also to share resources and expertise. In order to overcome barriers that often arose during the co-production of climate information is to form direct partnerships with climate scientists to co-produce usable information for decision-making. Furthermore, the community development division under the Ministry of Local Government should serve as an entry point to promote the integration of CbA and EbA actions across all the districts in the Seychelles. This will not only re-invent the wheel but will also harness local knowledge systems that are fast eroding while strengthening community participation in a bottom-up approach in the fight against the impacts of climate change. The role of technology transfer could solve some of the legacy problems and lesson could be learned from the Netherlands on what types of drainage systems to construct given that the water table in some locations in the Seychelles especially on Mahé Island is very close to the surface.

131 Linking Adaptation and Mitigation Toward a Resilient and Robust Infrastructure Sector in Kenya

Onkangi Ruth, David Lagat, and Ondari Lilian

Contents

Abstract

Sustainable city is an oxymoron to many especially in developing nations where the ever extending urban fabric has consequently degraded natural habitats, altered species composition, changed energy flows, and immensely affected biogeochemical cycles. This dims the vision of meeting the present needs with a nondecreasing level of well-being while not compromising that of the future

generations to meet theirs. Nairobi as other cities in peer nations is associated with socioeconomic vulnerabilities as well as visible and “invisible” ecological problems such as pollution, climate change, spatial competition, dependency in natural capital use, and congestion. Nevertheless, this is uniquely both a problem and a solution.

Nairobi has grown from a small railway station at the turn of the twentieth century to one of Africa’s largest cities. With this growth, comes an oversized ecological footprint and complex challenges of stresses and shocks. Infrastructure development in developing nations is gaining momentum. It is one of the development indicators and a major contributor to the GDP. However, it is very vulnerable financially and functionally to extreme weather events such as intense and prolonged periods of rainfall, inundation, low retreating rates of flood waters, increased temperatures, and unpredictable wind patterns. This study sought to establish the level of integration of adaptation and mitigation measures to climate change in selected infrastructure projects. It further evaluates the performance of key action plans, projects, and efforts made to enhance resilience to climate change. The study supports the integration of broad investment flows instead of the project-by-project approach.

Keywords

Climate change · Adaptation · Mitigation · Infrastructure · Policy · Cities

Introduction

There has been increased deliberate effort to build the technical capacity within cities in developing countries to combat climate change through developing long-term national climate action plans thus creating an enabling environment for low carbon development. However, mitigation of climate change has received more financial, technical support, and mention in policy documents compared to adaptation. Climate change is a current phenomenon and no longer an anticipated occurrence. Developing countries are very vulnerable to climate change and a lot of natural resource-driven economic development is ongoing. Therefore, there is need to embrace low emission development pathways which integrate climate adaptation and mitigation activities for future proofing of the built environment.

According to UNEP, sixty-six percent (66%) of infrastructure in developing countries is yet to be built. This is an opportunity to make carbon-efficient cities a reality and not just rhetoric. This uniquely makes developing world cities both a challenge and a solution to climate change. With this unique opportunity to have mitigation and adaptation march in lockstep as well as avert high carbon stranded assets in the future, emerging economy cities need to gravitate toward sustainable development and keep their carbon footprint low. Embracing a responsible resource consumption and production approach will not only avoid locking in of unsustainable lifestyles and technologies but will also concurrently support both adequate mitigation and adaptation measures to climate change.

Linking adaptation and mitigation is imperative if developing countries are to keep their emissions low in the face of future developments and if the overall carbon emissions globally are to be reduced to safe levels in the near future.

Developing countries as far as infrastructure is concerned need to be climate wise if they aim to avert retrogression (*economically and socially*). Being climate wise in the built environment means adding the data layer to planning and designing, conducting mapping of vulnerability for infrastructure assets, as per location, exposure level to climatic changes, sensitivity, type of asset, design life and its adaptive capacity to support adaptation actions, and disaster preparedness as the built environment expands with economic growth. Also, industry professionals need to have climate change adaptation and mitigation knowledge to incorporate it in design of current and future projects.

This can be achieved through integration of climate change adaptation and mitigation knowledge in the curriculum of construction industry professionals. Conducting research on suitability of materials for adaptation and mitigation and offering a knowledge platform for the same will support timely climate proofing for the ongoing delicate economic progress.

In addition, adaptation and mitigation can march in lockstep to enhance resilience through broad investment flows in policy, education, and planning by review of physical planning policies to support a negative feedback loop in growth and expansion. Planning needs to precede infrastructure development (Yigitcanlar and Kamruzzaman 2015). Government should not authorize any project in an area without prior and authorized physical planning. Further, every mega development project needs to have reliable enforceable measures stated in the Strategic Environment Assessment Study report to counter the positive feedback loop associated with the project. Further, Nairobi can adopt a form-based code that encourages building out instead of uncontrolled infill development. Incorporating population growth data, flood estimation in the design of roads, culverts, and stormwater drainage systems as well as wastewater infrastructure enacting policy to support uptake of protective engineering in the coastal area.

The National adaptation and mitigation plans need to have targets attached to sector-specific responses to climate change. This will support a coordinated response to climate change that will favor integration of broad investment flows instead of the project-by-project approach (*silo responses*).

The rapid growth and extending urban fabric in Nairobi bring with it an oversized ecological footprint and complex challenges including increased natural capital dependency more spatial competition and congestion. This rapid unsustainable development translates to rapid carbonization of developing country economies.

Environmental degradation in Nairobi has majorly and anecdotally manifested through:

1. Reduction in green spaces, over the years, as vegetation and trees are cleared to pave way for construction (see an attached satellite map in Fig. 1 showing the changes that have occurred over years in Kilimani area and around Nairobi National park) (*which translates to loss/reduction of carbon sinks*).
2. Shrinking and polluted blue features.

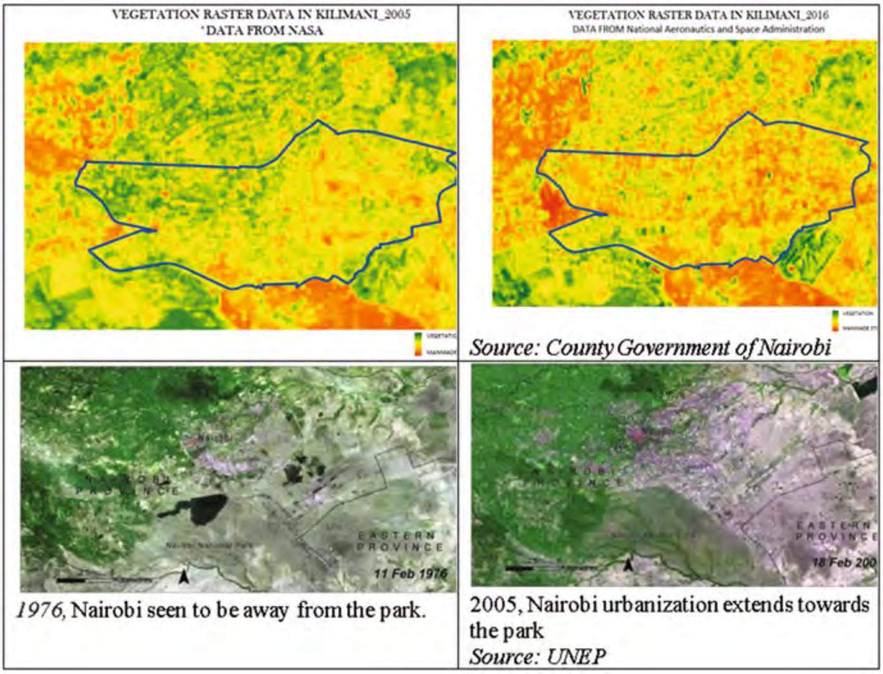

Fig. 1 Spatial representation of decreasing green spaces in Nairobi

3. Increased use of motor transport and traffic congestion.
4. Sudden and rapid decrease of groundwater table due to less percolation as most surfaces are paved, and extraction rate of water exceeds recharge rates.
5. Flooding, water, noise, and air pollution.
6. Inadequate waste management-illegal dumping and inability to collect and dump at the designated place. The waste finds its way to drains hence causing blocking of stormwater drains and natural stream channels.
7. Heat island effect and increased energy use.

Despite devolution of the Government in Kenya, Nairobi's urban population is far from taking a plunge. Therefore, problems plaguing the city of Nairobi now need a lasting solution that will be immune to climatic changes for continuity and quality standard survival of progeny.

According to Kenya urbanization review conducted by World Bank, urban areas in Kenya at the moment play host to over ten million Kenyans. Nairobi hosts the majority with over four million people. World Bank estimates that by 2050 as many as 48.46 million people in Kenya will be living in cities this is equivalent to the country's entire present population (World Bank 2016). Rural to urban migration is informing the rapid expansion, however, the population of Kenyans migrating to cities is of a high fertility rate; this means urban population will continue to increase amid efforts to decentralize systems and discourage rural to urban migration (Hope 2012).

Consequently, as a proactive remedy, sustainable development is to be inculcated here and now in the face of future growth and expansion. Linking adaptation and mitigation in Nairobi will set precedence in other emerging urban areas as well as in two other developing cities in Kenya like Mombasa and Kisumu. If unsustainable urbanization as of the moment in Nairobi continues then the problem will be repeated in emerging urban areas hence weakening national future proofing efforts and further enhancing vulnerability. The reverse is also true; a success story of linking adaptation and mitigation to climate change in Nairobi will reverberate in the entire urban ecosystem of the country. This chapter evaluates level of integration of adaptation and mitigation measures to climate change in infrastructure projects (in three areas: climate data integration in infrastructure development, water security, and gray to green infrastructure ratio) in Kenya's capital as a partial and major contributor to the shift to sustainable city status.

Climate Change Issues Affecting the Built Environment

According to the Intergovernmental Panel for Climate Change (IPCC) GCMs (Global Circulation Models), Kenya is likely to experience adverse climate changes between the late 2020s and 2100. The GCMs projections based on a grid resolution of 200 $\times$ 200 km though having not included altitude modifications indicate that both rainy seasons are likely to become wetter especially the short rains that normally fall between October and December every year. Increased rainfall intensity events will lead to more flooding events in frequency and severity. Sea level rise will also have 17% of Mombasa (Kenya's second largest city) flooded.

The northern part of Kenya as per the GCMs will have 40% rainfall increases by 2100. By 2020s temperature are postulated to rise by 1 °C and 4 °C by 2100 (Parry et al. 2012).

These climatic changes will affect not just biodiversity, agriculture, and health aspects of the populace but infrastructure is vulnerable as well. By the fact that infrastructure underpins every sector, it is crucial to future proof assets to reinforce the efforts in other sectors to combat climate change for holistic resilience.

The infrastructure sector is vulnerable and responsible for climate change (to a large extent). Overall, the construction industry is responsible for one third of greenhouse gas (GHG) emissions. And depending on how you apportion it, buildings are contributing to almost half of GHG emissions.

Changes associated with climate changes are forecasted to contribute to degradation of infrastructure and building materials (Wilby 2007; Onkangi et al. 2019). Water availability is likely to affect demand and supply especially in prolonged dry spells; this can affect construction projects as they are heavily reliant on water. Increased precipitation will affect stormwater drainages, load, wastewater treatment systems and road networks causing project delays and reducing lifetime of infrastructure (Nelson et al. 2009; Onkangi et al. 2019). Cascading of failures due to linkages of infrastructure will have a knock-on effect on operations and the economy. Mitigation of and adaptation to climate change in the building sector are imperative (Onkangi et al. 2019).

Infrastructure more so in urban areas is interdependent especially through the water and wastewater systems as well as the drainage system. Infrastructure-to-infrastructure ties are also very present (water or non-water); therefore, weather-related disruptions whose genesis is hydrologic floods and intense precipitation can reverberate through the entire system. Therefore, management practices in one infrastructure will impact another (Onkangi et al. 2019; Wilbanks and Fernandez 2014).

The building sector like other sectors needs to play its part in lowering global temperatures to below 2 °C above preindustrial levels as agreed in the Paris Agreement 2015 in which Kenya is signatory to. The Building's day in the COP 21 gave birth to a commitment among participating nations that the construction sector will reduce emissions by 84 GtCO2 by 2050 (Paris Agreement 2015).

Through "adaptable architecture" or "adaptable buildings," both adaptation and mitigation can be adequately addressed in the built environment. Mitigation can be addressed through adaptation. "Adaptable architecture" or "adaptable buildings" are "concepts that feature flexibility in the function, physical form or experience in buildings along with a desire to develop systems for mass customization as well as pre-fabrication of building components with the end-use of buildings in mind" (Dave et al. 2016).

Where there is adequate planning, infrastructure informs cities. Greening infrastructure is the ignition key of a sustainable city. Nonetheless, mitigation and adaptation efforts in developing countries are biased to agriculture, human health, and biodiversity. Infrastructure is yet to be looped in adequately. It is crucial to ensure food security in the future, but if connectivity in the transport and communication is lost due to climate and weather-related interruptions then the farmer's produce fails to reach the market, and food security is jeopardized.

People spend 90% of the time in buildings, when adaptation to climate change is not incorporated in design and implementation then challenges due to extreme weather events compromise user comfort and threaten overall well-being (Klepeis et al. 2001). The research on building failures in Kenya indicated that more collapses happened in the rainy season. With climate projections indicating increased rain intensity and flash flooding in the future, a major threat looms for nonresilient assets whose numbers are evidently not few neither are the users (NCA 2017).

Study Methodology

Through desktop study and literature review, criteria for evaluating mitigation and adaptation measures shown in Fig. 2 were adopted. In the period of August 2016 and November 2016, a descriptive survey tool of 72 structured questionnaires assessing the measure was administered to contractors, engineers, architects, quantity surveyors, construction firms, project managers, and construction managers. 51 questionnaires dully filled were collected giving a response rate of 71%. Further, desktop study, observation, and assessment of infrastructure more so where failures were reported yield information to complement the feedback from questionnaires on

Infrastructure Adaptation

- Policy and legislation on adaptation of infrastructure to Climate Change (CC)
- Infrastructure climate change adaptation plan
- Incorporation of adaptation to CC in the Building code
- Capacity building of industry professionals on adaptation to CC
- Integration of adapation measures to climate change
- Political goodwill
- City specific Climate data availability
- Level of integration of climate data in design and construction
- Disaster response system for infrastructure
- Level of integration of the data layer in infrastructure development

Infrastructure Mitigation

- Sector specific policy and legislation on mitigation
- Infrastructure climate change mitigation plans
- Perceptions and attitudes to incorporating mitigation measures
- Sectoral mitigation targets
- Grey to green infrastructure ratio
- Operational Knowledge
- Commitments to Multilateral agreements on sustanaible and climate resilient cities
- Level of integration of climate data in design and construction

Fig. 2 Adaptation and mitigation evaluation criteria

integration of mitigation and adaptation. These findings gathered from the expert community were analyzed using SPSS, and the evaluation forms the bulk of this chapter.

Results

Climate Change Mitigation and Adaptation Interventions in Nairobi City

Gray to Green Infrastructure Ratio

The green infrastructure concept is an integrated approach that connects services, ecology, land use, and heritage. This "joined up" thinking delivers critical environmental services presenting a sustainable alternative to growth and development while upholding both mitigation and adaptation measures. Green infrastructure is multifunctional compared to gray infrastructure that is mostly single function. Both are critical and investment in both should be simultaneous. With decreasing green spaces, Nairobi has increasingly experienced the harshness associated with their reduction and loss.

Nairobi's builtscape was previously nested in green spaces. The world's only urbanite national park, an array of city parks, botanical gardens, and arboretum earned Nairobi the title "green city in the sun." However, the spaces have been decreasing as shown in Fig. 1.

The new construction projects including roads in Kenya such as Thika road have a high gray to green infrastructure ratio, see Fig. 3.

As the urban fabric continues to extend, green spaces continue to shrink (see Fig. 1). The concrete jungle is gaining dominance. In many Environmental Impact

Assessment project reports, developers commit to landscaping and site restoration as far as possible. In the Environment Impact Assessment (EIA) reports, each project needs to state and commit to adaptation and mitigation measures adopted to combat climate change. But there are no set targets of the percentage of the project area that should be landscaped in the EIA reporting. This indirectly encourages the high gray to green infrastructure ratio. As seen in Fig. 3, lofty expansive buildings have dots of green spaces as part of landscaping and for aesthetics.

However, there is lack of targets on what percentage of the project area should have open spaces. Neither is there a policy push to have pervious spaces given a percentage priority in open space management. To create space for parking, many of the spaces surrounding are highly paved. The green to gray ratio in projects needs to be given a baseline per square meters of gray space; there should be greening of an equivalent space to counter negative impacts guided by adaptation and mitigation targets. The Government is yet to offer incentives to encourage sustainable construction to counter high paving of buildings. Policy to encourage silo parking and green roofing is a better option.

Illegally, numerous projects more so in low income neighborhoods construct beacon to beacon. And in upmarket areas, service paving is widespread. Increased paved surfaces ushered by rapid urbanization with gray infrastructure has aggravated

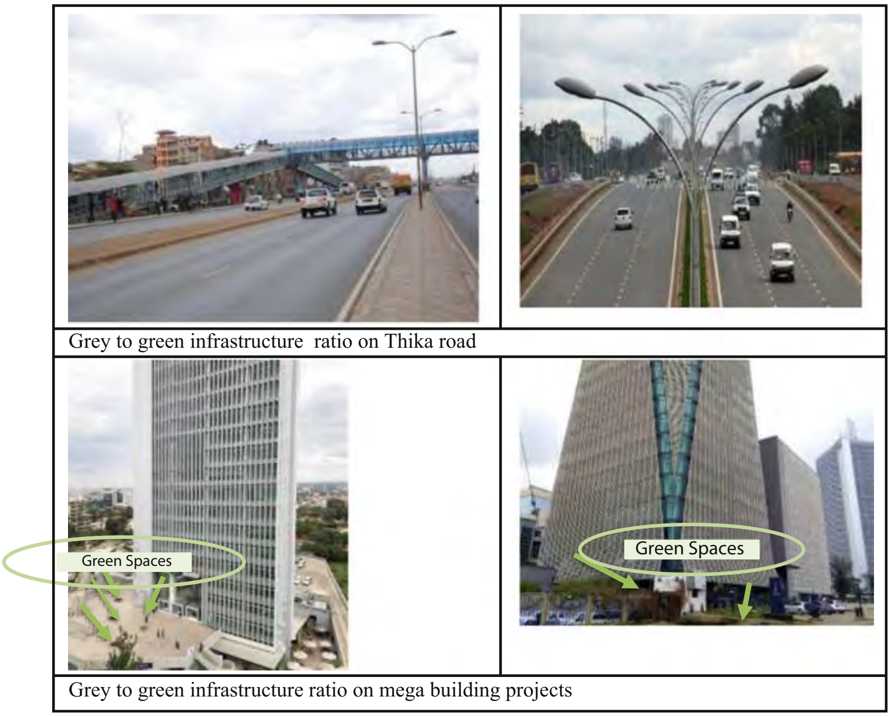

Fig. 3 Green to gray infrastructure ratio in mega projects

Fig. 4 Poor solid waste management has aggravated inundation in Nairobi

inundation as flood waters flow rapidly to rivers rather than being slowed by natural means through underground seepage and uptake by vegetation (green infrastructure). In addition, natural and manmade channels have been obstructed due to poor management of solid waste as shown in the Fig. 4.

The old concept of draining water away from cities through stormwater collection is not only contributing to pollution of water bodies but water insecurity in the face of climate change as aquifers are not recharging at the same rate as extraction. Population explosion has also overwhelmed the drainage system and increased urbanization of river catchment areas through illegal settlements and encroachments (Douglas et al. 2008). Consequently, small downpours translate to flash floods due to surface runoff from the paved surfaces and drains. Wastewater systems get overwhelmed, and sewage overflows are a common site. Further, in cases where rivulets and stormwater flows through a series of concrete passages and culverts, they are unable to adjust to rain intensity and frequency as natural streams do. This is largely attributed to lack of incorporation of the demographic data layer in city planning, infrastructure design, and construction.

Depleting Aquifers

With the heavy downpour in certain periods of the year, the water table in Nairobi is still receding at a fast rate threatening subsidence of buildings. According to numerous studies and the National Environment Management Authority, increased hard paving and construction of buildings has reduced percolation to recharge the groundwater. Vegetation, soft landscaping, or pervious paving systems are crucial for recharge and cooling. However, wide hard paving as is the case in Nairobi at the moment causes most of the rainwater flows as surface runoff and is rapidly conducted to streams and rivers due to a high gray to green infrastructure ratio.

As the built environment has extended, the groundwater level has decreased, this is evidenced in various studies. Through the years with growing demand the number of boreholes sunk in Nairobi has increased drastically from 2 in 1927 to over 2500 in the year 2009 (Mathu et al. 2014). Also, the average depth of the water table has alarmingly decreased. In 1920s boreholes were sunk to a depth of only 20–22 m.

As of 1950, the groundwater level was 80 m deep while in 1996 it was about 140 m. This has been receding further at a rate of 1.8 m per month or even faster (Mathu et al. 2014; Olingo 2011; Foster and Tuinhof 2005).

The study by Mathu, Onyancha, Mwea, and Ngecu (2014) on "Effects of Drilling Deep Tube Wells in The Urban Areas of Nairobi City, Kenya" where the researchers used Surfer 9 software to analyze level of groundwater static variations in space and time in boreholes between 1927 and 2009, established that "groundwater rest levels have dropped with an average of 79 m in the last 80 years and a probable settlement of 0.34 m to 5.9 m could result from groundwater depletion from aquifers and clay aquitards over a long period of time. This should serve as a wakeup call to put up measures that can mitigate subsidence and the related consequences in Nairobi City." The study also verified that 67% of the drop in groundwater rest levels has happened in the last two decades with sinking of boreholes in thousands (Mathu et al. 2014). The law requiring boreholes to be sunk at least 100 m apart is also not observed (Kenyan Parliament 2016). There is a continued scramble and siphoning of the Nairobi groundwater. The biophysical transformation due to urban sprawl is not making it better due to little recharge.

