Abstract

A survey approach was applied to examine the technical characteristics of fish farming practice in Egypt and Nigeria. Critical issues such as floods and other vices were considered in bringing out the inference and level of aquaculture in both countries. Multistage sampling technique was used to select the study area and the number of respondents. Both primary and secondary data were used in the analysis. Eighty fish farmers were randomly selected from each of the country, making a total of 160 respondents. The socioeconomic characteristics revealed that aquaculture is an antique venture in Africa with Egypt taking the lead, i.e., 99% of the respondents practice in large-scales production of more than 11 Fadden/acre per, and 100% males depend mainly on agricultural drainage water for their earthen ponds. Ninety-eight percent cultured tilapia (*Oreochromis niloticus*) which was believed to have originated from the Nile River. In terms of financial performance and partial economic analysis, tilapia production commands more sales in Egypt, while catfish (*Clarias*) production is seen as a promising venture in Nigeria. The fish farmers have various perceptions and reactions toward environmental changes factors such as cost of labor/manpower and inputs, poor water quality, and fish extension services, and climate change impedes aquaculture development in the countries. To achieve the scale of aquaculture expansion as observed in Asian and other developed part of the world, efforts should be geared toward continental and regional integration in order to encourage aquaculture practices in Nigeria and other parts of Africa. More so, government intervention and incentives should be paramount in Egypt to reduce the excessive exploitation of the private input suppliers.

Introduction

Aquaculture is an organized process in which the cultivation of aquatic animals and plants in fresh, brackish, and marine water is made, to increase fish production above the level that would be produced naturally (FAO 2016). Fish is the most-traded food commodities worldwide; more than 3.1 billion people depend on it for their average per capita intake of animal protein which is about 20%. Aquaculture has increased the world per capita fish supply to 20 kg in 2014 (FAO 2016). Global fish forecast model predicts that the share percentage of capture fisheries is expected to fall by half in 2030 compared to the 60% global production in 2011 after growing only by 2.8 million. Aquaculture is expected to grow by 30 million tons over this same period. In terms of food fish production, the model predicts that aquaculture will contribute 62% of the global supply by 2030 (FAO 2016). The problem of feeding the more than 9 billion people in the world by 2050 in the context of climate change and uncertainty (World Bank 2013) will be rightly addressed if improved aquaculture management is adhered.

Aquaculture seems to be multilocational and isolated. The Egyptians were probably the first in the world to culture fish as far back as 2500 B.C. from Japanese Resource Council, Science and Technology Agency as cited in Jhingran (1987). Aquaculture production in Egypt far exceeds that of the rest of the other Africa countries. It is a 2.2 billion USD in 2015. Egyptian aquaculture currently provides almost 79% of the country's fish needs, with almost all the output coming from small- and medium-sized privately owned farms (GAINS 2015).

Aquaculture was introduced into Nigeria in the 1950s. Recently, it is one of the fastest growing agricultural enterprises in the country. It impacted the nation's economy in terms of contributing over 1 million metric tons to Gross Domestic Product (GDP). It is best alternatives to meet protein demand; it is a business with brighter opportunities. Despite the fact that aquaculture is an age-old practice in some regions of the world, it is relatively new in most African countries and is significant to the economic, livelihood, and nutritional welfare of the populace. From all indications, Egypt has the largest aquaculture industry in Africa (Sumaila et al. 2014).

Therefore, the research questions, what are the technical factors to be considered in order to shrink the disparities? And environmental changes impact on fish production in Africa. This chapter classically, therefore, examines the technical characteristics of fish farming (Aquaculture) practice and impacts of environmental change on fish production in Egypt and Nigeria. Specifically, the socioeconomics characteristics of the respondents were determined using Kobocollect, fish farming system and operation were examined, and critical issues and institutional framework were considered bearing in mind the fish farmers' awareness on environmental changes.

Methodology

The Study Area

Egypt (see Fig. 1) is located between 30° 06′ N and 31° 25′ E. Based on the US estimates, the current population of Egypt is 94,660,721 which is equivalent to 1.27% of the total world population (Worldometers 2017), and the total land area is 995,560 km^2 (384,388 sq. mi). The climate is arid where most of the rains fall in the winter months with an average of 2–5 mm (0.1–0.2 in)/year with the exception of the Northern coast which sometimes can be as high as 410 mm (16.1 in) between the period of October and March (Worldometers 2017). The temperature range from 49.1 °F to 73.4 °F in low wind and sometimes average high temperatures vary from 62.6 °F in wintertime to 89.6 °F in summertime were recorded.

The Nile is the primary water source of Egypt and provides more than 95% of all water available to the country. Over 60 million people are connected with the agricultural sector which constitutes 20% of GDP and consumes about 80% of the

Fig. 1 Google Earth Map showing the study area in Egypt. (Source: Authors creation, 2017)

water budget. Aquaculture in Egypt is supported by water from irrigated agriculture and lakes such as lakes Burullus, Manzala, and Edku all located in Egypt.

Nigeria (see Fig. 2) lies exclusively within the tropical zone in West Africa. It borders with the Republic of Benin in the west, Chad and Cameroon in the East, and Niger in the North. The current population is 190,423,532 which is equivalent to 2.55% of the total world population and ranked 7th in the list (Worldometers 2017). The total land area is 910,802 km^2 (351,662 sq. mi) with 9° 82′ 00″ N; 8° 67′ 530″ E coordinates (see Fig. 2). The northeast and southwest winds are the two principal wind currents that make Nigeria to be distinguished with two distinct seasons: a wet season from April to October, with generally lower

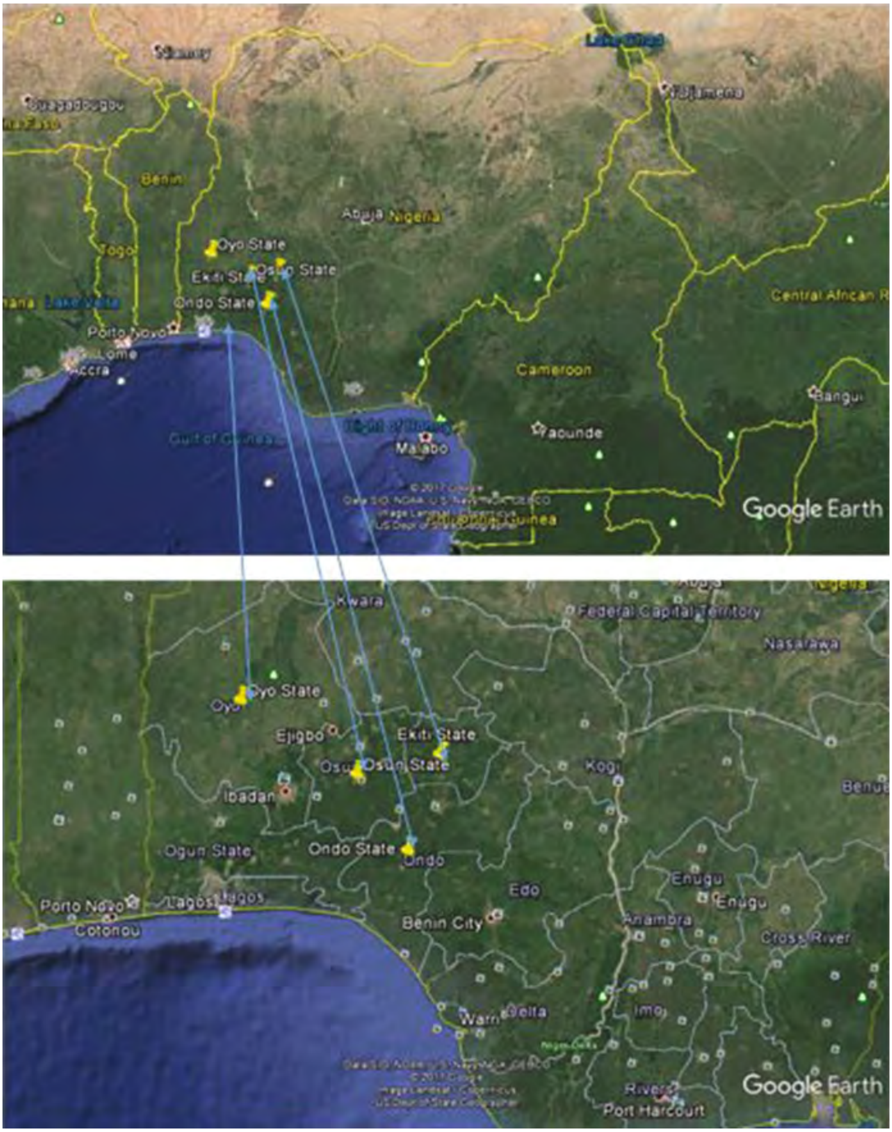

Fig. 2 Google Earth Map showing the study area in Nigeria. (Source: Authors creation, 2017)

temperatures, cloudy and rainy weather upshot of the southwest wind current. There are wide climatic variations in the country depending on the season and region. Nigeria got her name from the river, Niger River. Nigeria is indeed blessed with marine, brackish, and freshwater in addition to lakes, rivers, deltas, reservoirs, dams, rain, floodplains, inland, and coastal waters to support fisheries and aquaculture in the country.

The Design

In this research, explanatory mixed research design was applied to address specific objectives of the research work. The selected research design allows to collect data from different sources using various data collection tools. Quantitative data were collected using semi-structured and open-ended questions from key informants. Focus Group Discussion (FGD) checklists were also used to collect data. While, quantitative data was collected using questionnaire survey from the sampled fish farmers households. The questionnaire was used to collect data on the socioeconomic characteristics of the respondents, technical characteristics of the fish farms, the critical issues (water shortage, water quality, floods, and other vices), institutional framework, and respondents' perceptions of the environmental changes. Experienced male (six) and female (six) enumerators were recruited and trained.

Sample and Sample Techniques

A multistage sample technique was used to select the study area and respondents. Egypt and Nigeria were purposely selected because of the green and blue water-type availability for aquaculture, respectively. In Egypt, Kafr El Sheikh (KFS), Bahera, Shakia, and Port Said Governorates were purposely selected due to their aquaculture practice. Likewise in Nigeria, Ekiti, Ondo, Osun, and Oyo states were selected purposely in southwest of the country. This is because the states are in the same geopolitical zones. In the Egypt and Nigeria sites, a total of 160 fish farmers' households were selected using proportional random sampling method (see Table 1). The data collection was carried out between January and April, 2017, in Egypt and Nigeria.

Table 1 Distribution of questionnaire survey participants sample fish farmer households

	Egypt			Nigeria		
No.	Site	Total fish farmer households	Sample size	Site	Total fish farmer households	Sample size
1.	Kafr El Sheikh	35	35	Ekiti state	20	20
2.	Bahera	15	15	Ondo state	20	20
3.	Shakia	15	15	Osun state	20	20
4.	Port Said	15	15	Oyo state	20	20

Source: Authors Computed Field Survey

Data Collection Tools

Data collections were done by a six paired (male and female) trained enumerators who were trained on the use of Kobocollect and questionnaire administration. Data collections were done using Kobocollect application on the tablets/IPhones; in some cases, structured questionnaires, the completed questionnaire, were later keyed into the Kobocollect. Interview schedule and Focus Group Discussions (FGD) were also employed to get responses from the fish farmers in accordance to the set objectives and scope of the research work. KoboToolBar supported the participants to collect data online and offline especially during a logistical constraint. It gives room for backed up into secure servers. The questionnaire with similar content was prepared in two languages: English and Arabic. The English version was administered in Nigeria, while the Arabic version was administered on the respondents in Egypt.

Results and Discussion

Socioeconomic Characteristics of Fish Farmers in Egypt and Nigeria

The results of the Kobocollect analysis of the fish farmers' socioeconomic characteristics are presented in Table 2.

Gender: refers to the socially built characteristics such as norms, roles, and relationship of and between groups of women and men (male or female). Like age classification, it also varies from society to society. The result showed that the percentage of male fish farmers in Nigeria was 93% and that of the female was 7%. Though, this chapter revealed there was no female fish farmers in Egypt. This suggests that females might have been involved in other activities apart from fishing. The result also revealed that more males were in aquaculture than the females in both countries. This might be due to the fact that aquaculture production is more of manual labor/blue-collar job in which more physical energy are required. They are also likely to be involved in other fish farming activities like processing and marketing couple with their home cares which were sometimes uncounted (Adeleke 2013). The result also agrees with the study of Olufayo (2012); Adeleke and Fagbenro (2013) that women participate not only in the traditional fisheries sectors of fish processing and marketing but also in the nontraditional sectors of aquaculture, fisheries research, education, and extension.

Fish farming as main occupation: In Egypt, 89% of the respondents took fish farming as the main occupation, whereas the rest (11%) considered it as their secondary occupation. On the other hand, the result revealed that 41% of the respondents in Nigeria ranked fish farming as the main occupation, while majority (59%) chose it as the secondary occupation; other occupation engaged by the respondents in the study areas were civil servant, trading, carpentry, tailoring, teaching, agribusiness, and driver. This suggests that aquaculture in Nigeria is still

Source: Authors Computed Field Survey

at the developmental stage. Aquaculture production in Nigeria at present is fairly insignificant at 5000 tons/year (FAO 2000). FAO estimates that this could be increased to about 650,000 tons. Recent researches showed that aquaculture in Nigeria has potential to contribute to both food security and economic development of the country but is still in a promising business. Despite the fact that aquaculture is an age-old practice in Egypt, it is still contributing immensely to the country's GDP, employment, and food security as it is doing relatively in most countries and is significant to the economic, livelihood, and nutritional welfare of the populace.

Technical Characteristics of Fish Farming System and Operation in Egypt and Nigeria

Parameters such as scale of operation, types of pond, source of water, access to water, water quality parameters, types of fish produced/cultured species, fish with highest production and demand, venture profitability, continuity, and inputs sources were considered. The results were analyzed and presented accordingly.

Scale of operation and purpose for rearing fish: The study revealed that small-, medium-, and large-scale farming operations were practiced in the study areas (see Table 3). The scale of operations determined the purpose of rearing fish as designated by this study. Small-scale production implies for household consumption; medium-scale production is meant for household consumptions and sales, while large-scale production does mean for fully commercial/industrial/exports. The

Source: Authors Computed Field Survey

results revealed that none of the respondents in Egypt practice small-scale fish production; only 1% of them were operating their farms on medium scale, while 99% operate more than ten Fadden. This shows that fish production in Egypt is in a large-scale operation.

On the other hand, 63%% and 30% in Nigeria represented those that operate their fish farms on small scale and medium scale, respectively, while only 7% operated their fish farms on a large scale. The result also revealed that aquaculture in Nigeria is in small scale (93%) as compared to Egypt. The result indicates that fish farming operation in Nigeria is still at the subsistence level where production is mainly for the households with little or nothing for the market/sale. This implies that Nigeria will depend on import of fish to meet the demand of the common people.

The result supports that Egypt has achieved the scale of expansion and growth in aquaculture (Adeleke and Matthias 2017). Hence, aquaculture in Egypt is a 2.2 billion USD a year industry and has been supporting the country's GDP in recent years, making it the ninth largest global aquaculture producer in 2012 and by far the largest in Africa and the Middle East (FAO 2016). Efforts should be geared toward encouraging and promoting aquaculture practices in Nigeria in order to meet the demand of the households and consumers. Large-scale production should also be encouraged in order to expand the local and international market.

Types of pond: 99% of the fish farmers in Egypt cultured their fish in earthen ponds, while in Nigeria, 88% cultured their fish in earthen ponds. One percent and 12% of the fish farmers in Egypt and Nigeria, respectively, represent other types of ponds such as concrete, plastics, collapsible, and fiber tanks and vats. The results of the study revealed that earthen ponds are commonly used in both countries. The percentages of other types of ponds like plastics or tanks are more in Nigeria (12%) than in Egypt (1%). Because of the culture and environment, tilapia is most commonly grown fish species in Egypt. It can do well in earthen ponds where natural food is required; it cannot survive in very low or too high temperature. In contrast in Nigeria, catfish can be raised in an enclosure or tanks where it can thrive, and no artificial aeration is required, but artificial food is required for the survival of the enclosed fish. It implies that ponds type is a very vital parameter to be considered in aquaculture business.

Source of water: the results of the study revealed that fish ponds can get water from various water sources depending on the availability, location, and law. In Egypt, the following water sources and percentages were identified: lake (13%), river (6%), agricultural drainage water (78%), and mixed drainage and Nile (45%). It was observed that most of the fish farmers relied on agricultural drainage water. The result is not far-fetched from the fact that aquaculture is the last user of water in Egypt because it made used of reused water. According to the water policy in Egypt. On the other hand, the percentages of the sources of water in Nigeria are represented as follows: 36% stream, 11% river, 35% groundwater/boreholes, and 20% rain catchment/reservoirs. It was observed that in Nigeria, most of the water was freshwater sources; this also determined the type of fish to be cultured.

Apparently Egypt represents a good example of a green aquaculture because 78% of the fish farmers depend solely on agricultural drainage water while Nigeria is good representation of a blue aquaculture because the water sources were mainly fresh water hence, the type of fish to be cultured. In Egypt, recent research showed that the use of aquaculture drainage water for agriculture is better preferred to the existing practice of agriculture drainage water for aquaculture. The use of aquaculture drainage water is best practice due to its numerous advantages. Aquaculture drainage water contained a lot of nutrients for the crops than the agricultural drainage water which might at the same time not be good for the cultured fish. Efforts should be geared to convince the government in Egypt to pay more attention to the reused of aquaculture drainage water for effective and maximum utilization of water in the country. Eighty percent (80%) of the fish farmers in Egypt that the source/s of the water to their farms/ponds is/are challenging while only 20% believe the source/s of water is/are good and not challenging (Table 3). Despite the natural and blue water sources in Nigeria, 41% believed the water source/s posed a serious problem to their fish farms, while 59% were comfortable with the water source/s to their fish farms.

In Egypt, the problem that was highlighted and emphasized mainly on water sources was pollution, while in Nigeria, the problem was water shortage as a result of dry season. In Egypt, 57% of the respondents have taken precautionary measures as regards reducing the effect of pollution on the water source that enters their farms by checking the water qualities, filter the water when pumping, treatment of water and pond, but 43% are yet to take any precautionary measures. The reason might be due to the fact that they are constrained to the available water source to be used for aquaculture in the country. In Nigeria, 60% of the fish farmers have alternative source of water such as getting water from other ponds, buying water from water tankers, damming of stream water to pump into the pond, boreholes, or well, and reducing stocking density, to their fish farms during dry season in Nigeria, while 40% of the fish farmers have not taken any precautionary measures. The reason might not be far-fetched from the facts that most of the fish farmers in Nigeria practice on subsistence level, and lack of capital is also a limiting factor from the Focus Group Discussion (FGD). Freshwater is the major water source in Nigeria and there are no restriction as to the use of water in the country, is a great opportunity and advantage for citizens who are willing to practices aquaculture to really venture into it because aquaculture is "no restriction of person."

Environmental Changes Impacts on Fish Production in Egypt and Nigeria

Table 4 presents the impacts of environmental changes on aquaculture in the study areas. The study revealed that 76% of the fish farmers in Egypt were aware of the environmental changes and its impacts on aquaculture. From the FGD, the fish farmers highlighted some observed effect of environment change on the fish production in their countries. In Egypt, the following were highlighted: reduction in rain and increase in level of temperature particularly during summer period (July); movement of the fish in the pond; sudden suffocation/floating of fish and death; low oxygen; extreme cold during winter; increase rate of fish mortality; weather change; negative change in fish feeding habit; observable differences in weather temperature; breeding time changes as the weather changes; outbreak of diseases that affect the fish resulting into fish death; sudden death of fish without reasons; change in climate in Europe; appearance of disease; increase humidity; and extreme temperature. While in Nigeria, change in raining pattern and hot temperature; pollution of air; observation of weather change; reduction in water level; negative change in fish feeding habit; flood; present of climate that is affecting hatchery; and changes in fish habit were the observed environmental changes in aquaculture practice in the country.

The research presented the evidences that there were similarities and disparities in environmental changes manifestations in both countries. The level of environmental changes' awareness of the respondents in both countries might be as a result of their level of education (Table 2). Education gave them edge on the changes that are occurring in their environment either positively or otherwise. It implies that

[a]Multiple responses

respondents in both countries are acquaintance with the changes in their environments (Maddison 2007; Nhemachena et al. 2014). Respondents' multiple responses on other means of environmental changes' awareness might not be unlikely from the global climate change program going round the world because it has brought much anxiety to all countries of the world, hence, the multiple responses.

Environmental Changes Parameters in the Study Areas

Some environmental parameters such as temperature, rainfall, wind speed, solar radiation, waves and tides, and relative humidity were further considered in the study to ascertain their effect on aquaculture practice and production in both countries. The result revealed that 99% of the fish farmers in Egypt were aware of the change in environment as a result of temperature. Sixty-three percent ascertained that rainfall pattern and volume has also changed in the country. Fifty-four percent believed that there are changes in the environment as a result of the change in wind speed. Also, 61% perceived that the change in solar radiation has affected the environment and impacted their fish production. Waves and tides are other environmental parameters that 18% of the fish farmers in Egypt perceive it change and effect on fish production. Also, 92% of the respondents further ascertained the fact that changes in relative humidity have impacted their fish production.

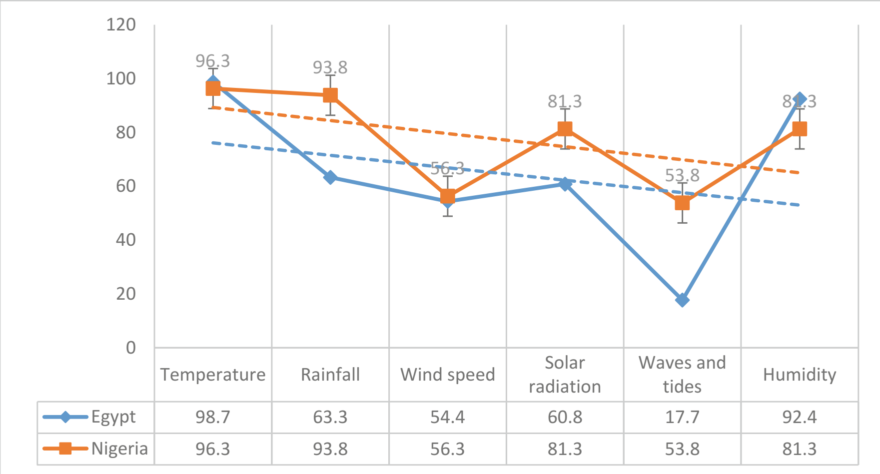

Fig. 3 Environmental changes parameters in the study areas. (Source: Authors Computed Field Survey)

In Nigeria, 96% of the respondents ascertained that temperature change is an environmental factor that affects their fish production in the country. Ninety-four percent perceived change in rainfall pattern and volume, 56% perceived change in wind speed, 81% perceived change in solar radiation, and 54% perceived change in waves and tides, while 81% also perceived change in relative humidity as environmental factors that have change in recent years (Fig. 3 and Table 4).

The FGD revealed the effects of these environmental parameters on fish production in both countries. Death of fish/mortality; reduction in fish production/growth rate; frozen of fish in winter/low temperature; rise in cost of inputs; and weakness/low appetite in fish were observed in Egypt. Some of the measures taken by the fish farmers to alleviate the adverse effect of the environmental changes were to improve their management practices and also change their production season as the environment is changing. The effects on aquaculture as expressed by the fish farmers in Nigeria were as follows: low fish production; low feeding in fish; reduction in fish growth rate; more stress for farmers; color of water changes; flooding; and death of fish. Based on the Focus Group Discussion (FGD), the following measures were adopted by the fish farmers in Nigeria change feeding formula/pattern and time, low stocking, pumping or alternative water sources, constant change of water, study/observe the weather before feeding, minimize feeding in the morning and more in the evening, stop stocking, freshwater and good feeding, removing fish to the other ponds and applying alternative means.

Critical Issues on the Study

Change in fish production in recent years in the study areas: Change here means positive or negative, increase/decrease, and adverse/mild depending on the previous position of operation of the fish farms/farmers. In Egypt, 96% confirmed that there has been change in fish production in recent years. This might have been to the various problems such as change in climatic factors which have direct impacts on fish production and pollution of water to the fish farms (agricultural drainage water). The chapter reveals that, climate change affects and impacts agricultural crops, the end users of the irrigated water will suffer directly or indirectly from the effects. Policy makers should look into the plight of the fish farmers in the country and make available use of other means of water to aquaculture. In the contest of Nigeria, the fish farmers (71%) did not affirm any serious problems during the course of this study. The reason might be to the fact that aquaculture is still at a promising stage which is best described as the first stage of production (stage 1) where there are still increasing rate of returns (IRR).

Other critical issues observed from the study as presented in Table 5. Most of the respondents (92% in Egypt and 79% in Nigeria) do not belong to any cooperative society. Bearing in mind the numerous advantages of belonging to a group, unlike in other section of agriculture, e.g., the Cocoa Farmers Association in Nigeria. In addition, the fish farmers in both countries were deprived of the benefits of the

Schematic 1 Major challenges faced in aquaculture in the study areas

extension agents as revealed by the results of the study: Egypt 76% while Nigeria 90%. These issues were observed as critical; hence, urgent or future attention should be provided in order to protect the future strides of aquaculture in both countries.

Major challenges faced in aquaculture in the study areas: The cost of fish feeds and other inputs contributed to the challenges facing aquaculture; 34% of the fish famers established this fact. The result buttressed the dependence on private input suppliers who supplied most of the fish farmers on credit and later get all the gains/profit of the fish farmers; hence, the fish farmers have no say in his farm. That is why most of the fish farmers wanted to quit fish business in Egypt. Forty-one percent were facing water problems; this has to do with the agricultural drainage that they were using, and many of them were not comfortable but have no choice because it is the entitled water for aquaculture in the country. Twenty-five percent were faced with fish disease problems. This suggests urgent call for policy makers for intervention. Finance is the major problem facing aquaculture in Nigeria. Most of the respondents (54%) confirmed that finance is the major challenge unlike in Egypt where water is the major delinquent (Schematic 1).

Conclusion and Recommendations

The research revealed that there were similarities and disparities in environmental changes indications in Egypt and Nigeria. Though the level of environmental changes awareness of the respondents in both countries varies, the fish farmers were aware of the environmental changes and its impacts on aquaculture. Aquaculture is an age-old practice in Egypt; however it is still contributing immensely to the country's GDP, employment, and food security as it is doing relatively in most countries and is significant to the economic, livelihood, and nutritional welfare of the population. Conversely, Nigeria's aquaculture has the potential to contribute to both food security and economic development of the country, but it is still in a promising business. Efforts should be geared to address the critical issues such as climate change and other environmental factors that affect aquaculture practice in Nigeria. Continental and regional integration of aquaculture practices should be encouraged in Nigeria and other parts of Africa.

Abstract

Between 1994 and 2006, an 18% increase of freshwater flow into the earth's ocean was recorded, as well as extreme weather events such as prolonged drought and intense floods. Following this period was an era of increased evaporation from oceans and seas, which heightened global warming in Africa. This chapter proposes the use of man-made aquifers recharge processes as methods of draining water into the soil before the runoff water reaches water bodies. **Source control** involves controlling the volume of water entering drainage systems or rivers by cutting off runoff water through storing for reuse or evapotranspiration as seen in green roofs. **Pre-treatment** is the use of trenches to filter and remove

contaminants from water before getting to water bodies. **Retention systems** on the other hand is controlling the rate at which water is discharged to waterways by providing water storage areas such as ponds, water retention areas, etc., while **Infiltration Systems** are areas that allow natural soaking of stormwater runoff to the ground naturally recharging the water table. The proposed methods will see replenishing of the water table, a great leap in the efforts of curbing global warming. This practice can easily be adopted by both individuals and government as we build more and more buildings creating a balance between the need for human settlement and the natural way of water replenishing itself. The methods do not introduce extra costs to an already existing budget. In some cases, the methods help to reduce the costs of projects especially in urban areas. Africa which hosts many of the growing countries sees and will continue to experience surges in urbanization. For such, these methods presented in this topic will be, if implemented, a best method to solve the urban drainage problems before this even occurs.

Keywords

Aquifer · Hygiene and sanitation · Groundwater recharge · Global warming · Urban water balance · Universal water security · Topographical land

Introduction

Since 1990, water rise in the sea and oceans has been recorded and is now more visible than any other time in human history (The Ocean Portal Team 2018). The highest attributed factor has been melting of glaciers on ice topped mountains and concrete constructions. This ice melts and flows as runoff water into small water collection points such as ponds and swamps to bigger water bodies such as rivers, lakes and oceans increasing water flow into water bodies. All these changes result in an increased global water cycle where water moves cycles through evaporation, precipitation, and runoff, an aftermath of increased rate of global warming.

Methods of mitigating the negative effects of climate change in Africa have become a big issue. Individual companies and governments in Africa are trying to implement resilient ways that adapt to the effects of climate change. African countries are prone to the effects of climate change especially because of the higher levels of industrialization. On the other hand, developed countries that have implemented ways of harnessing water and avoiding runoff water directly to catchment areas at all costs is something Africa has not been able to fully accomplish (The United Nations-Water 2015). According to a report by UNEP, by 2020, between 75 million to around 200 million people in the African continent are projected to experience water stress due to climate change (UN Environment Programme 2020). In this twenty-first century, most countries in Africa are becoming urbanized; modern housing, infrastructure, access to water, and implementation of technology has become common (Ogwu 2019). Narrowing down to East Africa, Kenya is the most urbanized country and then followed by Rwanda. Cities are evolving and the idea of implementing sustainable urban drainage is still an issue as they improve the topography of cities.

Kenya's fastest growing cities include Nairobi, Mombasa, Thika, Machakos, Nakuru, Malindi, and Kisumu. Untapped but identified as potentially stable upcoming cities include, Tatu city and Konza city. This research identifies these two areas as the best place to promote sustainable urban drainage (SUD) systems and aquifer recharge is implemented. Other cities will follow the example set by these two as the benefits come to play. The total population for Kenya currently is at 54 million, according to the 2019 census; Nairobi, the capital city has just over four million people (Kenya Data Portal 2019). Water Security in a country is one of the major issues facing each country worldwide. According to Sustainable Water Partnership, water security is the adaptive capacity to safeguard the sustainable availability of, access to, and safe use of an adequate, reliable, and resilient quantity and quality of water for health, livelihoods, ecosystems, and productive economies (Viala 2016). UN Water defines water security as the ability of a community to protect their sustainable ways of accessing quality water (UN Water 2013). This is very vital especially to areas that have a huge population. Insufficient water in some areas is caused by drying up of the aquifers, while some areas are faced with excess water either due to flash floods, or rainwater runoff, which in turn leads to less aquifer recharge. These imbalances are a clear result of insufficient aquifer recharge. With no improved strategies to better ways of harnessing water, especially with the current climate projections showing irregular weather patterns, aridity of these cities is prone to increase at a very high rate. A case point is Two Rivers Phase II project, a modern residential center hosting a mall in Nairobi and Kiambu Counties in Kenya, which if the runoff water is not taken care of, the drying up of aquifers might kick off. Water in Two Rivers in which the development seats are likely to rise. Coastal areas are also facing similar issues. A case of concern there is salty water finding its way into the water table recharging the aquifers and thus making the water for consumption saline.

Rural-Urban transformation has improved the topography of most countries in Africa. Although, this has culminated in the improvement of settlement areas as well as the economic status of residents, it has heightened developmental challenges such as making water runoff move to a collection base settled in one area, which either flows to other big catchment areas or slowly evaporates. This chapter aims to put more emphasis on ensuring that sustainable urban drainage systems are implemented in a bid to see that boreholes that source water from aquifers are managed responsibly ensuring water availability and safety. Africa has not yet formulated the policy of adapting the best practices of sustainable urban drainage systems and natural aquifer recharge methods. Aridity of land, increase of saline water, drying up of aquifers, and increased water wastage, especially with increased upcoming constructions, are an indication of the state of globalization and effects of climate change in a country. Sustainable Urban Drainage Systems are drainage networks that act as collection points, transport, treat, retain, infiltrate and drain runoff water in sustainable ways that are beneficial for living things and the world in general (Hidrologia

Sostenible n.d.). Given this background, the aim of this chapter is to review the status of sustainable urban drainage and Aquifer recharge within African context, highlighting some technological advances to be used in the current scientific and topographical challenges of climate change.

Related Works and Existing Gaps

This chapter uses referencing points, of developed countries, and how they implemented the SUDs, which affects the natural recharge of Aquifers. According to Matos (2003), drainage systems are not necessarily a rule when it comes to construction of infrastructures, and runoff water would cause flooding of the roads or clogging of the sewers. On the other hand, Tim (2008) speaks of the Christian era, where drainage systems constructed by the Romans in the BC to AD are still functioning till date. Introduction of sanitation began in Italy after an incident of septic tank sinking due to floods and the country was forced to eliminate flooding areas and adapt underground channels, which was a wake-up call to other European countries in adapting sanitation systems (Poleto and Tassi 2012).

The use of green gardens in developed countries that substitute farming due to construction of buildings covering the whole land makes it necessary to adapt previous ways of MAR. An important agenda highlighted in this chapter is to understand how policies are followed to the latter for avoidance of implementing after math eqs. A study conducted in the United Kingdom regarding their technical, legal, and planning methods of control for urban runoff water in their country was done to ensure countries that do not have policies created to govern engineers before starting projects (Woods et al. 2015). Governance of Aquifers needs to be implemented. There are three aspects done in developed countries as to the governance of aquifers, management of discharge of water, management of recharge, and substituting alternative water sources.

Management of discharge of water from the aquifers currently is important as drawings from these sources are at a high rate, especially due to the domestic use of the water. Some countries use water mainly for commercial use while others use water to pump for electricity, irrigation and domestic use as well. As depletion of aquifers becomes more and more real, countries are forced to dig deeper boreholes with extra costs to incur to reach water levels (Dillo et al. 2011). These scenarios put more weight on the need to ensure recharge of the aquifers is managed well. Management of Recharge to the aquifers can be implemented both artificially and naturally. If 95% of the land is covered with soil and grass then the possibility of water sipping into the soil is most likely to happen faster reducing the amount of water that flows into water bodies. With increased urbanization, more innovative methods of recharging of aquifers are practiced by directing water to catchment bodies, and using filtration methods that enable water to be soaked into the soil and thus refilling the aquifers. Other alternative ways of using water sources include using rainwater and customizing it for consumption use.

Due to urbanization, most countries experience a lot of runoff water, which therefore needs a number of managements of aquifer recharge procedures through identifying a number of solutions that gets back to the aquifers. These processes have been practiced before, and there is a need to introduce them in developing countries especially due to the increase of urbanization in these same countries. Use of permeable floors could be one of the implementing ways.

There are other substituting alternative water sources, which are currently used all over the world. Some authors have done research on how to tap water and collect it in a catchment where one can fetch for domestic use. Other water sources enhancements include channeling rain water through use of gutters, tapping water from a river into a house. More methods have been adapted in today's world to ensure that they have sources of water. Some negative points have been brought forward, such as some of these ways being harmful to the humans and the animals. A case study was carried out in Kilifi County in Kenya where the test was to find out the presence of arsenic in water and the pH of the same water. According to the World Health Organization (2003), pH of consumable water should be between 6.5 and 7.5.