Heat Island Effect

The heat island effect serves as the basic climate response to urbanization. Due to Nairobi's location at the tropics, the heat island effect is not as significant as it is in cities located in the temperate regions. "An investigation of urban heat island phenomenon in Nairobi" by Reginald Ambona over the period of 1991–2011 using the wind rose technique to examine presence of the heat island plume confirmed that Nairobi experiences heat island effect though not large enough (Amboga 2013). This was similarly observed in an earlier study which warned that with current trends of population increase, greater motor vehicle density and higher industrialization and urban spread, the anthropogenic waste heat ejection would be large enough to modify the heat balance of Nairobi city appreciably by the year 2030 (Opijah et al. 2008).

In 2009, Makokha and Shisanya found that cooling and warming rates were highest at the suburban study site and lowest at the urban canyon study site. The built environment in the study sites explained the differential cooling and warming rates. The study recommended proper planning of the built environment to ameliorate the problem of excessive nocturnal heat loads within the built environment (Makokha and Shisanya 2010).

A similar study by Silas Owiti in 2016 indicated that there is a growing distribution of heat islands in Nairobi. There was negative correlation between land surface temperature (LST) and normalized difference vegetation index (NDVI) implying that vegetation alleviated the heat island effect, while the positive correlation between LST and urbanization indicated that the urbanization increases the heat island effect. Owiti's study concluded that with the rate of urbanization, the distributed heat island effect, with time will conglomerate into a large heat island in the city (Owiti 2016).

These results are attributed to infill development as well as urban sprawl in Nairobi which is causing enormous vegetation loss. Impervious surfaces such as buildings, parking spaces, and tarmac roads have affected the heat balance regulated by the natural ecosystem.

Passing environmental laws, policies, action plans that are definite and give project specific binding targets on mitigation will help foster sustainability. In addition, project environmental audit reports should include mitigation and adaptation achievements and opportunities. Providing a business case for integrating climate action in city projects as well as creating a knowledge platform and increase awareness on adaptation and mitigation for infrastructure projects will support adoption of environmental stewardship in the built environment in Kenya.

Transport Infrastructure

The 1997/1998 El Niño rains are estimated to have caused the country's roads, water supply infrastructure, buildings, and telecommunication infrastructure damage of US$0.8–1.2 billion equivalent to 11% of Kenya's GDP (MoE 2010, 2013). "Other losses amounting to US$9 million arose from flooding, property destruction, soil erosion, mudslides and landslides, surface and groundwater pollution and sedimentation of dams and water reservoirs" (MoE 2013).

The National Climate Change Action Plan 2013–2017 directs that "new investments in infrastructure must consider expected changes in temperature and precipitation." According to the Plan for a low carbon climate-resilient pathway, infrastructure should be "climate proofed" the plan elaborates on climate proofing to mean "designed, constructed and operated in a way that accounts for anticipated risks and opportunities that result from climate change, ensuring that infrastructure investments are not compromised in the future." Further, it states the need to account for sea levels rise in infrastructure, port facilities, roads, railways, and bridges.

However, emerging from this study is that there is low integration of climate data in new infrastructure development. The sector is yet to adopt action plan measures to enhance resilience, ongoing, and newly completed projects use historical data, but future predictions are not factored in. This is attributed to level of availability of meteorological (met) data. Many study respondents indicated that they do not have access to meteorological data and that which is available is expensive thus adding to the project costs.

A price-based economy is seemingly not supporting many key interventions that could be costly in the short term but avert bigger costs in the long term. Also, the met stations are few, monitor particular elements and inconsistencies in data records affect reliability.

The Government is building a sea wall to protect a monumental site (Fort Jesus) from sea level rise. The reactive adaptation to sea level rise on this centuries old monument is a step in the right direction; however, new developments are not taking up proactive adaptation measures against sea level rise as seen in the new Mombasa road by the seaside (see Fig. 5). Prioritizing maintenance of infrastructure in vulnerable areas, incorporating climate change in maintenance, and retrofitting of structures are recommended proactive measures for state and non-state entities to increase adaptation to climate change.

Fig. 5 The new Mombasa road by the seaside in Mombasa city

Thika Superhighway Case Study

The 8-lane highway project by the Kenyan Government was done to reduce congestion and increase connectivity between the capital city and the industrial town of Thika. Endless hours were spent in traffic to and from the city when the road was only two lanes. However, the problem of traffic congestion still persists.

The climate action plan recommends a mass transit system Bus Rapid Transit (BRT) complemented with a light rail as mitigation measure against climate change. This measure is estimated to abate approximately 2.8 $MtCO_2$ emissions by 2030. At the moment there is a sharp increase in car ownership in Kenya. On average at least 20,000 cars are added to the Kenyan roads every month as illustrated in Fig. 6 majority of which are used in Nairobi metropolis.

The Government of Kenya is aiming to introduce BRTs in 2019 and has already marked dedicated lanes in the superhighway for the BRTs (see Fig. 7).

In addition, the Kenyan Government sought to introduce two car-free days every Wednesday and Saturday with the introduction of BRTs in 2019. These car-free days policy was dead on arrival due to lack of alternative means of transportation as the BRT is yet to arrive, and public consultation was not conducted. There has been wide resistance among the masses on the same leading to cancelation of the two car-free days (Okinda 2019; Ondieki 2019).

If the BRT system proves reliable in the long run, it will contribute to promoting sustainable transport and reduce emissions associated with personal car use. A major boost to mitigation efforts.

Introduction of BRT will also enable decongestion of the city roads and reducing traffic snarl ups. Laudable mitigation efforts. Nonetheless, the transport infrastructure needs to adapt to climate change. This same superhighway with lanes

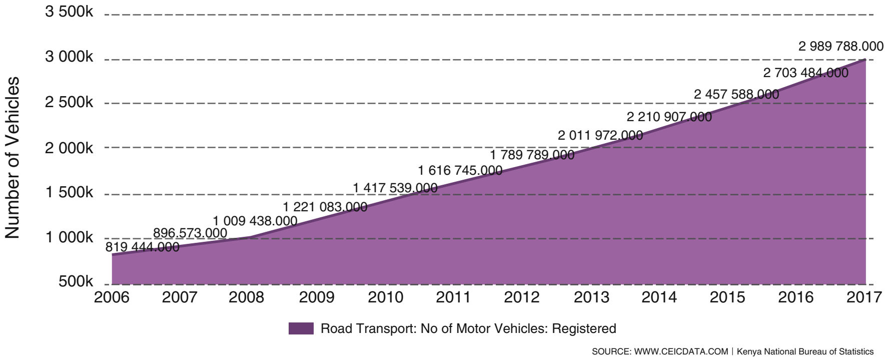

Fig. 6 Yearly number of motor vehicles registered in Kenya Road Transport. (Source: Kenya National bureau of Statistics)

Fig. 7 Lanes marked on Thika superhighway for BRT buses to be introduced by the Kenyan Government in early 2019

marked for BRT has faced inundation challenges (see Fig. 8), as adaptation measures were not incorporated in design. The gray to green infrastructure is high, and future climatic predictions did not inform the design. Poor solid waste management exacerbates the problem due to blocking of drainages. Without

Fig. 8 A flooded Thika superhighway after a downpour

incorporating adaptation measures, mitigation measures laudable as they may be will soon become laughable as the climate changes and weather events become extreme.

The Government is currently constructing bypasses around the city to manage traffic as well as expanding city roads. This is a short-term solution as seen from Thika superhighway case. More road networks, more expansion, and more cars and BRT lanes adding to climate change. Any magnitude of rainfall even light showers causes unprecedented traffic snarl ups in all Nairobi city roads. One can only imagine how chaotic the scenario will be as the climate continues to change in an unpleasant manner. The impact that will have on the economy is big due to productivity losses as the human capital is wasted in traffic jams that also contribute to more carbon emissions – a double loss.

To adapt and mitigate accordingly the Government needs to implement policies that counter this positive feedback loop associated with road expansion or "reliable" transport. In the Thika road scenario after road expansion, settlement along the highway exploded. The population shifted to Thika roadside and mostly young people, with young families hence more and more cars on the road. Infrastructure in every aspect has been stretched, wastewater systems are strained, and sewage overflows are common and worse when it rains. Clean water supply to homes is increasingly inadequate as more apartments are added per mile. Adequate physical planning and dedicated implementation to guide human settlement will support mitigation measures and enhance adaptation.

Non-motor Transport

Among the incremental investments required to ensure that all infrastructure developed is climate-resilient, Kenya's National Climate Change Action Plan envisions that bicycle lanes and sidewalks, to be developed in parallel with the transit system, will contribute to an emission reduction of 4.1 $MtCO_2$ of emissions by 2030 (MoE 2013).

New roads outside the central business district (including sections of Thika road) have cycling lanes; the old roads and those running through the central business district were not designed for cyclists as they lack cycling lanes. At some point a cyclist has to share a road with motorists as they make their way into the city. Cycling is a risky affair in most of Nairobi as motorists and cyclists have to share roads (see Figs. 9 and 10).

Cycling lanes are invaded by motorcycles that poorly observe road discipline. Pedestrians also leave sidewalks for cycling lanes. This fails to encourage uptake of non-motor transport in form of cycling.

This has not triggered nor supported a cycling culture. Besides cycling being viewed to be very risky, road discipline is very low for motorists and cyclists to share a road. The fact that the older roads were not designed for cyclists and lack of sufficient secure bicycle parking spaces indicates that local government leadership was not pro-cycling. The local government has banned public transport a couple of

Fig. 9 Motorcycles using lanes designated for non-motor transport

Fig. 10 Cyclist sharing a road with oncoming motorists

times which led to great inconvenience to commuters and the labor force. The idea succumbed to lack of alternative means for connectivity. Not once did the local government introduce bike share program as an alternative transport mode. Majority of the buildings also do not have cloak rooms with public showers to encourage a “cycle to work” culture, lack of pro-cycling policies do not favor a cycling culture or thinking to thrive. Legislating a policy to make accessories in every building that will encourage sustainable living basic is recommended. The policy can have a percentage of parking spaces and rest rooms dedicated for secure bicycle parking spaces, shower, and changing rooms.

Negative perceptions to cycling greatly contribute to its adoption level. A study by Mitullah and Makajuma (2013) analyzing non-motorized travel conditions on the Jogoo Road corridor in Nairobi established that 66% of the participants expressed views that riding a bicycle shows that one is poor: 3% of these strongly agreed to this, 19% agreed to it, and 44% felt somehow riding a bicycle is an indication of poverty. Therefore, to shift to sustainable modes of transportation requires education of the masses and example setting by the leadership to help eliminate such perceptions. Politicians embracing non-motorized transport will manage perceptions usher attitude change and show political good will.

Level of Integration of Climate Change Concerns in Design

Temperature rise received the highest percentage in design consideration and material use as 53.8% of the respondents indicated. Anecdotally, following registered complaints from a number of occupants some new buildings are designed for a hot climate. During cold season they are very cold necessitating use of heaters which raises energy use that upsets the sustainability message. But in hot season they have excellent occupant comfort.

A large number of participants (61.5%) indicated not giving high consideration to indoor climate in design aspects of a building. Water efficiency to improve water security was a high consideration to 38.5% of the participants and increased wind strengths was factored in design by 23.1% of the respondents.

Energy audit study jointly conducted by UN Habitat, University of Nairobi and Makerere established that buildings in East Africa designed before 1990 are more energy efficient while most of the buildings designed in the 90s are less energy efficient. This was attributed to abandoning of vernacular architecture for what is trending like glass building envelopes as they are aesthetically appealing without considering which materials the local environment supports or which materials support the local environment for occupant comfort.

Integration of Climate Adaptation into Transport Infrastructure Projects

Thirty-one percent (31%) of study participants were very confident that culverts and stormwater drains can handle some percent increase inflow due to intense rainfall. Use of insurance schemes against flooding damages was reported by fifteen percent (15%) of the respondents. Insuring of buildings against collapses was reported by twenty-three percent (23%) of the participants.

Conclusion

There is less target action in mainstreaming climate change in the infrastructure sector in Kenya. Climate change integration in infrastructure construction is very low. Barriers to taking action include low accessibility of met data to industry professionals, lack of sector specific laws and policies enforcing mainstreaming, low awareness of adaptation and mitigation measures for infrastructure, and perceptions of sustainability as a soft and foreign concept.

Uptake of measures stated in the National Climate Change Action Plan is very low in the infrastructure sector. The measures need to have targets attached to them. A low carbon development pathway is within reach of developing countries if they embrace both adaptation and mitigation measures in matching strength. The infrastructure sector in Nairobi has low resilience to climate change. Physical planning inadequacies and weak complimentary policies are reinforcing these weaknesses enhancing the city's vulnerabilities.

Overall mitigation has better attention than adaptation (Fig. 11).

There is a need to balance the equation (as shown in Figure 11) for a robust and resilient outcome in growth and development.

Climate change adaptation and mitigation in cities should not be addressed in isolation; attention should be given to all sectors to manage interlinkages and interconnectivities. While pockets of leadership are witnessed through a project by

Fig. 11 Mitigation and adaptation need to be adopted in marching strength for climate resilience to be realized

project approach (*tokenism*), broad investment flows yield synergy that is more impactful, realize greater resilience, and harness robustness.

addition, some coastal areas are excessively mined for sand, protective mangroves are destroyed, and coastal waters are overfished, affecting the well-being, safety, and livelihoods of local communities. These threats disproportionally affect the poorest and most marginalized groups, including women and children, leading to their increased vulnerability to climate change and adoption of negative coping mechanisms.

This chapter proposes an integrated people-centered approach, with a particular focus on women, to address the triple crisis – poverty, climate change, and nature – at the local level. Findings will be shared from a 2-year project implemented in the southernmost coastal region of Kwale County in Kenya, which aimed to achieve beneficial and interconnected social, environmental, and climate outcomes. The chapter discusses findings, successes, and lessons learned from the action and the requirement to position vulnerable groups at the center of initiatives designed to address the triple crisis. Limitations of the study and main recommendations for future programming in similar contexts are also shared.

Introduction

Climate, Poverty, and Nature: Three Interconnected Societal Challenges

Originally, 2020, now running into 2021 – due to the ongoing global pandemic – is expected to be a pivotal year for the promotion of a more sustainable and climate-resilient future. Major events are scheduled where decisions will be made around development targets (UN Sustainable Development Goals will be revised), conservation of biodiversity (UN Convention on Biological Diversity), and climate actions (review of the Paris Agreement targets).

In the last few years, there has been growing recognition among the scientific and development community that climate change, nature, and poverty are interconnected – often described as *triple crisis*, *triple emergency*, or *triple jeopardy*. Various publications and institutions are attempting to identify the linkages between the three areas and are currently promoting integrated approaches to better inform the Sustainable Development Goals (SDGs) and advocate for national and international policy changes (WWF-UK 2018; People and Nature Campaign 2019). In a review of recent literature, Howe et al. (2013) attempted to elucidate the linkages between climate change, ecosystem services, and poverty alleviation. The authors identified the need for further research to focus on how those pathways work to promote policy changes and ways to adapt to and mitigate climate change on the ground.

There is significant evidence climate change has already affected and is likely to drive even more biodiversity and ecosystem services loss (Turner et al. 2012; Gosling 2013; Boone et al. 2018; van der Geest et al. 2019) over the coming decades. This disproportionately affects the poorest people and communities who rely on sustainable ecosystems for their livelihoods, health, climate regulation, shelter, security, and social relations. Worsening biophysical conditions such as ecosystem degradation, biodiversity loss, and less productive agricultural lands compromises people's ability to move out of poverty (Barbier and Hochard 2018; Hansen et al. 2019). Conversely, increased poverty is widely recognized as a key factor contributing to increased climate change vulnerability (Leichenko and Silva 2014).

While ecosystem services are essential to sustainable development and human well-being, they are also a key component in helping to adapt to changes in climate patterns, providing carbon sinks, and reducing disaster risk (MEA 2005; Munang et al. 2011; Temmerman et al. 2013; Lo 2016). According to the IPCC Special Report on Global Warming of 1.5 °C, there is high confidence that constraining global warming to 1.5 °C instead of 2 °C will result in many benefits for the preservation of ecosystem services to humans (Hoegh-Guldberg et al. 2018). With this in mind, the 14th UN Convention for Biological Diversity (CBD) in 2018 formally integrated climate change issues into national biodiversity strategies and vice versa, stating "that climate change is a major and growing driver of biodiversity loss, and that biodiversity and ecosystem functions and services, significantly contribute to climate change adaptation, mitigation and disaster risk reduction" (CBD 2018).

The role of ecosystem losses in the loss and damage to human well-being has also been a new emerging topic that needs further investigation (UNEP 2016). Since 2016, nature-based solutions (NbS) have received increasing levels of attention as sustainable solutions to meet societal challenges. A global standard for NbS is currently under public consultation, but two definitions are presented below. The IUCN defines NbS from the perspective of societal good as "actions to protect, sustainably manage and restore natural or modified ecosystems that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits."

The EC definition of NbS focuses on an element of cost-effectiveness: "inspired and supported by nature, and which simultaneously provide environmental, social and economic benefits and help build resilience, with positive benefits in urban environments, landscapes and seascapes" (EC 2018). A further report released in May 2019 by the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) on biodiversity and ecosystem services highlighted the importance of promoting nature protection and restoration and its critical contribution to the global economy and people's ability to withstand future climate-related, economic, social, and additional environmentally driven shocks that a changing world may bring (IPBES 2019). Healthy mangroves, as an example, and the restoration of mangrove habitats, in particular, have been identified as important resources to help coastal regions withstand climate-related hazards and promote carbon sequestration (McIvor et al. 2013; Murdiyarso et al. 2015) as well as support rich biodiversity and contribute to replenishing decreasing fish stocks (Hutchison et al. 2014; IUCN 2017).

While interest and investment in people-centered bottom-up approaches to address any one of those challenges have slowly increased, little attention has been paid to the potential those interventions have in helping people manage the triple crisis (Reid and Swiderska 2008).

This chapter provides an overview on the interconnections between climate-, nature-, and poverty-related challenges at the local level and in a coastal context and the role and benefits from taking an integrated pro-poor people-centered approach in addressing them.

Main findings are presented from a case study in coastal Kenya (Kwale County) where Plan International is working with local stakeholders. The limitations of the study and recommendations for similar interventions are also shared.

Context: Kenya and Kwale

The blue economy is a relatively new concept that promotes better management of the oceans and coastal resources and includes all economic activities related to oceans, seas, and coastal areas. As Kenyan national and local government departments are now recognizing the growth potential of the blue economy, it is important to understand how biodiversity and ecosystem service loss, climate change, and poverty intersect with this. According to the Kwale County Integrated Development Plan (Kwale County Government 2018), the blue economy demonstrates a potential for growth that could positively impact on peoples' income levels and contribute to climate change adaptation and mitigation outcomes in the coming years. This potential can only be achieved by investing in fisheries, improved regulations, ocean monitoring and surveillance, coastal protection, and improved waste management (Kwale County Government 2018), and it should be assessed through a people-centered approach that looks at the local challenges and linkages across the triple crisis.

As in most contexts, men and women, girls and boys, experience and respond to challenges differently – this includes natural resources, social structures, and physical environment. Women and girls relate to forests, rivers, and land differently than men (Kimani and Kombo 2010). Gender considerations are included in more recent Kenyan government policy (Republic of Kenya 2018), but the link between gender and climate change and, to a lesser extent, environmental considerations is still not well established despite an understanding the unequal impact climate change has on women and girls and their adaptation capacity. Likewise, child protection risks are starting to be understood in economic activities in Kwale – with the fishing sector and tourism being self-identified by children as being among the most harmful to them. The "sex-for-fish" phenomenon – which refers to the practice by which poor and vulnerable women and young women fish processors and traders are at risk of being coerced into sex in order to buy and/or sell fish products – has been widely reported over the past few years and remains an issue in Kwale County (Nyawade et al. 2019). This practice (alongside the sex trade) often affects underage boys and girls, some of whom are at risk of being victims of human trafficking (IOM 2018), and has been identified as one of the harmful consequences of poverty and a lack of income-generating activities (UNICEF and the Government of Kenya 2006). There is also increased reporting of children being forced to drop out of school and co-opted into mangrove cutting, charcoal production, and agricultural activities for household and community income generation (Nyawade et al. 2019).

Fisheries research, management, and policy have traditionally focused on direct, formal, and paid fishing activities that are often dominated by men, ignoring roles performed by women that are indirect, informal, and/or unpaid (Harper et al. 2017). Indeed, the economic activities related to fisheries value chains are still very much determined by the traditional gender division of labor, power, and the patriarchal system of male dominance (Kizito et al. 2017). The gendered labor pattern concentrates production in hands of men with women at the periphery of postharvest processing and retailing. The role of women is largely marginalized to *fish mammies or mama karanga* in terms of resources and training (Nyawade et al. 2019). In Kenya, *mama karanga* is the name given to women who buy fish from fishermen, process the fish (usually through deep frying it), and sell it in their local communities or those nearby. Women report that they engage in this activity due to the lack of alternative income-earning options as the work does not require much education and skills, and although the barriers to entry are low, the profit margins are also very small (Matthews et al. 2012).

The case study for this chapter draws on Plan International's experience of working in Kwale County in Southeast Kenya. Situated along the southernmost Kenya coast and bordering Tanzania, Kwale County is divided into 4 constituencies and 20 county assembly wards. The total population of Kwale County was estimated at 820,199 (397,841 of which were males and 422,358 were females) in 2017 and is projected to rise to 909,929 in 2022. The County is one of the poorest, and youngest, in Kenya: as of 2013, 48% of the population of Kwale County was 0–14 years old, and the poverty rate was 71% (UNICEF 2013) – with high levels of unemployment or underemployment (30% of the total labor force between 15 and 64) (Kwale County Government 2018). In coastal communities, the population is exposed to rapid-onset weather-related events such as flash floods and slow-onset ones such as rising temperatures, recurrent droughts, rising sea levels, land and forest degradation, and loss of biodiversity. The economy in Kwale is highly sensitive to its climate, with water, agriculture, forestry, health, and tourism among the most affected sectors by weather and climate extremes (Ngaruiya et al. 2018).