A study research was done on SUDs in low-income countries in Africa outlining the disadvantages that runoff water instills such as soil erosion and siltation (Reed 2004). Some special cases have been raised, for instance, constructing riparian lands and coastal areas. These areas have a land mass that is not stable with fault lines that aid in the recharge of aquifers experience. Kenya has had cases of demolition of buildings due these buildings being on riparian lands, this was a threat not only to the SUDs not being observed but also to the lives of people who were meant to live and operate in such areas. Other concerns raised, is the groundwater overexploitation in the coastal regions and these buildings being on riparian lands. Groundwater overexploitation in the coastal regions leads to intrusion of salty water (Geiger 2020). This chapter will help us understand the options that a country has in case it is forced to build on riparian lands.

Some practices recommended in this chapter exist in developed countries and can be very effective in African countries in understanding climate change and how to deal with the effects of those changes. There are challenges facing the Kenyan topography such as cases of constructions being done on riparian lands. Such areas are not stable and could result in the collapse of such buildings. It has resulted in the government demolishing such houses and prosecuting responsible constructors for not adhering to the rules and policies that guide the said industry. Coastal lands on the other hand have cases of saline water recharging the aquifers, making it difficult for consumption especially to humans. The best result in these situations is to ensure filtration methods are used.

Policy making for engineers and owners is one of the proposals for governments to implement. Adaptive measures of some proposed solutions are suggested in order to ensure smooth implementation of SUDs and aquifer recharge as well. These include filtration methods and systems of reducing salinity and the productive measures of constructing buildings in riparian lands. Resolving these issues with the proposed methods will see an increase in the amount of water that goes back to the water table, replenishing it, as opposed to flowing into the ocean and seas. On a concrete surface, 95% of water on the surface runs off, only 5% gets absorbed into the soil. With natural aquifers taken into account in the landscape planning and designing, the 95% of the runoff water will be adsorbed to soil, resulting in only 5% of the water being drained to the oceans and seas. This mode of replenishing the water table ensures that wells and boreholes dug in arid and semi-arid areas do not dry up fast. The benefits of this extend to what such areas can do in their economic ventures and other activities made capable by the presence of stable water supply.

Aquifers

When Water soaks into the soils from the rivers, melted ices, and rain, it is concentrated in one area that forms its own settlement, which is referred to as an aquifer. This settlement of water is formed in different bowl-like areas that form a well and are all in different areas with different levels. A number of aquifers formed in one area are referred to as the water table level forming the zone underneath the ground. There are two types of aquifers, the confined aquifers and the unconfined aquifers. Confined aquifers are one that is way below almost at the bedrock of the rocks and formed by permeable rocks due to the pressure of non-permeable rocks. However, getting to the confined areas at times seems difficult and collapsing of the rocks could hinder reaching the aquifers when drilling boreholes. Unconfined aquifers are the ones that are directly refilled with the water soaking directly from the surface of rivers or when in a swampy area or irrigation is taking place. The unconfined aquifers are the ones that rise or drops depending on the amount of water stored.

Aquifers in rural areas and with a water source around are less tapped as compared to an arid area. In semi-arid areas where these boreholes are drilled with the changing weather conditions and less water source reservoirs, humans turned to aquifers, through drilling boreholes in pursuit of water. Sometimes the water turns to be saline, depending on the locality. For instance, coastal areas tend to have more saline aquifers as compared to fertile moisture soil with cold weather conditions. As urbanization in coastal areas increases, the drilling of boreholes is increasingly at a higher rate. This in turn, due to unconfined aquifers being empty, is refilled with saline water from the ocean. This is reusable, however not as drinkable water for humans nor animals as well.

Consistent use of these aquifers without recharges is only sustainable for a few decades. According to Kansas States University in Manhattan, a 4-year research of the Ogallala Aquifer was conducted to identify the use of aquifers for irrigation and consumption use in Kansa, they found out that continued use with no recharge could cause depletion of food production in that area (Chow 2013). Glaciers melting sorted that situation for a while with the chances of aquifer usage to be in survival for 50 years, after it only used up to 30% of the water.

Glacier melts in areas whose topographical land is associated with mountains and areas that are cold and can experience snow. Africa, has very minimal of such topography and therefore, a few proposed solutions on ways to manage the discharge of the water from the aquifers, how to recharge them and alternative ways of water use to avoid depletion of the groundwater.

Research Framework

Looking at the sustainable urban drainage practices that are done to the developed countries and the effects of aquifer recharge, there is an understanding that SUDs consideration will be established in Africa. With a different topography, there is a need for an analysis of the geographical area to determine any potential trends that are made or can be made. The analysis done is to determine a number of things, the risk factors involved in case an SUD is proposed in that area, and the number of SUDs to be implemented in that area, and the demographics as well. After analysis, the topographic area will help in determining the type of qualitative criteria to be used for the SUDs.

Criteria	Relevance	Category
Guidance documents	These are the documents to be used as the implementation process for the SUDs in Africa. The use of these documents either required by the government or voluntarily offered to the government by the implementing partner shows the extent to which the SUDs would have effects on the aquifer recharge. These guidance documents can be used as practices that any organization or individual looking into SUDs should have, and also used as ways to overcome over implementation of SUDs in one area	Guidance documents not specified to SUDs but to construction – Policy constructions documents Standard government guidance for a country from the National Construction Authority Relevant government planning policy statements concerned with hydrology, and water as natural resource, e.g., a) delivering sustainable development policy b) Planning and pollution control policy c) Disaster and risk management policy – This looks deeper into drought and floods as ways of managing disasters and risks in a county
National Construction Authority Consultation	In order to ensure involvement, in the case of Kenya, it is important to ensure the National Construction Authority is involved for assessing the area, and the risk factors that could be involved	Consulting the National Construction Authority of a country, for location intelligence analysis, through the use of documents, records of previous assessments, reports, and telephone and email conversations.
Constrains	Financial constraints in case of a collapse of a borehole drilled or a pond created are some of the constraints involved when it comes to implementation of SUDs	Other constraints could be through desktop and site survey CLA not specified and not included in analysis due to no knowledge of contamination at site. 1 – CLA through desktop survey only. 2 – Desktop and site survey

(continued)

Criteria	Relevance	Category
SUDs type	This chapter categorizes SUDs into substituting alternative water sources control, Management of Aquifer recharge, and Management of Discharge of water	**Substituting alternative water sources control** (a) Green roofs (b) Rainwater harvest (c) Redirecting water retention systems **Management of Aquifer Recharge** (a) Infiltration systems (b) Treating municipal wastewater (c) Treating storm water (d) Treating irrigation water **Management of Discharge of water** (a) Retention systems (b) Wetlands
Numbers	Identifies current practice and baseline data	Types of SUDs to be used in that area
Size	Identifies current practice and baseline data	How large or small will the SUDs be used
Efficiency	Identifies current practice and baseline data	How sustainable is the SUD used
Maintenance	Identifies current practice, baseline data, potential barriers, ways to overcome them, and trends	How frequent should it be maintained and treated
Good practices	Africa as a developing continent, most of the topographical area is improving day by day, which makes runoff water become a potential problem especially to rural areas. Therefore, different mitigation process of water should be implemented in the policy making and as part of construction when it comes to buildings and roads	Use of best practices. Evidence of National Construction Environmental Management Plan or equivalent.

Proposed Solutions

On the account that there is uncertainty when it comes to climate change and the shortage of water especially in Africa, adaptation strategies on water usage and refilling of aquifers should be prioritized. Clear projections on water demands in the future are merely determined by the climate change, sustainability imbalances between freshwater, and demand for it (Taylor et al. 2009). There is a huge difference of climate change association in developed countries as compared to the developing countries. In addition, the fact that most countries in Africa are in the sub-Saharan desert, the usage of water is more likely to be at a higher demand and also depletes at a higher rate.

Although, some of these solutions are implemented in other countries, recommending them to African countries, suits best especially during this time of globalization. African countries are known to be experiencing different kinds of weather conditions, as compared to developed countries. The Sub-Saharan desert covers most parts of Africa. Solutions proposed in this chapter targets what African countries would experience when it comes to recharge of aquifers as well as substitute water sources. Runoff water and the impact it has on climate change has the need of ensuring that the community is able to implement SUDs and redirect water to aquifers. This chapter discusses the methods to be used in African Countries in the management of discharge of water, management of recharge, and substituting alternative water sources.

Substituting Alternative Water Source Control

It is clear that using water from Aquifers is not only the one area that humans should depend on if it is for consumption at home or commercial level. There are other means of attaining water with source control implemented. Source control is a way of managing the volume of water entering drainage systems or catchment areas by cutting off runoff water either to be redirected into another source stored for reuse or evapotranspiration or to absorb into the soil as a way of recharging the aquifer (Geiger 2020). Mostly runoff water will be from rainwater, flash floods, or melting of glaciers. Besides, source control can be exercised when the water is settled in one area with no use of it. Wet areas are an example of how source control can be used.

A country's topography has around four features that affect how humans will cultivate and settle around that area (National parks Association n.d.). These are the landforms, which include the hills, valleys, gullies, and mountains, etc. These places act as animals settling places but as a tourist attraction to humans, which affects the economic status of a country. A water source is another feature of land topography, which mostly includes the rivers, swamps, coastal oceans, etc., which have a great impact on affecting our sources of water. Vegetation includes the national parks, the farmlands, etc., acting as the main source of food to both humans and animals. Manmade topographic features, which fall under the category that most humans ensure that they plough and invest in, comprises of buildings, roads, property boundaries etc.

The four features of land topography have a huge effect on aquifer recharge; the recharging of the aquifers depends on how much is interrupted. For instance, if the sources of water, rivers, swamps, oceans are polluted, the same water used to recharge the aquifers will reach the table water polluted which becomes harmful to human beings and animal consumption. On the other hand, if manmade features of the topography are not structured in a way that allows runoff water to seep back to the ground the possibility of the aquifer to recharge is of bare minimal. The untapped areas such as landforms and vegetation are most likely to have the water table to be fully recharged or at least for use through soil moisture and suitable for plantations.

Green Roofs

The level of a city becoming smart has better ways of ensuring that it implements source control mechanisms. Green roofs are a way of turning barren landscapes into a living network of gardens (Willem 2005). It is a type of urban agriculture and a way of saving space and at the same time living expenses are reduced. Green roofs have a number of advantages such as:

(a) Reduction of runoff water – one of the main aspects that African Countries are trying to fight
(b) Act as a temperature buffer for the home. The plants combat the natural heat and coolness from the atmosphere
(c) Economical potential of cultivating food from the green roofs

Green roofs comprise a multilayered system that covers the roof of a building with vegetable landscaping. The roof is likely to consist of an impermeable layer, a growing medium, and a drainage layer. The impermeable layer aids in the survival of the plants by increasing the retention time of water in the substrate layer thus increasing the soil moisture. The Substrate layer or the growing medium layer retains the water and uses the right amount of organic and mineral proportions. The drainage system is the most important part in setting up the Green Garden. There are different types of drainage systems; however, the ideal one is that which provides good circulation and evacuation while at the same time offering water supply to the crops. In today's modern green garden drainage system, they use rigid and open mesh structures plastic sheets (Critical Concrete 2018).

Although, not to say that green roofs should be used in places where aquifer recharge is a priority, it only states that it can be used as an alternative source of acquiring water for consumption use and irrigation use as well. The implementation of Green roofs especially in urban areas of a country ensures hydrologic-hydraulic invariances in that area. This is one of the main areas that this chapter tries to focus.

Rainwater Harvest

Rainwater harvesting refers to different methods used to channel rainwater into an area where it can be used for other purposes (Black et al. 2012). There are various types of rain water harvesting systems used in different countries, which depends on the cost, size, and the complexity of the technology involved. However, the main aim is to ensure utilization of rainfall to be used as an alternative source of water both domestically and commercially. The beauty of it is that it can be used in a small or large industry or even at the homestead level. With the current climate changes, using resources to ensure the survival and usage of clean water in the future has been one of the ways to fight drought.

The collection of rainwater from rooftops, or other surfaces or even open space into a catchment area is known as rainwater harvesting. This harvested rainwater could be used commercially, domestically, or for farming purposes (irrigation). On the other hand, harvesting rainwater could act as an advantage by providing stormwater management especially in urban areas thus leading to detention pools, which are used to recharge aquifers. Slow runoff water has a higher chance of soaking into the ground, which has other advantages such as reducing contamination and avoidance of soil saturation.

The types of rainwater harvesting include:

1. Domestic rainwater harvesting. There are two types of harvesting systems used especially in developed countries: gravity systems and pump feed systems. Gravity systems are positioned at the top of a building, which uses gravity to propel water to different parts of the house. Examples are the use of gutters to direct water to the tanks. Pump feed systems on the other hand, is when water is pumped upward toward different water holding objects or tanks to be used for domestic use. Drilling of boreholes is an example of pump feed systems.
2. Commercial rainwater harvesting. There are different types of harvesting systems that are used in large farms. The most common one is water butts, which is one of the common harvesting systems used in the UK. Water butts are barrel-like or bin-like tanks that collect water from drain pipes to store water that could be reused for farm use (The Renewable Energy Hub UK 2018).

Although, at times the collected water may not be user friendly, the level of treatment when it comes to harvested rainwater depends on the use required and the dimensions of the size of a home or industry. Water required for Aquifer Recharge will definitely undergo a strict way of treatment as compared to one used for irrigation purposes. Also, water required for human consumption will require strict treatment unlike farm use or irrigation; some TDS would be left in the water in order to give nutrients to the plants.

Redirecting Water in Retention Systems

Urbanization in today's world is more of covering all land with cement, leaving only the rural with soil. This significantly increases the runoff water to drainage systems, which are redirected to the rivers or other water catchments. In Rural areas the rate at which water soaks back to the soil and absorbed back to the soil is at around 95% as compared to an urban area, in which the water soaks only 5% that at least lands on soil, leaving only 95% running off. Urbanization in a retro sense has its effects on affecting water that flows. However, there are precautions that engineers can take when constructing buildings and roads.

In cases of riparian lands, as stated earlier in the two rivers case, policies and design ideas ought to be structured to ensure that water is not blocked. Water flowing rates, its magnitude, frequency, and duration should be part of the measures that are included when constructing in riparian lands. In addition, these features can determine at what rate and amount it will soak into the ground and down to the aquifers. Therefore, channelling the water and either use it is another means of source of water for commercial use or constructing measurable ways of ensuring that there is no runoff water. For swampy areas, at times the ground is too full to absorb more water and will result in flooding of homes, in this case there should be a channel that redirects where this water needs to be absorbed back to the ground in a land that is a bit semi-arid.

Riparian land has been managed before using three practical methods, the Proper Functioning Condition (PFC), the Hydrogeomorphic Approach (HGM), and the index of Biological Integrity (IBI). In spite of the advancements in technology, African Countries have not yet implemented such strategies. PFC is a qualitative approach and depends on the knowledge and judgment of a team of experts. HGM and IBI on the other hand are based on quantitative data gathered and analyzed from unaltered to degraded sites prior to assessor's involvement (National Research Council 2002).

Management of Aquifer Recharge

Infiltration Systems

In the intent of refilling deep aquifers, a process involved, happens at a gradual rate through the unsaturated zone all the way to the aquifers. Although, there are underlying factors that depend whether the aquifer is suited in an area where it was used repeatedly then refilling it might take ages to do so. The creation of infiltration systems will look into a number of risk assessments, which include, land cover, soil characteristics, soil saturation, slope of the land, and evapotranspiration (Alley et al. 1999).

Dependency on water and the rate at which the water is used while it depletes in the aquifers depends on the population of a country; it is not only used by humans but also animals. Controlled ways of recharging the aquifers need to be implemented in order to ensure safety for the consumption of water. There are two ways of recharge, artificial recharge and Natural recharge. Artificial recharge is the process by which excess surface water is directed into the ground either by spreading on the surface, using recharge wells or altering natural conditions to increase infiltration. It is a way of storing water in case of a shortage.

There are a number of ways recharged water can be used. It can be redirected to semi-arid areas and arid areas for consumption and irrigation schemes. In coastal areas, with the use of artificial recharge, since it is fresh, this could be used as a control mechanism in avoiding seawater or saline water intrusion to the aquifers. There are three types of infiltration systems for aquifer recharge as a source of water, Treated Municipal Wastewater, Storm-water runoff, and irrigation water. In order to implement infiltration systems, risk assessments should be conducted by the government to ensure safety measures are in order. Infiltration systems largely influence ground stability and water quality as the latter flows to water streams. Examples of such systems are infiltration trenches, basins, and permeable paving.

Treating Municipal Wastewater

For the Municipal water of a country ensures that it treats and input infiltration systems there are a number of things they would consider. The quantity and quality of wastewater in an area, the commercial and industrial establishment off an area, and the condition of the sewer system. The municipality has to analyze the wastewater at their disposal and then run the ingredients they are to concentrate and

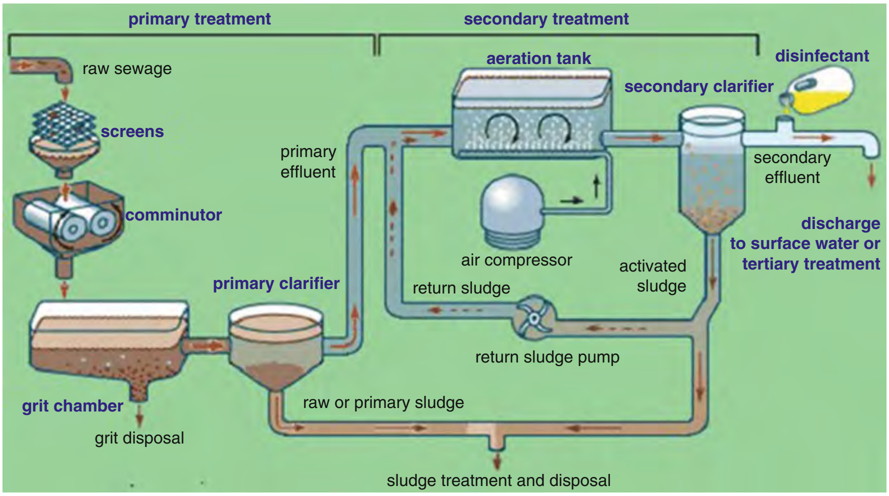

Fig. 1 Figure of the treatment process of Municipal Wastewater Infiltration process. (Eschool 2018).

dissolve. Untreated wastewater contains an amount of microorganisms' concentration. These factors include originality of the water used, the general health of the contribution population (are they in a slum area or in an urban area), and the infectious agents that survived outside the hosts under a variety of environmental conditions (The viruses, in a group become resistant to the environment that kills bacteria). Wastewater treatments are classified in primary, secondary and advanced level (Fig. 1).

The wastewater is first pumped to the system, and as a primary treatment, it is screened, then taken through to the grit chamber where the solid and huge particles are released, and finally to the secondary stage through the clarifier. The secondary treatment stage incorporates aeration process, which after takes the advanced treatment stage, which is the final stage before the water is directed to the aquifers for refilling or tanks for industrial or household use.

a) **Primary treatment of municipal wastewater**

This is the first step that includes screening of the state of the wastewater and grit removal. Once the water is screened, large solid particles are removed to avoid any interference at a late stage of treatment. Grit chambers are created as part of the infiltration systems to remove sand, seeds, glasses, eggshells, etc. There are other preliminary treatment operations such as the flocculation, odor control, chemical treatment, and pre-aeration. Primary treatment has very little effect when it comes to the removal of other biological species, which means it does not remove viruses at this stage

b) **Secondary treatment of Municipal wastewater**

This step is intended to remove soluble and colloidal biodegradable organic matter and other suspended solids (SS). This treatment involves an aerobic biological process whereby microorganisms oxidize organic matter in the wastewater.

c) **Advanced treatment of Municipal wastewater**

This is the third stage of removal of nutrients, for instance, phosphorus and nitrogen and SS. This is the physical, chemical, or biological treatment process used to accomplish a degree of treatment. It removes SS and dissolved substances either organic or inorganic in nature. This is necessary especially if there is a direct injection into the aquifers for recharge. The major processes in this stage include, coagulation-sedimentation, filtration, nitrification, denitrification, phosphorus removal, carbon adsorption, and reverse osmosis.

Stormwater Runoff

Stormwater runoff is one of the main contributors when it comes to aquifer recharge. However, pollution of the stormwater may contaminate the aquifers as well once they reach them, which needs treatment before they reach the aquifers. It is erratic in quantity and the timing as well could be when flash floods happen, or when a heavy rain has occurred. According to Larry, he tends to believe that season has a major impact when it comes to storm-water runoff quantity and the base flow (Mays 2001). The topography of an area has a major impact when it comes to stormwater pollution concentration, which tends to filter the pollutants. Impervious surfaces on driveways, parking areas, gutter drainage systems, and roads reduce infiltration of runoff and runoff to the ground.

Detention ponds are constructed for specifically recharging groundwater through the bottom of the pond. The water filters slowly through the ponds and to the aquifer, they are created deep enough to prevent water plant growth but shallow enough to prevent anaerobic conditions formed at the bottom. Inspection is necessary occasionally to ensure that treated water is what recharges the aquifers.

As a concept of salt evaporation ponds, water is directed into a pond where it is stored while it slowly soaks into the ground to the aquifers. In Kenya, Kitui District, Sand dams were created in order to store water, although this was only done in large-scale farms. A sand dam is constructed as a small dam, in and onto a riverbed of a seasonal river, where it is accumulated with sand. The sand layer acts as a filter for removing contamination and enabling water to reach the aquifers and recharge them. With areas that frequently receive huge rainfalls, there are chances of groundwater levels being high considering the use of multiple sand dams.

Subsurface dams is another way of ensuring an aquifer recharge is exercised. They are created in semi-arid areas at the seasonal riverbanks, by digging a trench to the bedrock or other impervious layer. This is something that is exercised in Brazil and can be implemented in Kenya especially in semi-arid counties, such as Kilifi county. To prevent particles soaking into the ground, use of canvas when creating the trench is necessary to act as filters, which could puncture the fabric used.

Treating Storm-Water

Hydrogeologists ensure that they calculate the right places for constructions on ponds and measure input when it comes to treating the water to be used to refill

Fig. 2 Figure of Filtration process for stormwater runoff (Fluence News Team 2017).

the aquifers, as well as calculating the right places that have aquifers that have enough water to be used. Sedimentation is the process of allowing suspended particles in water to settle out of the suspension under the effect of gravity. These particles become sludge, which is assisted by mechanical means that cause it to thicken (Bache and Gregory 2007).

Although removal of particles can vary from one version to the other, the variations of storm-water filtration may include vegetation filtration, drainage systems, and impervious pavements. The settlement of particles in ponds varies in different ponds in different areas. Therefore, when it comes to filtration either natural cause of treatment could occur when it comes to biodegradation, biotransformation, and bioaccumulation or the sedimentation process (Fig. 2).

Irrigation Water

Irrigation is considered one of the most important roles in food production in pursuit of food security of a country. Although exploitation of aquifer water for irrigation, and consumption use, particularly during dry season, has caused the groundwater level to decline in semi-arid and arid areas, there is no direct recharge of shallow aquifers. With the increasing use of groundwater, the rise of hydrogeological and climate change problems are becoming major setbacks of certain countries. However, Irrigation Return Flow (IRF) is a promising way of recharging the aquifers for better sustainability in the future.

Irrigation return flow is the excess drainage water collected from irrigated farmland, which is considered as not evapotranspiration or evacuated by surface water and is returned to the aquifer (Dewandel et al. 2008). Depending on the types of crops, there are likely to be a number of agricultural chemicals applied, with a varying range of quantity input to enable growth and avoid pests. Irrigation is mostly used in semi-arid and arid areas; this increases the salinity of the IRF to three times that of normal water.

Treatment

Numerous things are involved in the irrigation return flow water that includes TDS, nitrogen and phosphorous compounds, pesticides residues, and, at times, metallic substances. There are different kinds of technologies that have been implemented in different countries, especially with advanced technology, to ensure removal of such pollutants.

Reverse osmosis system is one of the technologies used; it is a process that uses a permeable membrane to remove TDS. The first step of reverse osmosis is the sediment filter. It is a polypropylene sediment pre-filter that removes SS from the water. Then the carbon granule filter is activated, which removes the chlorine and other organic substances, unpleasant color, tastes, and odors from the sediment water. The third stage is to activate the carbon block filter, which removes the remaining chlorine and organic substance without the carbon fines. The RO Membrane is the fourth stage that rejects the wide spectrum of impurities including bacteria and viruses. Finally, the polishing resin carbon filter dissolves gases to ensure freshness and natural tasting clean water (Hydrolink Technologies 2014).

Farm-led management is another implementation that most developed countries are undertaking. This involves training farmers on crop selection in relation to soils, methods of increasing yields, community-based pond water monitoring, and evaluation and knowledge management on aquifers. Besides that, training the farmers on the consequences of excessive use and implementation of well-directed aquifer protection measures has helped farmers to understand the quantity of water usage, fertilizers, and wastes to use.

Management of Discharge of Water

When water moves out of the saturated area or ground to the surface through springs or seeps, it is referred to as groundwater discharge. However, at times, groundwater discharge can be controlled, where water is pumped to a retaining tank or catchment basin. To ensure that water is used at a manageable rate, to avoid depletion of groundwater, control has to be instilled to ensure that this happens. There are various ways to ensure this happens, through creation of retention systems, existence of wetlands, and others.

Retention Systems

These are water systems meant to control the rate at which water is discharged to waterways by providing water storage areas such as ponds and small-scale basins. Retention systems are systems used to store water that is likely to be used for a longer period unlike detention systems that only store water for a short period and thereafter redirect filtered water back to the ground to refill the aquifers.

A case in point is, as the rainfall season approaches, seasonal rivers tend to overflow and at times cause flood in certain areas especially ones that are arid. In this case, building of retention systems to pump water from the river to the systems could help in the use of the water during dry seasons.

Wetlands

Another way that discharge of groundwater happens is through the existence of wetland areas. The riparian lands as well as the swampy areas are in balance due to the discharge of the groundwater. Though wetlands also come with various benefits of ensuring that the soil is hydric and at the same time maintaining the ecosystems habitant in these areas, the increase of groundwater discharge to springs and streams dampens the amplitude of flow fluctuations thus sustaining associated wetland environments. As a control mechanism, artificial wetlands are best ways to mitigate stormwater runoff issues.

Conclusions

This chapter recommends the smart infrastructure management methods and mitigation of rainwater and runoff through practices that direct water to catchment areas with a purpose of meeting the needs of saving water and utilization of water especially for African Countries. The focus on African countries is due to some falling under dry regions which means the possibilities of these countries being faced with reduction of water in the 50 years from now would be high in case they do not observe the different methods of mitigating water. Besides, the use of these mitigation processes has socioeconomic impacts, which include the reduction of negative impacts of disaster risk management such as floods and drought on social life and reduction of energy costs, which is economical to a country.

Most countries in Africa are currently adapting the advanced technologies such as Internet of Things (IoT), and Artificial Intelligence, either, in their cities, homes, or work environments. Implementation of MAR with such technologies has a likelihood of ensuring quality, and sufficient water for most African countries, thus improving the country's economic status. The main agenda is to ensure that we avoid urban flooding in African Countries, with the implementation of infrastructures that help in redirecting runoff water to refill aquifers when already treated. This chapter suggested a number of solutions such as permeable pavements, implementation of green roofs, retention systems, rainwater harvesting methods, and use of catchment areas.

Policy-making guidelines is another way to direct constructors on how to implement certain measures when constructing a structure that could distract water flow to reach the aquifers when treated and safe. Use of these guidelines ensures to incorporate the decision making and avoid constraints such as environmental constraints (instability) and financial constraints (more expenses in water treatments and retention systems).

Water harvesting and other techniques have been used to help preserve water before runoff, the use of man-made aquifer recharge methods as a form of SUDs is a natural and more efficient way of helping runoff water to seep back to the water table and ensure a balance. This allows the table to follow its natural way of seeping in between permeable rocks from saturated to unsaturated areas. While trying to curb global warming, this is a step toward managing the effects of the melting ice caps through the natural replenishing of the water table. This practice can easily be adopted by everyone as we build more and more buildings creating a balance between the need for human settlement and the natural way of water replenishing itself.

Building Livelihoods Resilience in the Face of Climate Change: Case Study of Small-Holder Farmers in Tanzania

44

Saumu Ibrahim Mwasha and Zoe Robinson

Contents

Abstract

The impacts of climate change are already being felt on human and environmental systems, with the brunt of the impacts being felt by communities in the Global South, particularly small-holder farmers due to their poverty levels and greater direct dependency on natural resources for their livelihoods. Hence, there is a need to understand how to build small-holder farmers' resilience to climate change. Climate change adaptation strategies need to build livelihood resilience

in the face of climate change as well as address the factors that contribute to farmers' vulnerability. This chapter draws from a mixed-method study conducted in three villages each in a different agro-ecological zone in the Kilimanjaro region, Tanzania, to explore how to build farmers' livelihood resilience through addressing factors that increase livelihood vulnerability to climate change. These farmers' livelihoods are vulnerable because of both the impacts of climate variability on the farmers' livelihood assets and certain social and environmental structures and characteristics. Building small-holder farmers' livelihood resilience that can ensure the desired levels of livelihood outcomes in the face of climate variability and change, requires integration of strategies across household resource management as well as farm-based livelihood assets, and a holistic rather than piecemeal approach to small-holder farmers' livelihoods.

Keywords

Climate change · Adaptation · Small-holder farmer · Livelihoods · Resilience

Introduction

Background

The impacts of climate change are expected to affect human and environmental systems across the globe but the more devastating impacts are projected to occur in developing countries particularly affecting small-holder farmers (Serdeczny et al. 2017). Many small-holder farmers especially in Sub-Saharan Africa farm and live in an extremely challenging environment. The production environment is characterized by reliance on rain-fed agriculture, a low level of economic diversification, and low livelihood productivity (Output per unit of input (Yu et al. 2002)) (Di Falco and Veronesi 2013). Climate change is expected to intensify existing challenges and thus there is an urgent need for adaptation of the livelihoods of small-holder farmers to enable them to thrive in the face of climate change.

Addressing how to build resilient small-holder farmers' livelihoods through adaptation to climate change is vital for food security as well as livelihood development (Afifi et al. 2014). To address these issues, considerable emphasis is placed by researchers on describing specific locally relevant agricultural or natural resource management practices or innovations that could potentially deal with impacts of extreme events at the farm/household level. However, it is important to note that the application of these strategies is context-specific and that several constraints exist that may limit farmers' capacity to optimize their benefits. Therefore, there is a need to develop adaptation tailored to the need of that community (Ebi and Burton 2008). The context-specific adaptations result from examining the vulnerability of the target community empirically, and utilizing community experience and knowledge to examine exposure and sensitivity of the community to climate change (Ebi and Burton 2008). The context-specific adaptation strategies or practices based on examination of adaptation needs of the specific community will generate more practical measures (Ebi and Burton 2008). Adaptation based on this approach is less developed (Paavola 2008), and this research helps fill this gap by presenting potential adaptation strategies that small-holder farmers in the Kilimanjaro region of Tanzania can use to adapt to increasing climate variability. Further information about the exposure and sensitivity of these small-holder farmer communities can be found in Mwasha (2020).

Description of the Study Areas and Methodology

Study Area

The study was conducted in the Kilimanjaro region located in the North-eastern part of the Tanzania mainland. The region is divided into four agro-ecological zones; the forest reserve and Kilimanjaro mountain peak where no farming activities take place, and the highland, midland, and lowland zones where farmers are located (Fig. 1). Although all zones receive rainfall twice a year, the amount in each zone differs. Characteristics of the different zones are shown in Table 1.

Research Methods

Underpinning Theoretical Frameworks

Two lenses of analysis were used in this research; a livelihood approach drawing on the sustainable livelihood framework of the UK Department for International Development (DFID) (1999) and socio-ecological resilience drawing primarily on the work of Biggs et al. (2012, 2015). The sustainable livelihood framework is an analytical structure to facilitate understanding of broad factors that constrain or enhance livelihood opportunities, and puts people and their access to assets (financial, human, social, natural, and physical) at the center of this understanding (Reed et al. 2013). This framework also considers livelihood diversification as a risk management strategy and the role of institutions' structures and processes in shaping peoples' livelihoods (Ellis 2000). One of the main proponents of the use of a sustainable livelihood framework to studies of climate change resilience of poor communities is Tanner et al. (2015). They argued for resilience studies to incorporate a livelihood approach in order to pay attention to fundamental issues of human agency and empowerment, putting people at the center by focusing on capacities for human (rather than environmental) transformation.