Coastal communities suffer from high-income inequality, and fishing communities are highly impoverished. Artisanal fishers earn around $3–4/day and retain some of the fish catch to take home as food. Low economic returns have contributed to the emergence of destructive fishing practices to reef habitats and fishery resources (Global Coral Reef Monitoring Network 2017). Outside of the four marine parks (fully protected) and six marine reserves (partially protected), fishing has been difficult to regulate. Beach Management Units (BMUs), established under The National Kenyan Fisheries Act of 2007, were introduced in order to provide increased community participation in inshore marine management. This relatively new initiative still has a way to go and requires additional support in areas of reporting, record-keeping, financial sustainability, resources, and cooperation (SmartFish 2011). The lack of resources and pursuit of short-term goals prevalent in most fishing communities means that harmful practices persist.

Kwale County has suffered from significant deforestation over the past few decades: since 2000, the county has witnessed the loss of 20% of tree cover. Local communities engage in tree cutting for a myriad of reasons: agricultural expansion, rapidly growing populations, charcoal production, overreliance on wood energy, and, to a lesser extent, mining – exacerbated by weak governance (Ministry of Forestry and Wildlife 2013). Deforestation contributes to soil erosion by water, wind, and activities associated with land-use change, increasing soil degradation, and water resource loss and exposes vulnerable populations to the more extreme climate and weather events. Likewise, mangrove forests have been subject to alarming levels of destruction in Kwale over the past few decades – generally for firewood and pole production despite their importance to the region's biodiversity. According to the 2017 National Mangrove Ecosystem Management Plan, the mangroves of Kwale County comprise Vanga-Funzi, Gazi Bay, and Ukunda areas covering an area of approximately 8354 ha, with 3725 ha (45% of the area) of mangroves requiring rehabilitation.

Mangrove destruction results in a decreasing amount of coastal wood, fish and prawn stocks, shoreline erosion, storm surges, and eventual reduction of seagrass and coral reefs, which could have a damaging effect on coastal livelihoods and tourism. Recent government initiatives are promoting reforestation activities, and carbon offsetting provides direct financial incentives for tree planting alongside the indirect benefits of greater forest and mangrove cover.

Kenya has been at the forefront of climate change strategy development and launched the National Climate Change Response Strategy (NCCRS) in 2010 and the National Climate Change Action Plan (NCCAP 2013–2017) in 2013 and submitted its intended nationally determined contributions (INDC) in 2016. Specifically, in Kwale County, historical records indicate a significant increase in average temperatures over the past 20 years, with the number of heat- and drought-stressed days expected to continue to increase under future climate projections. At the same time, extreme precipitation is expected to become more frequent (MoALF 2016).

Over the past couple of decades, the Kenyan government has developed a raft of policies and legislation addressing poverty, environment, and climate change. The 1999 Environmental Management and Coordination Act (EMCA) provided the foundation for Kenya's first framework environmental law – the National Environmental Policy – launched in 2013. The Poverty Environment Initiative (a joint UNDP-UNEP program launched in 2005 in nine countries, including Kenya) began to detail the poverty-environment nexus and suitability of using economic valuation of environmental and natural resources. Likewise, Kenya's National Environmental Policy in 2013 referenced poverty, climate change, and environment in its situational analysis – although it was yet to draw on the triple crisis as interconnected factors. In the past few years, national policies and frameworks have addressed specific components of Kenya's environmental policy, the 2005 Forests Act for preparation of management plans for all gazetted forests, the National Climate Change Framework Policy of 2016, and the National Mangrove Ecosystem Management Plan of 2017, which provides a road map toward sustainable management of mangrove ecosystems in Kenya for enhanced livelihoods and climate regulation.

Conservation and Sustainable Management of Marine Ecosystems in Kwale County Project

In 2016, Plan International Kenya and Plan International UK developed the *Conservation and Sustainable Use of Marine Ecosystems in Kwale County* project – from now on referred to as the COSME project – as a response to a lack of viable income-generating activities, increasing environmental degradation, climate threats, and dwindling fishing returns along the southernmost coast of Kwale County. The project aimed to improve the lives – and livelihoods – of coastal communities, particularly women, through participatory and sustainable development (including the introduction of diversified responsible economic opportunities), promoting environmental conservation and management of environmental risks and increasing resilience to climate-related extremes. The project activities formally started in January 2017 and closed in May 2019, with the final evaluation finalized in June 2019. An ex-post-evaluation exercise was conducted in February–April 2020.

The COSME project mobilized groups in the Lunga Lunga and Msambweni constituencies and reached the community groups listed in Table 1.

Overall, the COSME project reached 4145 people (1440 directly and 2705 people indirectly).

In partnership with the Kenya Marine and Fisheries Research Institute (KMFRI), the project sought to introduce improved and environmentally sustainable fishing techniques and promote alternative and supplementary income-generating activities (seaweed farming being the most prominent and successful intervention) among communities heavily reliant on the fishing economy – and alleviate the pressures on the stressed fishing waters. The activities were informed by research into current and alternative livelihood practices, the viability of local fisheries, and child protection and gender dynamics in the local coastal economy.

Interventions also included awareness raising and education in local schools and communities aiming to increase knowledge and capacity around natural resource management and environmental protection – particularly focusing on the impacts of illegal forest cutting, mangrove destruction, and unsustainable fishing practices. As referenced previously, engaging in illegal practices and natural resource degradation are partially a result of negative coping mechanisms of community members and fishing groups when the returns from fishing are inadequate. With technical support from the Kenya Forestry Service (KFS), the project worked with schools and community-based organizations to promote tree and mangrove seedling production with the long-term goal of encouraging a rejuvenation of fish stocks, reestablishing

natural defenses against flooding, and promoting soil and water resource management.

A People-Centered Approach to Address the Triple Crisis at Local Level

Figure 1 illustrates the integrated people-centered approach developed and used in the COSME project (2017–2019) to bring together actions that seek to address climate, nature, and poverty issues at the local level.

In the diagram, the main activities of the project and their contributions are listed at the center of the pie, under the domain of the main challenge they explicitly aim to tackle. The integrated nature of the project means that subsidiary results of the activities will contribute to addressing other challenges and was a key project goal. The diagram also identifies the components of the approach that promote community ownership and leadership, facilitated through engagement with self-managed community groups. Those components have been grouped under three categories, represented in the diagram using icons: (i) local environmental stewardship, (ii) women's inclusion and agency, (iii) pro-poor responsible value chain development. The emphasis placed on the role of local communities in catalyzing social,

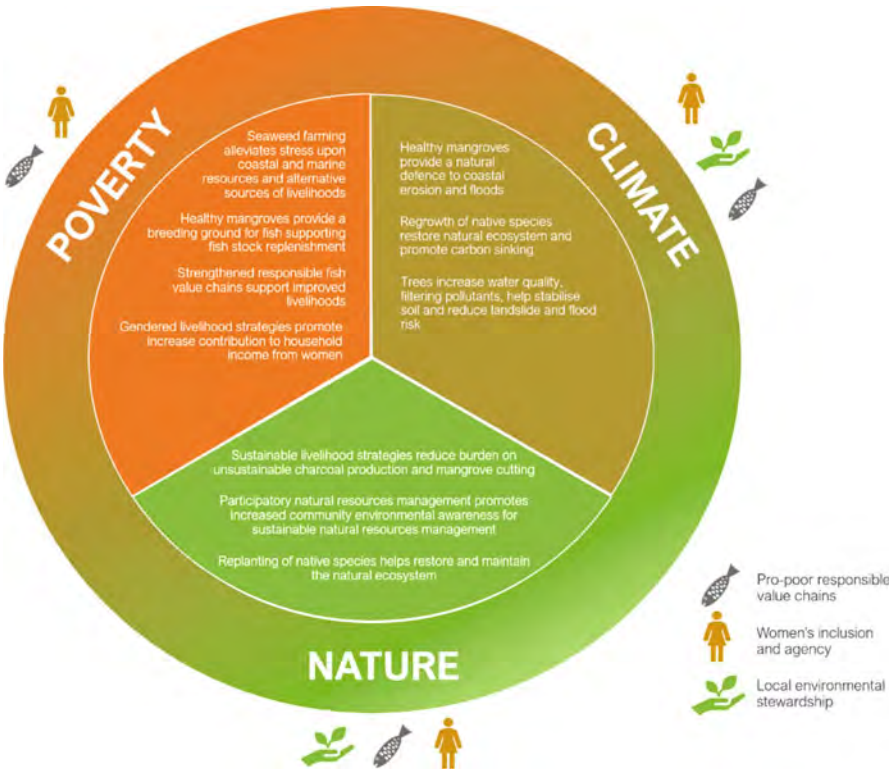

Fig. 1 People-centered approach to address the triple crisis in coastal Kwale County, Kenya. (Adapted from WWF-UK 2018)

economic, and ecological transformation is central to the approach – promoting ownership of local natural capital and transparency in its management while valuing and strengthening traditional knowledge and ability to identify solutions. Local communities are critical to the design and implementation of interventions due to their wealth of knowledge and experience in dealing with localized climate and ecological risks and their role as long-term stewards of natural resources. Local ownership is also central to ensuring long-term sustainability and scale-up of the project interventions.

Local Environmental Stewardship

Local environmental stewardship is defined as the sum of the actions taken by individuals, groups, or networks of actors, with various motivations and levels of capacity, to protect or responsibly use the environment in pursuit of environmental and/or social outcomes (Bennett et al. 2018).

Restoration of local natural capital, particularly in the form of mangrove ecosystems, which has been emphasized as one of the planet's most efficient carbon sequestration ecosystems, helps mitigate the risks of coastal erosion and coastal floods and promote breeding grounds for local fish species (Kumar 2019).

Over the years, illegal logging, charcoal production, encroachment of forested areas, overgrazing, and other human activities have all contributed to forest loss and degradation. Along the Kwale coast, mangrove forest has been degraded and overexploited primarily for timber and firewood from within and outside the communities. In Kwale County, most of the mangrove forest are currently found in the Shimoni-Vanga area where a number of successful community-based conservation initiatives have been established, notably the Mikoko Pamoja project in Gazi.

Led by coastal community mangrove groups and tree planting groups in the upstream communities, the COSME planting activities have returned increasing yields in terms of numbers of trees growing and their survival rate. Over the 2-year period, 127 people across 4 groups, of which 50% members are women, planted 137,000 seedlings of mangroves, with an additional 56,000 since the project formally closed. Additionally, 820 (women, girls, boys, and men – with a 50% female participation rate) have planted 7940 seedlings for reforestation of fruit-bearing trees, native forest species, and sustainable charcoal replacement trees. Although there has been some attrition rate with seedlings being lost at the project start due to poor management, the survival rate has subsequently grown and stabilized at 80% on average. In addition to this, one of the groups – a charcoal cooperative – involved in tree production and planting has decided to cease with charcoal production all together and is now focusing their income-generating activities on goat-rearing and beekeeping. The group is now hoping to work with the local government partners to identify and receive further training on additional alternative and sustainable income-generating activities.

Community groups have shown a high level of understanding of the relevance of the activities, the expected positive ecological and disaster risk reduction outcomes, and the beneficial effects resulting on their well-being and livelihoods. Since project closure, 80% of the groups continue to be active. Additionally, a number of mangrove groups have, independent of the project, started to engage in money-saving practices through village savings schemes to invest in project-related activities. Individuals contribute funds which have been used to secure formal registration of the savings group, which will allow the group to access additional funds and purchase products to continue and expand operations – including signs to identify the sites under rehabilitation, seedling inputs, record-keeping material, and a boat to reach the areas under rehabilitation. The engagement of fisherfolk through the community BMUs and mangrove groups has been critical to ensuring commitment from the wider community demonstrating the beneficial effects of a healthy mangrove forest for the local economy and livelihoods. These activities have been complemented with sensitization on the negative effects of illegal fishing practices, particularly the use of explosives, seine nets, and poison. Orientating fishing groups around destructive fishing practices that have a degrading effect on the ecological balance of the reef and the seafloor has been complemented by the promotion of responsible fishing techniques which contribute to long-term environmental benefits attached to a key economic activity.

Women's Inclusion and Agency

Gender consideration is particularly important in coastal communities as (i) the responsible management and use of marine and coastal resources can offer an important entry point and opportunity for women's economic and social empowerment, alongside strengthening resource governance and conservation, and (ii) gender-based violence (GBV) is a specific concern in the fisheries sector (Siles et al. 2019). FAO estimates that women directly engaged in some form of primary fishery production account for more than 15% of the people engaged in fisheries and aquaculture, with 90% of those engaged in processing activities. However, while women often play significant roles both in the fisheries value chain and in providing support to the organization – e.g., repairing fish nets, processing, and marketing fish – they often have limited decision-making power and tend to be absent from leadership positions (FAO 2016a). Additionally, failure to engage women in management efforts, coupled with women's prominent roles as environmental stewards, results in lost opportunities to improve conservation practices and sustainably manage natural resources upon which these communities' livelihoods depend. Integrating gendered considerations into conservation and development interventions increases the likelihood that they will achieve targeted outcomes of poverty alleviation and improved food security in coastal communities (Matthews et al. 2012).

Findings from the project highlighted high vulnerability of women and girls to GBV, particularly exacerbated by decreasing fishery resources – women and girls are at greater risk of GBV from fish sellers and traders in order to be able to sell or purchase fish (Siles et al. 2019). Women reported supplementing the household income through activities such as soap-making, animal husbandry, farming, and selling firewood.

Through analysis of the women's unique contribution to the local economy, their capacities, needs, and constraints placed upon them, the project has identified strategies to better involve women and uphold women's interests at varying stages of the intervention.

The project was largely successful in reaching women and girls through awareness-raising and education initiatives – where they have been prominently involved in promoting reforestation activities and in-school education. Further to this, women have been supported and have strongly engaged in seaweed farming and the monitoring, management, and promotion of environmental conservation activities. The project evaluation also found reports of improvement on issues related to children and girls' welfare at the local level, including a reduction in reported cases of child trafficking, a reduction in reported child pregnancy among fishing communities, a reduction in girls dropping out of school to engage in fish processing and marketing, a reduction of children (especially boys) dropping out of school to engage in local touristic activities, and a reduction of children supporting parents in boat and local furniture production and in mangrove harvesting.

Pro-poor Responsible Value Chain Development

Value chain development refers to extending or improving the productive operations of a value chain and generating social benefits – e.g., poverty reduction, income and employment generation, economic growth, environmental performance, and gender equity (UNIDO 2011). A value chain refers to the full range of activities that are required to bring a product, or a service, from conception through production, delivery to final consumers, and disposal after use. Pro-poor value chain initiatives often try to overcome entry barriers for poor producers to inputs and services, including technical capacity, and help them gain access to output markets.

As part of the project, research activities were conducted to investigate feasible alternative livelihood activity (a completely different occupation from the usual primary occupation practiced by the individual household), supplemental livelihood activities (a portfolio of activities that are added to and complement the usual primary occupation practiced by the individual household), and strategies and barriers that stop income diversification within coastal households. As part of the research, extensive consultations were held with key actors, including community members, KMFRI, and other relevant local government agencies. Researchers reported that discussions on alternative livelihoods are not straightforward with fishing groups, referencing that fisherfolk "will continue to fish till the last fish species is caught" (Nyawade et al. 2019). Identifying sustainable livelihood options in co-participation with the local communities, therefore, was one of the main objectives of the COSME project.

Findings from the research study reported a declining trend in fish productivity and diversity, and a low level of income diversification among coastal community households. That led to an increase in vulnerability to climate-related, idiosyncratic, and economic stresses. Willingness and readiness to diversify to supplemental and enhanced livelihoods, rather than alternative livelihoods, has been indicated as preferential by the interviewed households (Nyawade et al. 2019). As part of this exploration into income diversification, the COSME project explored opportunities to decrease gender inequalities within the household and community – to ensure that unequal power relations between men and women did not negatively impact diversification activities. Likewise, assessing, and adapting interventions that address the roles men, women, girls, and boys play in the value chain, contributes to increased household income that is increasingly more resilient to economic and climate risks.

Seaweed farming emerged as one of the preferred supplemental livelihoods. With that in mind, the Kenya Coastal Development Project (KCDP), a World Bank project that set up the Kibuyuni seaweed farmers association and individual seaweed farms in Kibuyuni, offered insights on the viability of the businesses and value chain market.

Historically, seaweed farming was considered “not [to be] a major livelihood and is mainly left for the women to perform,” according to respondents from a male focus group discussion.

Seaweed farming is characterized by low barriers to entry and low risk for the poor while being particularly promising in its potential for scaling up across the communities. Seaweed farming provided an opportunity for the women to exploit the blue economy and meaningfully contribute to household earnings. In the last year of implementation, however, the COSME project has seen an increase in popularity of seaweed farming among men. This will need to be closely monitored and managed to ensure that seaweed value chains do not start to reflect the gender disparity witnessed in fishing value chains.

The initial cost of investment is very small, with only a few tools needed – e.g., ropes, footwear, knives – and a growing cycle of roughly 45 days. On average seven cycles are expected per year with a productivity of 600 kg on average per cycle as reported by the interviewed group members. Since October 2018, the seaweed farmers have been selling to a single buyer for 25 KES/kg.

Among the communities, there is a supportive environment for seaweed farming and interest to expand their operations. One seaweed farming group was able to leverage public investment from the county government for the construction of a seaweed drying and processing facility, which is under planning. The end-line survey revealed that women participating in seaweed farming had increased their base of consumer and household assets. During focus group discussions, some women stated that they had used some of the additional seaweed income to purchase land and build permanent houses (a rare phenomenon before the COSME project in the local communities) and to pay school fees and medical expenses, and a number of female seaweed farmers have shown an interest in possibly expanding their farms.

Findings and Recommendations

The 2-year-long COSME project has shown encouraging results and demonstrated some positive outcomes that address poverty-, climate-, and nature-related issues. Experiential knowledge, monitoring reports, case studies, final qualitative evaluation, and a research exercise underpin the conclusions and recommendations for future initiatives and are shared here for consideration:

- While the ability – and appetite – to save income has sporadically been recorded in a number of community groups reached by the project activities, it has always been through independent actions and not formally facilitated by the project activities. Interviewed group members reported limited knowledge and increased desire to engage in community-level saving and loan schemes to reinvest capital to expand their businesses and increase their asset base. Financial literacy skills development and village savings and loan association (VSLA) schemes could offer a secure saving facility and access to loans to be reinvested into the family or group businesses, as well as to absorb any shocks the household may face.

- Seaweed farming has proved a viable and sustainable option, particularly successful in increasing economic and social empowerment of local women. Women have reported feeling proud to be able to contribute to the household needs and able to use the profits to purchase food for the family. Due to increased interest from men, it's critical to manage any potential conflict that might arise due to an increased product offer as well as the competition with other coastal users for surface area needed to develop viable operations.
- A lack of a ready market to sell harvested seaweed and tree seedlings from the nurseries set up in the upstream communities proved challenging during the project. It's important to identify any existing and foreseeable constraints to sustainable income-generating opportunities to ensure uptake in the long term is achievable. A detailed and contextualized value chain analysis, including buyers, distribution, and consumption markets for seaweed, particularly exploring monopsony (a situation in the market where there is only one buyer for a given product who is able to determine prices and exert power over sellers) power that could affect market prices, is advised.
- A number of seaweed farms had to be moved to new coastal locations less exposed from the impacts of storm surges and heavy rains. A feasibility study and coastal mapping in the design phase of the project would help identify those locations at a lower risk of weather hazards.
- Gender inclusion in the value chain promotes women's empowerment and increases their contribution to household income. At the end of the COSME project, women reported investing their earning in paying for their children's school fees and health-related expenses and improving their quality of life (e.g., safe water access, house improvements) with clear outcomes for the wider household and community, including household-level risk diversification, children's well-being, and a shift to more sustainable livelihoods. Based on the importance of women's roles in the coastal economy, their inclusion in the sustainable development of value chains should be promoted through addressing gender issues, community dynamics, and cultural norms and systematically examine gender-based constraints that prevent them from accessing the same opportunities as men. An increase understanding of vulnerabilities, including those to climate-related shocks and stresses, should also be sought.
- GBV prevention training and sensitization at community level and for relevant local authorities may help address the risk of GBV in coastal communities and promote preventive action. Likewise, any technical or advocacy training should include a strong gender mainstreaming thread.
- Robust environmental monitoring and data collection activities – e.g., monitoring of restored areas of forest using geographical information systems, geocoordinates, and monitoring of fish catch species and amounts and fish sold – particularly involving women, should be encouraged to improve information transparency and decision-making at community and local level.
- Anecdotal evidence of more frequent occurrence of dry spells and shortening of the rainy season has been reported from within the communities and matches

county-level historical records. Alternative and supplemental livelihood strategy diversification implemented through the COSME project has the power to enhance the ability to withstand climate and economic risks. To better understand their contribution to household-level climate resilience, initial analysis aimed to identify the drivers of household climate resilience should be conducted at the start of the initiative. Climate shocks and stresses that individuals, households, communities, and larger systems are exposed to, and the severity and duration of these, should also be analyzed to enable a more robust measurement of household-level climate resilience.

- Worldwide, payments for environmental services (PES) have been identified as a viable income-generating option with major potential to promote sustainable ecosystem management and forest conservation (FAO 2016b). Learning from existing payment schemes for ecosystem services in Kwale – e.g., Mikoko Pamoja in Gazi – should be facilitated, and the possibility for increasing participating households' earnings through selling carbon credits should be explored with the potential of improving environmental outcomes, specifically through the increase in carbon stock trading.
- Local government engagement is particularly important to ensure that continued technical support and innovation are promoted to local groups and new approaches and learnings are informing policy, regulatory, and legal changes. Civil society and local government partners are working together to provide a much stronger, coherent approach to natural resource management and environmental stewardship and opportunities for learnings and best practice to be shared more widely.
- Waste management needs to be explicitly incorporated into environmental and conservation activities. Increasing levels of plastic waste is affecting mangroves and fisheries; therefore targeting beach clearing and education among upstream communities, as well as coastal communities, regarding waste disposal is strongly advised.

Limitations of the Study

While the project has yielded promising results in addressing the triple crisis at the local level, it's important to note that the limited duration in formal project activities meant only limited short-term outcomes were measured by the project closure. Additionally, the narrow geographical extent and scale of the project mean the initiative remains limited in scope. Likewise, the relatively small population sample the project reached, and the corresponding qualitative methods used in the research, means that any causality to positive change needs to be understood within these restrictions. While the team is confident in linking those positive results directly to project interventions, it does consider attribution with caution, and an ex-post-evaluation is in process to better understand the contributions of the initiatives to the recorded outcomes.

Conclusions

In recent years, the triple crisis concept has emerged in response to the acknowledgment that climate change, degradation of nature, and poverty are fundamentally interdependent of each other and among the biggest global challenges.

The proposed people-centered approach developed under the COSME project draws from previous publications and research and attempts to address the triple crisis at the local level. The study specifically looks at those components that promote community ownership and leadership in order to catalyze social, economic, and ecological transformation at the local level. The central role women play with regard to natural resource management and coastal economies has been recognized. Understanding gendered dynamics of environmentally minded interventions and strengthening their decision-making and leadership capabilities and providing them with the skills and knowledge to meaningfully participate in coastal economy value chains could have a multiplying co-benefit on future initiatives.

While the study has been limited due to the geographical scope and size of the project, encouraging results have been recorded in relation to the ability of the communities to respond to climate risks, promote environmental stewardship, and enhance their household economic empowerment.

Initial findings are discussed, and recommendations for similar initiatives have been shared. Furthermore, an ex-post-evaluation is currently in progress and expected to be completed in the first half of 2020 that will focus on the medium-term outcomes of the project through the triple crisis lens.

Acknowledgment This work was funded through the Future Plan Fund, a Plan International UK programme supported by an anonymous donor with initiatives in Kenya, Colombia, and East Timor.

133 Land Use Cover Types and Forest Management Options for Carbon in Mabira Central Forest Reserve

Aisha Jjagwe, Vincent Kakembo, and Barasa Bernard

Contents

Abstract

Mabira Central Forest Reserve (CFR), one of the biggest forest reserves in Uganda, has increasingly undergone encroachments and deforestation. This chapter presents the implications of a range of forest management options for carbon stocks in the Mabira CFR. The effects of forest management options were reviewed by comparing above-ground biomass (AGB), carbon, and soil organic carbon (SOC) in three management zones. The chapter attempts to provide estimates of AGB and carbon stocks (t/ha) of forest (trees) and SOC using

sampling techniques and allometric equations. AGB and carbon were obtained from a count of 143 trees, measuring parameters of diameter at breast height (DBH), crown diameter (CW), and height (H) with tree coordinates. It also makes use of the Velle (Estimation of standing stock of woody biomass in areas where little or no baseline data are available. A study based on field measurements in Uganda. Norges Landbrukshoegskole, Ås, 1995) allometric equations developed for Uganda to estimate AGB.

The strict nature reserve management zone was noted to sink the highest volume of carbon of approximately 6,771,092.34 tonnes, as compared to the recreation zone (2,196,467.59 tonnes) and production zone (458,903.57 tonnes). A statistically significant relationship was identified between AGB and carbon. SOC varied with soil depth, with the soil surface of 0–10 cm depth registering the highest mean of 2.78% across all the management zones. Soil depth and land use/cover types also had a statistically significant effect on the percentage of SOC ($P = 0.05$). A statistically significant difference at the 95% significance level was also identified between the mean carbon stocks from one level of management zones to another. Recommendations include: demarcating forest boundaries to minimize encroachment, enforcement of forestry policy for sustainable development, promote reforestation, and increase human resources for efficient monitoring of the forest compartments.

Introduction: Land Use Change and Carbon

Representing 33% of the global land area (FAO 2011) and containing more carbon per unit area than any other land cover type (Hairiah et al. 2011), forests comprise the biggest percentage of biomass and play a big role in mitigating greenhouse gas emissions, especially carbon dioxide. According to the FAO (2010), biomass is the organic matter both above and below the ground. Forest biomass assessment is very important for national development planning, as well as scientific studies of ecosystem productivity and carbon budgets (Parresol 1999; Zheng et al. 2004). Considering climate change trends, there is a growing need for information on forest carbon stocks. Olson et al. (1983), Thornes (2002), and Schimel et al. (2001) point out that forests contain nearly 85% of the global above-ground carbon, and 40% of the below-ground terrestrial carbon stocks (Brown and Lugo 1984; Dixon et al. 1994). Land use/cover change (LUCC) has led to destruction of habitats, forests, exposed land to erosion, and affected human well-being (Foley et al. 2005; Kerr et al. 2007; Ellis and Pontius 2007; Arsanjani 2012). Alterations caused by LUCC account for the release of greenhouse gases into the atmosphere, resulting into global warming. Further effects are manifest in climate variability and change (Hashim and Hashim

2016). Studies by Watson et al. (2000), UNEP (2002), and Lambin and Geist (2008) have cautioned about instant and threatening effects of LUCC on agriculture, biodiversity, human health, and well-being. Despite its importance, accurate statistics on LUCC are not available in tropical countries (Ochoa-Gaona and Gonzalez-Espinosa 2000). Agriculture is still the most significant driver of global deforestation. Given the importance to the planet's future of both agriculture and forests, there is an urgent need to promote positive interactions between these two land uses (FAO 2016).

The rate of deforestation, estimated at 0.4–0.7% per year (Shrestha et al. 2004; Parry et al. 2007), constitutes immense environmental stress. Between 2000 and 2010, 13 million ha of world forest were lost (FAO 2010), implying an increase in the amount of carbon dioxide into the atmosphere. According to Baccini et al. (2012) and Harris et al. (2012), deforestation and forest degradation contribute about 20% of the greenhouse emissions. Land use change leads to alterations in carbon storage in soils and vegetation. Consequently, it strongly influences emissions and fixation of carbon in these ecosystems (Jandl et al. 2007). Jjagwe et al. (2017) identify the significant drivers of land use/cover changes in and around the Mabira CFR as: high household size, loss of soil fertility, poor agricultural practices, establishment of roadside markets, industrialization, and the unclear CFR boundary. Against the above background, that the main aim here is to estimate and compare total tree biomass and carbon stocks among the three management zones of the Mabira CFR.

Mabira Central Forest Reserve: Location and Management

Mabira Central Forest Reserve (CFR) is currently the largest natural rainforest region found in the Lake Victoria crescent of Uganda, spanning the districts of Mukono, Buikwe, and Kayunga (Fig. 1). It lies 54 east and 26 km west of the cities of Kampala and Jinja, respectively. It covers about 26,250 ha and is situated between 32 52°–33 07° E and 0 24°–0 35° N, at an altitude of 1070–1340 m above sea level. The topography is characterized by gently undulating plains that have numerous flat topped hills and wide shadow valleys. Temperatures are fairly constant throughout the year, with an average of 26 °C. It has two peak rain seasons between March–May and September–November. Rainfall ranges between 1250 and 1400 mm per annum.

The forest is globally recognized as an important conservation biome rich in biodiversity, with over 300 bird species (Lepp et al. 2011) and 365 plant species (Howard and Davenport 1996). Currently, the forest has 27 enclaves; considering its proximity to Kampala city, the area has attractions for commercial utilization. Uganda's population growth rate of 3.2%, as per the 2002 population census (UBOS 2010), is one of the highest globally.

Mabira CFR was gazetted as a CFR in the 1900 under the Buganda agreement. It has been protected as a Forest Reserve since 1932 and is currently managed by the National Forest Authority (NFA). Forest management is under three main zones, namely: the strict nature reserve where no extraction is permitted except for research activities; the recreation buffer zone where activities like ecotourism and limited harvesting are permitted; and the production zone which accommodates agriculture,

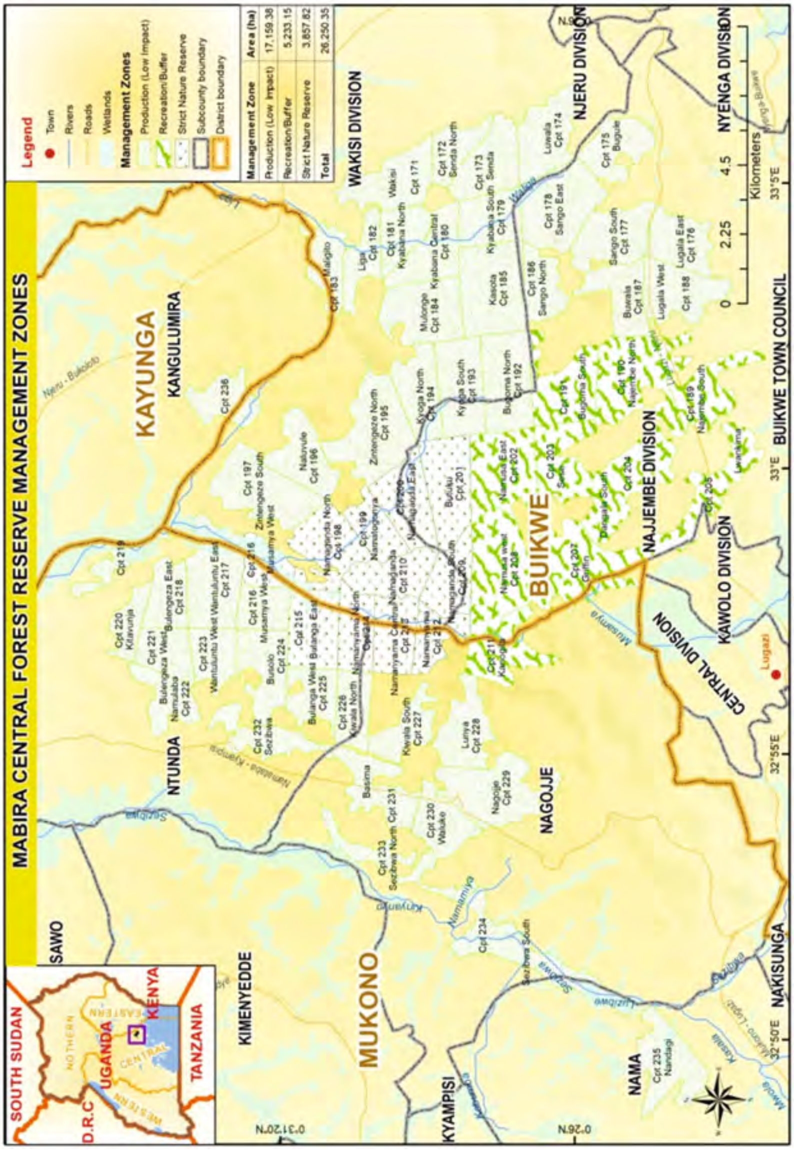

Fig. 1 A map showing the management zones of Mabira CFR and environs

livestock grazing, legal and unregulated harvesting of timber. The forest has undergone dramatic changes, especially since the early 1970s, in the form of encroachments and deforestation. These activities resulted from the desire by the government of the time to expand agriculture and permit free settlement anywhere. This forest region is estimated to have quite a high population density, with some places having an average of up to 15,122 people/sq. km in Parishes like Nakazadde (Schwarz and Fakultät für Geomatik, Hochschule Karlsruhe-Technik und Wirtschaft 2010) and an average of seven members per household. Over 80% of the population is heavily dependent on the forest ecosystem for their livelihood (Bush et al. 2004) in form of agriculture, lumbering, and brick laying. Studies by NFA (2009) indicate that population pressure coupled with high levels of poverty continue to constrain the remaining forest cover by way of conversion to other land uses. The high resistance over the proposal by government in 2007 to convert 7186 ha of forest to sugar production by the Sugar Corporation of Uganda Limited (SCOUL) is a case in point.

As a means to improve management in the forest reserve, several mechanisms have been devised in the revised forest management plan (MWE 2017), which include but not limited to: yield control and harvest, Collaborative Forest Management (CFM), licenses, silviculture, and rehabilitating encroachments. Despite the few success stories where CFM has been adopted, it is noteworthy that in the many communities where CFM agreements are implemented, no tangible economic benefits have been realized (Turyahabwe et al. 2012).

Estimating Biomass and Soil Organic Carbon Stocks in Mabira CFR

Estimating Above-Ground Biomass and Carbon Stocks

In order to determine the above-ground biomass (AGB) stocks, living biomass was considered. Studies by Djomo et al. (2010) and Brown (2002) have identified challenges of using the direct/destructive approach to estimate biomass. Consequently, we applied the indirect approach to estimate biomass content. The approach is not time consuming, cheap, and nondestructive, as borne out in studies by Tackenberg (2007), Chen et al. (2009), and Henry et al. (2011). The use of generalized allometric equations is proven and reliable in estimating AGB and carbon stocks and a number of them have been developed for different purposes, species, and regions.

More than 95% of the variation in AGB is explained by diameter at breast height (DBH) alone (Brown 2002). Studies by Djomo et al. (2010, 2016) and Ngomanda et al. (2014) show that the input of tree height improves the quality of AGB estimation. Biomass equations have been preferred, if a representative sample of tree-wise data is acquired (Brown 1997; Basuki et al. 2009; Djomo et al. 2010; Beets et al. 2012; Chave et al. 2014; Ngomanda et al. 2014; Mokria et al. 2015).

A team of eight people was employed in this process to survey management zones and take tree measurements. An NFA official with a security guard per management zone led the team in this exercise. Three management zones were surveyed, each representing unique but homogeneous blocks. From the three zones, four compartments were considered as summarized in Table 1.

Resource utilization and management in the respective zones varies. Under the strict nature reserve, no extraction is permitted except for research activities, undertaken under very restrictive measures. Whereas the recreation buffer zone permits activities like ecotourism and limited harvesting, the production zone accommodates agriculture, livestock grazing, legal and unregulated harvesting of timber.

Field sites were randomly selected, taking 20 square plots of 30 m × 30 m from the strict nature reserve, where 63 trees were sampled. The same number of square plots of 50 m × 50 m was considered from the recreation/buffer and production zones, where measurements of 50 and 30 trees were taken, respectively. The plot sizes varied, considering variations in tree densities and sampling intensity. Consequently, bigger plot sizes were designated in areas where the trees were more scattered (recreation/buffer zone) to enable capturing of more trees for assessment. Tree measurements by height, diameter at breast height (DBH), canopy, and coordinates were taken and recorded. The tools used in determining AGB included GPS receivers, Suunto clinometers, a compass, caliper, and diameter tape (Fig. 2).

The measurements taken were then used to calculate biomass using allometry. For trees with multi-stems, the quadratic mean diameter (QMD) was calculated using Eq. (1) below:

$$\text{QMD} = \sqrt{(\pi * BA)/(4 * N)} \tag{1}$$

Table 1 Sampled compartments

Management zone	Name and compartment number	Number of trees
Strict nature reserve	Compartment 209	63
	Compartment 212	
Recreation/buffer zone	Compartment 208	50
Production zone	Compartment 211	30
Total number of trees samples		**143**

Fig. 2 Measurements for tree parameters

Where:

QMD is quadratic mean diameter.
BA is total basal area = ba1 + ba2 + ba3... ba_N is the number of stems.

To estimate AGB, a number of models were explored and tested in relation to the variables. Models which included the diameter as predictor variable, a combination of diameter and tree height, diameter and crown diameter, and finally the diameter, tree height, and crown diameter were tested. These models are the most commonly used for allometry development (Brown et al. 1989; Chave et al. 2005; 2014; Djomo et al. 2010, 2016). The generalized allometric equation by Velle (1995) equations developed for Uganda to estimate AGB was applied as stated in Eq. (2).

$$\mathrm{Ln}\ (\mathrm{PWF}) = \mathrm{a} + \mathrm{b} * \mathrm{Ln}\ (\mathrm{D}) + \mathrm{c} * \mathrm{Ln}\ (\mathrm{HT}) + \mathrm{d} * \mathrm{Ln}\ (\mathrm{CR}) \qquad (2)$$

Where:

PWF is fresh weight of a stem and branches in kg
D is DBH in cm
HT is height of the tree in m
CR is the width of the crown in meters.
a, b, c, and d are constants for all the pooled trees which may vary according to the diameter class as indicated in Table 2 below.

The application of the generalized allometric equation is avouched by its use even in highly diverse systems, where more than 95% of the variation in AGB is explained by DBH alone (Brown 2002). The fresh weight was then converted to dry weight for biomass detection by taking 50% of the wet weight (Gates et al. 1982). Below-ground biomass (BGB) was estimated by taking 20% of AGB (Mokany et al. 2006). From this, the total biomass per tree and per hectare was also calculated. Subsequently, carbon was converted into carbon sequestered (CO equivalents) by multiplying it with a factor of (44/12), which is the carbon dioxide-carbon molecular weight ratio (Penman et al. 2003). To assess the variation in biomass and carbon stocks for the different management zones, Anova for XLSTAST (version 3.1.3) was applied.

Table 2 Constants for the varying diameter classes used to convert field vegetation measures

	Constants			
Diameter class	a	b	c	D
DBH <20 cm	−0.85989	1.5445	0.50663	0.333346
$20 \geq$ DBH ≤ 60 cm	−1.750891	1.943912	0.473731	0.245776
DBH ≥ 60 cm	−2.166502	2.032931	0.31292	0.436348

After Velle (1995)

The UBOS 2017 shapefile was used to estimate the total size of areas covered by the three management zones as indicated in Fig. 1. Data collected were analyzed using XLSTAST. The biomass was converted to carbon (C) by assuming a 50% biomass to carbon content (Brown 1997; Losi et al. 2003; Penman et al. 2003; Change 2006; FAO 2005).

Estimating Soil Organic Carbon

According to Rau et al. (2011), the excavation of soil pits has been identified as a widely applicable and universally accepted method for the assessment of soil organic carbon (SOC). Samples of 50 m × 50 m plots up to 30 cm deep for the SOC pool were taken from the three management zones of the Mabira CFR and environs. Four dominant land use types, viz.: built-up area, plantations (sugarcane and/tea), subsistence farming, and forest were considered in each management zone. From each zone, 44 samples were taken, considering at least 3 points in each land use/cover type. A total of 132 soil samples were extracted from the 44 spots, taking three replicates from soil depth of 0–10 cm, 10–20 cm, and 20–30 cm. On completion of sample collection, the unwanted materials like stones, granules, plant parts, leaves, etc. were discarded. The soil samples were kept in polythene bags, tightly closed and well labeled. The bags were stored at 5 °C to limit microbial degradation, oxidation, and volatilization activities.

In the laboratory, samples were air dried and sieved through a 2-mm sieve. The sieved sample was used for SOC estimation. The samples were analyzed using wet oxidation method (Walkley and Black 1934), using potassium dichromate ($K_2Cr_2O_7$) and concentrated sulfuric acid (H_2SO_4). The samples were oven dried and a sample reagent mixture was prepared using standard laboratory procedures. The mixture was titrated with ferrous ammonium sulfate to determine the amount of organic carbon. Back titration was then performed until the color of the solution turned brown, which marked the end point. A standardization blank (without soil) was also run in the same way. Equation (3) was used to extract the carbon content.

$$\mathbf{BT - ST(0.3 \times 5)/0.3 \times 9.8} \tag{3}$$

Where:

BT = blank titer, which was considered at 9.8
ST = unused dichromate

All data were analyzed using SPSS statistical software version 16.0. Analysis of variance (ANOVA) was carried out using the two-factor randomized complete plot design. Significant F-values were obtained; differences between individual means were tested using the least significant difference (LSD) test. To assess variations in biomass and carbon stocks for the different management zones, Anova for XLSTAST (version 3.1.3) was applied.

AGB and Carbon Stocks

Average AGB and AGC based on tree parameters comprising height, DBH, and crown diameter, as presented in Table 3 were 890.9 and 445.63 kg, respectively. Biomass and carbon totals of 1069.1 and 534.6 kg, respectively are also evident. A linear relationship between biomass and carbon stocks is presented in Fig. 3. The R-Squared statistic indicates that the model as fitted explains 100.0% of the variability in carbon stocks (tonnes per hectare). The correlation coefficient is 1.0, signifying a perfectly strong relationship between the two variables. Since the P-value is greater than 0.05, there is no indication of serial autocorrelation in the residuals at the 95.0% confidence level. BGB was estimated by applying the 20% conversion rate to AGB (Mokany et al. 2006). Similarly, 50% of the BGB is taken as the estimation for BGC, results of which are presented in Table 3.

Variations of biomass and carbon stocks were noted in the different management zones. The highest average total AGB was found in the strict nature reserve, where values of the multiparameters of DBH, height and crown diameter were highest as well. The production zone, which had scattered trees with smaller parameters registered the lowest average total AGB (Table 4). Whereas the strict nature reserve had the highest carbon stocks, the production zone registered the least (Tables 5 and 6).

The ANOVA (Table 7) decomposes the variance of carbon stocks (kg per tree) into two components: a between-group and within-group components. The F-ratio, which in this case is 13.97, is a ratio of the between-group estimate to the within-group estimate. Since the P-value of the F-test is less than 0.05, there is a statistically significant difference between the mean carbon stocks (tonnes per hectare) from one management zone to another at the 5% significance level. To determine which means are significantly different from others, multiple range tests were selected from the list of tabular options.

The multiple comparison procedure is applied (Table 8) to determine which means are significantly different from others. The bottom half of the output shows the estimated difference between each pair of means. An asterisk to signify statistically significant differences at the 95.0% confidence level has been placed next to the pairs. In the table, two homogenous groups are identified using columns of Xs. Within each column, the levels containing Xs form a group of means within which there are no statistically significant differences. According to Fisher's least significant difference (LSD) procedure used to discriminate among the means, there is a 5% risk of calling each pair of means significantly different when the actual difference is 0 (Fig. 4).