Biggs et al. (2012, 2015) distinguish between resilience as a property of social-ecological systems (SES) and resilience as an approach and set of assumptions for analyzing, understanding, and managing change in SES. As a system property, they define resilience of SES as the capacity of an SES to sustain human well-being in the face of change, both through buffering shocks and also through adapting or transforming in response to change (Biggs et al. 2015). In order to analyze or build the

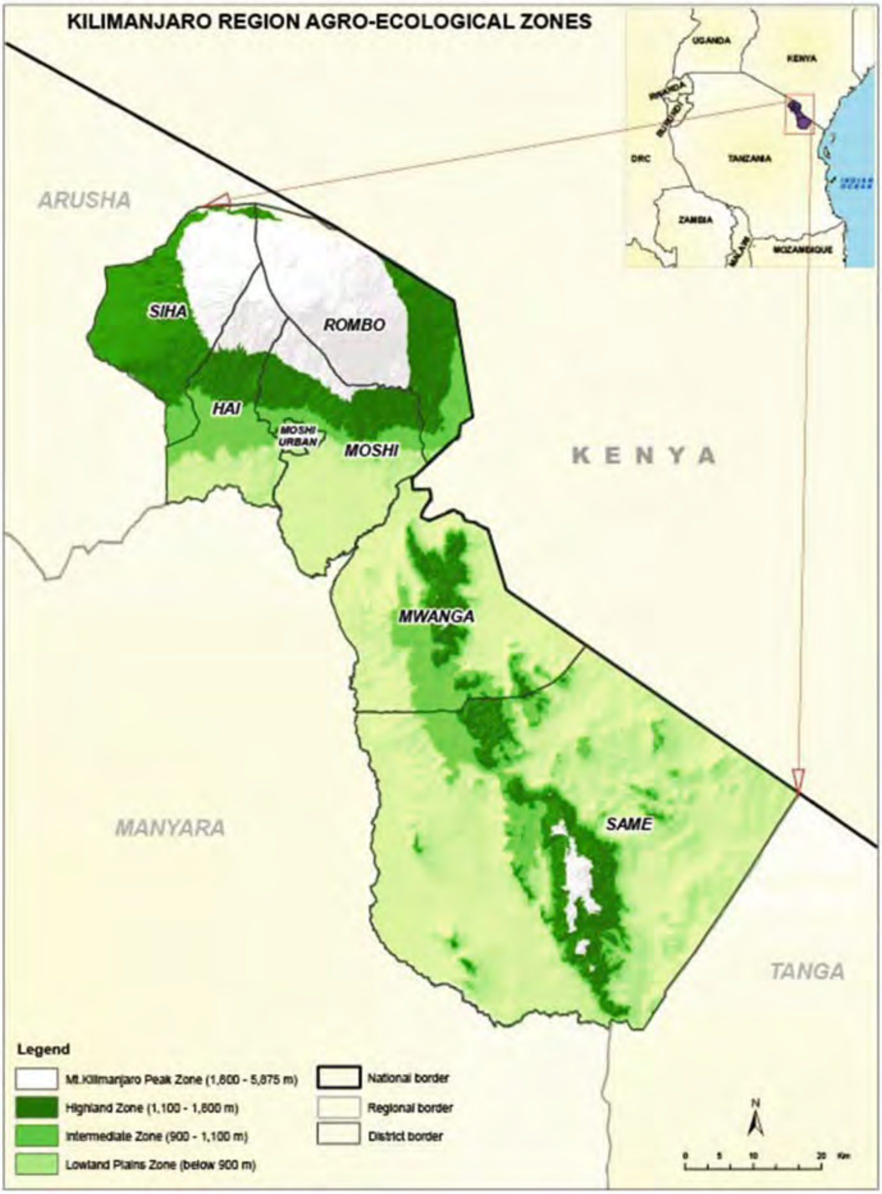

Fig. 1 Location of the Kilimanjaro region and different agro-ecological zones. (Source: Author 2020)

resilience of a system, Biggs et al. (2012, 2015) identify seven principles. The first principle refers to diversity and redundancy. Diversity involves the provision of different options for responding to change, achieved by ensuring variety (the number of different elements), balance (the number of representatives of each element), and

Table 1 Key characteristics of the three agro-ecological zones included in this study (information from Soini 2005; O'Brien et al. 2008; Regional socioeconomic profile, 2014)

Zone	Altitude (m above sea level)	Soil fertility	Rainfall (mm/a)	Temperature range (°C)	Population density (people/km^2)	Major crops	Livestock and additional comments
Highland	1100–1800	High	1250–2000	15–20	650	Wheat, beans, barley, coffee, banana, fruits, round potatoes	Majority of livestock are stall-fed. Some families own or rent plots of land in other zones particularly in the lowland zone.
Midland	900–1100	Moderate	800–1250		250	Coffee, banana, maize, beans	Dairy cattle, goats, pigs, rabbits, poultry farming
Lowland	<900		700–900	Average annual >30	50	Maize, cotton, rice, sorghum, cassava, pigeon peas	Beef cattle, goats, pigs, sheep. Provides fodder during the dry season for animals in all zones. Livestock mostly freely grazed because of the availability of open spaces especially after crops have been harvested

disparity (how different the elements are from one another). Redundancy describes the replication of elements within a system. The second principle is to manage connectivity, focusing on the way in which parts of an SES interact with each other. The third principle is to manage feedbacks and slow variables, such as long-term changes to environmental assets such as soil fertility. The fourth principle is to foster complex adaptive system thinking. The fifth principle is to encourage learning and experimentation. The sixth principle is to broaden participation and the seventh to promote polycentric governance systems. This chapter draws primarily on principles one to three, further analysis of the principles in the context of this study can be seen in Mwasha (2020).

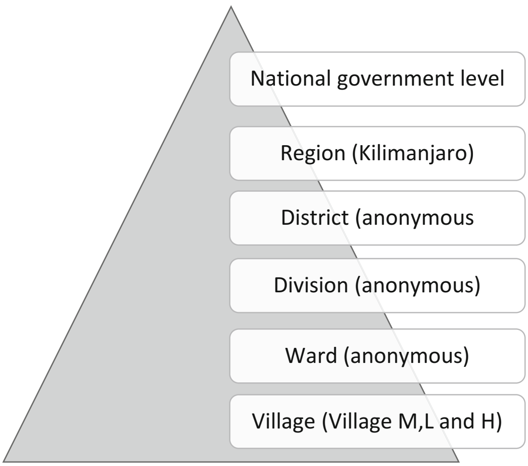
Study Site Selection and Sampling Methods

The administrative structure in which the villages included in this study site is shown in Fig. 2. The district in which the study was conducted was selected in discussion with the regional environmental officer (who oversees activities related to the environment in the region) based on preset criteria: accessibility, evidence of climate change, and the presence of the three agro-ecological zones. The Kilimanjaro region has seven districts, but only some have three agro-ecological zones. Simple random sampling was used to select one ward from each agro-ecological zone in the selected district, and to pick one village in each ward. The district, ward, and villages are not named in order to maintain anonymity.

Data Sources, Collection Methods, and Analysis

Data were gathered from individual household surveys of household heads (who were all small-holder farmers) in the study villages, focus group discussions in each village, interviews with key informants, and researcher observations. Although the survey did not ask about the total household size because I wanted to understand the labor force, the regional socioeconomic profile (2014) shows that the Kilimanjaro

Fig. 2 Administrative structure in Tanzania



region had an average household size of 4.3 in 2012 which is the lowest in the country compared to a national average household size of 4.8 in the same year. The household surveys collected quantitative and qualitative data on the household heads' perceptions of the impact of climate change on the livelihood assets and farm production practices utilized by the household. The total numbers of interviewed households were 47, 35, and 24 in the highland, midland, and lowland zones, respectively. The total numbers of village for highland, midland, and lowland were 946, 702, and 483, respectively. Except in the lowland zone where the focus group was mixed gender, the midland and highland focus groups were gender-based. The focus group discussions explored trends in crop production, soil fertility, animal keeping, water availability, and management practices and their implication to climate change adaptation, as well as information about social factors that contribute to small-holder farmers' vulnerability to climate change. Interviews were held with five key informants (a community development officer; a representative from the Tanzania Coffee Research Institute; a district and village agriculture extension officer; and a network of farmers' groups in *Tanzania which is Nongovernmental Organization)* to understand their roles in helping farmers successfully adapt to climate change, factors that hinder farmers' adaptation ability, and potential solutions. Observations in the villages by the researcher were used to inform understanding of existing farm production practices. The data were collected in the Swahili language and translation was carried out by the researcher alongside data transcription. Details of the socioeconomic characteristics of the villages and measures contributing to livelihood vulnerability are found in Mwasha (2020) thesis.

The household survey data arises from closed-ended questions and open-ended questions with brief answers. The analysis of closed question data was carried out using SPSS descriptive statistics and qualitative data were manually coded using in vivo coding and descriptive coding, and grouped under the themes identified and entered into SPSS for analysis.

Data from the key informant interviews and focus groups were manually analyzed (Basit 2003). The transcription text was analyzed using evaluative coding based on the research questions (Smith and Firth 2011). The codes developed were categorized into different topics and then linked to form themes (Saldana 2009; Smith and Firth 2011).

Results and Discussion

This section is structured around four key areas of focus to support small-holder farmer adaptation to increase resilience to climate change. The first section focuses on the role of maximizing existing household assets, focusing specifically on human and social capital. The second section focuses on the management of physical and natural capital, also referred to as managing slow variables in reference to one of Biggs et al.'s (2015) resilience principles. The third section looks at the role of livelihood diversification, a key component of the sustainable livelihoods framework (DFID 1999), in building livelihood resilience to climate change, and Biggs et al.'s (2012, 2015) principles for building resilience. The fourth section explores the role of government in supporting small-holder farmers' adaptation and resilience to climate change.

Maximizing Existing Household Assets: Household Decision-Making and Female Empowerment

The way in which a household's assets in terms of income and produce are utilized have a major role in building livelihood resilience. Both male and female focus group participants in the highland and midland zones gave examples of how division in household responsibilities (i.e., responsibility for keeping the family fed, sheltered, educated, clothed) and divided ownership of resources within households (i.e., certain cash crops typically belonging to male members of the household) could lead to resources being used without consideration of what is best for the whole household. Focus group participants in the highland and midland zones viewed it as preferable to have joint ownership of assets and shared household responsibilities, where what is produced in the household is considered to belong to the whole family; with couples planning together how those resources are used, creating more transparent and balanced decision-making in the household. In the lowland focus group discussion, division of ownership, and household obligation were said to have no impact on household resilience. However, as the lowland focus group was mixed gender, participants may not have been willing to discuss the issues arising from different gender roles within the household. The details of division of household obligations of gender roles are found in Mwasha (2020).

Achieving more balanced decision-making around resource use within households is supported by wider policies that promote the empowerment of women through increasing access to education and financial capital. The need to support female empowerment was supported in discussions within both gender focus groups in the highland and midland zones as there was no direct question asked about this mater but it came up during the discussion about household resource use and its impact on household resilience to climate variability and change. The empowerment of women is also reported in the literature as increasing household resilience to climate change (Almario-Desoloc 2014). However, not all women in the Kilimanjaro region, and Tanzania in general, have access to these opportunities (Kato and Kratzer 2013), and the slow pace of change requires other strategies to be adopted in some households to address problems of household resource utilization stemming from household inequities. In the highland and midland, there was discussion of how some women would hide some crop produce to be able to use this in times of adversity; showing how individual household strategies are used in helping build household resilience.

Another strategy farmers in all focus groups reported to use to build resilience relates to food storage systems especially after harvest to give food a longer life and protect it from damage. The focus group participants in all three zones mentioned the use of storage tanks which are tightly sealed after being filled with food, especially maize and beans (other crops were also mentioned by female participants), as their main method of storing food, to provide reserve food stocks in times of limited harvests. Although there was no specific question asked about food storage systems, these discussions came about while exploring hunger periods in the study area.

Building the Household Assets Base

Small-holder farmer livelihoods depend on the quality of the assets (human, social, financial, and natural capitals) to which a household has access. The available assets form the foundation upon which livelihoods are built and define the ability of the people in question to execute different livelihoods strategies (Chambers and Conway 1992; DFID 1999; Ellis 2000; Scoones 2009). The discussion below explores ways to further build human and social capital (assets) which were perceived by respondents to be decreasing in the study area, and through this build resilience to climate change.

Building Human Capital

Human capital can be defined as the available labor force within a household to contribute to agricultural production, income generation, and household management. The household surveys identified that human capital was negatively affected as a result of malaria which has intensified by increasing temperatures allowing the geographic spread of mosquitoes particularly into the highland zone.

Adaptation strategies are needed to deal with an increase in malaria and its impact on human capital (Onwujekwe et al. 2000; Teklehaimanot and Mejia 2008; Asenso-Okyere et al. 2011). Teklehaimanot and Mejia (2008) summarized malaria control strategies as follows:

- Provision of early diagnosis and prompt treatment
- Selective and sustainable use of preventive measures, including vector control
- Prevention, early detection, and containment of epidemics
- Strengthening local abilities and applied research

These strategies require actions at both government and household level. Households are responsible for using preventive measures such as mosquito bed nets, managing the environment to reduce mosquito habitats, and going to the hospital when they get ill for diagnosis and treatment. The government is responsible for educating people about control measures, ensuring access to control measures and medical services, and investing in research on prevention and treatment of malaria diseases. Poverty also plays a crucial role in explaining why certain population groups are more vulnerable to malaria, because of the inability to pay for insecticide-treated bed nets and access to medical health (Teklehaimanot and Mejia 2008). In the study area, the household survey showed that most families were provided with free mosquito nets by the government to prevent malaria disease.

Building Social Capital

The household surveys in this study show a perceived decrease in social capital (described as support that households provide to each other) partly caused by climate variability reducing the amount of crop yield. Social capital is important as it can help households survive the impacts of poverty (Baiyegunhi 2014) through providing security in times of distress and access to resources (Grech 2012). There are different ways that households or individuals can build social capital. Baron et al. (2000) identified two different aspects of social relations that can build social capital for households and individuals: (i) obligations, expectations, and trustworthiness; and (ii) norms and effective sanctions.

One core element of social capital is where people are willing to help each other and do things for each other, relating to Baron et al.'s (2000) "obligations, expectations, and trust." For example, if an individual (named A) does something for B, and trusts B to reciprocate in the future, this establishes expectations in A and an obligation on the part of B. As A does the same to more people, and these people are trustworthy and responsible, this creates good safety nets for A in the event that something happens to A. This study revealed one practice based on these concepts of social capital, in the saving of food resources by one household for another, to be taken back in times of need. This area of social capital was the preserve of females in the communities who reported to support each other in this way.

Social capital can also be developed through the development of norms and sanctions (Baron et al. 2000). However, these can be fragile as some people can misuse them for personal interest. Norms and sanctions relevant to this study include the promotion of norms that encourage family members and neighbors to act selflessly in support of others, which may be reciprocated, providing positive motivations. For example, a household which does not support another household may not be supported if they need help themselves (negative motivation), while the household which supports another during difficult times may be positively motivated by the possibility of needing support themselves in the future.

These aspects that develop social capital for households and individuals are strengthened by social structures with high interconnectedness and interdependency between all actors (Fig. 3; Baron et al. 2000). This can be seen as another form of social capital; the connectivity of social structures that allow the proliferation of obligations and expectations. For example, in a less connected "open structure"

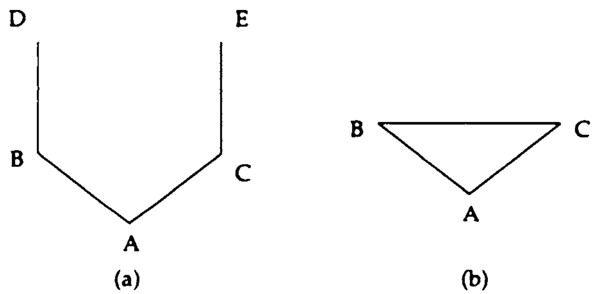


Fig. 3 Social networks without closure (**a**) and with closure within the social networks (**b**). (Source: Baron et al. 2000)

(Fig. 3a) individual A can carry out actions that negatively affect D and E who are not acquainted with each other, and therefore cannot unite to control the negative effects from A. In contrast, Fig. 3b shows that all actors are connected and therefore there will be stronger motivation for A to avoid negative effects on other actors.

The household survey and information from the community development officer shows that in the study area some households have developed structures that facilitate social capital. They support each other by forming groups based on similarities between members such as family relations, friends, or similar work space or type. The groups work as informal saving and credit institutions, and members get different services such as access to loans and social support in case they face shocks in their life. Based on information from key informants, there is some nongovernment organization capacity building of these groups by providing training into how groups select leaders and develop financial management and group policy. The government encourages group members to register through the community development office to increase accountability but most are reluctant to register because of registration fees. More government-subsidized training and waiving of registration fees could improve social capital in the area.

Drawing on the insights from Baron et al. (2000), households and individuals can improve their social capital by their own acts to support others and by developing trusted networks of individuals and households within their community, increasing their sources of support for times of adversity. Village-level initiatives based around these principles could also help develop social capital through promoting norms, trust, and responsibility and interconnectedness at the community level. Government-level initiatives can also help support more formalized social support networks such as credit unions.

Managing Natural and Physical Capital: Managing Slow Variables

This subsection adopts the concept of managing “slow variables” as used in Biggs et al.'s (2012; 2015) resilience framework. Slow variables are those variables that change slowly and can take time for changes in them to be noticed. The slow variables considered in this study focus on soil and water, two key areas of natural capital on which small-holder farmers depend, and which the results show have been affected negatively by management practices. Drawing on the study’s focus group discussions, household surveys, key informant interviews, and wider literature, this section describes strategies to ensure the adequate supply of water for agriculture, and strategies to improve soil fertility in the face of declines in these “slow variable” assets.

Managing Water Resources

Poor decisions and practices made by farmers, such as crop choice and inadequate water source management practices, can affect agricultural productivity particularly under weather-related stress (Bot and Benites 2005). This section looks at how farmers will need to adapt to climate change by choosing appropriate crops to grow by considering plant traits with tolerance of water stress, conservation of water sources, and employing farming practices that encourage water infiltration and conserve soil moisture.

Planting Crops That Can Survive Climate Variability

Data collected in the study area demonstrated that in all three zones the types of agricultural produce grown by farmers threatens the capacity of the existing water resources to sustain agricultural production in the area, particularly as available water resources are perceived to have decreased. Cultivation of high value, high water demand crops, particularly horticultural produce such as tomatoes, cucumbers, onions, and carrots, has increased, increasing pressure on water resources. Although there are benefits to practicing horticulture as produce can be harvested in a relatively short time, the viability of these choices of crop is in question because of the capacity to sustain production in the long-term with trends of declining water availability. In contrast, traditional maize varieties are perceived to take a long time to mature (~6 months) which makes them vulnerable to the more variable rainfall patterns, potentially preventing the crops from reaching maturity. One solution is to replace traditional maize seeds with early maturing maize varieties which can survive the increased rainfall variability. In addition, planting drought-resistant crops such as millet is another strategy for managing the effects of decreasing rainfall amount and increasing variability. However, the results from this study show that the use of these crops is low in all three zones. As some farmers have negative attitudes toward crops like millet and cassava (another drought-resistant crop), there is the need for the government to encourage farmers to grow these crops through the development of an effective market for these crops. Government can also play a role in supporting further research into alternative drought-resistant crops but with a need to ensure that these will meet the needs and wants of small-holder farmers.

Conservation of Water Sources

Across all three zones, there are a number of different practices that were discussed as being important for the conservation of water resources, including encouraging on-farm tree planting and avoiding the cutting down of trees. The relationship between trees and water resources is complicated (Ellison et al. 2017). However, there is some indication that increasing tree planting on farms can help preserve water resources through the effect of shading to reduce evaporative loss from soils (Clement et al. 2016).

The use of farming techniques for increasing infiltration, reducing surface runoff and evaporation, and improving soil water availability is essential in dealing with weather-related shocks (Biazin et al. 2012). There was evidence of these practices in the study area. For example, in the highland zone the use of terraces was reported to help control soil erosion, as well as reducing surface runoff and increasing infiltration (Biazin et al. 2012). In the lowland zone, farmers reported using minimal tillage in order to protect soil moisture.

Rainwater Harvesting

Rainwater harvesting may also increase productivity from existing rainfall. The harvesting systems mentioned by focus group participants can be categorized into two types: earth dams and spate irrigation. Focus group participants in all three zones reported the need for earth dams especially in the lowland zone, to harvest available rainwater and use it for supplemental irrigation.

The use of spate irrigation was mentioned in the focus group in the lowland zone, where floodwaters from the highlands are channeled to nearby fields through gravity or water pumps to irrigate farms in the lowlands. This approach is used to cope with dry spells by taking advantage of the rain happening in upland areas even though it has ceased in lowland areas, as the rainy seasons last longer in the highland and midland zones relative to the lowland zone.

In addition to providing additional water sources, farmers with access to spate irrigation reported other benefits such as improved soil fertility, reducing the use of fertilizer on their farms because the spate water comes with eroded materials that are nutrient-rich. Although this strategy has many benefits it may come with other challenges because large flash floods can potentially cause damage to crops and prepared land (Komakech et al. 2012), although this was not mentioned by any focus group or household survey participant.

In addition to direct interventions such as water-conservation farming practices, wider systemic issues leading to poverty need to be addressed, because in some cases it is these systemic issues that push farmers in this area to inappropriately use water sources as a survival strategy. For example, as a result of reliable crop market, farmers chop down trees to sell timber as alternative source of income.

Managing Soil Fertility

Management of soil fertility particularly where weather-related shocks are experienced is vital for reducing the impact of climate change on soils as well as improving water productivity (Biazin et al. 2012). Soil fertility-related land management practices include appropriate use of fertilizer and soil conservation methods to reduce erosion and maintain organic matter (Clair and Lynch 2010; Kaczan et al. 2013). Farmers in the study area identified strategies to increase soil fertility and conserve soil moisture such as mulching by retaining crop residues in fields, intercropping, the use of organic fertilizers, minimal tillage, and agroforestry as potential adaptation strategies. However, comparison between zones shows that while retaining crop residues, intercropping and use of organic fertilizers were mentioned in all three zones, minimal tillage was not discussed as a strategy in the midland and highland zones. In addition, the role of agroforestry was debated in the lowland zone, with the majority of participants believing agroforestry to be appropriate in the midland and highland zones but not in the lowland zone because they perceive the crops grown in the lowland zone (see Table 1) do not require the shade provided by trees.

Focus group participants believed that given the increased nature of climate variability and projected climate change, the benefits from retaining crop residues in fields were more important than ever. However, although maintaining crop residues in fields was seen as an important potential adaptation measure to build livelihood resilience to climate variability, it was also acknowledged that this is hindered by the free grazing of animals by livestock keepers residing in the lowland zone. This was particularly problematic for farmers in the highland zone who also held farmland in the lowland zone, and were not able to monitor their land in the lowland zone. In addition, the need for fodder for livestock kept in the midland and highland zones was partly met by the transport of crop residues from the lowland zone. Participants reported that the nature of the issues faced meant that farmers now needed to find the balance between livestock feed and improving agricultural soils through retaining crops residue.

In dealing with competing crop residue demands, agricultural intensification can help increase the amount of biomass produced which can be divided between livestock and that which can be retained in the soils. In addition, free-grazing animals in the lowland zone should be discouraged to motivate farmers to retain part of the residues in the farms. Livestock keepers should be encouraged to sell some of their livestock and retain only that which they can maintain using their own resources.

Agroforestry was also mentioned as a potential adaptation strategy to address issues of declining soil fertility in the study area in all focus group discussions. The household survey results showed that participants believed this strategy to have both socioeconomic and environmental benefits. Research literature has also reported several benefits of agroforestry, including an increase in soil organic matter, erosion control, reduced sensitivity to harsh weather, natural pest and disease control, and provision of an alternative source of income (Reyes et al. 2005; Nair 2007; Nguyen et al. 2013; Pumariño et al. 2015; Sepúlveda and Carrillo 2015; Schwab et al. 2015). It is important to acknowledge that, in the survey results, there were a small number of respondents who disagreed about the benefits of agroforestry (particularly in the lowland zone) when combined with cereal crops like maize. However, studies do suggest that there is potential for agroforestry within maize production (e.g., Garrity et al. 2010), which offers opportunity to explore further types of trees that could be relevant in the study area to be integrated with maize, but the acceptance of farmers would need to be developed.

The use of organic fertilizer from livestock is another potential strategy to enhance agricultural productivity (Clair and Lynch 2010) and was reported by focus group participants and key informants. However, farmers reported that the main challenge of using organic fertilizer was the inconvenience for some associated with transferring manure from the homestead where cattle are kept to the farm fields which could be up to 5 km from households. There are several potential ways to address these issues, including farmers cooperating with neighboring farm owners to hire transport and share the transportation costs. This shows the importance of social capital (in terms of a strong supportive community willing to work collectively) to address a range of issues. However, it should be acknowledged that any additional costs may be prohibitive for the poorest farmers highlighting that mechanisms to address financial capital and systemic issues leading to poverty underpin many different solutions.

Livelihood Diversification

Small-holder farmers in the study area have access to three different areas of livelihood contribution: (i) crop production for subsistence, (ii) livestock keeping for subsistence, and (iii) off-farm income activities, including small business such as small shops, street vending, and sale of agricultural products for income. The results from this study show that not all households diversify their livelihoods even though in the focus group discussions in all three agro-ecological zones it was reported that households should ensure they have more than one livelihood option as a risk management strategy, particularly important in the face of increased climate change variability. Given the types of livelihood options practiced in the study area, there are some similar dependencies in almost all livelihood options. For example, crop production and livestock keeping are all dependent on natural capital such as soil fertility and water resource availability. This suggests that if the flow and stock of these resources are affected by climate change or climate variability, the main livelihood contributions will be affected even where there is some diversity in income. Drawing on Biggs et al.'s (2012, 2015) resilience principles, it is clear that greater resilience can be achieved with greater disparity in the diversification options, and therefore having different livelihood options based around agriculture may provide less resilience than including diversification away from agriculture.

The Role of Government in Building Small-Holder Farmer Resilience and Adaptation to Climate Change

This subsection looks at the role of government in helping farmers to adapt to climate change in the Kilimanjaro region of Tanzania. The discussion is divided into two areas: (i) the role of government officials (e.g., agriculture extension officers and community development officers); (ii) government policies and directives. Nongovernmental Organizations also often play an important role in tackling livelihood adaptations in the Global South (e.g., Kajimbwa 2006; Oshewolo 2011). However, the role of NGOs was not a focus of this study and only one NGO was included as a key informant interview, nor were NGOs brought up by study participants in the discussions of livelihood resilience and adaptation to climate change. Government officials provide small-holder farmers with access to different services. For example, connections between farmers and agriculture extension services are an important way of providing farmers with timely and relevant knowledge on agricultural aspects of livelihood management (Fosu-Mensah et al. 2012) especially where traditional knowledge systems do not work in responding to climate change (Shackleton et al. 2015). The need to improve access to agriculture extension officers was mentioned by some respondents in the household survey as well as in key informant interviews. Access to extension officers by small-holder farmers could be improved by allocating more extension service providers to farmers as well as providing the service providers with improved means of transport to facilitate their transport to the small-holder farmer villages. The community development officers differ to agriculture extension officers in that they work with farmers to provide financial capital. However, the existing financial support given to women and youth group projects was reported to be inadequate compared to the demand. Therefore, the government needs to provide other sources of support such as credit, which farmers can exploit as access to financial capital is essential to facilitate adaptation (Deressa et al. 2011; Ndamani and Watanabe 2015; Belay et al. 2017).

There are a number of policy areas that were identified in the study where government could make adjustments to create more favorable conditions to support farmers' adaptation to climate change. These include: the 2007 Warehouse Receipt System (WRS) introduced to help farmers take advantage of price fluctuations by enabling farmers to store crops in warehouses and sell them when prices are high (MAFAP 2013). There was low use of WRS, especially for cereal crops. The government needs to increase the capacity of cooperatives unions, farmers' organizations, and savings and credit cooperatives to be able to implement the WRS for the variety of crops that are produced in the study area.

There are several areas of regulations where there is weak implementation causing availability of fake agricultural inputs in the market. Examples include, the Seeds Act (2003) which regulates the production and trade of all varieties of agricultural seeds including the mandatory provision of seeds for quality assurance; the Fertilizer Act (2009) regulates and controls the quality of fertilizer, either domestically produced or imported; and the Tropical Pesticides Research Institute Act (1979) which regulates research on pesticides for the purpose of ensuring their quality. The study participants reported poor implementation of these regulations with negative effects on the farmers. This shows a need for the government to ensure existing laws and policies are implemented more effectively to achieve the intended results. There were also government actions which small-holder farmers directly referred to as having a negative effect on their livelihoods. These included an export ban on crops preventing farmers from maximizing income in times of food scarcity in other countries (but supporting food security within Tanzania); government appropriation of resources (particularly water) for urban areas; and the lack of implementation of a requirement for using scales for measurement of agricultural produce meaning that farmers often ended up being short-changed by unscrupulous buyers.

Conclusion

This chapter discusses areas of focus to build the livelihood resilience to climate change of small-holder farmers in the Kilimanjaro region of Tanzania, drawing on results from a study of three villages in the region and key informant interviews. Building small-holder farmers' livelihood resilience needs to be tackled at different spatial and temporal scales; from individual farmer decisions to government interventions, from short-term to long-term strategies, and in different spheres from household management practices, agricultural practices, livelihood diversification, to the building of community and social capital, and the development of wider regulatory and economic systems.

These results highlight the importance of scale and context. Even a single region, such as the Kilimanjaro region studied here, is not a homogenous block. Although there were some similarities across the three agro-ecological zones such as the importance of measures to build social capital, control malaria disease, and the overall management of slow variables, there were some distinctions in the actual practices for management of slow variables as well as the existing social structures affecting resilience within the household. For example, the use of terraces and agroforestry was perceived as relevant in the highland and midland zones while leaving crop residues, minimal tillage, and drought-resistant crops were articulated more in the lowland zone. However, it should also be remembered that these zones do not exist in isolation, for example, some small-holder farmers own land in a different zone to the one in which they live, water resources from the highland zone travel through the midland and lowland zone, and forage for livestock may be sourced from a different zone. Therefore, changes implemented in one zone also have the potential to impact other zones, requiring adaptation measures to both respond to the specific context of an area and understand the interconnections between areas.

Combining a socioecological resilience framework and sustainable livelihood framework provides an important approach to understand small-holder farmers' assets bases as well as their vulnerability and sensitivity to climate change (Mwasha 2020). This combined framework also helps to understand the barriers to climate change adaptation strategies as well as strategies to build resilience to climate change across different temporal and spatial scales and spheres. Building resilience principles into sustainable livelihoods thinking clearly has a role to play in addressing the resilience to climate change of small-holder farmer livelihoods in the study region and likely throughout the Global South.

Abstract

Africa's urban morphology is expected to develop at a steady rate between 2020 and 2050. Population growth, rising urbanization rates, growing energy consumption, and industrialization are only a few of the reasons causing these changes. Likewise, waste production is projected to rise from 125 million tons in 2012 to 244 million tons annually by 2025. Around 60.0% and 80.0% of African waste is made up of organic material, which is a viable methane source. Fly tipping, free disposal, landfilling, and incineration have been used as a large-scale waste treatment system in most African cities. However, with the anticipated morphological changes, these solutions are no longer viable in the future due to lack of airspace, availability of urban land for new landfill sites, and concerns over carbon emissions. This chapter discusses the potential for improved adoption of material recycling facilities (MRF) in urban environments as an incentive to support waste diversion from landfills, decentralize waste separation activities, and increase the transformation of waste materials into valuable raw materials. A case study is discussed for Ethiopia, Ghana, and South Africa with the goal of explaining current processes, urban planning initiatives required for greater implementation, and how they can be interpreted as adaptation initiatives.

Introduction

Towards Zero Carbon Cities

Africa has 1.3 billion people (Worldometer 2020) and is the second largest continent after Asia. Many regional studies consider the socio-economic promise of the continent, propelled by urbanization, industrialization, and demographic growth. Achieving this potential would be confronted with a variety of obstacles. Solid waste management is currently one such problem particularly in urban areas. Ten of the fastest growing cities over the next decade are expected to be in Africa. Such cities include Luanda (Angola), Yaoundé (Cameroon), Dar es Salaam (Tanzania), Kumasi (Ghana), Kampala (Uganda), Lusaka (Zambia), Douala (Cameroon), Mbuji-Mayi (Congo), Antananarivo (Madagascar), and Tshwane (South Africa) (Knight Frank 2017). When these cities expand, accumulation of industrial waste becomes expected. Most African cities are generally planned and organized based on colonial urban planning (Home 2015). Little or no town planning has been undertaken since independence. That means little or no concern other than landfills and open dumps built in the 1960s and 1970s for urban waste management.

The main issue is the effect on carbon emissions in all municipal solid waste and cities. The African continent is vulnerable to climate change impacts. Urban areas are critical for effective adaptation to climate change (Revi et al. 2014). More than 50.0% of the world lives in urban areas and these communities partake in industrial practices that generate greenhouse gas (GHG) pollution. Socio-economic inequalities have also seen a dramatic rise in informal settlements in regions that are vulnerable to climate threats, such as natural disasters, public health, damage to homes, and income disruption. Inadequate provision of infrastructure and service delivery are exacerbating risks, especially for low-income households (Revi et al. 2014), and the pace of urbanization has exceeded the ability of many governments to handle it. In 2018, nine African cities pledged to achieve zero carbon cities by 2050. The cities include Accra (Ghana), Addis Ababa (Ethiopia), Dakar (Senegal), Lagos (Nigeria), as well as cities of Cape Town, Durban, Johannesburg, and Tshwane (South Africa). Nairobi (Kenya) and Abidjan (Côte d'Ivoire) are still expected to pledge. Drastic policy, human intervention, and finances will be required to reduce emissions from transport, construction, energy production, and waste management sector (The Economist 2018).

Waste management practices in Africa are not the most effective. Landfill alone contributes between 3.0% and 5.0% of overall industrial emissions (Zhang et al. 2019). Much of the academia and industry focuses on encouraging recycling practices not only as a method of waste disposal from landfills and open dumps, but also as a measure of climate adaptation and mitigation. Africa recycles only 4.0% of its total solid waste (Mohee and Simelane 2015; UNEP 2018). Before landfilling, further exploration of waste collection, separation, and beneficiation is necessary. More Material Recycling Facilities (MRFs) should be considered to boost recycling practices, waste data collection, and alleviate African cities from disposal pressures. Countries such as the United Kingdom have state-of-the-art engineered facilities that divert approximately 50,000 tons of waste per annum from landfills (Ali and Courtenay 2014). In the African context, academic research pertaining to MRF adoption and implementation is far and few in-between while industry or commissioned research is available but restricted between client and supplier. There is a global motivation to dispose of waste from open dumps and landfills as well as to reduce the contribution to emissions. With growth and urbanization proliferating in the coming decade, it is our view that urban planning has a role to play in rising MRFs as a way of mitigating the projected volumes of waste in urban areas.

Objectives and Chapter Outline

Urbanization and population growth are anticipated to be significant drivers of climate change and pollution in the Global South. Currently, cities accommodate over half of the global population, generate approximately 82.0% of global GDP, account for 70.0% of global energy consumption, and account for over 70.0% of greenhouse gas emissions (Godfrey and Zhao 2016). However, it is estimated that by 2050 global, urban population will exceed 6.7 billion and that nearly 80.0% of population growth will take place in low and middle income countries, where populations are already rising by over one million people per week (C40 Cities Climate Leadership Group 2016). There is therefore an urgent concern to increase climate change mitigation and adaption efforts in African cities. Thus, the main objective of this chapter is to determine how material recycling facilities can be used as tools to facilitate climate change adaptation (and mitigation) in African cities.

To this end, the approach used consisted of exploratory case studies of three waste disposal activities in Ethiopia, Ghana and South Africa, and a review of secondary data, consisting of project reports and scholarly articles. The report is organized as follows: section "Literature Review" addresses the evolution of urban planning in Africa and contextualizes the relationship between climate change and waste management in Africa as well as the rationale for improving waste management and introduces Material Recycling Facilities, how they are planned and designed. The aim is for readers to have an appreciation before going into the case studies. Section "Research Approach" discusses the exploratory case study approach. Section "Case Studies" discusses whether Ethiopia, Ghana and South Africa have urban, waste management, and climate change adaptation plans, strategies, and projects relating to MRFs. Section "Proposed Recommendations and Conclusion" offers climate change and waste management practitioners recommendations and concludes with an assessment of urban planners' roles and responsibilities.

Literature Review

Evolution of Sustainable Urban Planning in African Cities

Africa's towns and cities are shaped by laws imported from British colonial rule from the 1920s (Home 2015). Urban Planning, interchangeably referred to as Town and Regional Planning or City Planning, is a discipline within the built environment that is concerned with designing and developing land use (Lubida et al. 2019). It was officially recognized as a profession in the latter twentieth century (Home 2015). Key considerations range from transportation, engineered utilities (water, electricity, sewerage systems), infrastructure, communication, and social amenities (schools, hospitals, parks, economic activities). Spatial and land use planning are the most predominant specializations in the field of urban planning. This is a dynamic activity that requires juggling social, cultural, environmental, and political influences (Lubida et al. 2019). Decisions surrounding zoning, subdivision, and urban planning are taken by land use authorities, in consultation with different stakeholders (Home 2015). Amenities such as waste management have not been deliberate in planning strategies. While there is a global push for cities to become more environmentally responsive and to implement mitigation and adaptation initiatives through policies and strategies – Sustainable Development Goal 13, Target 13.2 – current urban systems are not conducive. A large part of African cities are still centered around colonial town planning principles and regulation, with a morphology characterized by informalities – informal settlement, informal structures, and informal waste pickers.