A comparison of tree carbon stocks and sequestration per management zone was also done, and it was revealed that the highest carbon is in the strict nature reserve and least in the production zone as shown in Table 9.

It is noticeable from Tables 9 and 10 that carbon sinking varies between the management zones. Table 10 shows that the strict nature reserve management zone sinks the highest volume of carbon of approximately 6,771,092.34 tonnes, despite its small coverage in comparison to the recreation/buffer (2,196,467.59 tonnes) and production zones (458,903.57 tonnes).

Total	143	887.516	1439.42	162.186	24.124	10,121.2

It is also important to compare SOC in forest environments. Comparison for variations of soil organic carbon in Mabira forest was done basing on the SOC percentage content. It was noted that there was no variation in the mean SOC for the three management zones. In terms of soil depth, the 0–10 cm and 10–20 cm soil layers had relatively similar variations of least square means for carbon than the 20–30 cm soil layer. The highest SOC was observed in the soil surface of 0–10 cm depth, with the highest mean of 2.78% across all the management zones. As expected, soil organic matter decreases with depth and varies with land use/cover type. Whereas the forest and subsistence farming land use/cover types had relatively higher means of SOC (with legumes and bananas as dominant crops), low mean variations for

carbon were recorded in both the tea and sugarcane plantations, and built-up areas (Table 11 and Fig. 5).

Among the three factors (soil depth, management zones, land use/cover types) assessed for SOC variations, it was soil depth and land use/cover types that had a statistically significant effect on the percentage of carbon ($P = 0.05$), as presented in Table 12.

Discussion

Velle (1995) allometric equation was adopted and here combinations of tree parameters are applied. Similar recommendations for specific diameter–height allometries are made in studies by Feldpausch et al. (2011) and Banin et al. (2012). According to Sharifi et al. (2016), blending parameters may give better results. Although DBH was found to be a significant parameter in determining AGB and C (Dudley and

Fownes 1992), it was also noted that higher estimations of AGB and carbon were indicated where DBH and H were combined. It was also noted that a coefficient of 1.0 indicated a perfectly strong relationship between AGB and carbon. Such a significant logarithmic relationship was also identified by Clark et al. (2001) and Krisnawati et al. (2012).

The results reveal a positive relationship between land use/cover and carbon sequestration, since the strict nature reserve has more AGB stocks. Therefore, conservation of forests with large carbon stocks would reduce carbon dioxide emissions than the production zone, where pockets of degradation are evident, despite isolated afforestation and reforestation attempts. The findings are in keeping with Sharma et al. (2010), implying that preserving old growth strands maintains large amounts of carbon stocks and also promotes sequestration of much more carbon than exotic forests.

The strict nature reserve covering 3857 ha sinks approximately 6,771,092.34 tonnes. However, government plans to reduce this area to 3189 ha and increase the production

zone to 26,785 ha (NFA 2017). This would reduce the carbon sink and pave the way for further global warming, related to unsustainable agricultural practices, which include deforestation, bush burning, overgrazing, monoculture, and overcultivation, all of which degrade the environment.

Soils are the main terrestrial carbon sink; the conservation of soil carbon reduces carbon emissions, as well as the risks of climate change. Land use and cover change are noted to significantly influence carbon variations. Under the strict nature reserve, where the dominant land cover type is forest, most of the activities are conservational, hence more carbon stocks, as opposed to the plantation area, which is more commercial with lower carbon stocks. This is in keeping with studies by Desjardins et al. (2004) and Meyer et al. (2012). Furthermore, SOC was found highest in the top layer of soil (0–10 cm). This is explained by the rapid decomposition of forest litter, which provides abundant organic matter. This is corroborated by studies by Mendoza-Vega et al. (2003) and Chowdhury et al. (2007), where more SOC was identified as located at the soil depth of 0–14 cm. Furthermore, the highest and lowest AGC concentration was identified in the strictly managed and production zones, respectively. This is in conformity with findings by Brakas and Aune (2011), who noted that AGC stocks were very low in degraded, as opposed to preserved forests.

Land management practices can significantly affect the content and distribution of SOC in different vegetation types (Li et al. 2014; Zhang et al. 2014; Baritz et al. 2010). The highest SOC concentrations were noted in the production zone and lowest in the recreation/buffer zone. By implication, if well managed through conservation attempts such as afforestation, reforestation, longer fallows and mulching, agricultural soils have a great potential for carbon sinking. Studies by McKinley et al. (2011) and Ryan et al. (2010) indicate that reducing the amount of

forest harvest can decrease carbon losses to the atmosphere. As stated by Schwilk et al. (2009) and Stephens et al. (2012), forest disturbances can lead to additional soil carbon losses through soil erosion inducement.

Conclusion

The main aim of this chapter was to assess the effect of forest management options on biomass and SOC variations in Mabira CFR. AGB and carbon stocks (t/ha) of forest (trees) and SOC were estimated using allometric equations and sampling techniques. A multiparameter assessment of DBH, H, and crown diameter, and soil samples of 0–30 depth provided replicable results for tree strand AGB and SOC.

The highest AGB was evident in areas where forest was still intact (strict nature reserve), as opposed to the degraded and encroached areas (production zone). SOC varied with soil depth and land use/cover types. Another important revelation in this chapter is that SOC concentration is greatest in the production zone. By implication, if well managed through conservation measures such as afforestation, reforestation, longer fallow periods, and mulching, SOC in legume enhanced agricultural soils have a great potential as carbon sinks. The lowest SOC was noted in the recreation/buffer zone (0.4%). Land use type, AGB, and forest management in the different zones are identified as the key drivers of carbon stock variations in Mabira CFR. Priority should be given to reducing deforestation and restore degraded areas. This can be achieved through demarcating forest boundaries to minimize encroachment, enforcement of policy on forestry for sustainable development, and promotion of reforestation programs.

Abstract

Despite the fact that land degradation is both natural and human-induced, it is proven that human activities pose greatest threat and these include unsustainable land management practices such as destruction of natural vegetation, over-cultivation, overgrazing, poor land husbandry, and excessive forest conversion. Other than reduced productivity, land degradation also leads to socioeconomic problems such as food insecurity, insufficient water, and regular loss of livestock which exacerbate poverty, conflicts, and gender inequalities that negatively impact mostly women and children especially the rural population. Increased efforts by governments, donors, and partners toward reversing land degradation through community-led, innovative, and effective approaches therefore remain to be crucial today than never before!

Farmer-managed natural regeneration (FMNR) is a proven sustainable land management technology to restore degraded wasteland and improve depleted farmland. This approach has been tested across Africa with high success rates. In spite of the huge local, regional, and global efforts plus investments put on promoting FMNR across different landscapes among vulnerable communities for climate resilience, the implementation of such projects has not been as successful as intended due to slow women uptake and participation in the approach. In order of ensuring women who are mostly at highest risk to impacts of climate change enjoy the multiple benefits that come along with FMNR, the success rate for uptake of FMNR especially among women need to be enhanced.

This chapter seeks to explore drivers and barriers of women participation in uptake of FMNR for climate resilience. Findings will be shared from a 3-year project dubbed Integrated Management of Natural Resources for Resilience in ASALs and a Food and Nutrition project both in Laisamis, Marsabit County, Kenya. The program interventions on natural resource management for livelihoods seek to integrate gender and conflict prevention and prioritize sustainable, market-based solutions to address the persistent challenges. The chapter discusses findings, successes, and lessons learned from the actions and the requirement to position women as vulnerable groups at the center of initiatives designed to address the climate change crisis. The outcome of this chapter will enhance gender-responsive FMNR programing through awareness creation, effective organization/project designs, strategies, and plans together with advocacy and policy influence. Limitations of the study and main recommendations for future programing in similar contexts are also shared.

Keywords

Gender · Mainstreaming · Women · Participation · FMNR Uptake · Climate resilience · Marsabit · Kenya

Introduction

Climate change is so far viewed as one of the greatest challenges facing humanity manifested in the form of variation in amount and distribution of precipitation, ocean salinity, wind patterns, and aspects of extreme weather leading to droughts and flooding, among others. These changes threaten community livelihoods, economy, ecosystems, and social cohesion. Africa is particularly viewed to bear the brunt of the climate change threats mainly due to its poor economic development and low institutional capacity. Vulnerable communities especially women and children within the continent are facing the highest pressure following conspicuous threats like decline in crop production, livestock deaths due to droughts, malnutrition, resource-based conflicts, and migration (Fig. 1).

Globally, women are underrepresented in natural resource management (NRM) and peace building, and they are also disproportionately affected by poor NRM because of gendered power relations that deny women access to resources such as land. Women especially in the rural areas are primary providers of water, food, and energy at the household level and therefore bear heaviest impact of poor resource management. In many of the ASALS areas of Kenya, the frequency and magnitude of droughts, floods, and famine have increased significantly in the recent past. This has impacted nega-

Fig. 1 Women in search of firewood, Marsabit, Kenya, February 2019. (Photo: Irene Ojuok, World Vision Kenya)

tively on the pastoralist communities and especially the women whose vulnerability to the impacts of climate change is necessitated by their roles at household level as caregivers. In Kenya, tens of thousands of hectares of farmlands have become so degraded that they no longer produce adequate or regular crops or pasture for livestock. Historically, there has been a male bias in development program research, planning, and implementation activities, which ignore women's role in dryland development and the challenges that they face. Moreover, women generally do not participate in the decision-making processes in the community. Increasingly, women and youth are usually the most marginalized groups often suffering first in situations of severe food and water shortage. They carry the largest burden of searching for fuelwood, pasture, cooking food, and gathering wild fruits, among others. Poor management of natural resources can lead to overuse and degradation, desertification, deforestation, soil erosion, declining water tables, and other effects that can threaten livelihoods and peace. Sometimes, this leads to conflict at household or even between communities. Forest goods and services are largely public in nature and therefore depend to a large extent on public funding. However, prioritization of public investment and incentives to the private sector for forestry development has been low partly as a result of low valuation of forestry goods and services leading to very slow growth of the sector. This has sometimes accounted for the increased utilization of the forest resources beyond its capacity to sustainably be replenished especially due to the fact that increased population and urbanization are largely dependent on these resources. In forest management, women's traditional roles (e.g., collecting water, growing food, etc.) are particularly crucial in drylands in terms of natural resource management and food security. Men have usually been responsible for decision-making and planning of farming activities especially where land is productive with high economic returns, but with the increasing land degradation, they leave the degraded areas to look for jobs in urban areas, leaving women to assume new roles and responsibilities on the farm. In such a changing context, it is fundamental to be aware of the obstacles hindering full participation of disadvantaged groups, including women in the adverse climate change conditions (Figs. 2 and 3).

Kenya has cited climate change as one of the most serious challenges affecting achievement of its development goals as described under Vision 2030. Toward this end, in 2010, Kenya developed a National Climate Change Response Strategy (NCCRS) followed by the National Climate Change Action Plan (NCCAP) in 2012, which recognized the importance of climate change impacts on the country's development and identifies significant adaptation measures in various sectors of the economy. However, there has been lack of gender-sensitive targets and indicators purposefully set to track progress. There is also need for capacity-building with respect to climate change and its implications for achieving Kenya's gender and development targets. Climate risk management efforts could equally be strengthened by improving understanding of the implications of climate change for Kenyan women and other vulnerable groups, deepening analysis of how to develop and implement adaptation measures that minimize adverse impacts on these groups, and integrating this knowledge into policy and program implementation. Creation of this understanding will likely need to be supported by extensive research and more awareness-raising with policy-makers and experts in this field.

Fig. 3 Women practising FMNR in Laisamis, Marsabit County. (Photo: Irene Ojuok)

Farmer-managed natural regeneration is a low-cost, sustainable land restoration technique used to combat poverty and hunger among poor subsistence farmers in developing countries by increasing food and timber production and resilience to climate extremes. It involves the systematic regeneration and management of trees and shrubs from tree stumps, roots, and seeds. World Vision has successfully implemented FMNR as a sustainable forest management approach among communities with tremendous uptake by communities especially in ASAL areas due to the sustainable benefits derived from the tree management systems. Among the tree based value chains are like sale of fuelwood, pasture bulking, and beekeeping which are some of the drivers identified that have motivated farmers to increase restoration efforts due to increased returns from wood and non-wood products. The main beneficiaries of this approach are those who depend more on tree resources: farmers, herders, and particularly women and children who harvest wood and non-timber forest products, which are based on documented economic values of FMNR.

There is, however, a need for in-depth analysis and dissemination of findings on the role of women in natural resource management with focus on drivers of women participation on FMNR for increased climate change resilience in ASAL counties of Kenya. In every society, there are marginalized groups, often including women and children, people with disabilities, and minorities. External parties can play a critical role in opening the eyes of all to the benefits of inclusion and in facilitating positive change sensitively hence need for this chapter in the climate adaptation hand book.

The case study for this chapter draws on World Vision that has wealth of experience in implementing FMNR approach which has been successful in different contexts in Kenya over the last 8 years including in semiarid areas. Between 2018 and 2021, World Vision Kenya (WVK) in partnership with Northern Rangeland Trust (NRT) and Stockholm Environment Institute (SEI) will be implementing a project dubbed Integrated Management of Natural Resources for Resilience in ASALs (IMARA). The goal of the project is toward increasing resilience of about 35,000 marginalized households to climate change-related shocks through diversified livelihoods and improved natural resource management and use in the ASAL Counties of Isiolo, Laikipia, Marsabit, and Samburu through funding from SIDA. The key objectives are as follows: (1) secure livelihoods and strengthened market systems (including for women and youth) that support sustained management of natural resources; (2) sustainable management and rehabilitation of land, forest, and water sources for strengthened ecosystem services; and (3) strengthened governance systems and structures for sustainable NRM at community, county, and national levels. As part of baseline and program intervention mapping, a gender and social inclusion assessment were conducted in the target program area to establish key sociocultural, economic, political, and technological issues that affect participation of women and youth. This is in line with the Swedish Development Cooperation Strategy for Kenya (2016–2020) which includes a focus on “A better environment, limited climate impact and greater resilience to environmental impacts, climate change and natural disasters.”

To complement these objectives, the proposed case study will be limited to identifying the key factors that drive or bar women participation in adoption of FMNR approach for climate resilience in Marsabit County. The findings will be used to develop strategies to effectively and meaningfully engage women in all stages of program implementation cycle. The study findings will strive to enhance women, girls, boys, and men in the community participate in a process which allows them to express their needs and to decide their own future with a view to their empowerment in sustainable NRM, livelihoods, and governance domains for increased resilience to impacts of climate change.

The study opted social research using qualitative survey approach. The main method was through interviews using focused group discussions (FGD) and key informant interviews (KII). In this process, KII guide and FGD guides were the main tools adopted for use during the research. The sampling was purposive since it was intended to get information from targeted audience with knowledge on natural resource management and FMNR approach. The interviews entailed for ten sets of respondents (three FGD comprising women only, men only, and mixed group of men and women of different age groups, KIIs including two government officers from environment and agriculture departments, woman FMNR champion, youthful male and female practicing FMNR, World Vision staff implementing the project in Marsabit, and a local chief). An interpreter from the local community supported translations during the interviews due to language barriers in some instances. Summary tables based on the study themes were employed for analysis using the QDA Miner Lite version 2.0.6. The analysis results were presented in terms of tables, graphs, and pie charts. Secondary data sources sourced from document review using document review matrix guide aligned with the key study objectives. Observations were conducted during field travels while doing data collection in the villages of Marsabit. Photography was equally used to obtain general status of the landscape encompassing key features, e.g., vegetation and habitat, migrations, human settlement, and human activities, e.g., trade, livestock rearing, land restoration efforts, etc. (Fig. 4).

Findings and Recommendations

To Identify Potential Risks Associated with Climate Change and Land Degradation Facing the Communities in Laisamis (Mention the Key Threats, Who Is Most at Risk, Why)

Overall, *extreme climatic conditions* linked to climate change mostly mentioned by the respondents include severe and prolonged drought, increased flood occurrences (El Niño), extreme heat caused by high temperatures, low and irregular rainfall

Fig. 4 FMNR benefits – gums and resins, flowers, and seeds used as livestock feed critical in drought season. (Photo: Irene Ojuok)

patterns, and disease outbreaks, e.g., malaria and diarrhea. In the month of April 2019 (Kenya 2019), seven people were confirmed dead following the outbreak of k**ala-azar** vector (sand fly) disease in **Marsabit County mainly** in Laisamis sub-county. This insect is most active in humid environments during the warmer months and at night, from dusk to dawn. According to the World Health Organization (WHO) 14 March 2019 report, this disease which mainly affects the poorest people on Earth is linked to environmental changes such as deforestation, building of dams, irrigation schemes, and urbanization. Environmental management hence cited important in reducing or interrupting transmission of this disease (Fig. 5).

Intensified **pressure on natural resources** is attributed to water scarcity, limited pasture, increased deforestation, limited access to firewood, soil and wind erosion, and along the river beds overharvesting of sand. Risks associated with climate change have also led to **loss of livelihoods and food insecurity** leading to death or poor health of livestock, low crop yields, increased charcoal burning for sale, and loss of wild fruits and seeds/fodder usually consumed by human and livestock during severe drought. Hunger and malnutrition manifest itself in these cases. Some of the social challenges include **displacements/migration**; **conflict over natural resources**; **increased crime**, e.g., cattle raiding; **school dropouts**; **family breakdown**; and **poverty**. One of the respondents emphasized that during drought "only one out of five children attends schools" hence higher levels of illiteracy in the region. In a men FGD, one respondent expressed threats associated *with morans marrying their women* since the younger men can offer better living conditions than the older ones.

91% of the respondents reported that **women and children are the most at risk** in these circumstances. The reproductive roles undertaken solely by women were emphasized to increase their vulnerability in negative climate change impacts. For instance, when men migrate in search of pasture, women take up full responsibility

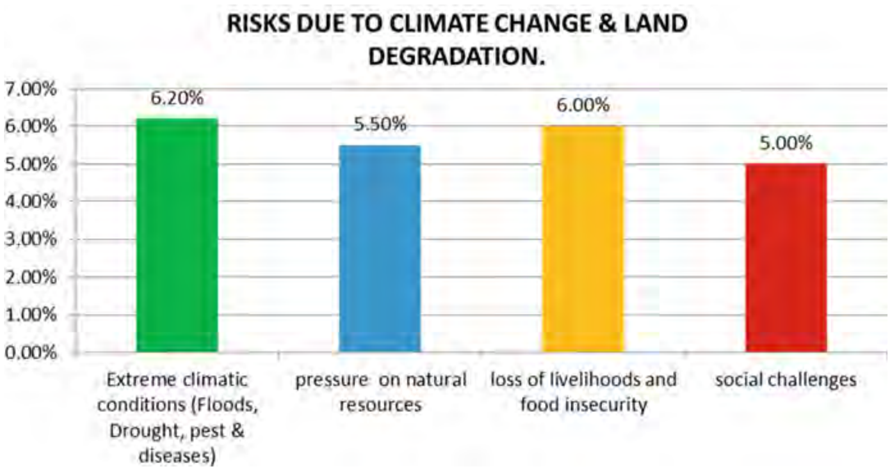

Fig. 5 Analysis of risks associated with climate change

for households; conflicts due to pressure on natural resources leave women most affected because of their weak levels of defense, and hunger caused by drought deteriorates health of pregnant and lactating mothers including children under five. The men-only FGD confirmed that a *woman had been killed in the process of protecting her children* when an enemy attacked their household and the man had migrated with large herds in search of pasture. Limitations on decision-making and utilization of valuable resources that can help support them while in need, e.g., livestock, land, and large-scale sale of tree value chains, are mainly men-dominated, and they shared justifications to this. This emphasizes the critical need of enhancing women participation in sustainable natural resource management while exploring the potentials FMNR has in increasing their resilience to climate change (Fig. 6).

Assess the Opportunities FMNR Has in Increasing the Resilience of the Communities to these Risks (Define FMNR, Its Key Benefits from an Environmental, Economic, Social View, etc.)

The FGDs and KIIs were sought to explore FMNR benefits in resilience-building among the communities (Fig. 7). Adaptation and mitigation opportunities came out strongly with environmental conservation benefits leading, followed by enhanced availability of pasture for livestock and increased food security which aside from addressing the domestic household needs also offered better economic opportunities. Respondents confirmed that FMNR is an **adaptable approach to land restoration** especially in an ASAL context since it is easy to apply and inclusive (done by men, women, people living with disabilities, and children) and has high success rates,

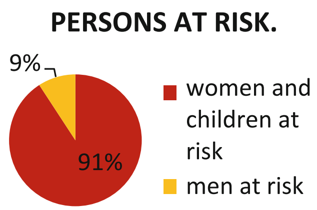

Fig. 6 Analysis of the most affected gender in climate change risk scenarios

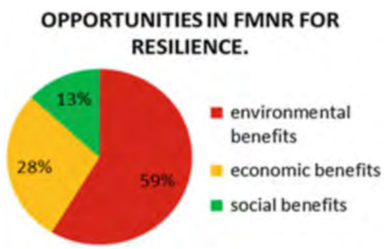

Fig. 7 Opportunities FMNR provide for enhanced resilience

community bylaws, and regulation control in tree harvesting, thus reducing pressure caused by overharvesting of trees. Invasion of *Prosopis juliflora* (*mathenge*) in Marsabit is a menace, but FMNR management practices applied to this species have enabled better management. Increased **access to high-value indigenous trees**, e.g., wild fruits and Acacia pods, was cited by the pastoralists especially women as a critical feed for human and livestock especially during severe drought and for medicinal purposes. Often, women are the repository of extensive botanical knowledge since they know the traditional uses of many species. One woman says "Such trees are a mystery to us, without which we perish. Acacia tree pods and flowers can feed livestock for 10 months in scarcity of grass." **Less migration of people and livestock** is experienced where FMNR is practiced due to availability of pasture/fodder throughout the year. This reduced the burden of women being household heads during prolonged drought. They also mentioned the link between **improved health and productivity of their livestock** which ultimately addresses food security and economic empowerment since their livestock fetches higher market rates and increased milk and meat production offers nutrition needs as well as excess for markets. FMNR strengthens knowledge in tree-based value chains, thus enhancing **diversification of livelihood opportunities** from wood and non-wood forest products (NWFPs), e.g., trade in gums and resins, honey, gum arabic, firewood, acacia pods, wild fruits, etc. Respondents also brought out the FMNR social aspects in which cultural and religious attachments to specific species of trees enhanced their protection and management, e.g., there are species used during marriage, circumcision, and sacred events.