Postindependence, there was very little evidence of the evolution of land use planning, especially the form that supports sustainability. Throughout the 1980s and 2000, several academics started to re-invent postmodern planning, one driven by economic development and environmentalism (Okeke and Nwachukwu 2019). An increasing body of literature on urban sustainability and innovative planning approaches has begun to shift urban development patterns (Lwasa and Njenja 2012). The term "green technology" was identified as a tool for modern urban planning. This includes deliberate coordination of activities that are energy efficient and promote renewable energy, recycling activities, and more. There are different technologies that contribute towards sustainable urban planning, such as the implementation of enhanced municipal waste management (Laffta and Al-rawi 2018). Four types of eco-technologies that urban planners can start implementing more are:

1. Environmental Technology: a range of technologies relating to waste management, access to water and energy
2. Information Technology: hardware and software coupled with environmental sensor technology to collect environmental data
3. Geographic Information Systems: collect, share, manipulate geographic data and incorporate with Urban Information Systems to guide design and development of land use and environmental plans
4. Communication Technology: software to transfer data and knowledge to different environments

Green technologies are most prevalent and commercialized in Denmark, Sweden, Japan, India, Iraq, Finland, Canada, and the United States of America, just to name a few (Laffta and Al-rawi 2018). Opportunities for African planners to leapfrog are bountiful. Such tools can be used not only for sustainable urban development and waste management but as part of climate mitigation and adaptation strategies. Kenya is not far from realizing the benefits of green technologies. Urban planners are responsible for solid waste management. The National Solid Waste Management Strategy is used to incorporate solid waste management and best practices into urban plans. The plans are then subjected to a Strategic Environmental Assessment, which assesses aspects such as sustainability, proposed waste management programs, as well as relevant services and facilities (Ozoike-Dennis et al. 2019). The authors further state that *solid waste management* (SWM) plans are included *in the Nairobi Integrated Urban* Development Master Plan (NIUPLAN). The SWM plans focus on "improving waste collection and transportation system, closing open landfills, and constructing Material Recovery Facilities, where waste material is to be separated to compost biodegradable material, and recycle non-biodegradable material." In South Africa, municipal departments in charge of solid waste management are required to develop Integrated Waste Management Plans as stipulated in the National Environment Management: Waste Act (59 of 2008). The IWMPs include practical aspects of managing waste in municipalities. It is one of the sector plans that feed into and is guided by the Integrated Development Plans (Sango et al. 2014).

Climate Change Adaptation

The mean annual temperature in Africa increased by 1.7 °C in the last two decades of the twenty-first century and temperatures are expected to increase faster than the global average in the last two decades (Revi et al. 2014). It negatively impacts on livelihoods, health and sanitation, access to water, agricultural production, and urban infrastructure as well as slows down sustainable development (Reda and Tripathi 2011). Climate change demands new sustainable development strategies through mitigation and adaptation measures. Africa generates just 4.0% of global pollution, but will suffer serious consequences (Reda and Tripathi 2011). Field et al. (2014, p. 1104) define adaptation as a "response strategy to anticipate and cope with impacts that cannot be (or are not) avoided under different scenarios." Adaptation has to do with strategies and plans that can be implemented. They should be linked to development strategies and plans and disaster risk management. By doing this, developmental benefits are identified for the shorter term while reducing vulnerabilities in the longer term (Mimura et al. 2014). The importance of adaptation is influenced by how the issues are outlined (Mimura et al. 2014). They are heterogenous and very few have been monitored and evaluated in great detail. The process of adaptation planning is a complex social process that can create unrealistic expectations. It is done at a national level and implemented at a local level. However, poor coordination as well as recent and quality data can also impede the transition from planning to implementation, as is the case for many developing and developed countries (Mimura et al. 2014).

Accordingly, adaptation responses differ from context to context and involve a multiscale perspective which takes into account cultural, social, environmental, and institutional factors. If climate change is moderate, sustainable development will be greater and if it is high, sustainable development has less impact (Field et al. 2014). It involves designing strategies in the sense of waste management which reduce generation. Given the expected population growth, waste generation is unavoidable. Several primary practitioners interested in adaptation responses are environmental planners as they are planning for physical environments, environments impacted by disasters of climate change (Mimura et al. 2014). They build land use plans enabling or avoiding climate-risk projects (Revi et al. 2014, p. 8). City planning and land management are important (but certainly not the only) resources for policymakers to create climate-resilient city systems and construct capacity for sustainable urban growth at local level, connecting adaptation and mitigation steps, and enhancing livelihoods and quality of life for urban communities. Attention should shift to integrated development planning (Reda and Tripathi 2011). Today, African cities face a critical urban situation marked by a failure of governance structures in the face of increasing waste production combined with strong demographic growth and proliferation of slums and poverty. Strengthening waste management capability is critical for fostering smart urban growth and maintaining cities' democratic, economic, and social stability.

Greenhouse gas emissions from urban waste in developing countries are expected to increase drastically in future (Friedrich 2013) which may result in increased emissions from the waste sector. Increasing recycling, anaerobic digestion, and composting activities can reduce emissions. Waste material is not the only aspect of the value chain contributing towards emissions. Collection and transportation consume approximately 5 dm^3 (liters) of diesel per ton of waste, which accounts for 15 kg CO_2e emissions from landfilling alone range from 145 to 1,016 kg CO_2e per ton of wet waste. Aerated and turned windrow composting releases between 172 and 186 kg CO_2 per ton of wet waste (Friedrich 2013).

Globally, landfills contribute 3.0% to 5.0% of total global emissions (Zhang et al. 2019) because methane gas is the main carbon emission (Couth and Trois 2012). In Africa, it remains the cheapest and most common disposal method. Landfills are categorized as controlled or uncontrolled dumping or semi/medium/highly engineered facilities. The status of landfill classification structures in sub-Saharan Africa between 2000 and 2018 was evaluated by Idowu et al. (2019). To name a few, they identified 31 landfill sites across South Africa, Botswana, Cameroon, Ghana, Uganda, Kenya, Tanzania and found that 80.0% were listed as 0 and 1 (where 0 was classified as open dumpsites and 1 as controlled tipping). Classifications as non-engineered landfills make it difficult to beneficiate waste and manage environmental impacts such as leachate, groundwater contamination, air borne particulates, and pollution. Vaccari et al. (2019) conducted a technical review of leachate characteristics in landfills and open dump engineering in developing countries. The authors found 21 engineered landfills and 13 dumpsites across Africa as well.

State of Waste Management in Africa

Local authorities in developing countries are facing significant waste management problems as a result of an increasingly rapid rise in locally generated quantities and the complexification of the forms of waste to be handled. Informal waste collection is also used as an external constraint: it usually takes place under unstable social and environmental circumstances and, a priori, makes waste disposal more complex, managed by a multitude of minor actors. Moreover, data on waste quantities, characteristics, and source is a major impediment particularly for proper planning, implementation, monitoring, and evaluation. Most of the data in this section is based on 2005 and 2012 statistics, which was also used to forecast waste proliferation by various regional bodies, namely, the United Nations Environmental Programme. The daily ratio is the amount of waste generated per capita and per day. Its knowledge is a crucial phase in the introduction of waste management approaches. The amount of waste produced is always very heterogeneous and variable depending on the region, the lifestyles and culture, and the socio-economic level. Changes in lifestyles, living habits, consumption, and demographic growth have a significant effect on the quantity and typology of waste generated. This development often varies from one city to another within the same region, or from one district to another within the same city also according to peoples "living conditions." In sub-Saharan Africa, though per capita waste production rates are lower than in other areas of the world, high population growth, combined with increasing urbanization, would increase unbearably waste generation beyond existing capacities. In this regard, Kaza et al. (2018) forecasts that the overall quantity of waste in Africa will double from 174 million tons per year in 2016 (2.1 billion tons globally) to 269 million tons by 2030 (3.4 billion tons per year in 2025). Africa's waste generation accounts for 9.0% of total global waste generation (Kaza et al. 2018). Developing countries generally have an average annual production of waste per capita ranging from 180 kg to 240 kg, a quantity that is likely to double as a result of industrialization and the evolution of production and consumption patterns if adequate measures are not taken to influence this progression.

Waste Services and Infrastructure: Municipalities are responsible for providing waste related services in most African cities (Friedrich 2013; UNEP 2018). Infrastructure includes but not limited collection, transportation, recycling, treatment, disposal, and beneficiation in some cases. However, expensive and insufficient capacity limits their ability to provide sound infrastructure and quality services to all its customers. Lack of payment by customers has a direct impact on municipalities' waste management budget, which restrains their ability to ensure quality services and infrastructure. To deal with this issue, private sector companies and community based organizations partner with municipalities (UNEP 2018). There is a relationship between Willingness to Pay (WTP), affordability, and quality of services rendered.

Waste Generation: In 2012 Africa generated an estimated 125 million tons, 65.0% of which was sub-Saharan Africa (80 million tons), and by 2016 it was an estimated 174 million tons. Waste generation is expected to more than double to 244 million tons per annum by 2025 (UNEP 2018) to 269 million tons in 2030 and 516 million tons by 2050 (Kaza et al. 2018). Some of Africa's big economies, comprising of Algeria, Nigeria, South Africa, Ethiopia, and Egypt, are expected to be some of the biggest generators of waste. The forecasted growth is likely to adversely impact the climate if adaptation and mitigation measures are poorly implemented (Fig. 1).

Waste Composition: Waste composition has direct implications about how it is collected and disposed. Increasing raising living conditions are correlated with a qualitative shift in waste. As a country's income rises, the biodegradable ratio of the waste often declines as plastic, paper, and other industrial material waste rises (Hoornweg and Bhada-Tata 2012). The environmental effects of such a qualitative mutation are negative as nonbiodegradable waste takes more time to decompose. For Africa, the organic component is still the largest and emits a lot of methane, but it is likely to decline with the economies "industrialization movement." Fifty seven percent (57.0%) of MSW comprises of organic matter (Couth and Trois 2012; Mohee and Simelane 2015; UNEP 2018), followed by plastic (13.0%), paper and cardboard (9.0%), glass and metal (4.0%each), and other material (13.0%). However, composition varies from country to country, depending on economic activities, income level, consumer attitudes, and culture (UNEP 2018) (Fig. 2).

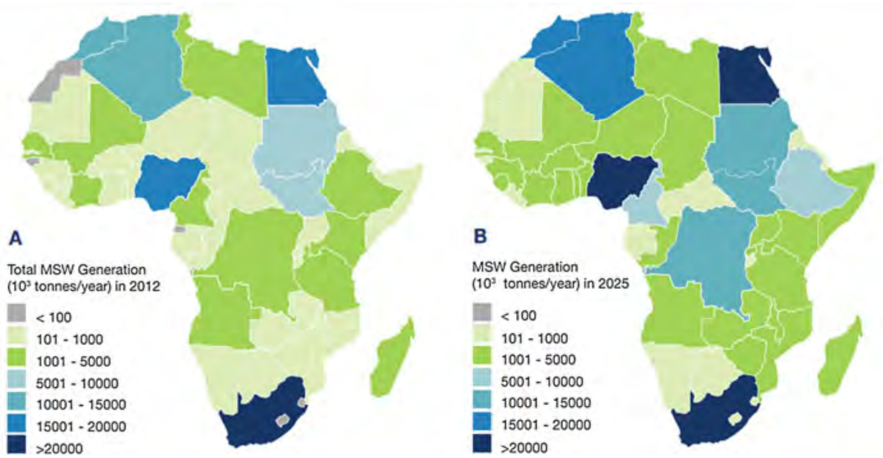

Fig. 1 Total MSW generation (10^3 tons/year) of African countries in 2012 (**a**) and 2025 (**b**)[3] (UNEP 2018)

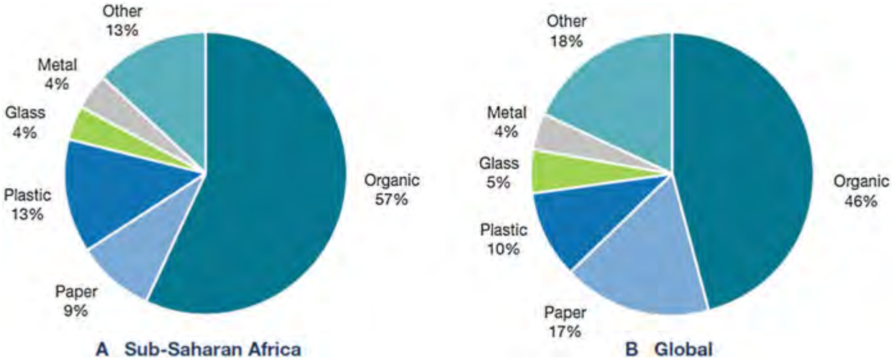

Fig. 2 Municipal solid waste composition (UNEP 2018)

Waste Collection: Uncollected waste remains very large in Africa. It might be necessary to note, however, that certain African cities have adopted improved management selection techniques. Some work has shown a spike in private-sector collections (UNEP 2018). Choosing a treatment method entails multiple economic, social, and environmental factors such as waste generation, population density, and location of waste collection centers (Mohee and Simelane 2015). Unregulated landfills and informal recycling are the main waste disposal methods in African countries and there is a high demand for waste services and low supply. Majority of the budget for MSW in developing countries is spent on waste collection yet only 55.0% of total waste generated was collected. Although waste collection is expected to increase to 69.0% by 2025 (UNEP 2018), where it will be disposed remains a concern. Collection services are most present in urban areas compared to suburban and rural areas. A common practice is door-to-door collection, by both public and private sector contractors. In peri-urban areas, community-based organizations are very important.

Disposal Methods: Landfilling and open dumping are the most common waste practice on the continent because both are considered the cheapest forms of disposal (UNEP 2018). Landfills are categorized differently, but the most common categories are controlled and uncontrolled. The nature of landfills and open dumps have little to no consideration for human health and the environment. Poor sanitary engineering and waste treatment results in groundwater contamination, leachate overflow, and an unpleasant stench. Across most landfills and open dumps in Africa, scavenging activities are inevitable (Idowu et al. 2019). Households near disposal sites are exposed not only to waste-borne diseases, but sharp objects and dangerous chemical excretions. Furthermore, GHG emissions are exacerbated due to poor waste minimization prior to disposal and open burning (9.0%). As the sites become full, the disposed waste is burned in order to reduce volumes and create more space (Fig. 3).

Opportunities for waste recycling: Most literature about recycling acknowledges the opportunities presented by such activities. In the African context, a lack of empirical data is one of the reasons why it is not a common practice particularly within the public sector. Recycling is not a well-known method in most municipalities, and this may be attributed to a lack of knowledge. Recycling activities are done by private contractors and informal waste pickers and they represent only 4.0% of total recycling activities on the continent (UNEP 2018). Although these are positive strides, waste material from developed countries continues to be dumped and lead to new waste streams, and most municipalities are not well equipped with the necessary logistics required for handling recycling. The informal sector, which comprises of mainly waste pickers, largely practices recycling for economic reasons. They play an important part towards reducing

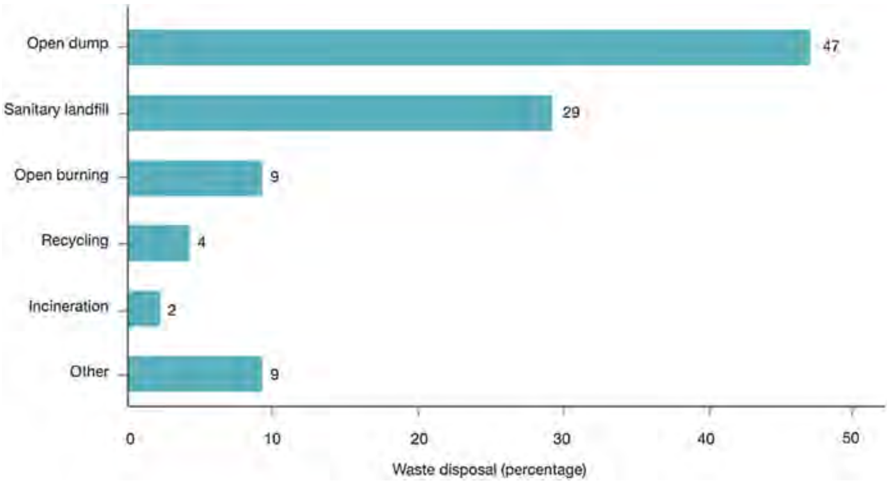

Fig. 3 Methods of end-of-life MSW disposal in Africa (UNEP 2018)

carbon emissions (Nzeadibe 2013; Oduro-Appiah et al. 2019). Recyclables such as plastic, glass, paper, and metals are supplied to commercial businesses. Organic waste which releases the most emissions due to its CH^4 composition is seldom recovered for large-scale impactful composting. Waste pickers in South Africa save municipalities an average of US$30 – US$70 million annually in landfill airspace, with little to no financial or operational support (Godfrey et al. 2016).

Material Recycling Facilities

There are many alternative waste management options available but not all are economically or contextually viable for the continent. Recycling activities and energy recovery technologies are currently being implemented but both on a very small scale. Technologies that can be reviewed are biological treatment, mechanical biological treatment, thermal treatment (incineration, gasification, and pyrolysis), and material recycling facilities (UNEP 2018). As mentioned in previous sections, Africa's recycling rate is only 4.0% annually. Municipalities are impeded by financial and infrastructure costs and private sector recyclers' business models do not cater to all waste producers due to affordability. Informal sector recyclers are an important aspect of the waste value chain (Godfrey et al. 2016). Material recycling facilities are an integral part of an integrated waste management model and offer a great opportunity for all the role-players to converge. The study focuses on material recycling facilities due to their ability to be implemented immediately, contextually, and cost-effectively.

Defining MRFs: An MRF is a plant where waste is received, sorted, and processed for revenue generation and to reduce negative environmental externalities (Hosansky 2018; Zafar 2019). The plants can be classified either as dirty or clean. Dirty MRFs process mixed waste which requires a lot of manual labor while clean MRFs tend to process waste that was separated at source and reduces waste contamination. MRF sizes vary from context to context. Zafar (2019) states that small MRFs process less than 10 tons per day and price ranges between US$500,000 and US$1 million. Price determinants are costs of building material, location, and the level of automation required. Large MRFs process more than 100 tons per day and are usually located in large cities. Due to the high automation process, the budget runs into millions of dollars. In a study by South Africa's Department of Environmental Affairs (2019), large MRFs can process between 1,200 and 1,500 tons of waste per month while small MRFs can process between 300 and 500 tons per month. Despite the varying sizes, MRFs have an important role within the waste value chain, primarily to improve waste separation and reduce waste streams before implementing additional management methods – see Fig. 4.

Role-players and Decision-Makers: there are many role-players along the waste value chain and their level of involvement is based on different contexts. Traditional actors include municipalities, private sector (business and industry), the informal market, waste producers, and civil society. Effective or noneffective coordination determines the level of successful implementation. During the planning stages, different levels of planning and decision-making constituencies in municipalities

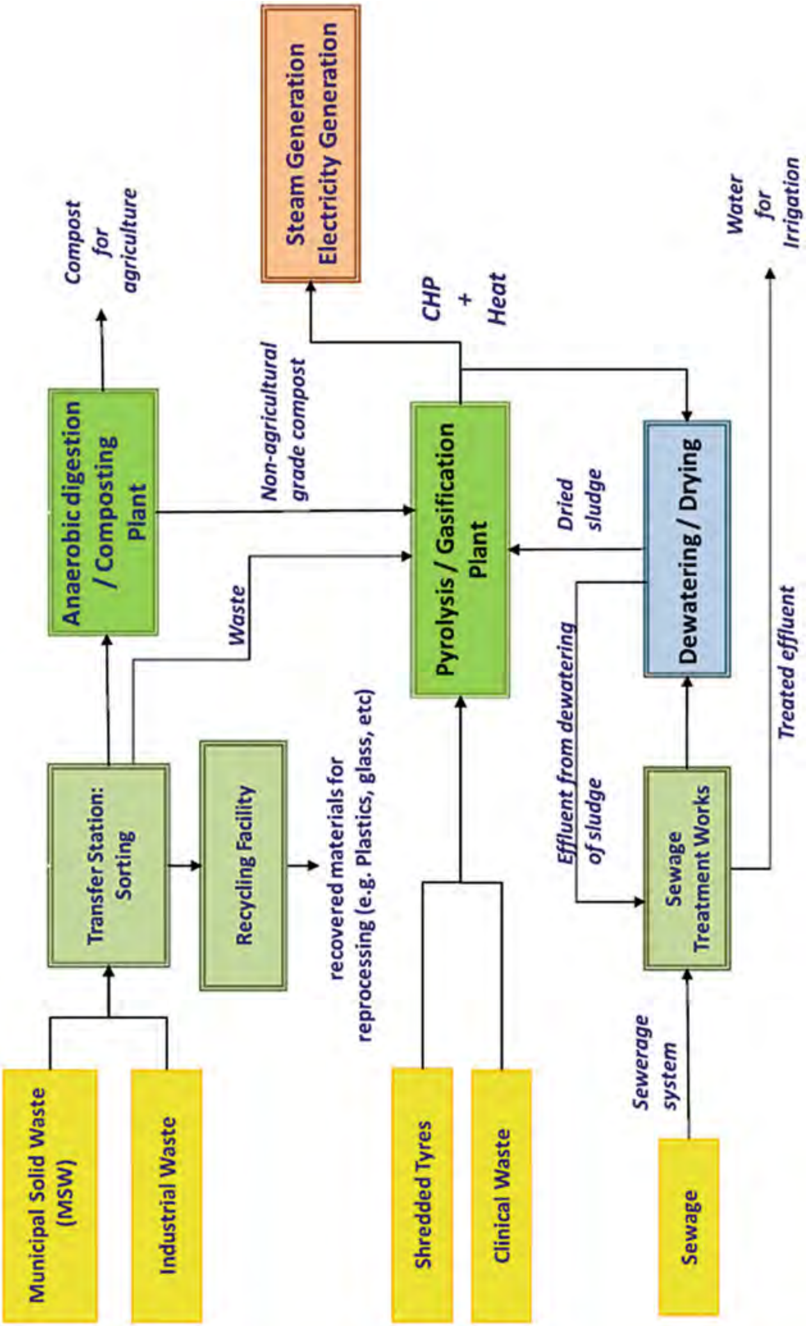

Fig. 4 Integrated waste treatment system (Trois 2014)

are involved. They need to be aligned to ensure sustainable waste management is implemented. According to Sango et al. (2014, p. 223) "*stakeholders in solid waste management include, but are not limited to, solid waste managers, technical/utility managers, municipal managers, chief financial officers, mayors, councillors and the public at the local municipal level.*" Their lack of involvement can negatively or positively impact technical design due to incorrect data, poor policy, and regulation considerations and accurate budgeting for building material and equipment. This is seen in the growing body of literature encouraging informal waste pickers to be integrated into solid waste management strategies.

Technical Design Considerations: Good knowledge and data on waste quantities and characteristics are imperative to an MRF's efficiency. However, 100.0% material recovery is not guaranteed due to the quality of materials and sorting efficiency as well as market conditions. Figure 5 presents a technical design for a proposed dirty MRF in South Africa. When waste arrives at the plant – either in waste bags or trucks – it is taken for preliminary treatment where waste volumes are reduced. Equipment such as bag splitters is used together with manual laborers to tear waste bags in preparation for sorting. At this stage, recyclables are sorted depending on the waste characterization (paper, plastic, glass, and metal). The quantities determine whether sorting will be entirely manual, semi-automated, or fully automated. Manual sorting is still important particularly for quality control purposes (Cioca et al. 2018; Department of Environmental Affairs 2019). The recyclables are then compacted and prepared for the market, for composting, and anaerobic digestion or residual is taken to the landfill.

Financing and Economic Instruments: It is important to standardize what a big and small MRF design will look like. The design should consider waste generation quantities and offtake markets for recyclables, supply and demand principles. Although mechanical MRFs are considered more economic because they can process 3.0 tons per hour with approximately seven operators compared to manual MRFs that process 1.0 ton per hour with 12 operators (Cioca et al. 2018), labor intensive activities should be highly considered in the African context because of job creation opportunities. Financing models range from public-private partnership, to fully publicly owned and operated. The proposed model is a public-private partnership where risks are shared and efficiency is maximized (Department of Environmental Affairs 2019). Economic instruments such as subsidies and taxes are designed to change consumer behavior. In the case of waste, they aim to reduce waste generation or induce waste diversion from landfills and dumps to recovery and recycling activities. Furthermore, they can also be used as a source of revenue for municipalities and implement service delivery (Nahman and Godfrey 2010).

Research Approach

An exploratory case study research approach was used. This involved empirical investigation of current consideration of MRFs in urban, waste management, and climate adaptation plans and strategies in selected African countries. The exploratory approach is intended to provide an understanding of what is available and set

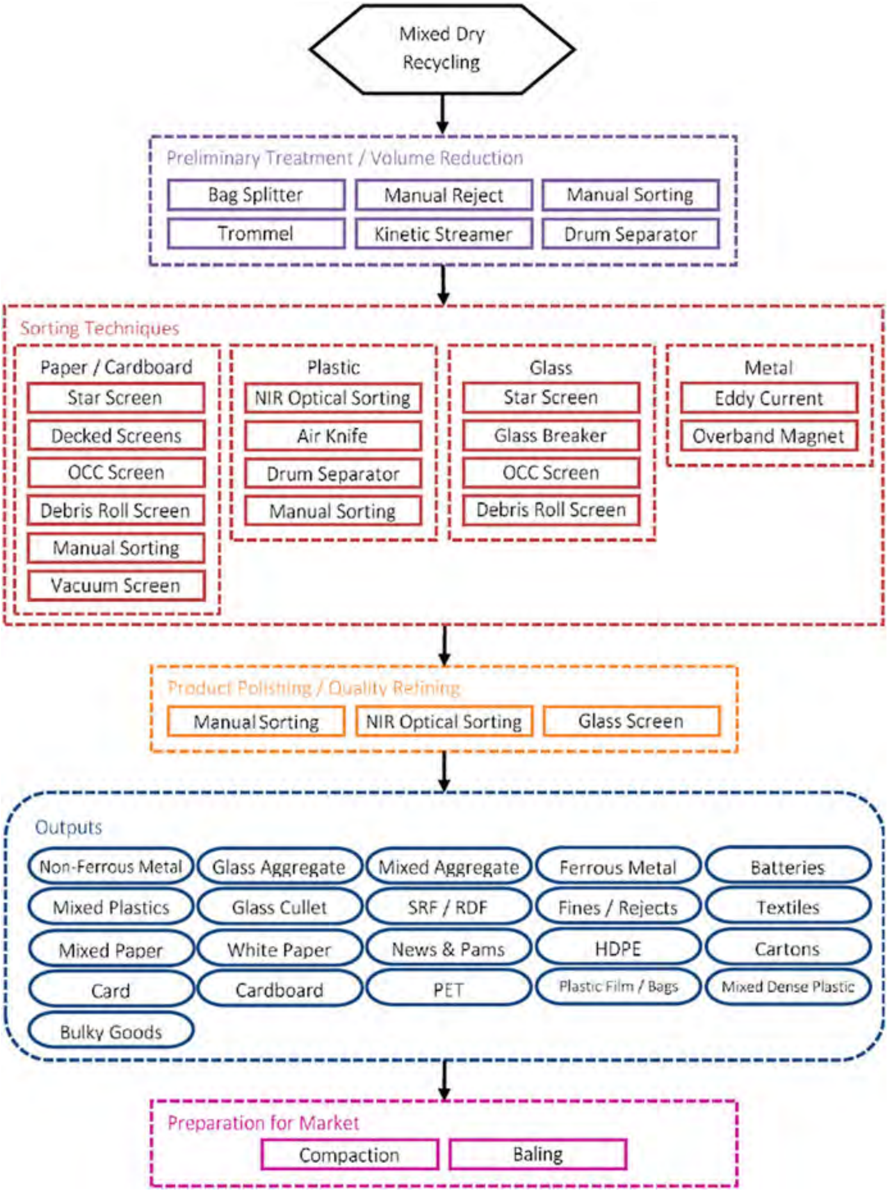

Fig. 5 Material recycling facility process (Department of Environmental Affairs 2019)

precedent for future investigation with participants and be more descriptive. Ethiopia, Ghana and South Africa were identified as targeted case studies based on three primary criteria: countries with the fastest growing cities in the respective regions, cities that committed to become zero carbon by 2050, and cities with some data on recycling, landfills, and open dumps – see Table 1. Selecting a case study

Table 1 Case study selection criteria of cities

Fastest growing	Committed to be carbon free	With landfills and open dumps
Angola (Luanda)	*Ethiopia (Addis Ababa)**	Botswana
Cameroon (Douala)	*Ghana (Accra)**	Cameroon
Cameroon (Yaonde)	Ivory Coast (Abidjan)	Dem.Rep of Congo
Dem.Rep of Congo (Mbuyi-Mayi)	Kenya (Nairobi)	*Ethiopia**
*Ghana (Kumasi)**	Nigeria (Lagos)	Gambia
Madagascar (Antananarivo)	Senegal (Dakar)	*Ghana**
*South Africa (Tshwane)**	South Africa (Cape Town)	Guinea Bissau
Tanzania (Dar es Salaam)	South Africa (Durban)	Kenya
Uganda (Kampala)	*South Africa (Johannesburg)**	Namibia
Zambia (Lusaka)	South Africa (Tshwane)	Nigeria
		Sierra Leone
		*South Africa**
		Tanzania
		Uganda
		Zimbabwe

KEY: * = countries with the fastest growing cities that are committed to being carbon free and have landfills/open dumps

per region allows for a comparative exploration. Secondary and grey literature provided further support and rationale for selecting these three countries. Two challenges experienced with Francophone and Lusophone countries were firstly, limited availability of recent data and secondly, some available data is presented in French and Portuguese.

Case Studies

Based on the range of impediments identified in section "Literature Review," the case studies explore whether the identified countries have urban, waste management, and climate change adaptation plans, strategies, and projects relating to MRFs. Discussions are themed according to factors used to determine suitable MRF design and adaptation planning, such as (1) Urbanization Dynamics, (2) Urban Waste Impediments, (3) Current and Proposed Strategies, (4) Role of Informal Waste Collectors, as well as (5) Nationally Determined Contributions (NDCs) focusing on waste management technologies.

Urbanization Dynamics

As in many African countries, rapid urbanization in Ethiopia, Ghana, and South Africa is a result of increasing economic activities particularly in large cities. Addis

Ababa is the capital city and seat of the Federal Republic of Ethiopia. It has a current population of 3.3 million (23.8% of all urban dwellers) and extends across 540 km^2 of land space. The administration is known as a City Government and it has 10 subcities known as *Kebele*. In Western Africa, the City of Accra – which is part of the Greater Accra Metropolitan Assembly – is the capital city of Ghana and accounts for 20.0% (1.5 million) of the country's total population (The World Bank 2017). More than 53.0% of Ghana's total population currently reside in urban areas and this figure is projected to reach 65.0% by 2030. The Accra Metropolitan Assembly (AMA) is responsible for all local government activities within Greater Accra. Further down south, the City of Johannesburg (CoJ) is the largest city in South Africa. With a population of 5.6 million (66.4%) spanning across 11 regions and 1,645 km^2 of land space. Like its counterparts, the City of Johannesburg Metropolitan Municipality is responsible for service delivery. Provision of basic amenities and infrastructure has not kept up with the urbanization rates in all three cities, thus resulting in more urban tensions such as social unrest and sprawling which induce climate change impacts.

Urban Waste Impediments

Waste management and poor sanitation infrastructure are a few of the services that governments continue to grapple with especially in low income areas. In 2013 Accra was generating 2,200 metric tons of waste per day and approximately 1,500 to 1,800 tons was collected by private sector. Between 2017 and 2018, generated quantities increased to 3,000 tons per day (Accra Metropolitan Assembly 2019). Waste collection and transportation alone cost the metropolitan GHC 450,000 (approximately US$77,000) per month and an additional GHC 240,000 (approximately US$41,000) to maintain dumpsites, resulting in 58.0% of waste and sanitation budget being spent on collection and transportation (Accra Metropolitan Assembly 2019). One of the factors that made collection and transportation difficult was the city's spatial planning. Oteng-Ababio et al. (2013) stated that "*Accra did not have the advantage of being a wholly planned city, since spatial planning was introduced after the town had developed on its own. Spatial planning is inconsistent at best, with semblances of colonial-era planning in (some) indigene areas such as Old Accra and Korle Gonno in Ga Mashie while migrant communities such as Nima, Sabon Zongo and Old Fadama continue to grow unplanned. Such unplanned settlements tend to be classified as 'poverty pockets' in the city, with a history of poor municipal investment in infrastructure services and under- and unemployment (particularly among the youth*)" (p. 98), resulting in lasting impacts on sanitary service delivery. Tuani (2008) resonates with the authors by stating that the unplanned nature of the city increased waste management issues, in particular land acquisition for landfills/open dumps and waste disposal sites. Additional challenges include poor separation at source, limited recent data, and limited optimization of other disposal plants.

Similarly, in Addis Ababa, waste collection and disposal are poorly managed. Citizens generate 730,000 metric tons of waste per annum (between 2,200 and 3,000 tons per day). Koshe landfill is the only landfill and biggest one in the city. It is located 13 km in the outskirts of Addis Ababa and the travel distances from other parts of the city make it inaccessible and costly. This results in poor collection and disposal in the nearest area. Just over 65.9% is collected by the metropolitan municipality and the remainder is disposed in unauthorized areas such as open fields, streets, ditches, and any available space within the city. Citizens do not have conviction in the metropolitan's ability to deliver waste management services, resulting in limited to no cooperation with waste related operations. Urban development and sprawling are occurring at a rate that government cannot service all households (Geda et al. 2011). Poor urban and road infrastructure make it difficult to collect data in highly dense settlements, further exacerbating effective implementation. The same sentiments are shared by Johannesburg where residents generate 1,492,000 tons of waste per annum and the four landfills cannot continue taking (City of Johannesburg Municipality 2011). Although other disposal measures such as recycling and composting are part of the city's management strategy, effective implementation is challenged by urbanization dynamics. In 2015, the Department of Environmental Affairs estimated that Johannesburg had between 5 and 8-years landfill airspace remaining (Department of Environmental Affairs 2018). Fast track to 2020, at least 5 years are up and pressure is increasing with population growth.

Current and Proposed Strategies

In Accra, AMA introduced two collection methods to help streamline collection and transportation: Communal Container Collection (CCC) and HtH (house-to-house). Households were required to pay a monthly collection fee, but those residing in low-income areas were daily and weekly wage-earners, they could not afford the service. Furthermore, areas where CCCs were located had bad road infrastructure. This presented locality and accessibility challenges. Since then there has been an increase in private sector participation, particularly waste collection. Affordability remains an impediment. Because waste was poorly collected, it was difficult for AMA to promote source separation. The ripple effect was poor planning and implementation of other disposal methods like composting, digestion, and recycling. Almost a decade later, waste management officials cite (1) community awareness, (2) effective collection systems, (3) limited disposal capacity, and (4) unplanned nature as ongoing challenges. Figure 6 discusses an investigation of Accra's urban planning, waste management and climate change plans and strategies to ascertain consideration for MRFs as an adaptation tool.

In the far East, containers are placed in common places each Kebele, close to main roads where waste trucks can access. Pushcarts are used to collect waste from each household at a fee. Those who cannot afford the fees carry their own waste to the container. Services are provided by Kebele workers and street sweepers (Cheru 2016). In 2017, the Reppie Waste-to-Energy Facility was commissioned, producing 25 MW of

Plans and Strategies - Accra

Accra Spatial Development Framework (2017) recognizes the various challenges presented by poor waste collection and disposal propelled by insufficient infrastructure and urbanization. It proposes that AMA 'explores job creation and economic opportunities associated with engineering service delivery, for example decentralize waste collection to locals / individuals. Furthermore, preparation and implementation of sanitation action plans for all leading urban centers, including related statutory regulations and by-laws ensuring effective collection, disposal and treatment of solid, liquid and toxic waste. The ASDF also proposes New Solid Waste Management Schemes and Environmental and Land-Use Policies but is not explicit about disposal methods, location determination or MRFs. Although it states that district level climate change mitigation and adaption strategies must be developed in order to plan for and implement requirements for climate change, additional details are not provided. However, detailed consideration is given in the Ghana National Climate Policy (2013). The policy recognizes the opportunities presented by beneficiating waste, problems with land acquisition for waste disposal as well as the need to increase recycling activities as means to reduce carbon emissions. It is reported that in April 2020, AMA entered into a public-private partnership (PPP) for Waste Transfer Site and Material Recovery Facility (MRF). Zoomlion currently operates a 200-tonne recycling plant in Accra. No reference of MRFs in Integrated Urban Environmental Sanitation Master Plan (IUESMP), Metropolitan Land Use and Transport Plan for Greater Accra Region, Emergency Solid Waste Management Improvement Programme13 (E-SWMIP), the Accra Climate Strategy and Integrated Urban Environmental Sanitation Strategy and Master Plan.

Fig. 6 Investigation and discussion of MRF consideration in Accra. (Source: Author's own compilation)

electricity. The facility is located next to Koshe Landfill site and waste has since been diverted for incineration instead, thus reducing emissions. There are traces of recycling activities but on a small scale at disposal sites (Geda et al. 2011). Private sector, community-based organizations, informal waste pickers, and international donor agencies are the main participants promoting some levels of at source separation and income generating activities. IGNIS was a joint project between Ethiopian and German partners. The project started in 2014, with the aim of implementing *income generation and climate protection by valorizing municipal solid waste in a sustainable way in emerging mega cities*. Strategies included creating individual waste recycling projects that could create employment and income opportunities while reducing GHG emissions. The project lasted until 2018 and provided valuable data to waste management agencies, namely composting (Gerji and Ataklet Tera Composting pilots) and biogas (Sidest Kilo and Menelik II preparatory School pilot) (Cheru 2016). Figure 7 also investigates Addis Ababa's urban planning, waste management, and climate change plans and strategies to ascertain consideration for MRFs for adaptation.

Johannesburg has better waste management infrastructure and initiatives. Pikitup is CoJ's waste management agency responsible for collection and disposal across 11 regions. As with many cities on the continent, increasing urbanization trends are causing stain on quality service delivery. CoJ has numerous private-public-partnerships throughout the waste value-chain to reduce the high costs of collection and disposal incurred. Most PPPs fall within waste collection and disposal. Formal urban areas have scheduled collection dates and residents have municipal bins. Some informal areas do have some sort of waste service and others do not. This results in pockets of illegal dumping. There are four landfill sites in different ends of Johannesburg and all four have reached their airspace capacity. Although CoJ has championed waste diversion activities such as recycling, composting, and pilot projects for small scale biogas projects, there is a need to increase these activities. The recycling sector is relatively well established compared to Accra and Addis Ababa. Associations such as South African Plastics Recycling Organization, National Recycling Forum, and the Institute

Plans and Strategies – Addis Ababa

Addis Ababa City Structure Plan (2017-2027) shares strategic plans and land use tools to improve urban development in the city. It recognises waste and climate related challenges as well as the need for improved recycling activities. The CSP states that it is preferable to make use of a mix of centralized and decentralized offsite and onsite liquid waste management systems as well as wastewater treatment technologies that do not consume large tracts of land. Interestingly, the plan proposes that three transfer stations with material recovery facilities (south, east, west) should be developed at each waste transfer station. The Draft Work Plan for Addis Ababa - Climate and Clean Air Coalition, prepared by the U.S. Environmental Protection Agency (2015) addresses the direct relationship between climate change and improved waste management.

The World Bank has a number of urban and climate change related projects underway in Addis Ababa. 'Enhancing Urban resilience Programme' was launched in 2013 to help cities strengthen their ability to prepare for and adapt to changing conditions, and to withstand and recover rapidly from disruptions related to climate change, natural disasters, and other shocks and stresses. The programme serves as an umbrella for delivering the analysis, rationale, and support local governments need to make resilience part of their urban management agendas. The 'Urban Local Government Development Project' (2008-2014) was designed to financially support the Ethiopian government "to support improved performance in the planning, delivery, and sustained provision of priority municipal services and infrastructure by urban local governments", inclusive of waste infrastructure.

Fig. 7 Investigation and discussion of MRF consideration in Addis Ababa. (Source: Author's own compilation)

Plans and Strategies – Johannesburg

Various national policies require municipalities to develop Integrated Waste Management Plans (IWMPs) and Integrated Development Plans (IDPs) every five years. The IWMP recognizes that development planning in the City must also consider waste service provision and therefore early engagement and communication between planners and those involved in waste management is needed. Composting facilities, MRFs and buy back centers are noted as action plans for waste diversion. Similarly, the IDP 2018/19 acknowledges the need to improve waste management infrastructure supportive of waste minimization and recycling as well as climate change. CoJ has Environmental Sustainability Strategy and Action Plan (2019) encourages spatial transformation in cities. This includes applying existing and develop municipal planning instruments to integrate and secure ecological infrastructure into the urban fabric.

Tedcor piloted a materials recovery facility (MRF) in Wadeville, near Germiston in Gauteng, in partnership with local buy-back centers. Droplets for Life – a private waste management company - have their own MRF situated in Wadeville, Gauteng. They receive waste through this facility from clients and from their our own waste. The facility processes approximately between 25 to 30 tons of recycling per month and employed 12 people currently from the disadvantage background. Training and up-skilling were provided to them according to their job specification. In 2014 CoJ commissioned a dirty MRF pilot at the Robinson Deep landfill in Turffontein, Johannesburg, Gauteng under the 'Separation at Source Programme'. The facility was processing 4,970 tons per annum of recyclable materials in 2014. MRFs do not tend to go beyond pilot stage due to low rate of recyclable recovery (Simelane, 2016)

Fig. 8 Investigation and discussion of MRF consideration in Johannesburg. (Source: Authors own compilation)

of Waste Management of Southern Africa collaborate with private sector, civil society, and academia to promote greater adoption. As with this Figs. 6, 7, and 8 discusses MRF consideration as an adaptation tool for Johannesburg.

Role of Informal Waste Collectors

Informal waste collectors play an integral role along the waste value chain. Through their activities, waste collectors assist municipalities to collect, separate, and recycle waste material because they do not have sufficient financial and nonfinancial capacity to provide efficient waste management alone. They operate in similar approaches despite not being recognized or integrated in municipalities' strategies and plans. Due to socio-economic factors, waste collectors continue to operate alongside the municipalities, collecting waste from household to household, designated communal containers and institutions.

In Accra, informal waste collectors continue alongside AMA but are not officially recognized. Known as Kaya Bola, they typically port waste from households or markets for a fee, separate the various material, and sell the recyclables for an income. Not being legitimized by local government induces ill-treatment and hostile social environment that keep them operating in an unorganized/informal manner (Oteng-Ababio et al. 2013). Presently, Kaya Bola collect and sort 25.0% of total waste generated for income but dispose worthless material in open drains and streams. The only sanitary landfill known as Knope has reached its capacity, leaving a few operational dumpsites scattered across the region, namely, Oblogo and Sarbah (Tuani 2008; Baah and Kharlamova 2018). It is located 37.0 km outside Accra which makes collection and transportation fees very high (The World Bank 2017). The distance and nature of road infrastructure from waste producers to Knope or other dumpsites is too far for informal waste pickers, more so for the small transport modes they use, for example, motorkings (Accra Metropolitan Assembly 2019).

Presently, informal waste collectors are not recognized as part of Addis Ababa's integrated waste management system. They are seen more as a potential enemy rather than partner (Cheru 2016). Waste pickers collect and sort for valuable recyclables and take them to sell at the Merkato Market place, the biggest market in Ethiopia. Various buyers are located there, ranging from independent buyers to factories. In Johannesburg, the lack of landfill space is increasing pressure on the municipality to integrate informal waste collectors along the waste value chain. The Wastepickers Empowerment Programme was launched in 2011 with the aim of creating a database of waste collectors in the metropolitan, skills training, assistance to establish cooperatives, provide protective clothing, and assist with fund raising. A pilot program was launched in 2014 and more than 500 waste collectors were registered and benefited from various skills training and personal protective equipment whiled 55 cooperatives participated in separation at source (Baker et al. 2016). The program can be scaled to other regions in Johannesburg but some lessons from the pilot would need to be considered:

- Consultation with different municipal stakeholders and recycling associations
  - Identifying suitable sites for sorting and storage
  - Establishment of guidelines for waste collectors
- Identification of waste collectors
- Sourcing external funding for training and equipment

There are opportunities to still officially integrate informal waste collectors in the city's strategies and plans. Associations such as the African Reclaimers Organization represent collectors' views in this regard. The Department of Environmental Affairs estimates that there are over 62,000 waste collectors in the country, with 40.6% operating as trolley-pushers (Mathye 2019).

Overall, various proposals and plans drafted by international organizations such as The World Bank and the African Development Bank stress the need to integrate informal waste pickers into waste management and increase waste transfer stations as strategies for climate adaptation. Their involvement in the waste value chain would boost collection rates and income.

Nationally Determined Contributions

The Paris Agreement requires every country to produce Nationally Determined Contributions (NCD). These are climate change policies detailing each country's plans towards adaptation and mitigation. Ethiopia, Ghana, and South Africa developed their NCDs. Ethiopia's plan recognizes carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) as priority gases that need to be mitigated by 2030. Key sectors producing these gases are agriculture, forestry, transport, industry, as well as waste and cities. In its medium to long term actions, drought relief is an action point where the government will "ensure the uninterrupted availability of water services in urban areas to make them comfortably and productively habitable irrespective of droughts through planning and construction of dams or deep wells, deployment of water saving technologies, and wastewater treatment infrastructure." South Africa's NCDs target agriculture, land use, and waste as targeted sectors for GHG reductions. However, energy is the primary focus.

Lastly, Ghana's adaptation and mitigation commitments strongly feature solid waste management in urban areas while ensuring positive socio-economic derivatives. The country committed to adopting alternative urban solid waste management by 2030. As an adaptation policy action, Ghana committed to building standards for urban waste management through city-wide infrastructure planning. Three mitigation action points include:

- Improve effectiveness of urban solid collection from 70.0% to 90.0% by 2030 and dispose all to an engineered landfill for phase-out methane recovery from 40.0% in 2025 to 65.0% by 2030.
- Scale up 200 institutional biogas in senior high schools and prisons nationwide.
- Double the current waste to compost installed capacity of 180,000 ton/annum by 2030.

There is an opportunity for MRFs to feature as adaptation or mitigation actions depending on each country's resources, more so for Ethiopia and South Africa.

Proposed Recommendations and Conclusion

It is evident from current strategies and plans in all three cities that there are opportunities for improved MRF adoption as well as consideration. Urban planners are responsible for designing and developing land, specializing in spatial and land use planning traditionally. Their involvement was seen in activities, decisions, strategies, and plans for infrastructure development and service provision which are prepared at local government, as seen in Accra's Spatial Development Framework, City of Johannesburg's Integrated Waste Management, and Addis Ababa's Urban Renewal Initiative. As part of the planning process, waste management and/or climate change officials could be included in the process. This was evident in the case of Kenya.

It was also evident that there is a need for the planning process to evolve with the profession and embrace the global push for sustainability and climate change by being more cognizant about waste management and climate change. A central point where all three disciplines converge is land: access to suitable land for disposal, proximity of land to citizens, and possibilities of land inducing negative or positive climate change impacts. In addition, knowledge and implementation of MRFs is generally unknown, with the exception of South Africa, where the Department of Environmental Affairs have taken interest. Climate change adaptation already

Table 2 MRFs as a climate adaptation strategy

Challenge	Recommendation	Adaptation strategy
Local governments spend at least 50% of total waste budget on waste collection and disposal	Consider exploring small-scale decentralized MRFs to address waste collection, transportation, logistics as well as improve data collection and beneficiation opportunities – climate adaptation strategy	Include more waste management and climate change matters in urban plans Integrate informal waste pickers in city waste management plans to create job in the informal sector
Waste generation and quantities are exacerbated by urbanization and population growth, straining local governments' ability to provide services	Using plans and strategies, planners identify land closer to waste producers and socio-economic activities driving waste generation Decentralize MRFs on a smaller scale to improve access. Closer to informal communities, shorter distance to travel and potentially more material recovery	Use Green Technology such as GIS and IT to map generation hot spots, determine material flows and data Design MRFs guided by technical and social dynamics around identified site
Informal waste pickers are not recognized by local governments despite positive impact in the waste sector	Decentralized small MRFs can assist to streamline waste pickers involvement Create associations or cooperatives for informal waste pickers	Provide training and technologies to women and people in informal communities to enable recycling of waste into other marketable products (e.g., paper briquettes, etc.)
		Develop zones in cities, suburbs and settlements to streamline the collection of waste by informal waste pickers

In Africa, where most countries are classified as low- and lower-middle income, there are many parameters to consider when selecting AWT technologies, including:

- sensitivity to the quantity and quality of waste;
- capital investment costs
- operation and maintenance (O&M) costs
- cost recovery potential
- efficiency of the technology
- end-product utility
- environmental impacts of operation
- land, energy and water requirements
- availability of local competences to properly manage the system
- inclusion of both formal and informal actors in the system

Guidance note: Lessons learned

- An appropriate technology should not be considered in isolation; it must be placed within an integrated waste management strategy.
- Both formal and informal actors must be considered to insure the efficiency of the waste management strategy (high level of waste collection, improvement of recycling and/or reuse, high material and energy recovery, social inclusion and income generation for the poorest people).
- The choice of the appropriate technology should consider the following:
  - The technology should be proven based on effective operating experience in African/low-income country contexts.
  - The technology should be economically viable in the context of low-income countries.
  - Technical issues related to the implementation of the technology should be easy to fix: the presence of qualified human resources for management and maintenance must be considered.
  - Low cost technologies are preferred as waste treatment solutions.
  - The technology should be an opportunity for social innovation (job creation, social inclusion, income generation).

Fig. 9 Measures to determine appropriate waste technologies (UNEP 2018)

involves plans and strategies, thus once again there is an opportunity to improve adoption and implementation of MRFs as a land-use and adaptation strategy, and urban planners can aid to drive that inclusion. Table 2 below suggests how including MRFs can be considered as a climate change adaptation measure for the three cities and beyond:

For MRF Facility Design: it is important to determine and measure the appropriateness of waste technologies for the continent because of varying drivers, pressures, and parameters (Fig. 9).

Although Africa contributes 4.0% of the worlds' GHG emissions, with these proposed adaptation strategies, many cities can reduce future emissions and leapfrog into full sustainability despite the current urban and waste related challenges.

Nigeria are likely to be large, motivating the need for additional knowledge to assess current practices and formulate appropriate modifications for both mitigation and adaptation. Some current farming practices are believed to be adaptive, but further study would provide better assessments. We also analyzed the trade-offs between household income and GHG emissions at two contrasting sites in northern Nigeria. A farm optimization model maximizing the value of crop, livestock, and tree production activities in a single representative year assessed the potential impacts for GHG reductions of 10% and 25% and the maximum allowable reductions of 26% and 30% on farm activities and income. Emissions reductions of 10% reduced annual household incomes by less than 5% but required substantive changes, especially in livestock owned. Maximum possible GHG emissions reductions (while still meeting minimum household consumption needs) would require marked changes in production pattern and would lower household incomes by 22–44%. We did not assess effects over longer periods, where the role of livestock as a key asset may imply additional negative impacts. Productivity-enhancing technologies that would simultaneously reduce GHG emissions and increase incomes are needed for smallholder farms to play a larger role in climate change mitigation without the burden of reduced incomes and greater risk. This suggests the need for programmatic and policy actions both by national agricultural research systems and the Consultative Group for International Agricultural Research (CGIAR).

Keywords

Climate change · Agriculture · Nigeria

Introduction

Agriculture is the major employer of labor in Nigeria (Hansen et al. 2017) for over 70% of the estimated 200 million inhabitants (United Nations Department of Economic and Social Affairs: Population Division 2020). Almost 80% of over 70 million hectares of Nigerian land areas are under rainfed agricultural production that translates to about 40% of national Gross Domestic Product (GDP) (World Bank 2020). Agriculture is also a major contributor to greenhouse gas (GHG) emissions, as described below.

Overview of Greenhouse Gas Emissions from Agriculture in Nigeria

Agriculture was the largest of the four major sectors that contributed to Nigeria's GHG emissions in 2015. Agriculture, Forestry, and Other Land Use (AFOLU) accounted for two-thirds of total net national emissions of Teratonnes (Tt) CO_2 equivalent (CO_2-eq). The AFOLU sector includes emissions from land use, livestock, and removals from harvested wood products. Land use accounted for an estimated 421 Tt CO_2-eq, or about 90% of emissions from AFOLU. One principal source of land-use emissions is methane (CH_4) and nitrous oxide (N_2O) from burning of rice, maize, sugarcane, and wheat residue biomass. Other sources include direct and indirect emissions of N_2O from nitrogen-based synthetic fertilizers used in managed soils, indirect emissions of N_2O from manure management, and direct CH_4 emissions from rice cultivation. For livestock, enteric fermentation and manure management for cattle, sheep, and goats contributed 29 Tt CO_2-eq, with the remaining amounts from camels, mules, swine, and horses. Enteric fermentation was 90% of total livestock-related emissions, with the remainder from paddock, range, and pasture and solid storage systems of manure management. N_2O and methane CH_4 were the most important GHG from manure management.

Total GHG emissions continue to increase. In 2019, the United States Aid for International Development (USAID) reported a 25% increase of 98 Mt. CO_2-eq in the country's overall GHG emissions from 1990 to 2014. The average annual change in total emissions was 1% and was mainly from the land-use change and forestry (LUCF) sector. Similarly, a trend assessment from the period 2000 to 2015 showed that AFOLU remained the highest emitter of GHG throughout the years under review (Federal Republic of Nigeria 2018). Emission from land-use category, forest land remaining forest land remained the principal source, and it increased by 25% during the period, whereas removals through HWPs declined by 28%. There was an estimated 37% increase in emissions from rice cultivation, livestock production, manure management, and nitrogen-based synthetic fertilizers in managed soils over the entire period. The increase was attributed to the increase in livestock populations and more utilization of nitrogen-based synthetic fertilizers in managed soils as well as forest biomass loss. Thus, Nigeria's emissions are projected to grow to around 900 million tons per year in 2030, which translates to around 3.4 tons per person (Change Climate Response Policy 2015).

Impacts of Climate Change on Agriculture in Nigeria

Changes in climate, in particular, the frequency or severity of extreme events, are likely to have serious implications for rainfed agricultural production. Given the diversified socioeconomic conditions of agriculture in Nigeria, climate change could affect crop yields, disease patterns, and compound ecological disasters that include quelea bird's invasion, floods, and drought (Ajetomobi et al. 2015). However, the impacts are likely to vary by region. A vulnerability analysis conducted in 2014 by Nigerian's Federal Ministry of Environment indicated that states in the north experience higher degrees of vulnerability to climate change than those in the south (Haider 2019).

Many crops are sensitive to the modest changes in rainfall and temperature (Haider 2019). For example, the annual mean temperature needed for photosynthesis and growth is about 29 °C for maize and soybean. Currently, mean annual temperatures ranges from 30 °C to 34 °C. A mean annual temperature of 33 °C is desirable for cotton, and temperature above this threshold can be harmful to plant development (Ajetomobi et al. 2015). The combination of increasing temperature and lower rainfall has hastened desert encroachment, with loss of the wetlands, and rapid reductions in the amount of surface water, flora, and fauna resources on land. Kebbi and Jigawa states observed 5–10% reductions in millet yields due to Quelea bird invasion, in addition to drought in Katsina, whereas Sokoto, Zamfara, Kaduna, and Kano states reported between 10% and 25% loss in groundnut yield from heavy floods (National Agricultural Extension and Research Liaison Services (NAERLS) & Planning Research and Statistic Department (PRSD), 2012). Rainfall intensity and distribution have been altered from the usual 500–1000 mm per year. Flooding in 2012 resulted in 363 deaths, massive economic loss, and the displacement of more than 3.8 million people. The total value of destroyed physical and durable assets was reported to be 1.48 trillion (US$9.5 billion) or about 2% of the rebased GDP of US$510 billion (Change Climate Response Policy 2015).

Under the business-as-usual scenario of the Change Climate Response Policy (2015), Nigerian agricultural productivity could decline by up to 50% by 2080, with reductions in GDP as large as 4.5% even by 2050. Consequently, in the absence of mitigating measures, there would be steady depletion of vegetation and grazing resources in affected regions. This could also prompt massive emigration and resettlement of people to areas less threatened by desertification. Subsequently, exacerbating communal clashes among herdsmen and farmers and inter-ethnic clashes (Haider 2019).

Adaptation and Mitigation Strategies for Nigerian Agriculture

Climate change mitigation is the improvement of agricultural production practices to reduce GHG emission, while adaptation involves the uptake of agricultural practices to be more suitable for a modified climate in a particular location (IPCC 2007). Nigeria is now implementing the reduction of emissions due to deforestation and forest degradation (REDD) (USAID 2019), through the national community-based forest resources management program. Other mitigations and adaptation strategies include the adoption of climate-adapted crops (e.g., drought-tolerant and early maturing varieties of crops) and in the livestock sector, improved feed, pasture, ranch, and paddock management systems (Change Climate Response Policy 2015). Programs are also being implemented to reduce the volume of irrigation water, while making more effective use of rainwater and groundwater. Other efforts are directed at providing early-warning seasonal climate forecasts to facilitate adaptation in a given growing season.

However, such adaptation and mitigation strategies are location- and context-specific and are described as autonomous or opportunist adaptation (Haider 2019). Planned adaptation strategies require additional knowledge about appropriate levels of inputs, tillage practices, and assessment of the future environmental conditions (e.g., rainfall, temperature, and relative humidity). Research to assess and implement actions for both adaptation and mitigation. Simulation modeling can support assessment of adaptation strategies, particularly when experimental data are limiting and future environmental conditions uncertain (Nicholson et al. 2011; Kopainsky and Nicholson 2015). Consistent with the ongoing need for site-specific quantitative studies, the remainder of this chapter describes the use of modeling to assess the impacts of potential mitigation strategies on smallholder farming systems in the Northwestern area of Nigeria (Ayinde 2019).

Farm-Level Impacts of GHG Emissions Mitigation Strategies in Sudano-Sahelian and Sudan Savanna Ecological Zones in Northwestern Nigeria

An important question concerns the trade-offs among agricultural production, household incomes, and environmental impacts. To date, there are few studies that examine what actions would be required to reduce GHG emissions from smallholder agriculture production systems, and to understand the implications for household well-being. Northwestern Nigeria provides a conducive context for quantitative assessment of farm-level GHG mitigation strategies because it is a highly degraded region with higher degrees of vulnerability to climate change (Haider 2019). Within this region, differences in agro-ecology and production systems necessitate separate assessment of GHG-reduction strategies. Ayinde (2019) thus explored the production practices at two sites, the Bunkure (Sudan Savanna ecology) and Maigateri (Sudano-Sahelian ecology) local government areas (LGAs) located in Kano and Jigawa States, respectively (Fig. 1). The objective of the analysis was to describe predominant farming systems and discuss the extent to which they are consistent with either adaptation or mitigation strategies, and to evaluate quantitatively the impacts on agricultural production and potential trade-offs between household revenue and GHG emissions.

Kano and Jigwa differ in multiple respects, which facilitates a comparative analysis of mitigation strategies at the farm level. Kano is the most-extensively irrigated state in the country for the cultivation of rice, sugarcane, and vegetables, which are important emitters of GHG (IPCC 2013; Dunkelberg et al. 2014). Jigawa is characterized by shorter rainfall duration that does not support irrigated farming but sustains hardier shrubs and trees. In the LGAs of both states, however, mixed farming of grain and legume crops, trees, and livestock keeping are practiced.

Ayinde (2019) used participatory rural appraisal (PRA) and key informant interviews to characterize existing production systems at both study sites. Data were collected on the economic and environmental performance of the predominant production systems, land preparation, retaining of trees on crop field, use of trees branches and stem for firewood, use of crop residue as mulch, modified planting dates, use of early maturing crop variety, and agrosilvopastoral system. Emphasis were on trees that could serve multiple purposes of dry season feed, enriching soil Nitrogen, increasing protein and energy content in fodder while mitigating GHG emissions. This information was necessary to assess whether the production practices employed aligned with either a mitigation or adaptation strategy. The key

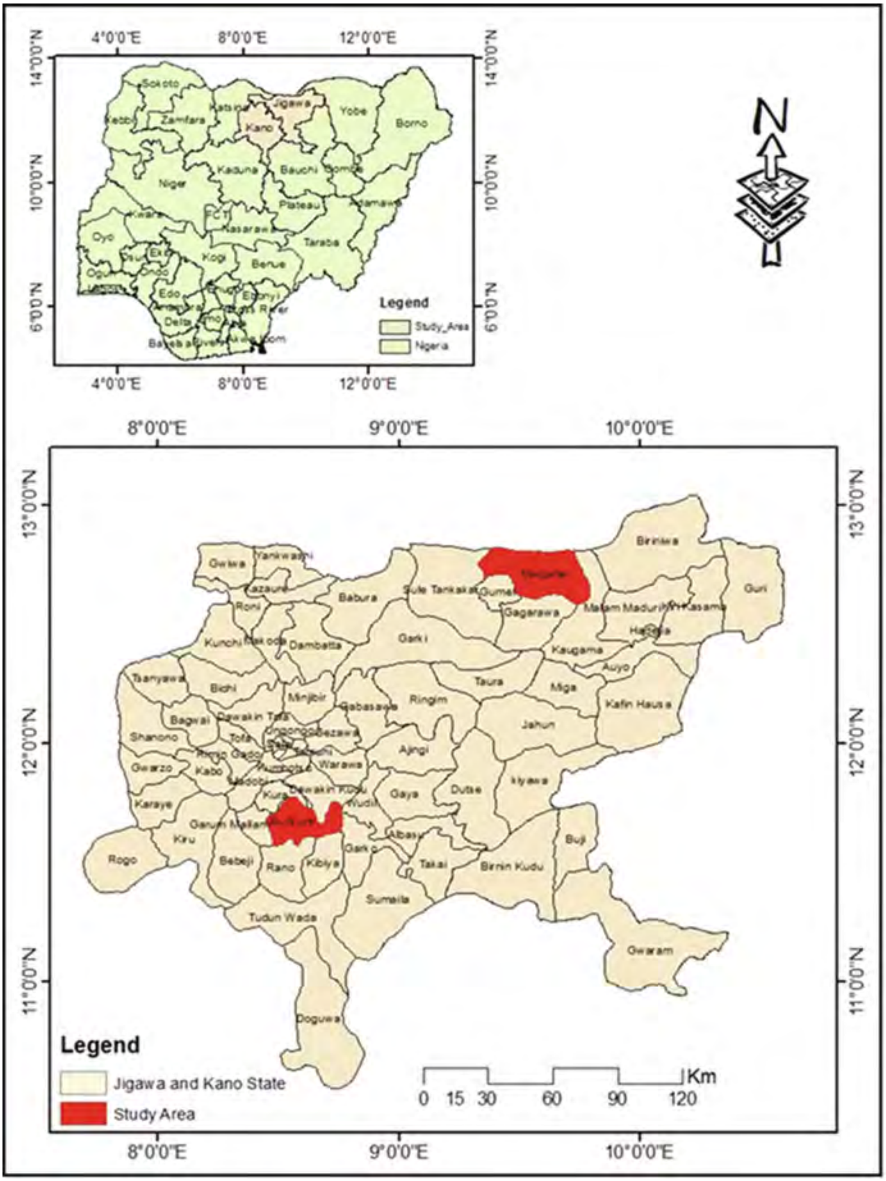

Fig. 1 Locations of the study sites Maigateri in Jigawa State and Bunkure in Kano State

informant interviews provided data of estimates of household-level expenditures on tree, crop, and livestock activities (See the assumed structure of inputs and outputs in the tree-crop-livestock production optimization model Appendix Table A1), the cost of animal draught, and the cost of manure applied. The description of the key specific inputs used in the current production practices were necessary to estimate the GHGs emissions (CH_4, N_2O, CO_2, and non-CO_2) in Appendix Tables A2.1 and A2.2.

The emission factors (EF) used to estimate GHG emissions to specific farm activities were obtained from IPCC Tier 1 default equations as well as methods from Standard Assessment of Mitigation Potentials and Livelihoods in Smallholder System (SAMPLES; www.samples.ccafs.cgiar.org) that corresponds to the predominant production systems in the study region. Data on dry matter (DM), metabolizable energy (ME), and crude protein (CP) that corresponded to the tree and crop yield levels were obtained from secondary sources such as feed composition tables or journal articles and grey literature including Feedipedia; FAO source: (http://www.fao.org/ag/againfo/themes/documents/PUB6/P620.htm); and (Dupriez and De Leener 1998).

To assess the potential impacts on agricultural production patterns and full household income scenarios evaluated a baseline (current practices and emission levels) and required GHG reductions of 10%, 25%, and the maximum reductions consistent with meeting assumed household consumption needs (26% and 30% reductions compared to the baseline). See the detailed description of the optimization model used to assess trade-offs between household welfare (income) and farm-level GHG emissions in Appendix 1.

Current Production Practices as Adaptation or Mitigation Strategies

A key finding was that farmers were aware of the multiple uses and economic value of trees for wood, food, fuel, fodder, soil protection, and soil reclamation (Table 1),

Table 1 Tree and crop (cereal and legume) production practices reported by households in Bunkure and Maigateri

	Bunkure		Maigateri	
	N = 50		N = 55	
Crop type and production practice	Frequency	Percentage	Frequency	Percentage

Legume				
Predominant legume grown	30	60	29	53
Sell	45	90	42	76
Fodder to own livestock	4	8	10	18
Soil amendment	1	2	3	6

similar to previous studies (Change Climate Response Policy 2015; UN-REDD Programme 2015). Consequently, not all trees were lopped on crop fields. For instance, 30% and 44% of farmers in Bunkure and Maigateri LGAs, respectively, predominantly allowed their Neem (*Azadirachta indica*) trees to remain on the crop fields validating the finding of (Bayala et al. 2011). About 36% (Bunkure) and 42% (Maigateri) of farmers sowed some selected trees that are used mainly as live fences around their farms with 38% of its biomass mostly used as fuel in Bunkure LGA and 31% as manure in Maigateri LGA.

Furthermore, of all the trees allowed to remain on the farm, none met the criteria for the study (i.e., dry season feed, enriching soil nitrogen, increasing protein and energy content in fodder while mitigating GHG emissions like Locust-beans (*Parkia biglobosa*), Camel's foot/*Kalgo* (*Piliostigma reticulatum*) and are distinctively the most popular leguminous tree owned by 10% in Bunkure LGA and 24% of farmers in Maigateri LGA. Personal conversation with staff members of the outstation office of Forestry Research Institute of Nigeria (FRIN), in Samaru (Zaria, Kaduna State) revealed that Locust-beans/*Dorowa* (*Parkia biglobosa*), *Kalgo* (*Piliostigma reticulatum)*, and *Gawo* (*Acacia albida*) trees were generally not planted because their seedlings or seeds were undomesticated thus, virtually unavailable. It is further compounded by the long period of growth (Bayala et al. 2014). However, efforts of FRIN were said to be underway to ensure the availability of Locust-beans (*Parkia biglobosa*) seeds or seedlings for propagation with growth period under 7 years as against the natural one of between 12 to 15 years.

Sorghum was the predominant cereal grown by over 50% of farmers in the two study locations. Most farmers in both LGAs (50% and 53%), reported that their sorghum residues comprised an adaptation plan for dry season supplementary feed/ feed reserve for their ruminant livestock. About 60% of farmers in Bunkure LGA cultivated Soybean while, 53% in Maigateri LGA cultivated groundnut as their predominant legumes. Despite the numerous benefits of soybean and groundnut residue biomass for nitrogen fixation and GHG mitigation when used for soil amendments as an adaptation strategy, majority of farmers in Bunkure and Maigateri LGA sold their crop residue biomass. The implication of these practices are consequential as it may lead to more emissions of CH_4, CO_2, and N_2O, which may result in accelerated nutrient depletion from burning of bushes and crop residues, leaching, and acid rains (NH_3 of volatilization) from the application of inorganic fertilizer (IPCC 2013). Once there is accelerated nutrient depletion, there may be gross production declines.

Farmers in the study zones claimed that unplanned consumption by free ranging livestock reduced the incentives for use of crop residues soil amendments. Therefore, except by-laws and community conventions are in place to restrict free grazing, the use of biomass for soil amendment faces constraints for the poorly sourced farmers of Bunkure and Maigateri LGAs, who would rather sell their crop residue than have them consumed by free-ranging livestock.

Adaptation strategies such as change in sowing dates and use of early maturing varieties were adopted by most farmers in the regions. However, such practices in addition to mulching are merely coping/autonomous or opportunist strategies by

Table 2 Livestock production reported by households in Bunkure and Maigateri

	Bunkure		Maigateri	
	N = 50		N = 55

Seasonal tethering/cut and carry	19	38	15	37
Intensive/peri-urban ruminant husbandry	1	2	1	2

farmers as described by Haider (Haider 2019). More is required of these practices in terms of investment in infrastructure, subsidies, research, innovation, and tax regimes to attain planned adaptation strategies.

Livestock production is a major activity among smallholder farmers in Bunkure and Maigateri, LGAs. During the focus group discussions, farmers reported that most crops were sold immediately after harvest. Revenues from crop sales were used to purchase animals, particularly ruminant livestock. The Red Bororo (100%) is the major breed of cow in Maigateri LGA, whereas Sokoto Gudali is reared by 60% of farmers in Bunkure LGA (Table 2). A cow, 5 sheep, and 6 goats are the average herd size of cattle, sheep (Uda), and goats (Red Sokoto or Maradi Breed) owned per household in Bunkure. Households in Maigateri owned an average of 2 cows, 12 sheep, and 14 goats. Livestock is fattened for up to 7 months and then sold. Part of the revenues generated from livestock sales is used to acquire farm inputs for another planting season.