What Are the Roles of Men and Women in Uptake of FMNR

The objective explored the different roles played by men and women in the uptake of FMNR practice. This was based on the domestic chores undertaken by men and women in the family and community setup. It was evident that women are directly responsible for **care and management of trees** due to many derived benefits they accrue from the trees that enable them run their families. In all the mentioned roles of women, protection and use of the tree resources were most significant. Men, on the other hand, mainly offer **administrative roles in control of the natural resource**. Out of the nine roles played by men in uptake of the practice, five are mainly in management and control of use of the resources. Both men and women have equally **economic interest** role rates in the practice of FMNR. **Trade** in livestock, gum and resin, seeds, and wild fruit collection is done by both. **Management and utilization** of tree resources especially in large scale is reserved for men. It was interesting to note that **development and enforcement of bylaws or regulations** for environmental protection significantly sit on men (Fig. 8).

Generally, women often manage sheep and goats as they tend to be kept closer to the homestead. Women also tend to be left responsible for the home herd of cattle and camels when men take others on migration. As such, women's roles in livestock and environmental management should not be underestimated, and often their

No.	Men	Women	Both Men and Women
1.	Decision making on management and use of trees	Taking care of trees	Prunning and thinning of trees
2.	Control over the tree resources	Feeding the family and small stock from tree products	Offer education on environmental conservation
3.	Administration of justice especially for tree offenders	Putting up shelter for the family using tree branches	Harvesting of Wood and NWFPs
4.	Only men practise bee keeping	Creating awareness and trainings to other women on FMNR	Trading in wood an NWFPs
5.	Guide ceremonies in which specific trees are used	Reporting tree offences to men/elders	
6.	Educating young boys on importance of taking care of the earth during initiation ceremonies e.g. circumcision	Small scale harvesting of Wood and NWFPs (firewood, acacia pods, wild fruits, herbs, gums and resins)	
7.	Long and short distance grazing for large herds especially during drought	Trading in wood and NWFPs to feed the family	
8.	Large scale Harvesting of trees especially mature/very old ones	Short distance grazing especially for small stock	
9.	Developing bylaws/regulations for tree management and use	Protecting and watering of trees e.g. the wildings	

Fig. 8 Roles of men and women in uptake of FMNR

knowledge on livestock as well as grazing areas, migration routes, and water points is rich. Women and men typically have different objectives for keeping animals, different authorities and responsibilities, and different abilities to access and use new information and improved technologies. These differences may lead them to have different priorities regarding investments in the adoption of new technologies and practices and/or different ideas about how best food and livelihood security can be attained through embracing FMNR.

What Drives Women to Participate in or to Adopt FMNR

From both FGD and KII interviews, FMNR ability to enhance **access to immediate household basic needs**, e.g., firewood, feeds (for human and livestock), building and fencing materials, and beddings, was cited as the most important driver to women participation in uptake of this practice (Fig. 9). Continued deforestation in Laisamis has led women walking long distances in search of firewood; one women reported walking 8 h (to and fro) to collect water and firewood from far off hills. Acacia pods offer nutritious feed for livestock especially during drought when pasture is limited, wild fruits have been a significant source of food in households, both seeds and wild fruits are also sold in the market, and women are mostly involved in this business. Alongside this, **economic returns from sale of products** from the environmental services accrued as a result of FMNR boosts women to participate in savings and loaning schemes, thus enabling them to expand and diversify their businesses/livelihood opportunities and increase their income levels. As they easily access basic immediate need through FMNR, women have more time to explore participating in other interventions like poultry keeping and kitchen gardening for nutrition and markets. One of the respondents noted that "Women

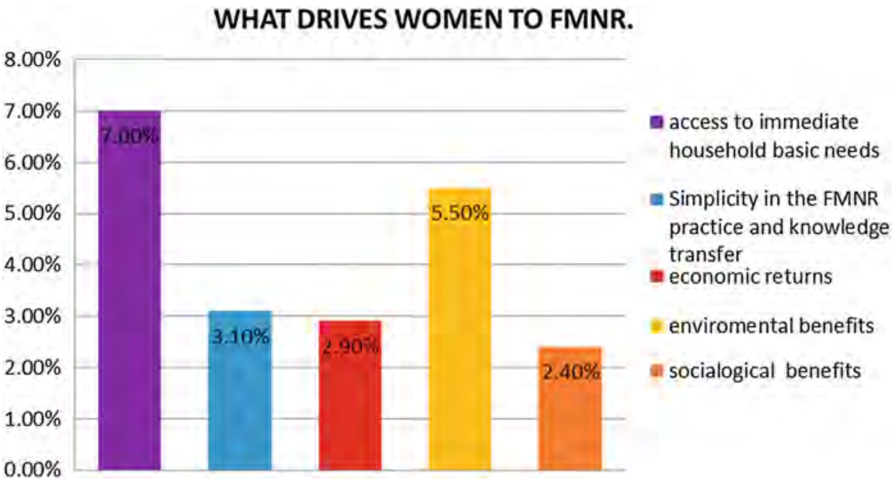

Fig. 9 Key drivers of women uptake and participation in FMNR

will go to great lengths to extract resources they need to take care of their families including entering dangerous insecure areas such as no-go zones which put them at risk of rape, kidnapping and killing." Improved health of livestock enhances the prices and increases milk production which is valuable to women. **Ease in application and transferring of knowledge** and practice of FMNR including its **social benefits was ranked third** in women drivers in uptake of FMNR. Participants affirmed the low-cost approach would best suit women since they are most vulnerable, and the more expensive an approach, the lesser application they would have of it. Majority of women in the region are illiterate; hence, the simplicity in the practice enhances women participation. **Environmental benefits** from FMNR were equally a factor since severely degraded landscapes are key threats to women because this deprives them access to basic ecosystem services. Marsabit is generally a dry place with high temperatures; FMNR increases tree cover that provides shade required by human and livestock. Women appreciated the importance of shade for resting and relaxing after daily chores. In some instances, goats have equally died due to prolonged exposure to very high temperatures, thus underpinning the importance of trees offering shade. Bare land exposes the community to excessive dust which further than contaminating food and causes eye and respiratory problems. Strong winds in the area have led to destruction of property; hence, trees play an important role as they serve as wind breaks.

Key Barriers Affecting Women Participation in FMNR

The main barrier limiting effective women participation in uptake of FMNR mentioned by all the respondents is **excess workload** on women which affects their concentration and consistency in rollout of FMNR since their attention is

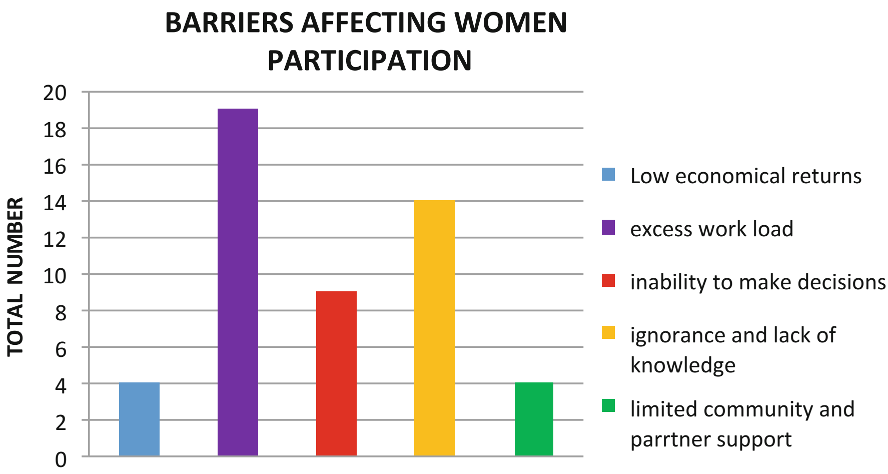

Fig. 10 Barriers affecting women participation in FMNR

diverged to addressing domestic chores and reproductive roles at household (Fig. 10). Severe drought and increased water stress necessitate this challenge overburdening women the more. **Ignorance and lack of knowledge** was cited as threat to uptake of this approach since it is likely to limit transfer of knowledge and skills. Most women in this community are illiterate, for instance, in women-only FGD, 90% of the respondents were only exposed to informal education and could only speak their local language, hence causing communication barriers in new knowledge transfers. Inability to make full decisions over management and utilization of tree resources as well as livestock that have direct linkage to success of FMNR was equally a challenge the women faced as observed by the respondents. Women's subordinate position in society, and their diminished access to information, education, and training, affects their participation in decision-making and public life. This is sometimes attributed to the cultural norms like overstocking by men depicting wealth and pride. Land ownership also rests on men; hence, women have limited power to make decisions on resources on land. Traditional institutions that offer guidance and leadership are mainly comprised of men; in fact, council of elders which is the highest traditional institution is purely composed of men. Women also need the security of knowing that they will have equal decision-making power in how resources and incomes from FMNR work will be used. This is especially important for women-headed households. **Low economic returns** and long-term benefits expected from trees and NWFPs minimize the interest of women in land restoration efforts including FMNR. The respondents acknowledged the many income sources from tree-based value chains, but the low market prices make the venture not worthwhile. For instance, they cited case of gums and resins which cost 200/kg in their locality, yet the same goes for 1000/= in the urban areas. This makes them feel exploited. Lack of organized market systems for the FMNR value chains limits women's return on the investments in the practice, thus derailing their efforts. **Vastness of the area and limited transport** means makes it even more difficult for knowledgeable people to create awareness of the approach due to logistical challenges. **Minimal community and least concerted partner support** to address this challenges derails passion among the existing women champions who strive to promote uptake of FMNR in the community.

Recommendations for Enhancing Women Participation in FMNR Uptake

Intense awareness and improved capacity for women to participate in FMNR was identified as most critical need in influencing their uptake of this approach (Fig. 11). This could be achieved through trainings, exposure to successful sites, and increased access to quality germplasm required by women. Gaps in effective monitoring and evaluation of projects have previously affected success of the projects; the respondents emphasized the need to have **community-led monitoring**, **evaluation**, and **learning model** for FMNR approach which are women-led, inclusive, and responsive. This will ensure women own this approach and integrate it in their daily activities. For instance, women are main beneficiaries of firewood; it's easy for them to include pruning and protecting of trees as they harvest firewood. The respondents also noted low **involvement of community and partners** in environmental conservation initiatives which then becomes a barrier to success of implementing this approach since it requires everyone. **Drought management and increased water access** is key in reducing pressure

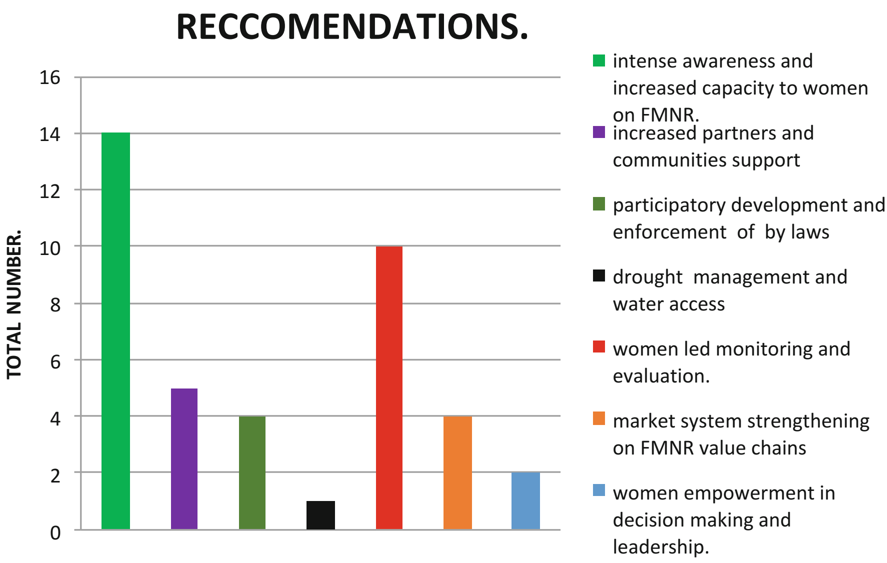

Fig. 11 Key recommendations for women participation in FMNR

women are exposed to in addressing household needs which would then give them time to get fully involved in FMNR activities. This continues to emphasize the need to invest more in adaptation and mitigation efforts to improve community resilience to climate change effects. More efforts are also required to **ensure women meaningfully participate in decision-making and have leadership roles** in natural resource management as they are the most at risk and have the ability to offer best solutions. In circumstances where women and men have equal access to productive resources, control over those resources is usually vested in men. Across all the above objectives, economic returns have been mentioned driver to investments by community in land restoration. While interrogating this further in the recommendations, respondents cited the need to strengthen the **market systems and value chains along FMNR** and other sustainable natural resource management approaches as this will attract more people to invest in the models. There are very many opportunities in FMNR that both address mitigation and adaptation which economic incentives would propel greatly. “Why can’t private sector and research actors explore marketing or adding value to acacia pods from acacia tree that is proved to enhance milk production and health in goats and is the main livestock feed of all pastoral communities that take them from one drought season into the rainy seasons? The market for this product is disorganized hence no adequate return on investment, yet this can be big driver for pastoralists to bring back acacia trees on land which provide other multiple benefits” reiterates one of the respondents.

Limitation of the Study

While the case study has established significant findings and recommendations in enhancing women participation in uptake of FMNR for climate resilience, it’s important to note that the limited duration in implementation of such findings may not yield to desired outcomes. The study also targeted a narrow geographical extent with small population applying the quantitative and quantitative data collection methods to derive the results; hence, the outcomes need to be understood within this scope. Intended, IMARA project evaluation in 2021 will additionally establish the contributions of these findings to the outcome of women participation in FMNR within Marsabit County. Additionally, it is important to note that in many communities living in ASALs, the status of women and girls is subordinate to that of men and boys. Key assets and resources, such as land, livestock, water, and cash, are generally controlled by older men rather than by women or youth, reflecting the subordinate position of women in society and the cultural limitations placed on their public role. The welfare of women and girls is also directly threatened by environmental problems, which increase the pressures of providing for the household, particularly water and fuelwood collection. Further studies are hence recommended in this field to bridge the gender gaps that continue to challenge women participation climate resilience initiatives or programs.

Conclusion

About 80% of Kenyan women spend about 1–5 h per day per household looking for fuelwood (p. vi), and in some rural locations (particularly in the ASALs), they spend 3–5.25 h a day collecting water (p. 20). Climate disasters can increase women's household responsibilities and cause disproportionate economic losses. During periods of drought, especially in the ASALs, women and children need to walk greater distances to fetch water and fuelwood. The household responsibilities of women can also increase, even more so if the able-bodied male members of a household leave in search of economic opportunities. Greater resource scarcity can also increase the likelihood of women and children being affected by conflict and violence. Women are at greater risk as well during periods of flood, when the occurrence of malaria, cholera, and dysentery – to which pregnant women and children are more vulnerable – can increase, particularly in areas where access to health care is inadequate. Despite women's multiple burdens, they have proved their capacity for effective collective action at the local level and shown that investment in their empowerment generates positive multiplier effects across communities in ways that improve human welfare.

IMARA program interventions on natural resource management for livelihoods seek to integrate gender and conflict prevention and prioritize sustainable, market-based solutions to address the persistent challenges. The efforts will transform the lives of communities and households in the four target counties and revitalize/preserve rangeland assets for the benefit of future generations especially women who are mostly affected by the negative impacts of climate change. According to the County Integrated Development Plans (CIDP) for Marsabit 2017, one of the key social problems in Marsabit County is high gender inequality as women and youth participation in development is low and there are few women and youth involved in leadership and decision-making; traditional and cultural practices are dominant. It is on this basis that the case study sought to investigate the factors affecting women participation in uptake of FMNR for climate resilience with the below summarized conclusion:

- There is evidence of risks associated with climate change linked to climate variability (drought, floods, high temperatures, disease outbreak), increased pressure on natural resources leading to resource-based conflicts, loss of livelihoods intensifying poverty, and social disintegrations causing lack of cohesion among communities. These increase vulnerabilities of communities, and 91% of the respondents noted that women and children as the most affected.
- Environmental, economic, and social benefits proved greatest opportunities FMNR has in increasing resilience of farmers to impacts of climate change.
- Women were cited to be more involved in the actual restoration and exploitation of the tree resources due to reproductive roles which are heavily dependent on sustainable landscapes. On the other hand, men are mainly into overall administration and management of the resources. This means women invest in what they have limited gains especially when there are huge returns.

- Main drivers to women participation in FMNR included access to immediate practical needs, environmental benefits, simplicity and adaptability of the approach, and economic and social benefits. These are in order of priority.
- The greatest barrier threatening women participation in FMNR is excess work load on women in the household following limited efforts to address the burden of women especially in ASAL communities. Ignorance attributed to high illiteracy levels, low decision-making powers, low economic returns, and inadequate partner and community support limits women participation.
- Recommendations, intense gender-responsive FMNR campaigns, women-led monitoring, evaluation and learning, partner and community support, market systems strengthening for FMNR value chains, participatory development and enforcement of bylaws, women empowerment in leadership and decision-making, and finally drought management and increased water access (Figs. 12, 13, 14, 15, 16, and 17).

Abstract

Port Harcourt, Nigeria, as with many cities in Africa, is already experiencing impacts from climate change while also facing development challenges and compounding vulnerabilities. There is often a gap between the adaptation recommendations of academia and international organizations and the conditions needed to achieve these recommendations given the realities on the ground in cities with vulnerable populations, pressing challenges, and minimal capacity. This gap can make it difficult to translate theoretically persuasive plans and guidance into practically sustainable actions. This chapter builds on the experience of CMAP, a Port Harcourt-based NGO leading participatory mapping, community media, and public space design programs in the city's informal waterfront settlements. Drawing on the perspectives of Chicoco Collective, the youth-led volunteer network which CMAP supports, and the datasets that they have built, the chapter explores local awareness and skills for climate change adaptation. This chapter concludes with recommendations relevant for Port Harcourt and similar African cities to build on such local skills and experiences and advocates for a partnership-based approach that brings together adaptation professionals and community-based actors for more effective critical analysis of local conditions and prioritization of actions to meet the development and climate change needs of local communities.

Keywords

Community development · Port Harcourt · Nigeria · Flooding · Community data · Awareness raising · Informal settlements

Introduction

There is growing global awareness and urgency about the need to accelerate action to adapt to climate change. Many cities and local communities, especially in Africa, are already experiencing the impacts of climate change, and risks and vulnerabilities are increasing. This chapter focuses on Port Harcourt, Nigeria, which is a secondary city in the most populous country in Africa and the oil capital of Nigeria. The chapter will share data and information gathered by CMAP, a local NGO, and Chicoco Collective, the youth-led volunteer network that it supports, to explore the risks and vulnerabilities in Port Harcourt, as well as the ongoing work of CMAP and the perspective of local communities, to identify some of the key challenges and to propose recommendations for how Port Harcourt and similar African cities could accelerate action on climate change.

The chapter also explores the gap between the adaptation recommendations of academia and international organizations and the conditions needed to achieve these recommendations given the realities on the ground in cities with vulnerable populations, pressing challenges, and minimal capacity. This gap can make it difficult to translate theoretically persuasive plans and guidance into practically sustainable actions. However, a partnership-based approach that brings together adaptation professionals and community-based actors for more effective critical analysis of local conditions and prioritization of actions can help to advance both the development and climate change adaptation needs of local communities.

This chapter presents findings from focus groups, mapping, surveys, and transect walks undertaken by CMAP and Chicoco Collective related to community development, vulnerability, and climate change awareness. It also provides a brief introduction to Port Harcourt, climate change in Nigeria, and a brief review of some of the latest literature and recommendations produced at the global level on adaptation to climate change in cities, Africa, and informal settlements.

Port Harcourt, Nigeria

Port Harcourt is the capital of Rivers State and is located in the Niger Delta region. The city lies at the mouth of the River Bonny. It is located approximately 25 km from the Atlantic Ocean and is situated between the Dockyard creek/Bonny River and the Amadi creek. It lies at an average altitude of about 12 m above mean sea level, although the waterfront communities tend to be below 4 m (Fig. 1).

Fig. 1 Map of the Niger Delta highlighting Port Harcourt's location 25 km inland from the Atlantic Ocean (created by CMAP in March 2020 using QGIS and data from Rivers State Office of the Surveyor General)

Port Harcourt was founded in 1912 during the colonial era as a railroad terminus and deep-water port for exporting coal, then later, oil and gas, after their discovery in the late 1950s in the Niger Delta. The oil and gas sector continues to dominate the local formal economy. However, despite the economic wealth generated in the region, many people in the city and state live in impoverished conditions. IMF-imposed structural adjustment in the 1980s and 1990s saw Nigerian cities such as Port Harcourt simultaneously grow and physically deteriorate. Even as they absorbed newcomers, they often lacked the resources to provide appropriate infrastructure and services to growing populations. With an economy so closely connected to resource extraction, long term plans are vulnerable to disruption by oil and gas-market downturns, as well as changes in state government. Historically, a drop in oil prices has corresponded to a shortage of resources for housing, water supply, security, or waste management in Port Harcourt and is often linked with the proliferation of informal settlements (Bloch et al. 2015). A series of abandoned Port Harcourt master plans and infrastructure projects, most notably the monorail, which starts and ends abruptly and has never been used, are testament to the absence of sustained urban planning and action as a result of low economic and political investment.

Despite its current ranking as one of the largest economies in Africa, Nigeria has failed to translate growth in output into an increase in formal employment, and this failure has resulted in significant underemployment. This is an even greater challenge for the country's growing share of youth. Fifty-five percent of the population is under the age of 20 (World Bank 2016). This nationwide trend is evidenced in employment rates in Port Harcourt where not only has youth unemployment increased, but is coupled with significant underemployment and a lack of productive opportunities for young workers. For many youth, participation in the illegal/informal crude oil refining process in the creeks around the city is seen as one of the few – but most lucrative – options in the local economy. Further exacerbating the issues, the city once known as the Garden City is now characterized by degradation of waterways, soil, and air largely due to the oil and gas industry (both legal and illegal).

Nigeria is a federal state with much of the governance power resting in state governments which have ministries for environment, urban development, education, etc. Despite this decentralized governance system, active city governments are largely nonexistent, and state governments have primacy over physical development in urban areas. This is the case in Port Harcourt.

The city of Port Harcourt has an estimated population of over 1.8 million, making it the sixth largest city in Nigeria and the largest in the South-South region (OECD/SWAC 2020). The climate is tropical monsoon with an annual mean maximum temperature 30.9 °C and mean minimum temperature 22.6 °C (www.wmo.int).

As noted in the 2009 Max Lock Centre study by Theis et al., spontaneous and uncontrolled physical growth driven by rapid urbanization in Port Harcourt over the last several decades has increased the settlement of the areas alongside swamps in the waterfront. Faced with high-cost inner-city rentals and a shortage of housing, many new urban dwellers are forced to settle in high-risk neighborhoods exposed to flooding and the adverse effects of climate change. These waterfront communities are now the largest informal settlements in the city, with some population estimates of over 480,000 people (Theis et al. 2009). While they have varying levels of development, with little to no government intervention or service provision, they can be characterized as lacking in many basic services including sanitation, water, and waste disposal. These communities also regularly face the threat of forced eviction with several large-scale demolitions taking place in 2009, 2012, and 2016.

Communities First: Effective Community-Led and Data-Driven Change

Collaborative Media Advocacy Platform (CMAP) has been working with residents of informal waterfront communities in Port Harcourt for over 10 years. CMAP began as an informal association motivated by building both local and global awareness of, and halting, massive forced evictions in waterfront communities. The project's animating impulse was the response of community members to the camera of the organization's now-project director when he found himself in the middle of a large-scale forced eviction. In the middle of the demolition, residents rallied around the camera, protecting it from the police and directing what it filmed.

In 2009, the then Governor of Rivers State announced the planned demolition of all the city's waterfront settlements. These settlements were not represented on municipal maps. They featured in the city's development plan only as undifferentiated zones marked for "clearance" through "major relocations." The resultant forced evictions and demolitions triggered not only widespread displacement, but also a conflict that threatened to become militant. In response, a group of local activists and international campaign organizations started to support mobilization of these marginalized waterfront communities, making visible the violence and disregard of state agencies through documentary photography, film, and recorded testimonies.

Following initial campaigning and legal advocacy work, there was a systematic broadening of engagement with different forms of representation – from the cinematic to the cartographic, from the voice on the street to the voice on the airwaves, and from architectural design to legal representation – and a strategic exploration of how they could be layered to support the struggle of Port Harcourt's waterfront settlements to be seen and heard. After several years of ad hoc activities, programs were solidified into the Human City Project, led by CMAP and a local community-registered trust. The project's programs – Chicoco Cinema, Chicoco Radio, Chicoco Sound, Chicoco Maps, and soon Chicoco Solar – are the focus of the Chicoco Collective. In its over 9 years of work, the project has established highly trained community mapping and media teams, including reporters, writers, presenters, broadcasters, filmmakers, photographers, actors, musicians, surveyors, and technical producers, with the capacity to manage a community radio and music studio.

The Chicoco Maps program, which launched as a direct response to communities not being recognized on any map or in official statistics, focuses on building the

Fig. 2 Household unit map of Ibiapu Polo Waterfront Community (CMAP 2018)

capacity of young waterfront residents to put their communities on the map, capture the information to tell their story on their terms, and generate the necessary data to negotiate with government authorities. Over the past 6 years, the volunteer community cartographers have created base maps of six waterfront communities and, for three of those communities, have developed the most thorough dataset on any community in the greater Port Harcourt area. An example of one of the community maps can be seen below which details structures and land use (Fig 2).

Their work has involved indexing every building, as well as conducting household surveys, gathering detailed community-level data on population, land use, employment, health, and service provision, among others. This data is fed into an encounter and exchange program in which civil society, government representatives, and community members are brought together in solution-focused discussions facilitated by project participants around their data and map outputs in each community.

Community Mapping and Data

The Chicoco Mapping team carried out detailed demographic and structure/infrastructure surveying of three waterfront communities. The team was able to survey

Table 1 Demographics of three waterfront communities in Port Harcourt: Ibiapu, Darick, and Amatari Polos (CMAP 2018)

	Ibiapu Polo	Darick Polo	Amatari Polo
Population	4,079	1,922	1,846
Number of households	969	447	504
Population density (ppl/km^2)	73,833	35,900	67,000
Number of businesses	126	69	97

77–80% of households in each community, which gave a representative number of responses to extrapolate total population as well as to understand the major trends in the community. The following overview statistics of Ibiapu Polo, Darick Polo, and Amatari Polo communities can be seen in Table 1.

These communities share similar topographical characteristics with other waterfront communities throughout the city, being 10–15 m below the rest of the city on land reclaimed from mangroves. Amatari Polo is the oldest of the three, settled over 60 years ago. Ibiapu Polo is approximately 40 years old, while Darick Polo is less than 20 years old and is the only community that has been sand-filled. The others are built on “chicoco” mud, extracted from the mangroves. Despite the majority of residents having lived in their communities for 5 years or longer, households predominately reported having only informal or community-granted documentation of rent or ownership.

All three communities have a young population, with over 50% of residents under the age of 25. Unemployment rates were reported as 10–12%, but it is likely that actual unemployment rates are higher, with many people reporting self-employed and not employed full-time. These waterfront communities are all managed by an Okrikan system of community leadership led by an elected community chairman and supported by a range of committee members including a woman leader, youth leader, sanitation chairman, light chairman, etc.

While the community mapping project was initially focused on collecting data for preventing forced evictions or negotiating with the government on security of tenure or service provision, it is a useful basis for understanding some of the existing climate change impacts or highlighting potential vulnerabilities. For instance, the household surveys found that over half of households reported that flooding after a rainfall event restricts their movement. Furthermore, 29% of households reported that they always have to wait a while after it rains before they can leave their home. The chart below highlights the impacts of flooding on individual households (Fig. 3).

Infrastructure networks including roads and pathways, electrical, water, and waste networks have also been documented in detail in the mapping process. This is often the first time community scale infrastructures have been documented. This aggregation of infrastructure often highlights the ad hoc manner in which drainage is implemented in the community and between bordering communities when the various community data are collated. For example, the map below indicates that the drainage network in Ibiapu Polo, one of the neighborhoods intensively mapped and surveyed by the Chicoco team, is not integrated and few of its channels are

Fig. 3 Households in Ibiapu, Darick, and Amatari Polo reporting the ability to leave their home after a rainfall event. The response options were that yes, they can always leave their home; yes, they sometimes have to wait; or no, they always have to wait for flooding to recede (CMAP 2018)

Fig. 4 Waste network map of Ibiapu Polo Waterfront Community, CMAP (2018)

ultimately connected to the larger network. These maps can serve as a base for understanding flooding bottlenecks and planning for improvements in each community. Insights into impacts of the poor drainage system and flooding are deepened by the household survey. Between 60% and 78% of households reported that drainage was one of the major problems facing their household (Fig. 4).

Another major problem raised by residents in the household survey was access to drinking water because the majority of households reported needing more than one source of drinking water. The two most significant sources of water reported are sachet water (i.e., water sold in small, sealed plastic bags) and private boreholes/taps outside their house. Less than one third of all households surveyed had access to piped water within their home.

Other issues raised by households in the survey included sewage leakage/lack of toilet facilities and management of solid waste. While these issues may not directly link to impacts of climate change at this time, they are likely to continue to exacerbate the impacts of climate change in these already vulnerable communities.

Documenting Sanitation and Exacerbating Conditions

There have been impacts at the community scale of the mapping work, but more significantly a shift in the citywide development dialogue. An African Development Bank-funded state water and sanitation services project in Port Harcourt claimed to be planning to reach 1.5 million people in Port Harcourt with improved WASH services. Yet, no waterfront communities or informal settlements were included in the initial designs. Data gathered by the Chicoco Maps team demonstrated the impossibility of reaching that many people unless the informal spaces of the city were included. In response, the project design was revised to include the city's waterfront settlements. Subsequently, as part of this larger project, in 2017, the mapping team led the data collection component of the World Bank-funded study "Technical Assistance to Fecal Sludge Management (FSM) Services in Port Harcourt, Nigeria."

While the data collection of this FSM study covered a range of urban morphologies, socio-economic conditions, and geographic locations, the project included a focus on low-income communities in Port Harcourt, and therefore a significant focus on waterfront communities. While the attention was primarily on documenting sanitation conditions and service provision, a number of climate-change-related risks and coping mechanisms were documented throughout the data collection process.

Both quantitative and qualitative research methods were employed to explore FSM practices along the entire service chain of collection, transport, treatment, and safe end use or disposal (World Bank 2017a). One of the data collection instruments used was a transect walk, during which enumerators walked through a community with several local residents to identify risks to public health, particularly with regard to the presence of fecal material and solid waste, and the proximity of these wastes to drainage channels and water resources. The World Bank defined objective was to observe environmental and public health risks along specified routes throughout the community.

The tool was revised by the community mapping team to fit the local context with revised survey questions and local terminology and piloted in two waterfront communities. The transect walk process was designed so that information on

Fig. 5 A flash flood in Port Harcourt Old Town during rainy season (photo credit CMAP 2016). (Permission obtained)

community characteristics, observed risks, and an estimate of how frequently these risks occur could be documented for each route and supplemented with GPS points and photo documentation. Observed risks were scored on a scale of "1 to 5," with a score of "5" denoting a particularly high risk.

Moreover, transect walks were helpful in: identifying and explaining the cause and effect of relationships among water uses, wastewater treatment, and sanitation conditions; identifying major problems and possibilities perceived by community members in relation to features or areas along the transect; providing an understanding of local technology and practices; and helping to triangulate and/or validate data collected through other tools.

Of the mix of 15 low-income informal settlements, middle-income neighborhoods, and high-income gated communities documented through transect walks, 73% experienced persistent flooding as a result of heavy rainfall and/or high tide (World Bank 2017a) (Fig. 5).

Furthermore, high risks were found to be more prevalent in low-income communities than middle- or high-income communities. Observed risks in these areas included unofficial dumpsites containing both solid and fecal wastes, pit latrines emptying into open drains, and evidence of open defecation. Low-income communities received a "high risk" rating of "4" or "5" for 75.8% of the observed conditions. In comparison, middle- and high-income communities received a high-risk rating for only 17.3% of the observed conditions (World Bank 2017a) (Figs. 6 and 7).

Fig. 7 The Chicoco mapping team conducting transect walks with community members to observe and record sanitation conditions in Baptist Waterfront (photo credit CMAP 2017). (Permission obtained)

The community team also received significant training on facilitating focus group discussions and developed a comprehensive questionnaire to gather qualitative data to compliment, validate, and/or challenge responses reported in the household survey. Information obtained from these discussions provided insight into household and community practices, service levels, and perceptions of past efforts to improve FSM services.

A focus group discussion was conducted at all 15 transect walk sites. Some focus group discussions were gender-specific. This was done because in mixed-gender sessions, men frequently dominated the discussions. Some men-only sessions were also held. Findings from these community focus group discussions stressed flooding challenges in the communities and informal methods being used to cope. Respondents in several communities mentioned that they themselves or others in the community were using nets or palm fronds to try to keep the solid waste and other debris that comes with floodwaters out of their homes. In three of the waterfront communities, it was mentioned that the community constructed a barrier, in some cases a metal plate or berm made of solid waste, along the riverbank to prevent flooding from seasonal high tides (seen below in Fig. 8) (World Bank 2017a).

Through the discussions, it was further revealed that flooding issues in waterfront communities were from the river and its high tide, as well as from drainage issues from upland areas and in the community. One respondent emphasized that, during rainy season, nets and barriers are removed to allow for waste to flow into the river (seen below in Fig. 9). A number of people also mentioned it was common practice in their community for people to use sticks or brooms to push the stagnant water and waste back out to the river after a rainfall (Fig. 9).

Fig. 8 A solid waste berm being created along the waterfront in Afikpo waterfront community (photo credit CMAP 2017)

Fig. 9 Nets installed in Baptist waterfront community to protect from waste flowing back into the community (photo credit CMAP 2017)

These focus group responses on flooding and their associated sanitation risks are supported by the findings of the Shit/Excreta Flow Diagram (SFD) created for this FSM project, which highlighted that other than the 13% of fecal sludge that remains unemptied in soak pits, there is no existing treatment of fecal sludge in low income areas of Port Harcourt, and it is directly entering the environment (World Bank 2017b).

Data and Media Advocacy

One of the unique aspects of the Chicoco Collective is that it brings together mapping and data collection with a range of advocacy platforms. The community mapping team has worked to analyze their data and has developed presentations to help the community and broader stakeholders think about how to best use the information to improve their community. In Ibiapu Polo, for example, the team was able to tally up all of the daily household expenses on drinking water into a yearly cost for the community. This totaled over 18 million Naira (approximately USD 50,000). Working with the community leadership, the cohort developed a proposal that is now being used by the community. The proposal seeks support to bring together these resources at a community level to implement a solar-powered public borehole, which is estimated to cost around seven million Naira, to serve the entire neighborhood's potable water needs.

A group of community mappers and journalists have built pilot air quality monitoring devices to document air quality conditions throughout the city. While their homemade devices do not yet yield data of sufficient accuracy or compositional detail to support rigorous analysis, their data does evidence alarming air conditions and reveals telling temporal and spatial pollution patterns. A team of campaigning citizen scientists has been working on how to use the data to create community awareness of air quality issues and is developing a citywide campaign. They have been able to further support this work through audiovisual documentation of illegal oil refining activities and their impacts on air quality, as well as interviews with community members and government representatives, including the then Rivers State Commissioner for environment.

These themes have also come together powerfully in other cultural and communicational forms, including as issues addressed through an original radio drama series "Angala Community," set in a fictional waterfront community. The most recent season of the radio drama, which will be aired citywide on partner stations, is focused on the gendered dynamics of waterfront communities, with an emphasis on sanitation and environmental conditions, including air quality. Numerous radio programs have been written, recorded, and produced by the community mapping and media teams addressing environmental issues in waterfront communities. One program in particular investigated the causes of flooding in the community, exploring the consistent blockage of drains and creeks with solid waste and the construction of unapproved buildings on waterways. This is an issue worsening rapidly as the waterfronts densify and expand into the mangroves, further compromising the capacity of these ecosystems to maintain hydrological balance, further undermining local livelihoods, and exacerbating entrenched economic and environmental inequalities.

The Chicoco Collective deploys a range of creative research, outreach, and engagement methods to bring climate-change-related issues to the forefront of community concern and broader popular conversation. Chicoco Cinema has used an inflatable pop-up movie theatre to raise awareness and keep local communities in the picture, increasing the accessibility of the discourse. The Chicoco Band, which includes a number of mappers, is currently working on their own cover of the well-known Nigerian artist, Fela Kuti's, "Water No Get Enemy" to address the current and looming issues of access to potable water in their waterfront communities and the country. Music can be a powerful medium of movement-building and a critical way of translating research findings into adaptation action.

The Chicoco team has established a program for prioritizing focal areas for their work each year. Focal issues have included housing, gender dynamics, and most recently, climate change. These issues are discussed through weekly sessions: "Bringing It Home: local impacts of global issues." These sessions focus on cohort-led research and discussion to understand the global context of the issues and how they can be contextualized in Nigeria and in their communities. CMAP has supported these research efforts by connecting participants with area specialists and staging expert-led workshops and trainings. Climate change has been a sustained focus of CMAP's engagement and capacity-building programs since 2017.

Climate Change in Nigeria

Climate change is a global problem, but the effects vary from place to place, based on different climate change threats. According to the IPCC Fifth Assessment Report (AR5), the extent of climate change effects on individual regions will vary over time based on different socio-economic and ecological systems for mitigation and adaptation (2014a). The same assessment stated that Africa is one of the most vulnerable continents to climate change (2014a). This vulnerability of Africa to climate change is driven by several factors of which weak/poor adaptation capacity is one (Ofoegbu and Chirwa 2019). Other studies revealed that the vulnerability of Africa can also be attributed to inadequate access to climate data, institutions, finance resources, and poverty (Ojomo et al. 2015).

Nigeria signed the 2015 Paris Agreement on September 22, 2016 and ratified it on May 6, 2017. Nigeria subsequently developed its nationally determined contributions (NDCs) and submitted it in May 2017. The NDC includes a section on adaptation but focuses primarily on mitigation actions. Nigeria has not submitted a National Adaptation Plan to the UNFCCC; however, it does have a National Adaptation Strategy and Plan for Action which was developed in 2011. This strategy suggests that large urban areas, including Port Harcourt, should develop and implement their own climate change adaptation plans. However, one has not yet been developed for the city.

In order to meet the required implementation of the stipulated provisions under the climate conventions, the department of climate change unit in the Federal Ministry of Environment was created to handle national climate initiatives (Nigerian Conservation Foundation 2008).

In 2003, upon realizing the need to produce observable information on climate change, the Nigerian Meteorological Agency (NIMET) was created, with a department for the development and delivery of climate information.

The majority of analysis on the potential impacts of climate change has been done at the national level. However, in some cases there is evidence of specific impacts in Port Harcourt, Rivers State, and/or the Niger Delta.

Increase in temperature is cited by several sources, with projections that Nigeria may experience as much as 2.5–4.5 °C by 2100 (Akande et al. 2017; Odjugo 2010; FME 2014). Variability in rainfall and the potential for the number of rainy days to decrease throughout the country and around 14% in the Niger-Delta coastal areas has been observed (BNRCC 2011; Odjugo 2005). While the number of rainy days may be decreasing, the frequency and magnitude of wind and rainstorms is increasing (Odjugo 2009).

The rise in sea level and flooding, especially in coastal regions like the Niger Delta, is another major concern (Matemilola 2019; Akande et al. 2017; Duru and Emetumah 2016, 2; Ebele and Emodi 2016, 7; FME 2014, 31; Odemerho 2014). This also impacts agriculture and provision of water due to salt-water intrusion (Odjugo 2010).

Frequent droughts, as the result of climate change, although mostly in the northern part of Nigeria, also have a negative impact on agricultural production and water security (Dioha and Emodi 2018; Elisha et al. 2017; Amanchukwu et al. 2015). Given some of the supply chain connections between Port Harcourt and the north of Nigeria, the impacts may still be felt by residents in Port Harcourt even if the impacts are not projected to take place in the Delta region.

There is some evidence that excessive heat, water stress, and air pollution will have an impact on health in Nigeria, especially in terms of water-related diseases (diarrhea, cholera, and skin diseases), respiratory diseases, exhaustion, skin cancer, and cataract according to one source (Odjugo 2010). Another study found that the four diseases most likely to be exacerbated by climate change in Nigeria are cholera, meningitis, malaria, and pneumonia (Omoruyi and Kunle 2012). A WHO report on climate change and health noted in the country profile on Nigeria that its “peculiarity as one of the leading exporter[s] of oil in Africa, faces [it with] the challenge of balancing global energy demands with the need to address climate and environmental considerations” (WHO 2015).

In Nigeria, the Federal Ministry of Environment defines vulnerability as the element of sensitivity to climate change that relates to how ready a specific system is to respond to changes in the climate, whereas exposure refers to the extent of climate stress to which a particular unit or system is exposed or the presence of people, livelihoods, species, environmental functions, services and resources, infrastructure, or economic, social or cultural assets in places and settings that could be adversely affected (FME 2014).

In an assessment of African cities’ capacity to adapt to climate change, Nigeria as a country was ranked 157 out of 192 countries for overall vulnerability based on exposure, sensitivity, ability to adapt, human habitat, and governance readiness (Leal Filho et al. 2018). The ND-GAIN index ranked Nigeria slightly higher, at 127 for vulnerability, but the ranking fell to 148 due to low readiness.

The adaptation gap is the difference between the level of adaptation action in progress and the anticipated needs given the projected climate change impacts. The African Adaptation Initiative’s discussion paper from 2018, Enhancing Action on Adaptation in Africa, found that Nigeria is one of the countries with the highest gaps, over 90%.

An analysis by IIED (Satterthwaite et al. 2018) for the 2018 Cities and Climate Change Science Conference assessed likely impacts of climate change specifically on urban populations living in informal settlements and working in the informal economy. This covers a range of climate change impacts that are observed for Nigeria and therefore is relevant to the waterfront communities of Port Harcourt. With higher maximum temperatures, the report notes that the high density, lack of open space, poor ventilation, and corrugated roofs of many informal settlements could contribute to even higher indoor temperatures in these communities. Many informal settlements are in areas at high risk of flooding. These risks are increased by projected intensifications of precipitation. Low-lying waterfront communities in Port Harcourt are clearly particularly vulnerable, and poor quality housing and lack of insurance exacerbate the impact in such communities.

The main outcome of that conference was the Global Research and Action Agenda on Cities and Climate Change Science which highlighted informality as one of six key research gaps as well as the importance of coproducing this knowledge to fill these gaps (World Climate Research Programme 2019). This chapter aims to contribute to the knowledge gap of informality and climate change action as well as the recommendation for the co-production of knowledge as the methodology of the paper, cowritten by community members of the Chicoco Collective with international experts and based on local data collection and global sources reflects this approach.

Climate Change Adaptation: Voices from the Community and Global Recommendations

Global Recommendations for Advancing Adaptation

Adaptation, especially in cities and developing countries, has increasingly become a focus of international organizations and academia, which has resulted in the production of recommendations, guidelines, and priority areas for action.