Farmers in Bunkure and Maigateri LGAs believe a successful adaptation strategy is “compound dairy” (a traditional system of milking in which animals are confined to the compound rather than allowed to graze). The cows supply the family with fluid milk for consumption and any excess above household needs is sold or processed into other dairy products. In this system, dairy animals were either tethered and fed on traditional cut and carry using cereal/legume crop residue or allowed to graze freely around the compounds in the day and confined in the night in the wet season. It was the most widely practiced adaptation mechanism among all households as confirmed by 98% of households.

A key issue with the compound dairy is whether it is possible to achieve higher productivity per animal from increased grain cultivation, without increasing GHG emissions. The use of concentrates or cultivation of pastures for supplementary feeding of indigenous Zebu and Ndama breeds of cattle is uneconomical and of doubtful feasibility (Ayantunde et al. 2007). Because, there is no strong evidence of economies of scale, due to under-utilized family labor and the ability of ruminants to exploit low-value roughage, including that gathered or grazed from public lands (Mcdermott et al. 2010). Moreover, higher-productivity breeds cannot generally replace indigenous Zebu and Ndama breeds of cattle, as these breeds are not suitable for North-western Nigeria (Ayantunde et al. 2011). Although studies confirm

Table 3 Optimal farm-level tree-crop-livestock production decisions for the three scenarios in Bunkure and Maigateri LGA

Outcome or activity	Units	Bunkure				Maigateri

improved feeding and manual management system as mitigation strategies that reduce total emissions of CO_2, CH_4, and N_2O in the livestock sector, the extent to which this is possible requires further study to determine appropriate strategies for location-specific reductions.

Farm-Level Trade-Offs Between Income and GHG Emissions

GHG reductions of up to 26% were possible with assumed minimum levels of household consumption in Bunkure LGA (Table 3), but reduction would require reductions in farm-level revenue of more than 20%. Reductions were achieved essentially from reductions in the sales of sheep meat, locust bean pod, branch, and trunk in addition to a reduction in the sales of sheep manure (Appendix Table A3). Maximum possible decreases in GHG emissions require reduction of livestock to minimum assumed household consumption levels and a reduction in profitable locust bean production through reduction in land area by 29%. Similarly, quantities of purchased input used for locust bean production, reduced significantly for urea, seeds, and agricultural pesticides. Below 26%, the model could not attain feasible adaptation strategies because it could not meet household requirements as assumed.

In Maigateri LGA, GHG reductions of up to 30.5% could be attained with minimum levels of household consumption. However, such reductions in GHG emissions would require reductions in farm-level revenue of about 44%. Reductions in GHG emissions were accomplished primarily decreases in groundnut, cow, and sheep production and from up 100% reduction in the sales in the livestock component as well as 55.7% reduction in sales of groundnut grain in the crop component. Maximum GHG emissions reduction implied decreases in groundnut production, in addition to the reduction of livestock to minimum assumed household consumption levels.

By implication, the assessment of trade-offs that indicate potential pathways for increased agricultural productivity with fewer negative environmental effects, are usually location- and context-specific, thus difficult to generalize, categorize, and describe in contrasting socio-ecological contexts (e.g., Thornton et al. 2018). Yet, it could be futile to identify win–win production without a framework to generalize them into policy recommendations and developmental actions. The major contribution of this chapter is the establishment of a generic conceptual framework that can be used across farms of different agro-ecological zone. Particularly for comparative assessment and prioritization of policy options, that could be scaled up from local/community or farm level to regional or country levels.

However, better understanding of trade-offs is needed to attain win–win scenario (Steenwerth et al. 2014; Klapwijk et al. 2014; Kanter et al. 2016). More accurate indices and numbers could be achieved with the use of system dynamic model analyses (Sterman 1989; Kopainsky and Nicholson 2015), and could be considered as suggestion for further studies.

Conclusions

This chapter has documented the importance of agriculture and land use in the generation of GHG emissions in Nigeria, and the need for both adaptation and mitigation strategies in smallholder agriculture. The farm-level impacts provide information needed to formulate appropriate mitigation and adaptation strategies for going forward in climate-smart agriculture. A key finding from the farm-level analysis is that revenue generated decreases with GHG emissions mitigation and adaptation. Maximum possible GHG emissions reductions (while still meeting minimum household consumption needs) would require marked changes in production pattern and would lower household incomes. There appear to be no win–win adaptation strategies with current production practices and technologies that both increase revenue generation and reduce GHG. Productivity-enhancing technologies that would simultaneously reduce GHG emissions and increase revenue are needed for smallholder farms to play meaningful climate change mitigation and adaptation strategies in Nigeria without the burden of reduced incomes and greater risk. We also did not assess effects over longer periods, where the role of livestock as a key asset may imply additional negative impacts. This suggests the need for programmatic and policy actions to be taken by both national agricultural research systems and the Consultative Group for International Agricultural Research (CGIAR) to promote climate-smart agriculture in Nigeria.

Acknowledgments This study was conducted with the financial support of the Standard Assessment of Mitigation Potentials in Smallholder Farmers Livelihood System (SAMPLES), a CGIAR Research Program on Climate Change, Agriculture, and Food Security (CCAFS).

Appendix 1: Detailed Description of the Optimization Model Used to Assess Trade-Offs Between Household Welfare (Income) and Farm-Level GHG Emissions

The Farm-Level Optimization Model

The farm model (Eq. 1) assessed the potential trade-offs between GHG reductions and farm revenue with the aim to identify the impacts of possible mitigation strategies and facilitate future analysis of potential adaptation opportunities through production practices that result in both reduced emissions and increased farm incomes.

The objective function Z maximizes net household full revenue generated, given by:

$$Z = -\sum_{m=1}^{12} W_m \cdot X_m^L - \sum\nolimits_{i=1,j=1}^{i=4,j=6} P_i \cdot X_{ij}^I + \sum_{j,p=1}^{20} C_{jp} \cdot X_{jp}^P \quad (1)$$

where

W_m= Wage paid per hour of hired labor in month m
X_m^L = Hours of labor hired by the household in month m
X_{ij}^I = Purchased input i for tree or crop production activity j
P_i = Price of purchased input i per unit
C_{jp} = Unit value per kg for subproduct p of tree, crop, or livestock activity j
X_{jp}^P = Production of subproduct p of tree, crop, or livestock activity j

The objective function maximizes the total value of products derived from activities $j = 1$ to 6 locust bean and camel's foot in Bunkure and Maigateri, respectively. Represented as tree species. Branches and trunk of the Locust bean and Camel's foot trees can be used to meet household firewood requirements. Sorghum, legumes species are predominantly soybean in Bunkure and groundnut in Maigateri. While livestock includes cows, goats, and sheep production. "Full income" is specified as sum of product sold by the household. In addition to the opportunity cost of product consumed by the household less the costs of hired labor and the value of purchased inputs $i = 1$ to 4 that include fertilizer (NPK mix and urea), agricultural chemicals, manure, and seed for grains and legumes. Each of the products has subproducts that are either sold to generate revenue or used as internally generated inputs (Table A3) or used as internally generated inputs on the farm (Table A1). A total of 20 *(j, p)* combinations of activities and subproducts are represented.

Land is one of the basic farm household resource constraint and the predominant land type (upland) used for rainfed production is modeled with the following equation:

$$L \geq \sum_{j=1}^{6} L \cdot X_j^P \tag{2}$$

which shows that the total land available to the household, L, must be greater than or equal to total land used for annualized production activities j, X_j^P. Thus, for model simplification, the agricultural activities were assumed to be yearly. Land rental is excluded to avoid unbounded solutions.

A labor constraint signifies that the sum of household labor H_m and or hired labor, X_m^L available must exceed or meet total labor required for agricultural production activities, X_j^p

$$H_m + X_m^L \geq \sum_{j=1}^{7} a_{jm}^L \cdot X_j^p \tag{3}$$

The purchase of inputs used for production activities is given by the product of the activity X_j^P and the fixed coefficient a_{ij}^I

$$a_{ij}^I \cdot X_j^P \leq X_{ij}^I \tag{4}$$

Inputs produced on-farm and used for other production include tree fodder, crop residue biomass, manure, and milk. Tree fodder and crop residues are used as animal feed or soil amendment. Tree components were partitioned using formula adapted from Powell et al. (1995) and Bayala et al. (2014). Residue obtained as by-product from sorghum production were derived, using formula for harvest index adapted from Powell et al. (1995). Similarly, manure is used as fertilizer, while milk is used to feed young livestock. Formula for calculating manure production was in line with Powell et al. (1995) and Ayantunde et al. (2000). The relationships are represented by this equation:

$$\sum_{j'} a^{R}{}_{j',j} \cdot X^{P}{}_{j'} \geq \sum_{j} a^{R}{}_{j,j'} \cdot X^{P}_{j} \tag{5}$$

The equation above requires that the amount available from the sum of production of *j'* sources must be greater than or equal to the sum of farm-generated resource used. The model includes constraints for animal nutrient requirements: dry matter (DM, kg/day), crude protein (CP, g/day) and metabolizable energy (ME, in mega joules, MJ) FAO, http://www.fao.org/ag/againfo/themes/documents/PUB6/ P6 20. htm: that states the recommended daily ME for maintenance of sheep and goat is 5.1 and for cow producing less than 5 lit per day is 46 ME MJ/day. Recommended daily CP and DM requirement is 3% animal body weight, with average weight of 350 kg cow, 20 kg sheep, and 20 kg goat translating to 400, 32, and 32 g CP/day, respectively

The constraint in equation 6 requires the diet fed to livestock must be less than or equal to the nutritional requirements for metabolizable energy (ME), crude protein (CP), and dry matter (DM) is represent thus:

$$\sum_{j',p} a^{NS}{}_{j',p,n} \cdot X^{USE}{}_{j',p,j} \forall j \in \text{animal}, (j', p) \in \text{feeds} \geq a^{NR}_{j,n} \cdot X^{P}_{j} \tag{6}$$

which indicates that the sum of the *(j,p)* the product of feeds allocated to animals of type j, $X^{USE}_{j',p,j}$ and the nutrient content of those feeds, $a^{NS}_{j',p,n}$, must exceed the required $n = 3$ nutrients for animals of type j, $a^{NR}_{j,n} \cdot X^{P}_{j}$

Products *(j, p)* allocated to household use $X^{HH}_{j,p}$, also must meet minimum household consumption requirement $\text{HHR}_{j,\,p}$, as follows:

$$\text{HHR}_{j,p} \leq X^{HH}_{j,p} \tag{7}$$

A balance constraint ensures that uses of products *(j, p)* for household consumption, sales, or use in production is less than or equal to the total sources supplied:

$$X^{HH}_{j,p} + X^{SALES}_{j,p} + \sum_{j'} a^{R}{}_{j',j} \cdot X^{P}_{j} \leq a^{YLD}_{j,p} \cdot X^{P}{}_{j,p} \tag{8}$$

Table A1 Assumed structure of inputs and outputs in the tree-crop livestock production optimization model

Activity (j)	Inputs	Output	Saleable output	Consumed output
Locust bean and Camel's foot trees	Seeds, urea fertilizer, pesticides, labor, manure	Fodder, pod, pod valve, bran, branches, and trunk	Fodder, pod, pod-valve, bran	Pod, branches, and trunk
Sorghum	Seeds, urea, and NPK fertilizer, pesticides, labor, manure	Grain, fodder, bran	Fodder, bran	Grain
Soybean and groundnut	Seeds, urea, and NPK fertilizer, pesticides, labor, manure	Grain, fodder, bran, hull	Grain, fodder, bran, hull	Grain
Cow	Sorghum Stover/straw, Soyhull/groundnut residue biomass	Meat, milk, manure	Meat, milk, manure	Milk
Goat	Sorghum Stover/straw, Soyhull/groundnut residue biomass	Meat, manure	Meat, manure	Meat
Sheep	Sorghum Stover/straw, Soyhull/ groundnut residue biomass	Meat, manure	Meat, manure	Meat

An additional constraint requires that the sum of GHG emissions $a_j^{GHG} X_j^P$ generated in the predominant farm practices must equal total *GHG* emissions per farm:

$$\sum_{j=1}^{6} a_j^{GHG} X_j^P = GHG \tag{9}$$

which is used in the specification of alternative scenarios about required GHG emissions reductions per farm. For simplicity, a_j^{GHG} does not include the effects of emissions from application of lime, pre-farm operations during storage, and transportation as well as all mechanized farm operations, as these are minimal in this farming system.

The Tier 1 default methods and emission-factors (EFs) from the 2006 version of the guidelines that considered management practices with soils containing N inputs (Table A2.1) was employed. The default Carbon (C) produced is less than the estimated C harvested, and dead wood and litter stocks present in the predominant production system are at equilibrium and specified as zero. The Tier 1 default EF of 0.20 representing 20% for CO $(NH_2)_2$ was assumed for calculating annual CO_2 emissions from urea application in kg C/yr. Amounts of CO_2 equivalents were calculated by multiplying CO_2–C emissions values obtained by 44/12. Non-CO_2 emissions due to fire were estimated from the product of land area, (hectare), mass of fuel available for combustion, (tons ha $^{-1}$), combustion factor values, and emission

Table A2.1 Assumed values of GHG emissions related to land use, Bunkure and Maigateri LGAs

factor (g kg $^{-1}$ dry matter burnt) for various type of burning. The carbon dioxide equivalents (CO_2eq) factor was set at zero based on the assumption that the conversion of CO and NO_x has weak global warming potential.

N_2O emissions include volatilization and leaching from manure management system (MMS) and managed soil (MS). Other N_2O losses considered are annual amount of N in crop residues (above and below ground), including N-fixing crops, and from forage/pasture renewal, returned to soils annually, (kg N yr.$^{-1}$). DAP composition for Nitrogen (N) content in 50 kg bag of NPK fertilizer with urea excluded is 0.20 kg N. All emissions were converted to N_2O by multiplying 44/28 with values obtained

In ruminant livestock production, MMS and enteric fermentation result in CH_4 emissions in (Table A2.2). The EFs for sheep, goat, and mature cow grazing on large areas in developing countries were used. One TLU represents 250 kg live weight; equivalent of 1 camel, 1.43 cattle, 10 sheep/goats according to Ayantunde et al. (2011). All results were converted to carbon-dioxide equivalents (CO_2eq). In accordance with IPCC, a unit of CO_2, CH_4, and N_2O represents 1, 21, and 310 units of CO_2eq, respectively

To implement scenarios requiring farms to reduce GHG emissions from current levels, an additional constraint was developed to ensure GHG emissions generated from the predominant production practice is less than the assumed amount:

$$\sum_{j=1}^{6} a_j^{GHG} X_j^P \leq GHGLIM \tag{10}$$

47 GIS-Based Assessment of Solar Energy Harvesting Sites and Electricity Generation Potential in Zambia

Mabvuto Mwanza and Koray Ulgen

Contents

Abstract

Land and environment are some of limited nature resource for any particular country and requires best use. Therefore, for sustainable energy generation it is often important to maximize land use and avoid or minimize environmental and social impact when selecting the potential locations for solar energy harvesting. This chapter presents an approach for identifying and determining the potential sites and available land areas for solar energy harvesting. Hence, the restricting and enhancing parameters that influence sites selection based on international

regulation have been imposed to the Laws of Zambia on environmental protection and pollution control legislative framework. Thus, both international regulations and local environmental protection and pollution control legislative have been used for identifying the potential sites and evaluating solar PV electricity generation potential in these potential sites. The restricting parameters were applied to reduce territory areas to feasible potential sites and available areas that are suitable for solar energy harvesting. The assessment involved two different models: firstly the assessment of potential sites and mapping using GIS, and secondly, evaluation of the available suitable land areas and feasible solar PV electricity generation potential in each provinces using analytical methods. The total available suitable area of the potential sites is estimated at 82,564.601 km^2 representing 10.97% of Zambia's total surface area. This potential is equivalent to 10,240.73 TWh annual electricity generation potential with potential to reduce CO_2 emissions in the nation and achieve SDGs. The identification of potential sites and solar energy will help improve the understanding of the potential solar energy can contribute to achieving sustainable national energy mix in Zambia. Furthermore, it will help the government in setting up tangible energy targets and effective integration of solar PV systems into national energy mix.

Introduction

The purpose of meeting human basic needs and curbing climate change by reducing greenhouse gas emissions both at local and global levels has led to search for and establishment of energy policies for promoting renewable energy (Samuel and Owusu 2016; Sanchez-Lozano and García-Cascales 2014). The energy policies not only emphasized on promoting renewable energies but also on protecting natural resources and supporting natural environmental sustainability (Ivan 2015). Electricity generation from solar energy is in constant increase across the globe, but its share in the total energy production locally and globally still remains low as compared to fossil fuels. However, due to continual PV price decrease, increase in efficiency and maturity of technology in the last decades, feed-in tariffs including other incentives in many countries, has led to remarkable boom in photovoltaic (PV) technologies deployment and development both at utility-scale and residential levels across the globe (Robert 2014). According to International Energy Agency (IEA), the production of electricity from solar energy is expected to continue growing up to between 20% and 25% by 2050 (SEFI/UNEP 2009; Yassine 2011; Yassine and Adel 2012).

Despite of the remarkable boom in the application of solar PV technologies across the world, the application of these technologies in the electricity production in many developing countries like Zambia is still very negligible (Bowa 2017). However, there are only a few examples of small isolated solar systems used by communities, schools, companies, private households, hospitals, and health centers. These systems are often used to meet the daily energy needs and to cover up energy needs during load-shedding period (MMWED 2008; Bowa 2017). One of the largest solar systems installed by government so far through Rural Electrification Authorities (REA) was built in 2010 in Samfya district Northern Province (installed capacity of 60 kW) (Bowa 2017). According to Bowa (2017), the estimated total installed capacity of solar photovoltaic-based power plants as of 2016 was more than 2 MW (small off-grid systems). Hence, despite of the country being located in most favorable solar belt (MMWED 2008) and receiving significant higher solar irradiation than most of world's largest solar energy utilizing countries, solar energy application for electricity generation has remained negligible. According to Meteorological Department of Zambia, the country has monthly average solar radiation incident rate of 5.5 kWh/m^2-day (Gauri 2013; MMWED 2008; Walimwipi 2012; IRENA 2013). The solar radiation intensity across the country varies with western part of country having the highest annual average of approximately 5.86 kWh/m^2-day and the eastern part with the lowest of 5.68 kWh/m^2-day as shown in Fig. 1. Therefore, Zambia has a favorable climate conditions for utilization of solar energy for both production of electricity and thermal use. The total annual average global solar radiation ranges from 1981 kWh/m^2 in parts of North-Western, Eastern, Northern, Central, and Southern provinces to 2281 kWh/m^2 in parts of Luapula, Northern, and Western provinces of Zambia as illustrated in Fig. 2.

In order to increase access to electricity for all, the Government of Republic of Zambia has set targets and plans to encourage deployment and development of renewable energy facilities across the country, with hydropower and solar energy based on photovoltaic technologies expected to experience the greatest growth. However, despite of several tools being available across the globe for estimating the solar energy potential for particular location, these tools do not fully take into consideration the environmental and social issues. In addition, the surface land areas and the natural environment are some of the world scarce natural resources that require selection of the best use of these rare resources (Ronald 2016). Therefore, in order to safeguard the natural environment and consider best use of available surface land areas, energy planning and site selection for promotion and deployment of renewable energy technologies in individual countries has become one of the most challenging aspect more especially in developing countries like Zambia.

In addition, unified planning and poor site selection for intermitted renewable energy source based power plant have resulted in mismatch between the grid capacity and PV power plant output during peak time in some parts of the world (Siheng et al. 2016; Ming 2015). On the other hand, arbitrary site selection and neglecting the transmission line available reserve margin in the procedure have resulted in some PV power plant exceeding the local transmission line reserve margin and grid unable to transmit the energy to the load centers during peak hours (Chinairn 2013; Aly Sanoh 2014; Quansah 2016). Therefore, preliminary estimation and mapping of potential sites, available areas, and technical energy yield potential for intermitted renewable energy source based power plant

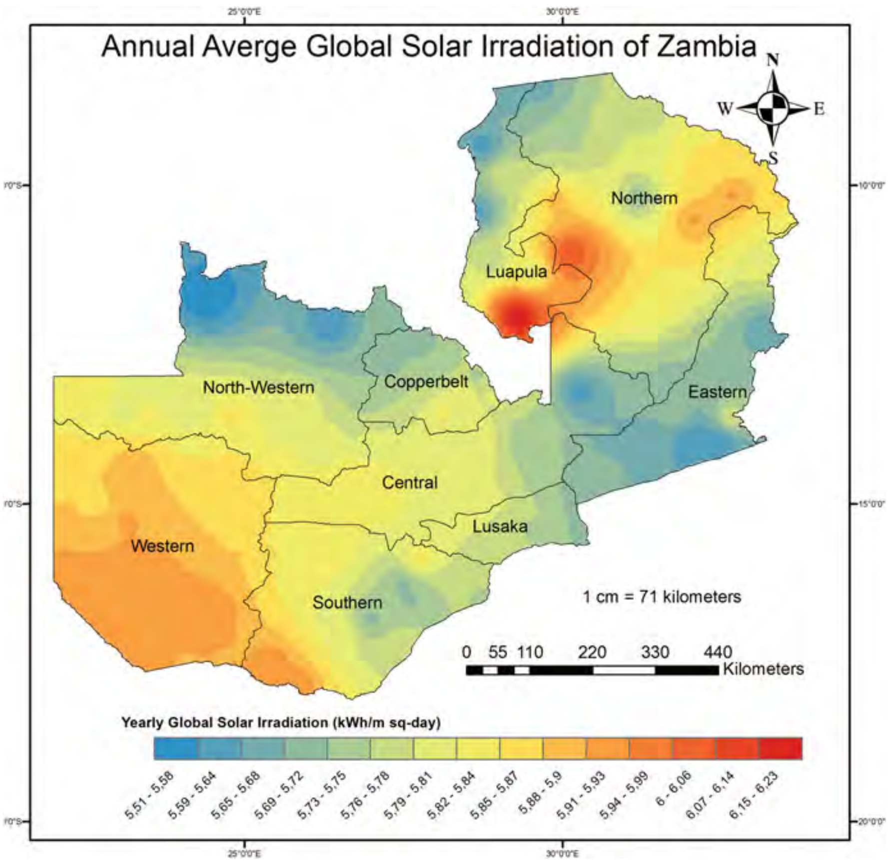

Fig. 1 Annual average horizontal solar irradiation

deployment while considering social acceptability and supporting natural environmental sustainability can be helpful to overcome these problems (Siheng et al. 2016). Doing so also helps to avoid and minimize potential negative environmental and social impacts associated with deployment of these technologies. The preliminary estimates and mapping of potential sites and technical energy yield potential for solar photovoltaic power plant development, however, have not been made in most developing countries like Zambia due to various reasons.

However, selection of potential site and evaluation of technical electricity generation potential requires a number of finer spatial resolution data, since not all locations of any particular country are suitable for deployment of these technologies due to local landscape terrain, climate, and environmental regulations (Suri 2005).

This chapter aims at providing a method for identifying and mapping a series of the potential sites and the available land areas suitable for solar energy harvesting in Zambia. The chapter further provides a method for assessing the electricity generation potential from solar energy based on commercially available solar photovoltaic technologies and available land areas. The evaluations in this chapter considered the

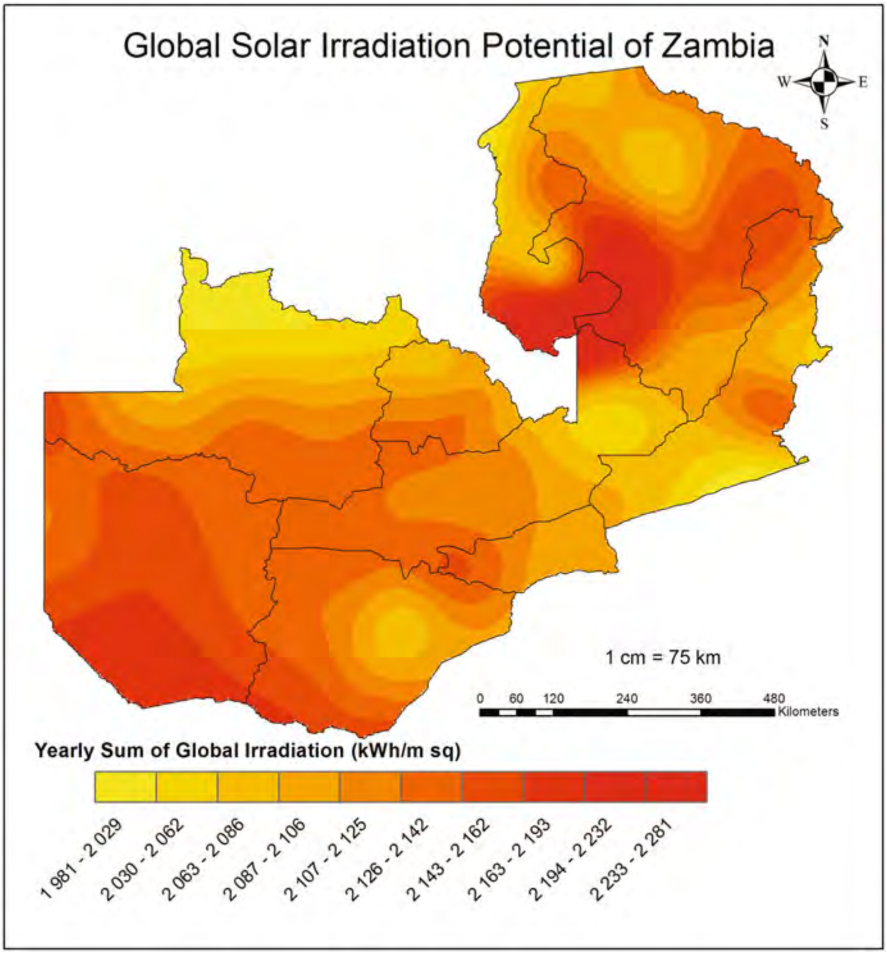

Fig. 2 Annual total global solar radiation intensity (Mwanza et al. 2016a)

modules of the solar PV systems mounted at optimal tilt position to the ground. The analysis focused on solar radiation, available areas, and typical energy that can be generated from the PV system considering the solar PV module characteristics and available solar radiation of the potential sites. The results of this study are important as it provides summarized information with regard to suitable potential sites, available land area, and technical electricity generation potential that can be attained from using solar photovoltaic technologies across Zambia.

Geographical Description

Zambia is unique country endowed with variety and abundant nature resources, such as wildlife resources, watercourse resources, forests resources, minerals resources, and renewable energy resources. Its abundant renewable energy resources such as solar energy are heavily untapped. The country is also blessed with unique climate and geography of flatland in most part of the country. It is situated between latitudes 8^0 and 18^0 south of the equator and longitudes 22^0 and 34^0 east of prime meridian. The country is landlocked by eight countries, Zimbabwe and Botswana to the South, Angola to the West, Democratic Republic of Congo and Tanzania to the North, Malawi and Mozambique to the East, and Namibia to the Southwest (Mwanza et al. 2016a).

Solar Photovoltaic Power Plant Sitting Considerations

Environmental and Social Issues

Solar energy is clean, free, and unlimited renewable energy sources that can be used for variety of purposes including pumping water for irrigations, drying and preparing food, and most importantly for electricity generation. However, just like any other alternative energy supply option, solar photovoltaic technology deployments at utility-scale are not free from imposing negative effects on both the environment and society (www.energy.gov) (Wang and Prinn 2010; Union of Concerned Scientists 2015). Most of these effects depend on development size, site, and the type of technology deployed and also site selection and environmental guidance procedure. The envıronmental and socıal impacts associated with renewable energy technology development are mainly grouped as listed in Table 1 (Ahmed Aly 2017; Turlough 2017; Shifeng and Sicong 2015; Kaoshan et al. 2015; Fylladitakis 2015; Saidur et al. 2011; Gipe 1995; Interior Department 2010; Damon and Vasilis 2011; U.S 2016; Geoffrey and Tidwell 2013; England 2011; Tsoutsos 2005, 2009).

Restricting Issues

The potential impacts associated with utilization of renewable energy technology have potential to hinder or delay deployment and development of solar photovoltaic technologies or facilities in potential sites. Table 2 and Figs.3, 4, 5, 6, 7, 8, 9, 10, 11, and 12 list solar PV systems deployment restricting issues that have, among others, been considered for inclusion, as appropriate, in the available land area, technical electricity generation potential, and potential sites assessment for sustainable solar photovoltaic facilities development in Zambia based on highlighted environmental and social impacts (www.energy.gov; Abdolvahhab Fetanat 2015; Alami et al. 2014; Ahmed et al. 2017; Arthur Bossavy 2016; Addisu and Mekonnen 2015; Marcos Rodriques 2010; Anthony Lopez 2012). Restricting criteria data are features that

Table 1 Summarized environmental and social impacts induced by solar photovoltaic power Plants

Type of impact	Causes	Factors contributing	Effects
Noise pollution	Inverter noise due to internal electronics, transformer noise, construction noise	Air temperature, humidity, ground surface material, background noise, heavy machinery, human activity	Sleep disturbance, hearing losses, headaches, irritability, fatigue, constrict arteries, weaken immune systems, annoyance, or dissatisfaction
Air and water pollution	PV module: Toxic materials, heavy machinery & transformers: Oil, switchgear breaker gas SF_6, ground clearing and grading	Fire, module cracking, leaking machinery due to poor maintenance, leakages in switchgear, transformers, & machinery, access roads & ground preparing	Death, injuries, loss of ecosystem, contamination of soil, water, and air
Water use	Periodic maintenance: PV module surface cleaning, construction activity, dust abatement activities	Dust, wind, location, size of facility, system performance, unpaved roads	Reduced underground water recharge, reduced surface water flow, agriculture water problem, wildlife water problem, human water problem
Climate Change & Greenhouse gas (GHG) emissions	Concrete and steel for PV array mounting foundations	Size of PV array, location of facility	CO_2 emission; global warming
Wildlife & Habitat loss	Excavation, grading, ground clearing, road & electrical grid construction	Location, landscape topography, size of facility, distance to road and electrical grid	Loss of feeding, nesting or roosting grounds for animals, birds, ecosystem disturbance, wildlife reduction
Visual impact	Distance to residential areas, size of facility, night lights at power plant, human perception	Scenic backgrounds, local landscape topography, local landscape between solar plant and viewers, location of solar farm, color of PV panels, layout of solar farm; irregular or regular, clear skies	Aesthetic effects, public health, negative perception of solar energy technologies, visual effect

(continued)

Table 1 (continued)

Type of impact	Causes	Factors contributing	Effects
Land use/ Soil & Land Degradation, fugitives dust	Power grid & access road construction, PV array foundation excavation, removal of surface plants, wastewater and oil from construction machinery, excess wastes from construction: Plastics, metal, glues, & inks	Layout of solar PV farms, location of solar PV farm, landscape topography, type of PV technology, tilt angle of modules, distance to access road and electrical grid, office wastes	Deforestation, soil erosion, loss of habitat, landslide, floods, air and water pollution, ecosystem disturbance, fugitive dust

Table 2 Restricting issue datasets

Type of impact eliminated, minimized or avoided	Site descriptions	Detail nature of sites descriptions
Water use, Wildlife & Habitat Loss	Wildlife sites	National parks and game reserves
Visual impact, Noise Pollution & Land use/degradation, fugitives dust	Community interest sites	Airfields, historical sites, archaeological sites, traditional and cultural heritage sites, national monuments sites and tourism sites, religious significance sites
Water use, land use/degradation	Agriculture sites	Crop areas and potential agriculture areas
Fugitive dust, water use, air/Noise Pollution & Visual Impact, land use	Settlement sites	Rural/urban and residential areas: Towns, cities, villages, and areas used extensively for recreation and aesthetic reasons
Water pollution, Wildlife & Habitat Loss, land degradation	Surface water bodies and surrounding sites	Rivers, lakes, streams, waterfalls, and wetlands
Land degradation, Wildlife & Habitat Loss	Landscape	Land elevation and slope (>5degrees), areas prone to flooding and natural hazards, zones prone to erosion or desertification, zones of high biological diversity, areas supporting populations of rare and endangered species,
Land use, Wildlife & Habitat Loss, fugitive dust, water, air and soil pollution, visual impact	Right of way	Transmission, roads and railroads network right of way
Wildlife & Habitat Loss, climate Change & Greenhouse gas (GHG) emissions, land degradation	Forest and surrounding sites	Forests: Low need-leaved deciduous forest and moderate evergreen deciduous forest, shrub-lands: Closed to open shrub-land and open shrub-land, grassland: Sparse grassland, indigenous forest

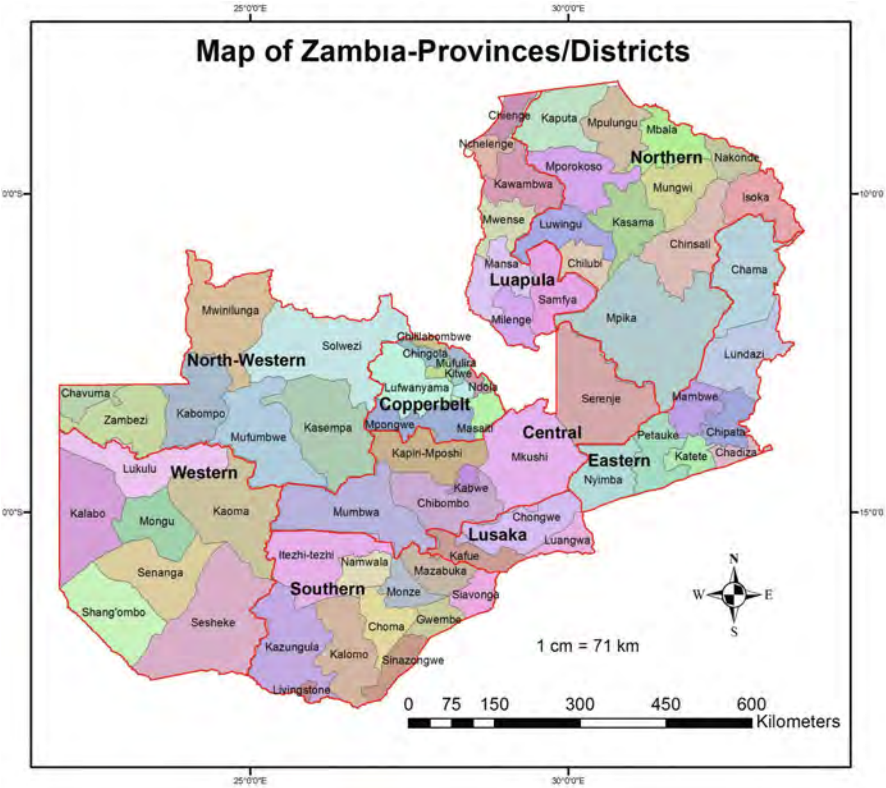

Fig. 3 Administrative boundary map

pose restrictions or limitations, that is, unsuitable or not preferred areas based on legislative laws of the country and nature.

Potential Site Identification and Mapping

Solar PV Potential Site Identification and Mapping

In order to assess the potential sites suitable for utility-scale solar photovoltaic deployment based on literatures surveyed and the laws of Zambia on environmental for development of any industry or plant on a particular site and restrictions datasets summarized in Table 2. Thus, the following environmental and social impacts and issues illustrated in Table 3, among others, are considered for inclusion, as appropriate, in the selection of suitable sites for solar energy facilities (ECZ 1994).

These maps included land elevation map (DEM), land use/cover layer map, town and village location map, community interest sites map, national parks map, surface water bodies map, roads and railway map, study area boundaries, and transmission

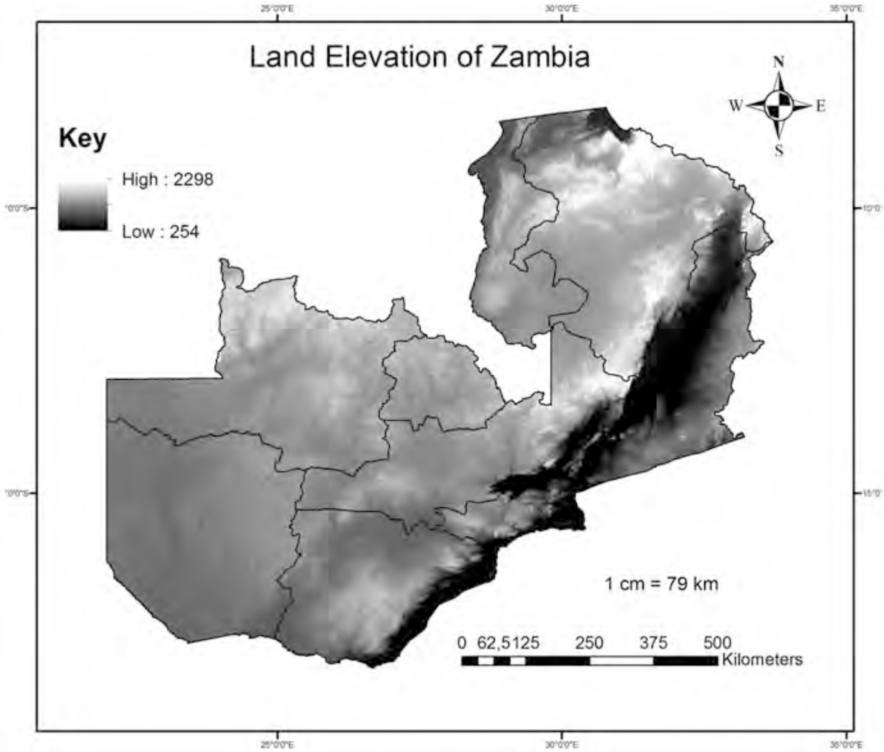

Fig. 4 Land digital elevation map

line maps (Nazli Yonca 2010; Sanchez Lozano et al. 2013, Brewer 2014, Chao-Rong Chen 2014, Charabi and Gastli 2011, Lopez 2012, Janke 2010; Uyan 2013). The rationale used for each restrictions are as follows:

- ***Land Use/Cover (C6, C9):*** This dataset has 10 classes including bare land, closed to open shrubland, open shrubland, sparse grassland, croplands, urban settlement, water courses, wetland, and forest sites; low need-leaved deciduous forest and moderate evergreen forest. For deployment of solar PV power plants only bare lands, sparse grassland and open shrubland were considered suitable due to easy accessibility considering an emerging economy and also to reduce land clearing costs.
- ***Wildlife Sites (C2):*** this dataset considers areas such as national parks, game reserves, and other natural resources since development in these sites will have adverse impact on birds, animals, and ecology, thus any construction in these areas may face public and international resistance. Therefore, these areas and the surrounding areas within the buffer of 2 km were considered not suitable (Nazli Yonca 2010).

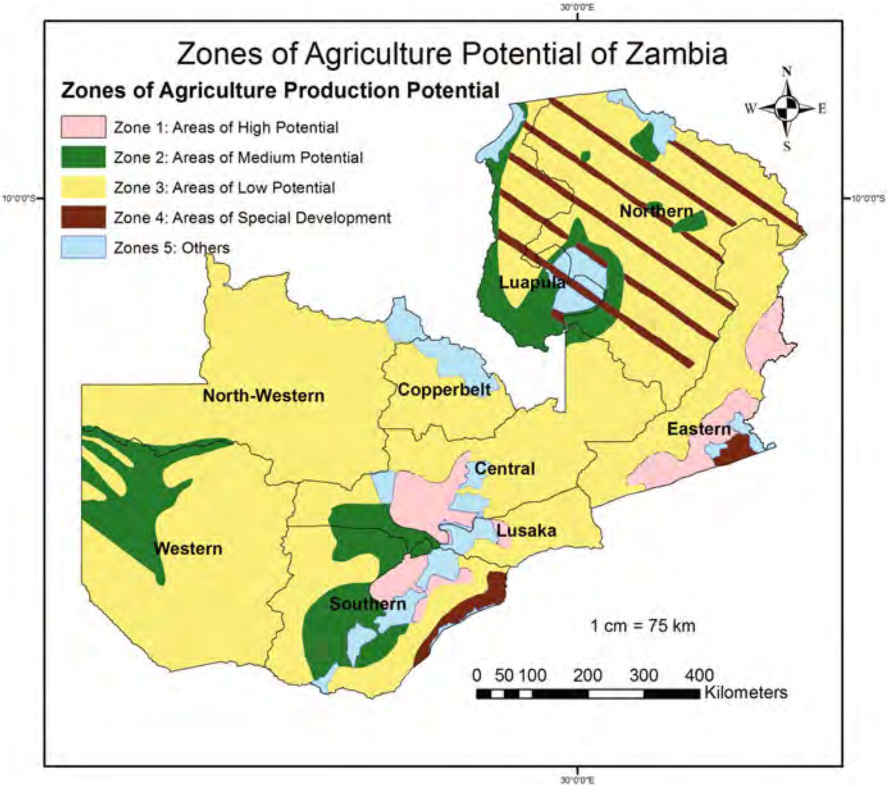

Fig. 5 Zones of agriculture production potential

- ***Settlement and Community Interest Sites (C4, C1):*** The dataset consists of settlement areas for both rural and urban such as airfields, airports, towns, villages, and other dwelling areas and community interest sites. Here a buffer of 3 km is considered to avoid aforementioned impacts and increase public safety and acceptance. All areas outside the buffer were considered suitable (Joss and Watson 2015).
- ***Land Elevation (C7):*** As it is expected that no one will install solar PV power plants in gorges or higher elevation due to construction costs. Thus, this dataset considered all higher and lower elevations such as mountains and gorges with steeper slopes above 5^0 as unsuitable areas.
- ***Surface Water Bodies (C8):*** In this dataset all surface water bodies such as rivers, streams, lakes, including waterfalls, and wetlands were considered as protected areas in order to avoid water pollution. Thus, a buffer of 2 km was considered with all areas outside buffer being suitable.
- ***Roads and Railways Network (C3):*** The dataset considers roads and railway network to be restriction since no one is supposed to build on roads or railway and

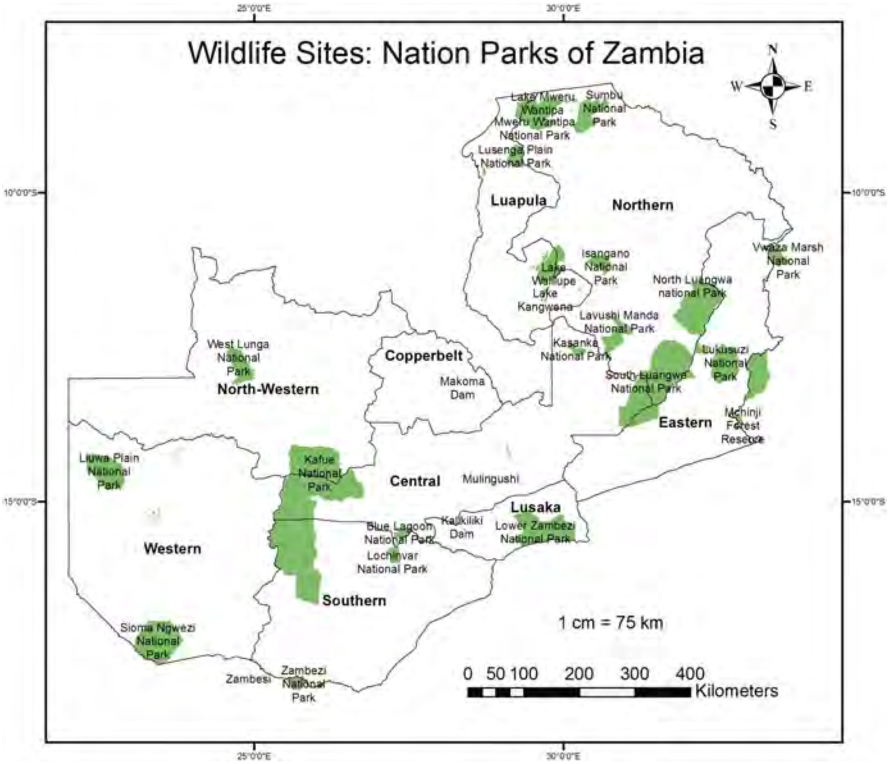

Fig. 6 Wildlife areas: national parks

also for the safety of the public. Hence, a 0.5 km buffer has been considered in order to increase public safety and also reduce cost of constructing access road which usually leads to land use/degradation, wildlife and habitat loss, fugitive dust, and air and soil pollution to the site and surrounding areas. Thus, the areas outside the buffer are considered suitable.

- ***Transmission Line Network (C5):*** In this dataset the right of way for transmission line were considered as unsuitable area for solar PV power plants, thus a 0.5 km buffer was used. Any areas within the buffer were considered unsuitable. The 0.5 km buffer were considered so that the cost of constructing new transmission lines is reduced, but at the same time to avoid conflict with right of way for transmission lines and avoid land use/degradation, wildlife and habitat loss, fugitive dust, water, and air and soil pollution to the site and surrounding areas.

After creating buffers, and changing some features from vector to raster, in order to evaluate available areas and identify/map feasible potential sites, the created buffers for the restricting layers were overlaid on each other using GIS spatial analysis. Figure 13 below shows the summarized analysis procedure.

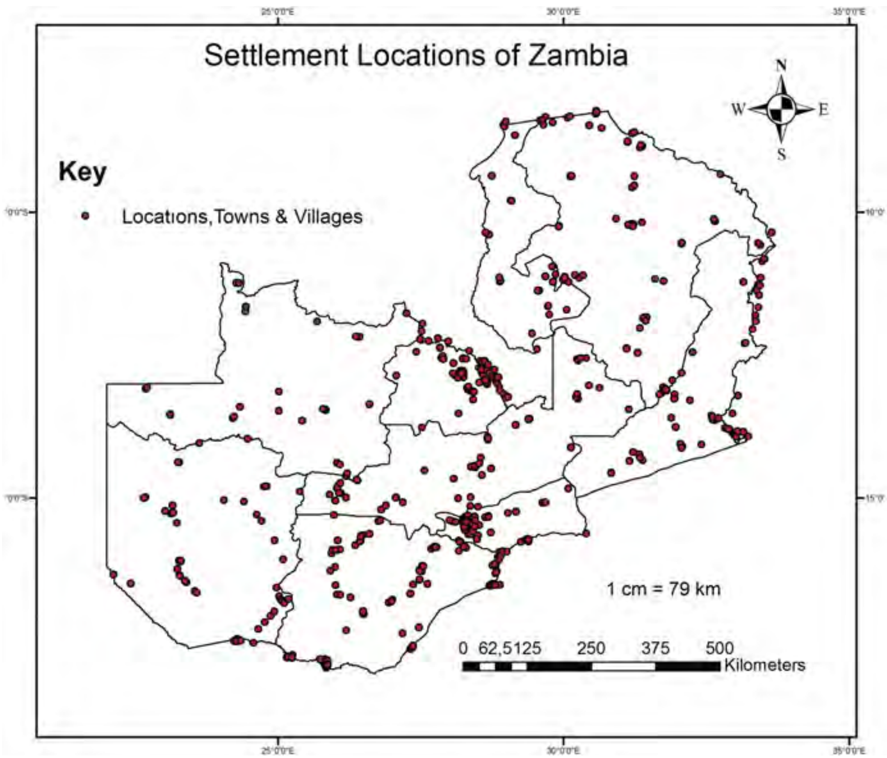

Fig. 7 Settlement and community interest sites

Available Land Area

In order to estimate the available suitable areas for solar photovoltaic power plant development based on aforementioned restrictions issues, a new factor called Area Suitability factor f_{SF} was introduced. It is defined as the ratio of total grid cells of suitable surface area to the total cells of the study surface area. The factor is estimated based on study area grid cells; here the total grid cells for study surface area are evaluated considering the sum of restricted and suitable surface areas' cells. Hence the factor depends on the ratio of available suitable area and surface area of the study area and it is calculated using the expression below.

$$f_{SF} = \left(\frac{C_{CSA}}{C_{CSA} + C_{CRA}} \right) = \frac{C_{CSA}}{C_{TSSA}} \qquad (1)$$

where C_{CSA} is the total number of cells of suitable areas, C_{CRA} is the total number of cells of restricted areas, and C_{TSSA} is total number of cells of study area.

Therefore, the total available suitable land areas for each district and for Zambia were evaluated using expression 2 given below

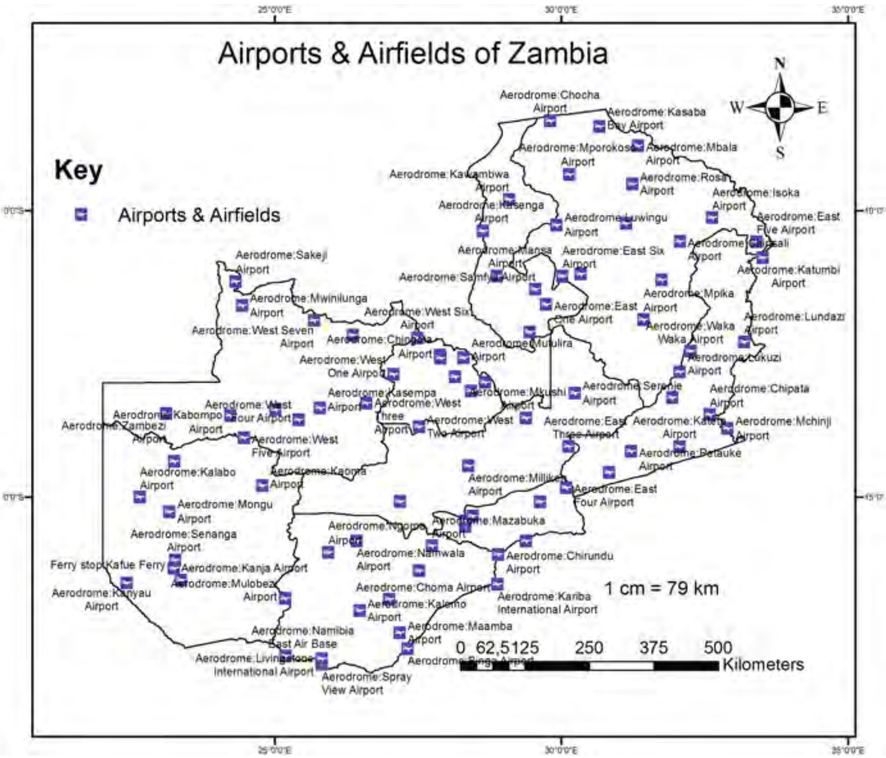

Fig. 8 Airports and airfield

$$A_{ADS} = f_{SF} \cdot A_{TSA} \tag{2}$$

where A_{ADS} is total available suitable areas (km^2), and A_{TSA} is total surface area of the study area (km^2).

Electricity Generation Potential

Solar Energy Potential in Zambia

According to the literature and data undertaken by Meteorological Department of Zambia, the country has a significant potential of solar energy for both electrical power production and thermal from solar energy technologies. The country has average peak sunshine of about 6–8 hours per day and monthly average solar radiation of 5.5 kWh/m^2-day throughout the year (MMWED 2008; Walimwipi 2012). According to International Renewable Energy Agency (IRENA 2012), the country has the highest total yearly solar radiation of 2,750 kWh/m^2-year with the highest average temperature of 30 °C, which presents good opportunity for solar systems deployment (IRENA 2012).

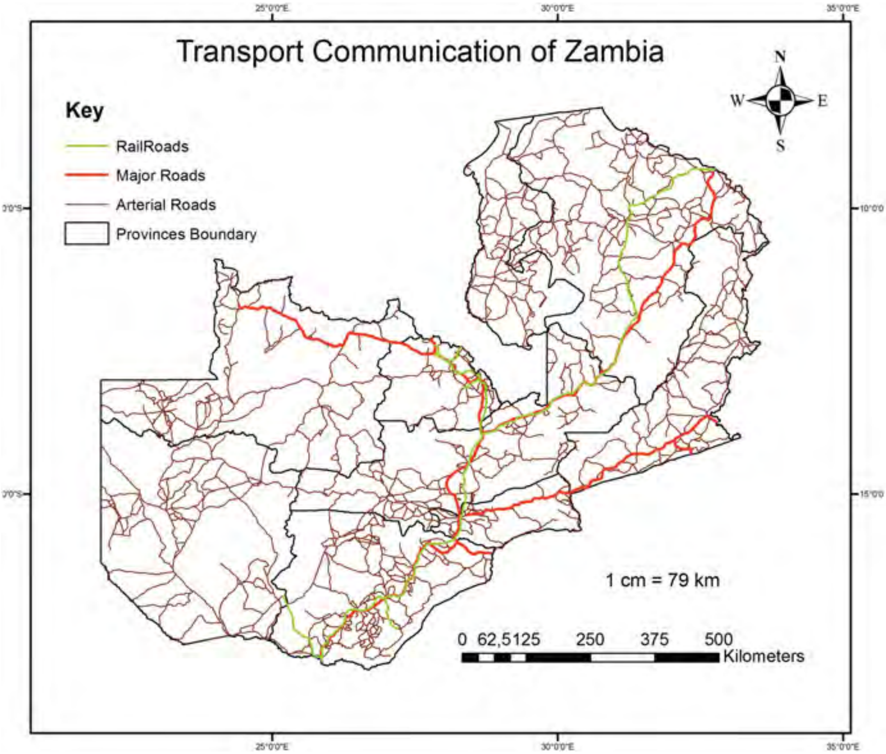

Fig. 9 Road and railroad networks

Performance of PV System

In order to evaluate the performance of grid connected PV power plants, the following performance indices are normally used: yields, normalized losses, and system efficiencies, performance ratio, and capacity factor – (British Standard 1998). However, in this chapter final yield, performance ratio and capacity factor have been adopted for analyzing the PV system performance of the various types of PV technologies commercially available on the market (Table 3) considering Zambia's weather condition. In addition, several PV technologies have been considered in the evaluation of technical electricity generation and power potential: firstly, because the energy generation by PV power plants with same peak power and receiving same amount of solar irradiation differs depending on the type of technology employed in the power plants, and secondly, the amount of peak power that can be installed at a given land area differ with PV technologies as shown in Table 4. Hence, it can be concluded that the type of cell technology has greater influence in the amount of land area needed for a peak power installation, the higher the efficiency the lower the land requirements for the peak power capacity installation (Martin-Chivelet 2016).

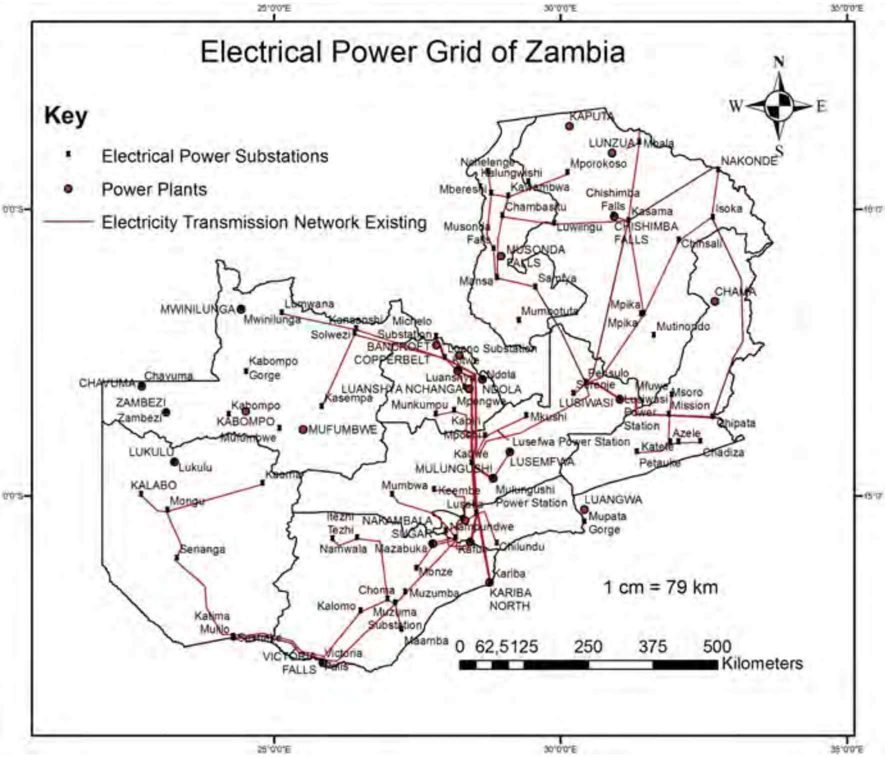

Fig. 10 Existing electrical network

Energy Model of PV Array

The solar energy resources are the key determinants of PV system electricity generation (IRENA 2012). The higher the solar energy resources, the more output yield of a PV systems per kilowatt. However, higher temperatures, dust, shading, balance of system inefficiencies, and PV technology characteristics have negative impact on the PV system energy yield (Didler 2012). Therefore, the electricity generated and supplied to grid by PV system considering these negative impacts has been estimated using Eq. 3:

$$E_A = A_{PV} \cdot H_R \cdot \eta_P \left(1 - \lambda_p\right)\left(1 - \lambda_C\right) \quad (3)$$

where E_A is energy output of PV system (MWh/year), H_R is solar radiation on the surface of module (kWh/m^2-day), A_{PV} is PV system active area (m^2), η_P is module efficiency under STC condition, λ_p is miscellaneous module losses due to dusty covering, and λ_C is losses due to power conditioning unit and cable losses. Module efficiency is a function of its nominal efficiency, η_r, which is measured at STC $T_r = 25$ °C (Didler 2012). İt has been calculated as:

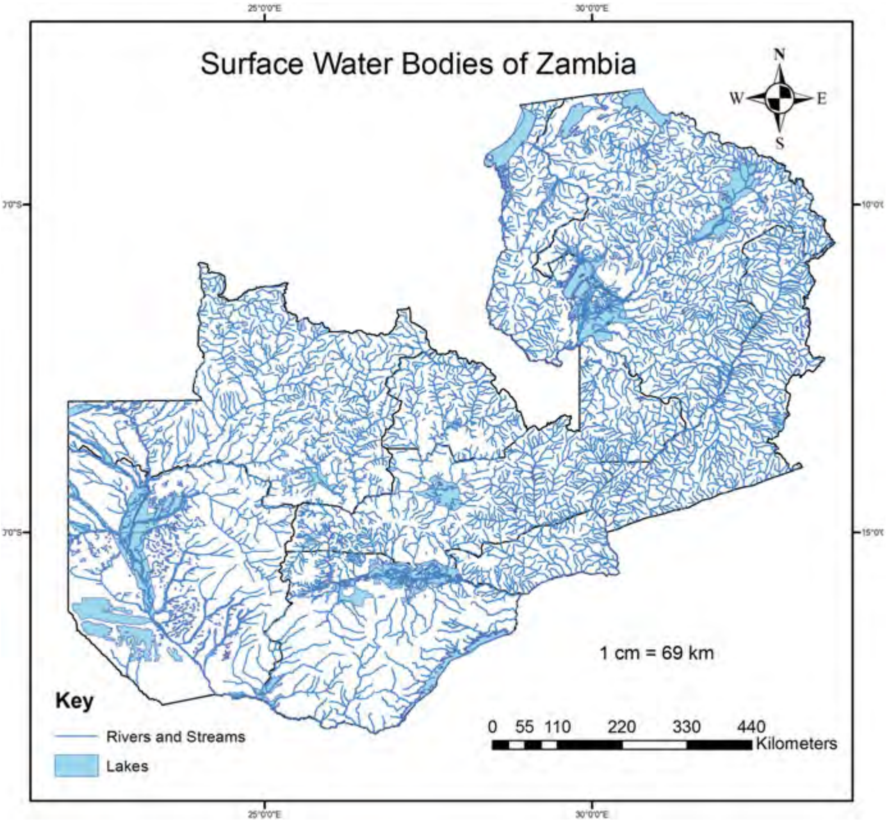

Fig. 11 Surface watercourses and streams

$$\eta_p = \eta_r \cdot [1 - \beta(T_c - T_r)] \tag{4}$$

where β is a temperature coefficient for module efficiency, T_c is a module temperature due to air temperature, and T_r is STC reference temperature.

Module temperature is related to the average monthly ambient air temperature, Ta, for a local condition has been calculated using Eq. 5 (Didler 2012).

$$T_c; = T_a + \frac{G_T}{G_{T.NOCT}}\left(\frac{9.5}{5.7 + 3.8V_W}\right)(T_{c,NOCT} - 20)(1 - \eta_m) \tag{5}$$

where G_T is solar irradiance (W/m^2), T_a is ambient air temperature (°C), and V_W is wind speed(m/s) for the location, $T_{c,NOCT}$ is nominal operating cell temperature (Table 3), it depends on type of PV technology, η_m is the factor less than 1 and normally neglected and $G_{T,NOCT}$ is 800 W/m^2.

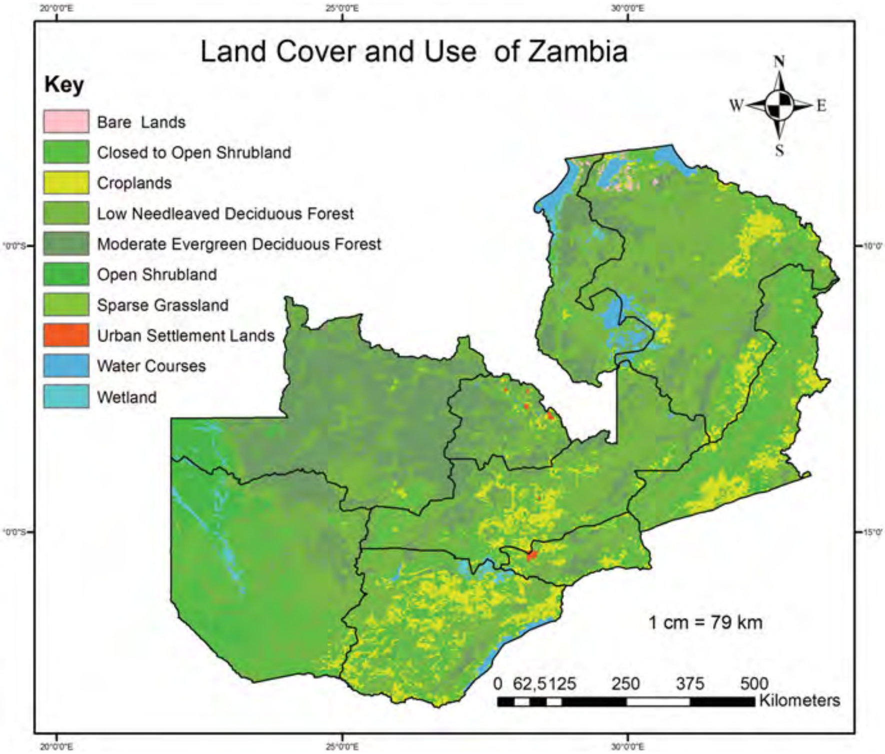

Fig. 12 Land aspects

Performance Ratio Model

Performance ratio is denoted by PR, this factor is important as it shows the overall effect of losses on the PV array's rated output power due to the PV array temperature, incomplete use of the solar irradiation, and PV system component inefficiencies or failures. It is calculated as (British Standard 1998).

$$PR_{.} = \frac{Y_F}{Y_R} = \frac{E_{AC}}{G\eta_{STC}} \tag{6}$$

where G-standard test condition solar radiance (1 kW/m^2) and η_{STC}-array efficiency at standard test condition given as.

$$\eta_{STC} = \frac{P_{PV}}{GA_{PV.A}} \tag{7}$$

where $A_{PV,A}$-Active array area (m^2) and $P_{PV,A}$- array rated power (kW$_P$).

Table 3 Environmental and social consideration for site selection in Zambia (ECZ 1994)

Issues	Considerations	Effect description
Ecological	(a) *Biological diversity.*	• Effect on number, diversity, breeding sites, etc. of flora and fauna • Effect on the gene pools of domesticated and wild sustainable yield
	(b) *Sustainable use including:*	• Effect of soil fertility • Breeding populations of fish and wildlife (game) • Natural regeneration of woodland and sustainable yield
	(c) *Ecosystem maintenance including:*	• Effects of proposal on food chains • Nutrient cycles • Aquifer recharge, water run-off rates, etc. • Aerial extent of habitats • Biogeographical processes
Social, economic, and cultural	• Effects of generation or reduction of employment in the area • Social cohesion or disruption (resettlement) • Immigration (including induced development when people are attracted to a development site because of possible enhanced economic opportunities) • Communication-roads opened up, closed, re-routed • Local economic impacts	
Land scope	• Views opened up or closed • Visual impacts (features, removal of vegetation, etc.) • Compatibility with surrounding areas • Amenity opened up or closed, e.g., recreation facilities	
Land use	• Effects on land uses and land potential in the project area and in the surrounding areas • Possibility of multiple use	
Water	• Effects on surface water quality and quantity • Effects on underground water quality and quantity • Effect on the flow regime the water course	
Air quality	• Effects on the quality of the ambient air of the area • Type and amount of possible emissions (pollutants)	

Capacity Factor Model

This is a model used to show the amount of energy delivered to the grid by an electric power generation system (Ayompe 2014). It is defined as the ratio of the output actual annual energy generated by PV system to the amount of energy the PV system would generate if it is operated continuously at full rated power for 8,760 hours in a year and it is expressed as (Ayompe 2014; Kynakis 2009; British Standard 1998).

$$CF_{.} = \frac{E_{AC}}{8760 \times P_{PV}} = \frac{PR \times H_t}{8760 \times P_{PV}} \tag{8}$$

where CF is capacity factor (%), E_{AC} is Actual annual energy output (kWh/year), and P_{PV} is Full rated PV power (kW_p).

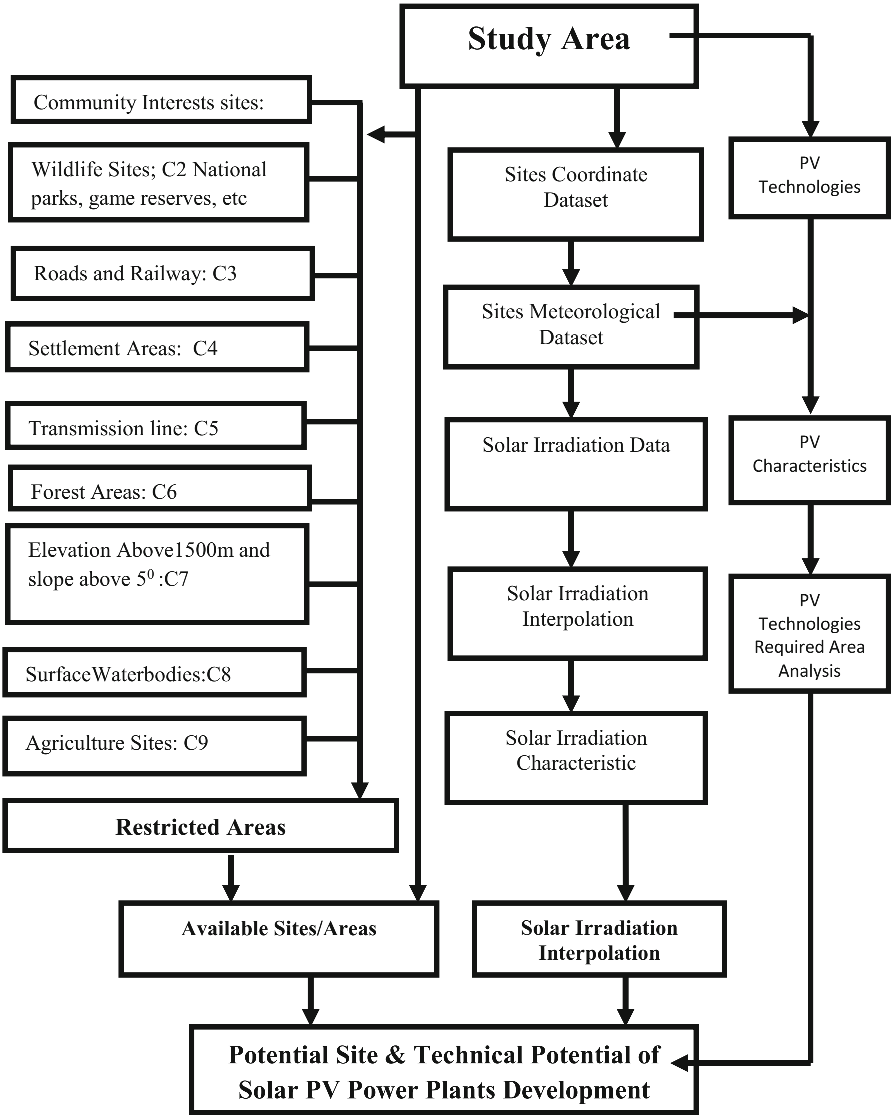

Fig. 13 Analysis Procedure

Solar Energy Potential Model

Theoretical Solar Energy Potential Model

Theoretical solar energy potential involves the assessment of the total solar energy that is received at the surface of the study area. This potential involves identifying the study area boundary and the size of the study land area, including total annual

Table 4 PV technology parameters

PV technology parameters	PV technologies					
	mc-Si	Pc-Si	a-Si	CIS	CdTe	Reference

BOS losses (%)	8	8	8.13	11.33	11.33	Various sources
Dust factor (%)	5	5	5	5	5	Various sources

average solar radiation magnitude. The theoretical potential has been calculated using Eq. 9:

$$E_{TH} = A_S \cdot H_P \tag{9}$$

where E_{TH} is theoretical solar energy potential (MWh/year), A_s is study area active surface area (km^2), and H_R is total annual average solar irradiance (MWh/km^2-year).

Geographical Solar Energy Potential Model

Geographical solar energy potential involves assessing the solar energy that is received on the available and suitable land area of the active surface land area of study area (Lopez 2012). Hence, the process of assessing this potential involved firstly excluding all the protected and restricted areas from the active surface area of the study area under consideration (Yan-wei 2013; Lopez 2012).

Therefore, the remaining surface land area is taken as the most suitable land area of the total study area surface land area for solar energy technologies development. In this study, the geographical solar energy potential has been estimated using Eq. 10 given below:

$$E_G = A_{AOS}.H_R. \tag{10}$$

where E_G is geographical solar energy potential (kWh/year), A_{ADS} is Available Suitable Area (m^2), and H_R is total annual average solar radiation (kWh/m^2-year).