The recent report Adapt Now: A Global Call for Leadership on Climate Resilience from the Global Commission on Adaptation states that a revolution is needed in three areas to advance adaptation action: understanding, planning, and finance. As part of the revolution on understanding, a better understanding of risks, solutions, and increased knowledge is cited.

In the report's chapter on cities, the main recommendations for the way forward are (1) mainstream information on climate risks in the planning and delivery of urban services, while strengthening local capacity; (2) harness the power of nature to respond to both water and heat risks; (3) build climate resilience by upgrading living conditions in vulnerable communities and informal settlements, drawing on community knowledge; and (4) increase climate-resilient investments and capture value from adaptation benefits (GCA 2019).

An in-depth analysis of several cities around the world and their adaptive capacity determined that cities should focus on the following: the need to prioritize actions, the importance of proper planning, the need for an integrated approach that takes into account structural and development issues, and emphasis on the poorer and more vulnerable communities (Leal Filho et al. 2019).

There has also been an increasing recognition internationally of the need to focus specifically on small and medium-sized cities; however, in a study of European cities, it was found that larger and more prosperous cities are the ones engaged in climate planning, whereas vulnerable cities are less engaged (Reckien et al. 2015). Although the study focused on Europe, the situation in Africa is likely the same and perhaps more so, however data and analysis on this is scarce.

There is not only a discrepancy between types of cities but also on the inequalities within cities and how this affects adaptation. The World Resources Institute (WRI) (2018) highlighted that "[c]ities around the world can thrive when they invest in climate-resilient infrastructure, information management system and risk-reduction programs. But, most often residents who live in risk-prone areas are often left out of the planning and implementation process, leaving them even more vulnerable."

This report highlights that reducing vulnerability is not only about reducing exposure to hazards but also includes a socio-political aspect. Findings from the Urban Community Resilience Assessment program highlight the importance of social cohesion to increase individual and community resilience. This is one reason why relocation can be so damaging to resilience levels. Poor access to information communication systems for early warning and awareness of risks has also been shown to lower resilience (WRI 2018).

Given the importance of public awareness, a report by BNRCC (2011) revealed that the level of public awareness on issues related to climate change in Nigeria is considered to be low. Inadequate information is considered to be one of the key constraints encountered in adapting to climate change in Africa (Otitoju and Enete 2016). Anabaraonye et al. (2019) recommend that information and knowledge about climate change, its causes, and its impacts, as well as mitigation and adaptation strategies, should be made available in simplified, more accessible, forms and translated into local languages. Other technological tools and platforms, such as mobile phone applications and social media, should be utilized in improving information literacy, access to information, and awareness creation (Ayanlade et al. 2017; Duru and Emetumah 2016).

These reports and recommendations suggest some key areas of action that a city like Port Harcourt and organizations like CMAP and the Chicoco Collective could focus on to initiate and strengthen climate change mitigation and adaptation measures, principally: (1) increase understanding about climate change through both the collection and dissemination of locally relevant data and information; (2) carry out long-term and integrated planning; (3) build the local capacity of diverse stakeholders; and (4) prioritize vulnerable communities living in waterfront communities.

Unfortunately, despite the risks and vulnerabilities and the clear need for adaptation measures in Nigeria broadly and Port Harcourt specifically, actions to date have been limited. The reality on the ground presents many challenges to effective action. However, building on the overview of CMAP's work above, the next two sections will further explore the perspectives of local communities and then summarize how the work of CMAP, Chicoco Collective, and local communities can provide a basis for effective action.

Port Harcourt in Focus: Climate Change Adaptation Awareness and Action

The Chicoco Collective devised and conducted a focus group research program to establish a baseline understanding of local perceptions of climate change impacts and adaptation approaches undertaken at the household and community level.

The sessions offered rich insights into local knowledge of climate change, and the various adaptation methods already adopted by informal waterfront communities. The following focus group questionnaire was created to guide the discussion.

Topic	Primary question	Secondary question	Tertiary question	Other question
Climate change awareness	Have you heard about climate change?	What have you heard about		

(continued)

Topic	Primary question	Secondary question	Tertiary question	Other question
		climate change?		
	What do you know about the impacts of climate change?			
Effects of climate change	Have there been changes in your community or city that you can attribute to climate change?	If yes, what are the impacts?	If no, have you experienced extreme heat or cold, flooding, changes in rainfall, more extreme storms, etc.?	
Adaptation	Are you or your household doing anything to adapt to the impacts of climate change? If yes, please explain. If no, why not?	What about your community?	Is the government doing anything?	
Solutions	Can you think of any solutions to adapt to the impacts of climate change?	At the household scale?	Community scale?	Government scale?

The focus group sessions were staged in three different parts of the city. Another session was held for members of the various Chicoco programs. The Chicoco cohort is drawn from waterfront communities across the city. Five men and five women of the Chicoco cohort were randomly selected to participate in that session. Focus group sites were selected to achieve a cross section of neighborhood types and to capture a holistic range of experience across age, socio-economic status, ethnicity, and location. Two communities were chosen from the Old Port Harcourt Township, one of the older colonial areas of the city, which is ringed by over half of, and some of the oldest, waterfront communities in the city. One community was selected from the Diobu axis of Port Harcourt, which is home to over 20 waterfront communities. These communities were selected based on their diverse situations, but also due to existing knowledge of and relationships with community leadership, which facilitated access. Importantly, each of the communities is also host to some aspect of the informal oil and gas industry. The discussions were held in a community space, either a town hall or central area in each community, and participants were recruited

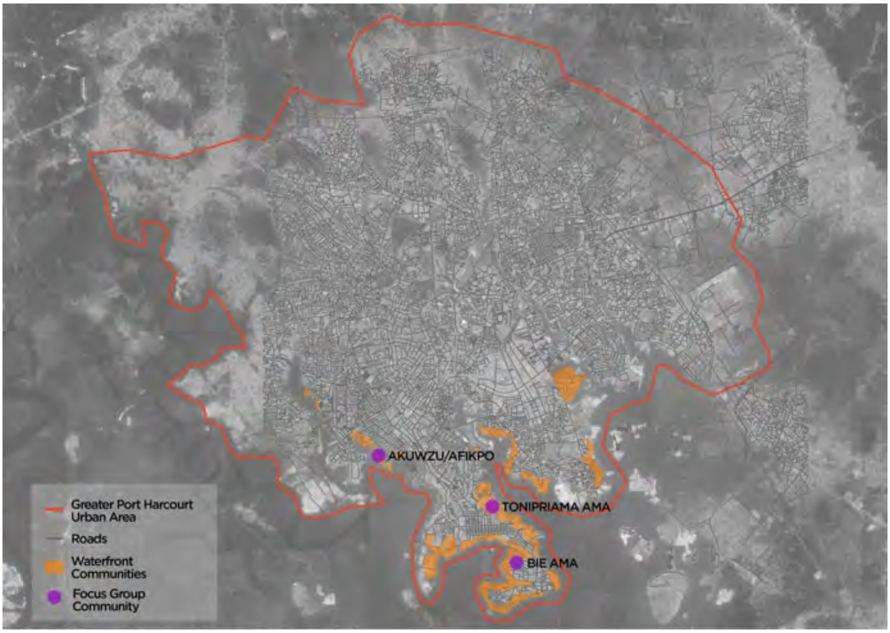

Fig. 10 Map of the greater Port Harcourt highlighting waterfront communities and selected focus group community locations (created by CMAP in March 2020 using QGIS and data from Rivers State Office of the Surveyor General)

with the help of community leadership to include a mix of men and women. A map of Port Harcourt highlighting the focus-group communities can be seen below (Fig. 10).

Akwuzu/Afikpo is a low-income waterfront community in the Diobu area established over 40 years ago. Entrance to the community is through a community market at the top of a steep laterite slope. The community is only accessible by pedestrians on poorly maintained concrete steps. The community has had minimal government-led interventions and minimal community provision of drainage systems, security, schools, and toilet facilities or potable drinking water. Along with other waterfront communities in the Diobu axis, in 2009, Akwuzu/Afikpo was faced with the threat of demolition. Many residents of the community are actively involved in the fishing industry. The community is also a major hub for oil bunkering activities, also known as kpo-fire. The area is predominantly occupied by Kalabari people.

Ten people, five men and five women, attended the focus group session in Akwuzu/Afikpo: the community chief, four fishermen/women, two higher institution students, a retired nurse, and two traders.

Bie Ama Community is a mixed middle- and low-income community in the Old Port Harcourt Township located on a reclaimed wetland area. Bie Ama is made up of five smaller communities or "polos" and is predominantly occupied by Okrikan people. Bie Ama is popularly known as New Road in Borokiri and was established on a sand-fill project in the early 1980s. This community has over 800 structures and has been developed with some regard to a layout plan. It is comprised primarily of cement block structures with aluminum, asbestos, and zinc roofing materials. The community has several churches and a mix of private nursery, primary and secondary schools. Residents include civil servants, teachers, artisans, traders, and contractors. As a waterfront community, the trading of illegally refined or bunkered products is prevalent.

Ten people, seven men and three women, participated in the focus group: two medical doctors, the community youth leader, two bunkerers (workers in the informal oil sector), a retired Nigerian national petroleum company worker, the former Radio Rivers/Nigerian Tide managing director, the female community leader, and two traders.

Tonipriama Ama is the host community of the Chicoco Collective. This waterfront community is comprised of seven smaller communities or “polos.” It is predominately occupied by Okrikan people and has existed for over 60 years. This community has over 2,000 structures, constructed from a mix of concrete block and less durable materials such as zinc or wood. The community has a busy commercial dock that is a hub for ferries, fishermen, and oil bunkering boats. There are also several marine companies located in the community. The community has had several government interventions, including the paving of several access roads and the construction of a private government jetty. There are two roads running through the community, and it is easily accessible by motor vehicle. There is one major community public toilet facility and several public boreholes.

The Tonipriama session also comprised ten participants, four women and six men: the Ama (the collective administrative unit containing the polos) chairman, four traders, a teacher, two fishermen, a bunkerer, and a student.

In the focus groups, participants were first asked if they had heard of climate change and what they understood by the term and of the phenomenon. Responses evidenced a general familiarity with the term and an understanding that climate change is related to changing weather conditions and caused by humans. Despite some familiarity with the term climate change, it was evident that many respondents used the phrase to describe any environmental issue, without a clear understanding of the differentiation between degradation (air quality issues, water pollution, etc.) and changes in climate (changes in precipitation, flooding, increased temperature, etc.).

Climate Change Impacts Observed

All of the communities shared experiences that they attributed to climate change and the sense that its impacts are felt citywide, increasing in intensity and frequency. Heat and flooding (both from sea level rise and excessive rainfall) were raised across groups as an observable impact of climate change, popular perceptions aligning with current scientific research on impacts of climate change in Nigeria.

Food insecurity and hunger, as a result of food scarcity, increased food prices, difficulty of farmers to predict the weather for planting seasons, scarcity of seafood due to decrease in catch or the catching of dead fish, and food storage and spoilage issues were raised by all groups. More research is needed to ascertain what links, if any, these issues have to climate change. However, these are clearly primary concerns for communities and should be addressed in adaptation and/or development research and action.

Health issues were also raised by all groups: Disease burden increase, with measles and chicken pox cited specifically, rashes, dehydration, respiratory issues, cancer, and eye conditions were all perceived by participants as being linked to climate change. While such attribution is far from clear for all the conditions mentioned, connections to air pollution seem to be a reasonable assumption, and it is likely that the dehydration and rash conditions are related to heat and/or water quality and access. More research would be needed to confirm such links. Nevertheless, it is clear that here too, adaptation and development measures would need to address community-identified health priorities.

The issues of pollution and environmental degradation were another focus of all groups. The black soot crisis has gained citywide attention recently, and this was reflected in the group discussions. The toxicity of rainwater, rendering it unusable for consumption or cooking, was mentioned by many. Marine habitat pollution and its impact on fish stocks were another commonly voiced concern for waterfront communities with members who still depend directly on aquatic urban ecosystems for their livelihoods. Again, while air and water quality may be linked to climate change-driven dynamics, not all of these issues are necessarily directly attributable to climate change. Nevertheless, it is likely that climate change exacerbates these problems. It is clear that environmental degradation is a major concern and in Port Harcourt the drivers of climate change are the same causes of environmental degradation. Therefore both mitigation and adaptation efforts should address these environmental issues.

Other issues raised in different groups, relating to migration, cost of living increases, and security, may involve interesting direct or indirect relationships to climate change. For instance, migration is a much researched topic in this connection, but more area-specific data would need to be gathered to determine causality and appropriate adaptation actions.

Adaptation Actions

As the effects of the climate crisis intensify, residents of Port Harcourt have developed different coping techniques for them. The participants of the focus group highlighted some of the ways they or their neighbors are changing their behavior. For increased heat and rising temperatures, coping techniques included: bathing with cold water three to four times a day, showering multiple times at night, and sleeping outside till late in the night to get some cooler air before going indoors and then sleeping on relatively cool mud or stone floors.

Increases in water intake to mitigate dehydration caused by the heat have significant financial impacts on households that spend disproportionately high proportions of their income on food and water essentials. Participants reported that water is also used to keep food cool and to slow its spoiling in the absence of reliable power for refrigeration. Other practices of drying food with salt were also emphasized as a way to preserve their food and kill pests, such as worms. Additionally, as a result of increased food prices, some respondents say that they are eating only once a day. Self-rationing is increasingly common.

Adaptation methods to address flooding include improving waste management by methods such as establishing more designated dumping sites to discourage people from throwing waste in waterways. Other discussed methods included community gutter cleaning efforts, construction of high tables to store personal belongings, blocks to raise beds, and raised doorsteps to prevent water ingress.

Respondents discussed their discomfort with and concern for the black soot air quality crisis facing their city. Concern for their health has prompted some to start wearing facemasks on days when air quality was visibly bad. The wearing of facemasks was practiced before the recent coronavirus pandemic.

Despite being asked about their adaptive practices, several of the responses were not necessarily relevant as adaptation measures, but really more about other impacts related to a changing climate, particularly increasing temperatures. Many focus group participants brought up the issue of increased lethargy and unproductivity at work from the higher temperatures. Others mentioned the need to increase their use of generators, which although not explicitly said, is likely related to needing to run fans.

It is clear that most adaptation efforts are at an individual level or household level. Knowledge of adaptive practices at community or broader scale was quite limited. But, as noted in the findings from the fecal sludge management study, some communities are undertaking collective adaptation actions, such as managing flooding issues in a coordinated manner with berms and nets. It is unclear as to whether focus group participants are simply unaware of any actions that their community or the government may be undertaking or whether they are not able to relate any actions specifically to a response to a changing climate. This highlights the need for more awareness raising of potential adaptation actions as well as planning for more coordinated efforts.

One of the communities is making efforts to curb issues of poor sanitation and dumping by discouraging the act of disposing waste in waterways by fining offenders. Two of the communities have active community leadership committees and subcommittees in charge of sanitation, and community electricity and light, among other specialized issues. These committees are tasked with maintaining community infrastructure and solving challenges that arise in the community by enacting rules and regulations, sometimes including fines or punishments for breaking these rules, or introducing levies to construct new infrastructure. Tonipriama Ama, for example, has been charging for use of and maintaining a public toilet, and likewise through its light committee, has organized levies to replace light poles and broken transformers. Although currently these committees have not addressed impacts directly related to a changing climate, these initiatives demonstrate a capacity to develop and deploy adaptations at community level.

Proposed Adaptation Solutions

When asked about other potential solutions for addressing climate change, the participants highlighted the need for education, behavior change, infrastructure projects, and government intervention. They proposed that, to tackle the effect of the climate crisis, government and relevant stakeholders needed to be more responsive, accountable, and active. They criticized lack of action, insufficient resourcing, and lack of human and technical capacity. Government and relevant stakeholders were urged to lead sensitization efforts and to provide basic amenities. There was a clear understanding of interplay between behavior and infrastructure. For example, on the one hand, the need for changed waste dumping practices, particularly regarding waterways, and for waste disposal practices that facilitate recycling and reuse was recognized. On the other hand, groups also stressed the need for better waste management systems including the placement of proper disposal containers within the communities and the construction of better gutters and drainage systems.

Groups proposed awareness-through-action and learning-by-doing approaches, as well as the need for more active community debate. Tree planting and community town hall programs were mentioned in this connection. Community sanitation exercises – the mobilization of the entire community to clean streets, drains, and public spaces – were also mentioned. Indeed, this capacity to mobilize, *en masse*, *as* a community is one of the significant resources that such settlements can draw on.

Energy was a perennial topic of debate. Gas flaring has long been a highly visible example of the violent environmental externalizations of the hydrocarbon economy in the Niger Delta. People linked the demand to end flaring with the desire to transition to renewable energy. Respondents wanted to see oil and gas companies halt polluting activities and proposed "trapping" carbon emissions. The technical approaches to doing so were not detailed. Security forces tasked with policing the informal oil industry often spill confiscated hydrocarbon products directly into waterways or set them ablaze. Respondents voiced strong opposition to these practices and proposed that, instead, confiscated product should be taken to official refineries. The retraining of bunkerers and the regulation of the informal economy to improve the environmental standards of operations were also proposed. While these are not strictly adaptation efforts, they can be considered as modest mitigation efforts and community actions aimed at a cleaner community environment.

Conclusions and Recommendations

Port Harcourt and many other cities in Africa face a multitude of climate change, environment and development challenges. These challenges are greatest in informal settlements. As informality is the dominant mode of African urbanism, it is critical that interventions respond to the situated constraints and potentials of informality and how it is variously manifested in communities and neighborhoods across the continent. To date, climate change adaptation has not necessarily been a priority in and for informal urban settlements. Many of the requirements for effective action –

from data to finance – are often lacking. Too often, the priorities, knowledge, skills, and participation of local residents themselves are missing from external interventions. However there is growing awareness of the problems and initial steps and information that can be built upon for effective solutions. Below are recommendations drawn from the experience of CMAP, Chicoco, and the waterfront communities in Port Harcourt. As the formulation of these recommendations has been led by residents and through partnership with international experts, we hope they might serve as a basis for mobilization and action in other African cities facing similar constraints and opportunities.

- *Awareness and local knowledge.* There is a of lot consistency between scientific findings on the impacts of climate change in Nigeria and those observed and recorded in local focus groups. This suggests that, while innovation is needed in the popular dissemination of research findings, many residents in informal settlements may not be aware of the latest research on climate change, they are acutely aware of direct impacts from their own lived experience and are developing local adaptations. This experience, critical awareness, and approach to situated adaptation are a potentially valuable asset for climate change response efforts.
- *Building awareness through local methods.* International organizations and governments should draw on locally established information sharing and storytelling initiatives and networks. Chicoco Radio and Chicoco Maps' Encounter and Exchange program are examples of the potential of community media and action programs not only to raise awareness and strengthen networks locally, but also to catalyze citywide dialogue. The roadshows, concerts, town hall listening clubs, broadcasts, and live discussion programs that were part of Chicoco's first radio drama season successfully stimulated citywide debate around issues of forced evictions and police brutality. Such a platform could easily be mobilized for climate change adaptation and environmental justice issues.
- *Inclusive data and knowledge collection and sharing.* There is a need for more institutional investment in knowledge and data gathering efforts on climate change impacts in Nigeria at the national and local levels. To collect and disseminate knowledge and data relevant to informal urban settlements in Nigeria, residents of those settlements need to be successfully involved. The deep, detailed, accurate, and appropriate datasets gathered by the young Chicoco Maps team with CMAP's support demonstrate a successful methodological approach to, and effective methods of, participatory data gathering and sharing in Nigeria's informal settlements. This participatory, partnership-based approach can be mobilized in a more focused way on climate change research and the development of sustainable local adaptations.
- *Integrated solutions and local context.* Adaptation solutions need to tackle development and environmental justice issues alongside climate change adaptation action, especially health issues. It is also important to recognize the context of the local economy – both formal and informal. In the case of Port Harcourt, this includes reckoning with the economic domination of the oil and gas industry.

- *Small and local efforts can be compounded for larger impact.* Some routes to scale involve a concert of small-scale interventions. CMAP and Chicoco Maps' citywide sanitation research found that the solution to Port Harcourt's sanitation crisis is not a billion-dollar central sewerage system. Rather, onsite community solutions, manageable at neighborhood-level and network-scalable, offer a sustainable approach through which many small actors can coordinate to achieve scale. As found in the focus groups, individuals and households will take adaptive measures that can be effective for reducing loss and vulnerability.
- *Large-scale responses are also necessary, with community involvement and input.* Local communities have devised some effective individual or neighborhood-level adaptation techniques, but larger infrastructure interventions, requiring access to significant capital and technologies, are necessary. Yet, for these solutions to achieve sustainability, they nonetheless need to engage and involve community actors. In a city like Port Harcourt, where the government suffers a deep trust deficit, large-scale interventions often fail because of a lack of local cooperation or even active resistance. The trust and involvement of community actors is crucial to large-scale climate change responses, particularly as large-scale behavior changes and cultural shifts are necessary for success.
- *Bottom-up collaboration to build accountability.* A bottom-up approach follows from the previous recommendation. While community members have raised the need for government intervention and effective government service provision, heavily top-down approaches to external interventions in communities with already strained relationships with their representatives are going to be difficult. Involving communities, not merely in consultation exercises, but actively in project design, is key. This is likely both to increase the appropriateness of adaptation measures, and importantly, to build a robust demand for duty bearer accountability. Demand-side platforms for accountability for climate change action in cities like Port Harcourt are critical to counter a culture of flourishing impunity that has allowed staggering environmental degradation and unsustainable exploitation to go unchecked for decades.

Acknowledgments In-kind financial support was provided by the Chicoco mapping team for research, data collection and analysis, and the focus group discussion support team, namely the recording technician, George Sosipiriala, and community engagement specialist, Fubara Tokuibiye Samuel. Michael Uwemedimo, Ana Bonaldo, and the rest of the CMAP team also provided in-kind support and guidance for this chapter.