Solar PV Technical Power Potential Model

The process of assessing the feasible solar PV technical potential, that is, the maximum power capacity that can be installed for any country without environmental and social impacts involves firstly by excluding restricted areas and areas not suitable for utility-scale PV systems development within the defined boundaries. Furthermore, considering technical characteristics of solar PV technologies (Table 3) to convert the solar energy to electrical energy, the total solar energy that is received at the surface of the solar PV module and the area required by the PV system and its supporting infrastructures. Hence, the technical solar PV potential has been estimated using Eq. 11 (Yan-wei 2013; Lopez 2012):

$$P_{TP} = \left(\frac{A_{ADS}}{A_{PVSA}}\right). = P_{PD}A_{PV} \tag{11}$$

where P_{TP} is Solar PV Power Potential (MW), A_{PVSA} is Solar PV system and Supporting Infrastructure Occupied Area per MW (km^2/MW), A_{ADS} is Available Suitable Area for Study Area (km^2), A_{PV} is total geographıcal occupied area by PV system and supporting infrastructure (km^2), and P_{PD} is solar power density of the area (MW/km^2).

Solar PV Systems Electricity Generation Technical Potential Model

The total AC electricity generated by the PV system is the sum of the electricity produced by all array in the PV power plant measured at the point where the system fed to utility grid. The total daily $E_{AC,DP}$ and monthly $E_{AC,mP}$ AC energy generated by plant are expressed as (Ali et al. 2016; Tripathi et al. 2014; Siyasankari and Babu 2015):

$$E_{AC,DP} = \sum_{t-1}^{24} E_{AC,t} \tag{12}$$

$$E_{AC,mP} = \sum_{d-1}^{N} E_{AC,DP} \tag{13}$$

where N is number of days in the month, and $E_{AC,t}$ is energy produced by PV power plant per hour (kWh).

Utility-scale photovoltaic are large-scale solar PV power plant that can be deployed within the boundaries of the country on an open space land area (Lopez 2012). Several studies have considered that the modules covers the available suitable areas on horizontal; however, the method proposed in this study seeks to consider the active area of PV arrays only and also the supporting infrastructures in the evaluation of technical potential. The process of assessing the extractable electricity generation potential from the sun for any country involves firstly by excluding areas not suitable for utility-scale PV systems within the defined boundaries, and secondly, considering technical characteristics of PV systems to convert the solar energy to electrical energy and the area required by the PV system and its supporting infrastructures. In this study the technical solar energy potential was estimated using Eq. 14 (Yan-wei 2013; Lopez 2012):

$$E_T = P_{TP}.CF.T_{TSH} \tag{14}$$

where E_T is Solar PV Electricity Generation Potential (MWh/year), P_{TP} is the technical power potential (MW), CF is Study Area Capacity factor (%), and T_{TSH} is the hours of the whole year (8,760 hours/year).

Potential Site and Electricity Generation Potential

Solar PV Potential Sites and Mapping

Figure 14 presents the map of solar PV potential suitable sites evaluated for Zambia, which indicates that the country has large land areas suitable for solar PV power plant development both at district and provincial levels. The aim of this case was focused on mapping the potential sites suitable for PV power plant installation with minimized or no environmental and social impacts. Therefore, all limiting factors considered not suitable for PV systems and those areas likely to have environmental and social issues were eliminated in the analysis using GIS spatial analysis. Hence, the Solar PV Potential Sites atlas shows that the country has the largest suitable site for solar PV power plant development in the Southern Province with Lusaka Province having the least. However, it can be observed that the available suitable areas are distributed throughout the country, hence providing opportunity for wide deployment of the solar PV technologies across the country. In addition, the atlas also shows that regions near to the national power grid contain suitable sites for easy integration of these technologies into the national energy mix and national power grid. The atlas provides essential information for sites close to villages and towns far from the grid offering opportunity for mini off-grid systems. Therefore, the atlas offers vital information for setting targets for electrification of both rural and urban areas of the country.

Available Suitable Land Area

Table 5 shows the annual average solar irradiation, total surface area and the available suitable areas for each district of Zambia. This reveals significant differences in suitable available areas within the 75 districts and 9 provinces across the country due to the availability of the aforementioned restricting factors considered in the evaluation. It can be observed that the districts in Eastern Province have lowest ratios of suitable area to surface areas in the ranges of 1.57 to 11.61% mainly due to the availability of restricting factors such as escapement, protected areas (e.g., National Parks, Zones of higher Agriculture Potential), and agriculture activities.

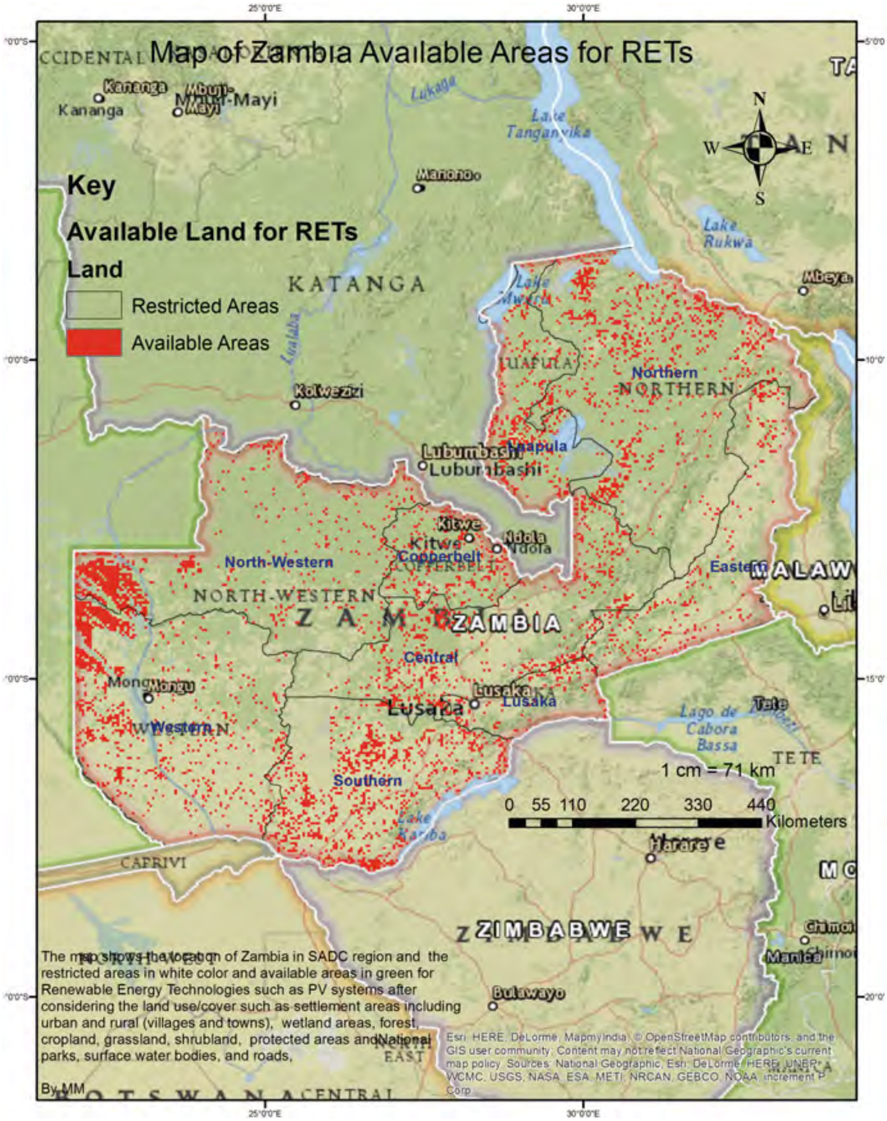

Fig. 14 Potential suitable sites for utility-scale solar PV power plant deployment

The provincial total suitable areas available for utility-scale solar photovoltaic power plants development as shown in Table 6 ranged from 2,151.70 km^2 (Lusaka) to 16,593.56 km^2 (Southern). As earlier stated, Eastern Province has the lowest annual average solar irradiation and also the overall percent suitable area (6.61%) whereas Southern Province has the largest (19.33%). However, Lusaka Province due to its size and population has the lowest overall suitable area (2,151.70 km^2) followed by Copperbelt (4,475.66 km^2) and highest being the Southern Province

Eastern	5.68	69,208	4,572.0376	6.61
Zambia	**5.78**	**752,614**	**82,564.6007**	**10.97**

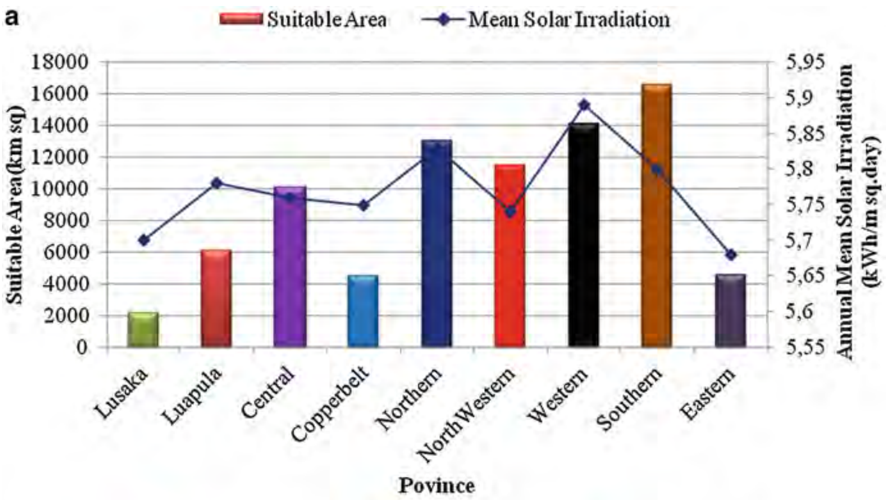
(16,593.56 km^2) (Fig. 15a, b). In short, comparing only available suitable areas where installation of PV system is suitable, Southern province has about 7.71 times more suitable area than Lusaka Province. However, there are large differences in surface area size between the two provinces, with Lusaka having 3.92 times less surface area than Southern Province. The country has approximately 10.97% equivalent to 82,564.60 km^2 of the total suitable surface land area for development of utility-scale solar PV power plant (Table 6).

Electrical Power and Electricity Generation Potential

Table 7 shows district solar energy theoretical and geographical energy potential. Since these potentials depend on the solar irradiation and available surface area and available geographical suitable areas. Hence areas with larger surfaces and receiving the higher solar irradiation such as Northern, Western, and North-Western have the highest overall theoretical potential whereas areas with larger suitable areas such as Southern, Western, Northern, North-Western, and Central Provinces have higher geographical solar energy potential (Table 8 and Fig. 16).

The district-based solar PV technical power potential by technology (Table 9) shows that crystalline silicon based solar PV technologies possess large potential due to less land requirements for installation, with monocrystalline-silicon technology having the largest technical power potential of 5,897.46 GW whereas amorphous-silicon having the lowest potential of 2,752.16 GW due to huge land requirements. The variation in power potential per district is highly depended on the available suitable areas in each district which is as a result of local geographical and terrain features.

The provincial solar PV technical power potential per technology (Table 10 and Fig. 17) shows that Southern Province, followed by Western have the highest potential and Lusaka Province being the lowest. Figure 18 shows the comparison



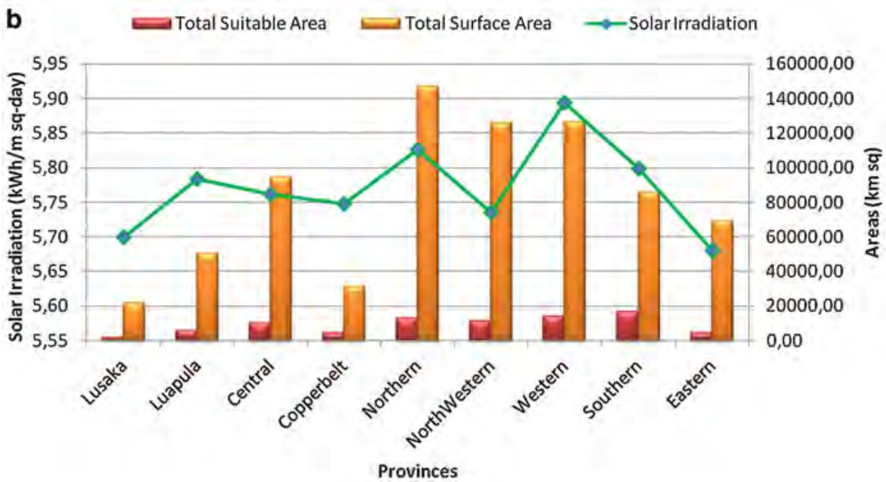


Fig. 15 (**a**) Provincial total suitable areas for utility-scale solar photovoltaic power plants. (**b**) Comparison of provincial total surface areas and suitable areas for utility-scale solar photovoltaic power plants

of solar PV technologies peak power potential for Zambia, with monocrystalline silicon having the largest whereas amorphous silicon having the lowest potential.

In absolute numbers, the highest electricity generation can be generated in the Southern, Western, Northern, North-Western, and Central Provinces due to large available suitable land areas for utility-scale solar PV system development (Table 12 and Fig. 19). Table 11 illustrates the district solar PV technical electricity generation potential by technology. Just like technical power potential it can be observed that districts with large suitable areas have the largest electricity generation potential.

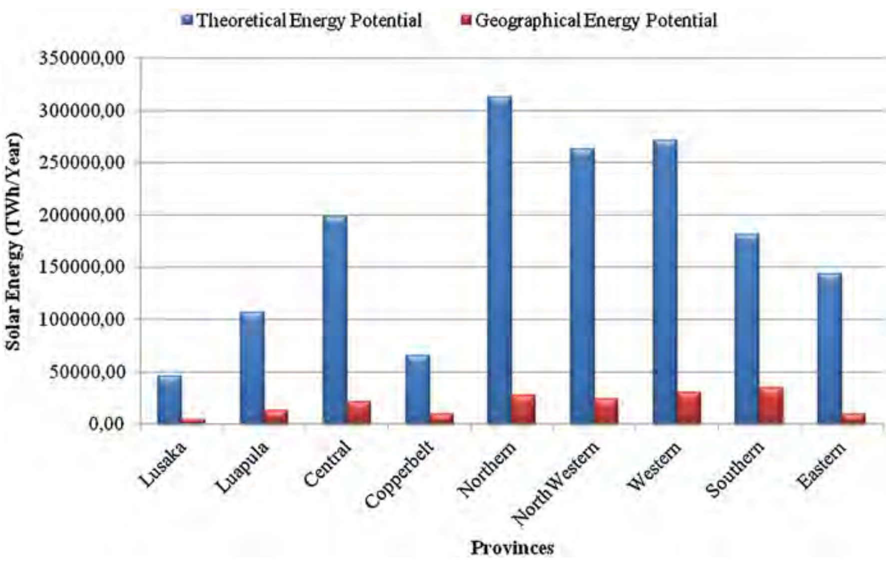

Fig. 16 Provincial solar energy theoretical and geographical potential

Table 12 and Fig. 19 show that Southern Province, followed by Western Province have the highest potential while Lusaka province has the lowest potential for electricity generation from solar PV based technologies due to aforementioned issues. Figure 20 shows a comparison of the provincial theoretical and geographical solar energy potential and the technical solar electricity potential. It is worth noting that due to technical characteristic of the solar cell technologies and land requirements the technical solar electricity generation potential is lower as compared to the solar energy received on these potential sites. Hence, this presents the need to select

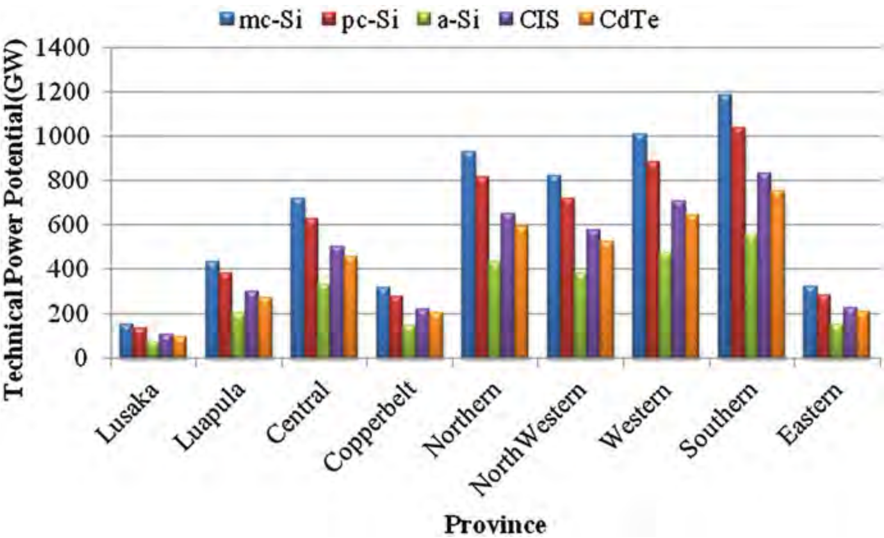

Fig. 17 Provincial solar PV technical power potential per technology

suitable solar cell technology for application in the solar energy harvesting systems for optimal solar energy utilization.

Figure 21 shows the comparison of solar PV technologies for electricity generation potential for Zambia considering the available suitable areas and the technology characteristics. İt is observed that monocrystalline provides the highest electricity generation potential followed by polycrystalline and least amorphous. This is mainly due to the differences in amount of land area requirements for the same peak power and the ability of the technology to convert the solar energy into electrical energy (efficiency).

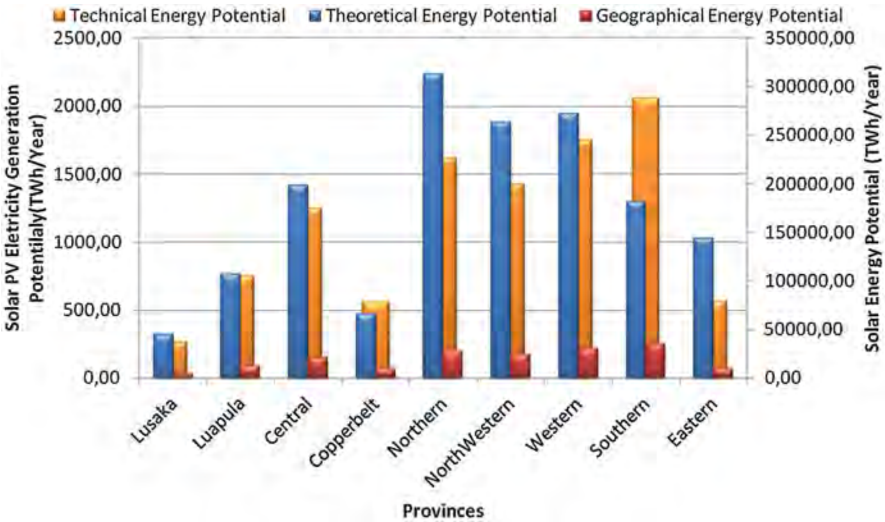

Fig. 20 Comparison of theoretical, geographical, and technical solar energy potential

While Zambia has abundance suitable areas (Fig. 14) and almost evenly distributed sunlight (Figs. 1 and 2) across the country, the focus on surface and suitable areas in the nine provinces and solar irradiation levels, the following can be identified. These factors however should be considered in the planning of national energy mix and also for management of electricity in the national grid once the penetration of solar PV technologies increases and becomes a significant part in the national electricity generation.

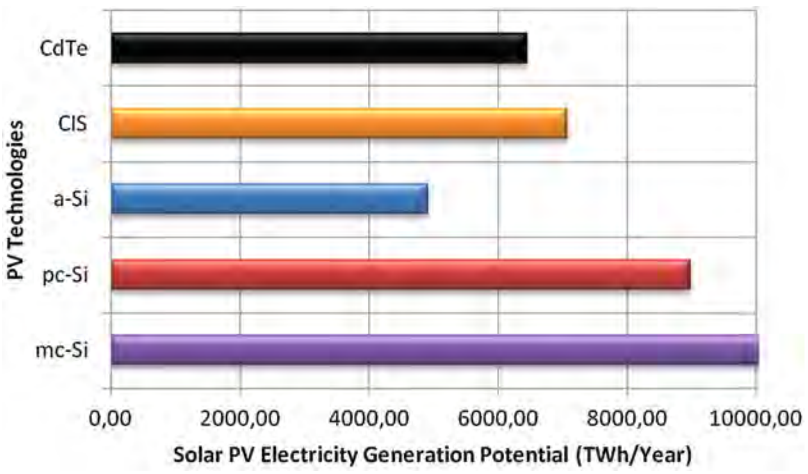

Fig. 21 Comparison of solar PV cell technologies electricity generation potential

- The highest theoretical solar energy potential is in Northern Province (313,025.37TWh/year) due to large surface areas of the province.
- However, the highest geographical and technical solar energy potential for solar electricity generation is in Southern Province (35,117.56TWh/year) due to large available suitable areas.
- From highest yield point of view, due to abundance of sunlight received by Western province (5.89kWh/m^2-day), the annual yields per installed solar PV systems peak are expected in Western province as compared to the rest of the country.
- Comparing the PV technologies, large electricity generation differences can be observed not only at district level but also at provincial levels. Table 13 indicates crystalline silicon based PV technologies have higher electricity generation potential as compared to thin film per square kilometer.

Table 13 summarizes the estimated solar PV technical electricity generation and solar PV power capacity potential in Zambia for each nine (9) provinces investigated in this chapter.

Conclusion

This chapter provides an approach for identifying and mapping the potential sites for sustainable development of solar PV technologies based power plants using GIS spatial analysis. The chapter has integrated the geographical and technological factors as well as the Laws of Zambia on environmental protection and pollution control legislative framework for evaluating the electricity generation potential and feasible sites suitable for sustainable PV systems deployment across Zambia.

Thus, this chapter shows that Zambia has vast available solar energy technical potential for PV electricity generation. The larger PV electricity generation potential variability at district and provincial level is highly linked with the local geographical features and terrain which affect the availability of suitable area and also local solar energy resource. Therefore, integration and generation of electricity from PV systems has greater potential to mitigate the current energy shortage and increase access to energy for all in Zambia. Furthermore, the suitable land areas in almost all districts and provinces is large enough for solar energy harvesting at utility-scale PV system capable of covering the present and future total electricity demands for Zambia. The identified potential sites have a total of available suitable area of 82,564.601 km^2 representing 10.97% of Zambia's total surface area equivalent to 5,897.46 GW technical power potential. This translates to 10,240.73TWh/year electricity generation potential considering annual average solar irradiation of 5.78 kWh/m^2-day and monocrystalline silicon solar PV technology mounted at optimal tilt angle. This potential has capacity to reduce CO_2 emission and contribute to achieve energy access for all and Sustainable Development Goals (SDGs).

The identification of potential sites and solar energy potential analysis will help improve the understanding of the potential solar energy, and PV technology can contribute to achieving sustainable national energy mix and increasing energy access for all in Zambia. Furthermore, it will help the government in setting up tangible energy targets and effective integration of solar PV systems into national energy mix. Hence, it is hoped that the suitability map established and the technical potential evaluated will help guide the decision makers and also the investors for planning future electricity generation targets and investment across the country and achieve the 2030 development goals.

Panel Analysis of the Relationship Between Weather Variability and Sectoral Output in Kenya

48

Olga Nekesa Mulama and Caroline Wanjiru Kariuki

Contents

Abstract

Climate change and economic growth are closely connected. Climate change has the potential to reduce economic growth in developing countries due to their limited ability to respond to the negative impacts of a changing climate. A better understanding of weather variability can enhance climate change policies, which

would help to support economic growth in these countries. As such, this research sought to examine if there is a long-run relationship between sectoral output and weather variables (temperature and rainfall) and to analyze the effect of weather variability on sectoral output using a panel of 13 sectors in Kenya.

A Pedroni cointegration test was carried out to find out if there exists a long-run relationship among the variables and thereafter, a fully modified ordinary least squares regression was conducted to establish the effect of weather variability on sectoral output. The results indicate that there is a long-run relationship between temperature and sectoral output. Moreover, temperature has a larger effect on sectoral output compared to rainfall. With the evidence gathered from this research, it can be concluded that weather variability has an economic effect on sectoral output in Kenya. Given this, the Kenyan government needs to take a keen interest in understanding the effect of weather variability on the economy and in the broader picture, take steps to mitigate climate change.

Introduction

Weather refers to the temporary conditions of the atmosphere, which is the layer of air that surrounds the earth. There are various factors that can change the atmosphere such as temperature, air pressure, humidity, wind speed, wind direction, altitude, and topography, among others. Together, these factors determine the weather in a certain area (National Centers for Environmental Information 2018). On the other hand, climate refers to the state of the weather over a long period of time in a specific area. Predictable weather is important for social and economic planning as it results in sustainable development. However, climate change could affect health, infrastructure, transportation systems, as well as energy and food supplies. There is also a global challenge of acute water scarcity, which can be attributed to the extreme temperatures. On a global scale, there is a cry for environmental conservation since extreme weather occurrences have been found to be directly linked to the environment's state. Through their research, Mortimore et al. (2009) provide insight on the pattern that developing countries have recorded in terms of extreme weather occurrences. The authors find that there has not been much investment and development to aid in preventing the damages that come with extreme weather occurrences in these countries. Developing countries are currently faced with considerable development constraints and to top it off, their poor coping and adaptation strategies to a changing environment push them deeper into development issues. The agricultural, livestock, fisheries, tourism, energy, forestry, health, and water sectors usually take the biggest blow when extreme weather events take place due to their relation and dependent nature on weather. The labor force and industries are also affected due to extreme weather events and this eventually ends up having an adverse effect on the peace and stability of a country.

In Kenya, the country's wildlife and other tourist attractions are vulnerable to the impact of climate change. Ferrara's (2015) research revealed that tourism in Kenya would be significantly affected by a change in wildlife migration patterns (e.g., wildebeest migration) caused by changing weather. Consequently, this would have a negative effect on the country's economy given that tourism is one of the major contributors to Kenya's Gross Domestic Product (GDP). Mount Kenya, which is another major tourist attraction, has snowcaps that are melting due to increased global temperatures. Additionally, the Kenyan economy is highly dependent on agriculture which contributes approximately 33% to the nation's GDP. The agricultural sector in Kenya employs about 40% of the total population with more than 70% coming from rural areas (Food and Agriculture Organization 2019). The Food and Agriculture Organization (2019) also reports that farmers who are used to rain-fed farming systems are being pushed to areas that are vulnerable to drought due to increased human population. Furthermore, the unpredictability of weather patterns resulting from climate change does not favor their farming practices. In many developing countries, households face difficulty in adapting to climate change and very few households make a step and change their farming practices in response to climate change. Okoba et al. (2013) argue that despite the possibility to change this, many households are unable to make the costly investment and join the bandwagon in the agricultural shift. Despite developing countries having information on extreme weather occurrences, the impact of the occurrence of an extreme weather event is still very high. News of extreme weather patterns across Africa is increasingly becoming frequent and policymakers can no longer overlook this effect, which is a result of climate change. As temperatures continue to rise as a result of global warming, there are bound to be water shortages in Africa causing droughts and in the short term, occurrences of flash floods as well. The cycle effect is that agricultural output will be affected thus causing a drop in rural incomes for farmers who depend on agriculture and resulting in a decline in consumption and investment.

Evidently, climate and agriculture are highly correlated as discussed by Linke et al. (2015) who carried out a research on the relationship between climate and social instability in Kenya. Agriculture is highly dependent on favorable weather conditions. Low output from farming during unfavorable weather conditions would result in low returns on the farmers' investment and in the next agricultural season, farmers may not have enough capital to invest for their next harvest. This is a vicious cycle whereby output that is affected by the weather would affect levels of income and this in turn affects the input necessary to produce more and the cycle continues. Dell et al. (2012) seek to bring out the evidence that in fact weather and economic variables do have a direct relationship. Their research examined the relationship between temperature shocks and economic growth in both rich and poor countries. Their findings show that higher temperatures reduce agricultural output, industrial output, and political stability. Not only do changes in the weather affect the agricultural and industrial sectors of a country, but the health of the population as well. The general health of a population is usually at risk in cases of extreme weather occurrences like drought and floods. In Kenya, infectious disease outbreaks such as waterborne, rodent-borne, and vector-borne diseases have been associated with flooding especially in areas with poor drainage systems (Okaka and Odhiambo 2018). Moreover, being on the equator, the temperate climate provides a perfect breeding ground for mosquitoes that spread malaria. Yanda and Mubaya (2011) report a rise in mosquito population in the occurrence of erratic weather where the spread of malaria and other waterborne diseases causes Kenya's income to shrink in affected areas. This is because the current labor force must attend to their sick family members and current and/or future labor force could also decrease should they succumb to diseases. Furthermore, the World Health Organization (2018) reports that diseases transmitted by insects are emerging and reemerging and epidemics are reported more frequently than before in Africa. Evidence points to climate change being a major contributor to this public health crisis. With the weak adaptive mechanisms in developing nations, adverse weather patterns are bound to have a huge impact on the entire economy affecting the majority of the population. Thus, there is a need for policymakers to plan accordingly and most especially conserve the environment and thus the economy for future generations. The erratic nature of weather patterns without adequate adaptation mechanisms has cost Kenya much more than it would have cost the country to put in place preventative measures that would reduce the scale of damage. For example, During the El Niño that occurred in 1997, Kenya made losses of up to USD one billion (Ngecŭ and Mathu 1999). The lack of preparation in the country adversely affected physical infrastructure due to the heavy downpour and further affected road, air, and rail transport networks.

Given this, Nyangena (2016) studied the impact of weather variability (rainfall and temperature) on economic growth in Kenya. Nyangena (2016) cited the need for further empirical explorations and as such, this research analyzed the effect of weather (temperature and rainfall) variability on sectoral output in Kenya using panel data. Specifically, this research sought to establish if there is a long-run relationship between temperature, rainfall, and sectoral output in Kenya and to determine the effect of temperature and rainfall on sectoral output in Kenya. The sectors captured in this research were agriculture and forestry; mining and quarrying; manufacturing; electricity and water; construction; wholesale and retail trade; hotels and restaurants; transport and communication; financial intermediation; real estate, renting, and business services; public administration; education; and other services.

It is important to remember the past so as to model better decisions for the future. Consequently, this chapter will make a contribution to literature by providing a deeper understanding of the effect of weather variability on economic output in Kenya using historical data. This will ultimately aid policymakers in planning and making decisions that will have a positive effect on the welfare of future generations. More specifically, the findings from this research will provide further insights on the effect of weather (temperature and rainfall) variability on sectors that contribute to Kenya's economic growth. Further, the results will assist environmentalists in campaigning for environmental conservation and promote the use of environmentally friendly products, methods, and clean energy. Institutions such as The National Environment Management Authority of Kenya and the Green Belt Movement together with the Ministry of Environment and Natural Resources and are not only involved in environmental campaigns but also advocate for policies and strategies that will help conserve the environment and mitigate the effects of climate change. The Ministry of Agriculture also stands to make more informed decisions that will benefit farmers and offer insight on policies regarding food security in Kenya related to weather variability.

Theoretical and Empirical Context

Theoretical Context

Chaos Theory

Making future weather forecasts is hard. It is only predictable to forecast the weather behavior in the future when a trend is observed from some initial weather conditions. Stephens et al. (2012) state that it is easier to predict climate than weather because weather is governed by an imbalance of the world's energy forces. A chaotic system is purely deterministic assuming absolute dynamism to the extent of exhibiting unpredictability in standard statistical tests, rendering it chaotic. Chaos theory, as described by Lorenz (1963) is the confusion, disorder, unpredictability, turbulence, and uncertainty in a spectrum of things. A chaotic system is one that is affected by initial occurrences and dynamic nonlinear patterns that are not fundamentally random. Understanding the initial points is fundamental for predictability to hold. Weather patterns are nearly impossible to predict due to their chaotic nature. However, with the advent of computers and their ability to handle massive amounts of data, there is a better possibility of predicting the weather. An essential observation would be to see how many times the weather predictions have merged with the actual weather occurrences. As observed from past weather occurrences, there is generally a disparity most times and this is attributed to the possibility of climate change taking place. A general standard stochastic test can be useful in distinguishing a set of randomness and chaos.

Climate Change Theories

Hulme (2009) describes climate science as a function of the limits of science itself. Mathematicians working on climate systems find that uncertainties in climate prediction arise not only from initial conditions and forcing scenarios but also from model formulation. Further, the anthropogenic global warming theory admits that the climate system is naturally chaotic. Most people are familiar with anthropogenic global warming, which is manmade global warming. Under the theory of anthropogenic global warming, it holds that manmade greenhouse gases are the main cause of global warming that has occurred during the past 50 years. As the years have progressed, loopholes have been found in this theory and new evidence shows that other natural factors contribute to modern global warming. The theory of anthropogenic global warming is contested by other theories, some of which include the theory of the Bio-thermostat, which claims negative feedback from biological and chemical processes offset whatever positive feedback might be caused by the rising carbon dioxide levels (Idso and Singer 2009). Sud et al. (1999) observed cloud coverage and formation. They found that the cloud coverage acted as a thermostat to regulate sea surface temperatures to a temperature of 28 °C and 30 °C. In a separate theory on human forcing, Matsui and Pielke (2006) explain that human activities such as deforestation, aerosols and ozone, coastal development, and jet contrails (the trail left behind by jets) transform the earth's surface. Additionally, carbon dioxide emissions as a result of human activities play a dominant role on long-term climate change. The US Global Change Research Program (2014) reports changes in the earth's climate due to the earth warming, with a key indicator of climate change being extreme weather and climate events.

Economic Growth

The neoclassical theory on economic growth states that the stock of capital, supply of labor, and technological developments are factors that affect the growth of an economy. The theory further explains the law of diminishing returns where increasing capital and labor have a limited impact on increasing economic growth. The new economic growth theories criticized the neoclassical theories stating that labor productivity does not have diminishing returns but rather has increasing returns and emphasis is put on the type of capital investment. Smith (1776) emphasized the dependency of economic growth on labor efficiency through division of labor. Additionally, Montesquieu and De Secondat (1748) argued that excess heat made men slothful and dispirited. As such, adverse climatic conditions affect laborers' well-being and this in turn affects their output ultimately affecting economic growth. Moreover, the Malthus theory predicts that economic growth may have limitations caused by changes in the climate, overpopulation, and scarcity of resources.

In his earlier studies, Barro (1999) explains that the growth rate of real per capita GDP was associated with higher levels of schooling. This is because an additional year in school enhances workforce capability to work and increases productivity. Real GDP per capita as used in this context is the measure of the economy's total output in a country divided by the population and further adjusted for inflation. Workers level of education is a measure of human capital and is directly related to productivity. Under the Harrod–Domar theory, capital formation is given more weight on its effect on economic growth. The Harrod–Domar theory emphasizes the importance of national savings and productivity of capital investment as central to economic growth. The growth of an economy is dependent on demand created from newly generated income such that output produced by new investments can be fully absorbed. Ultimately, this should increase the production capacity of the economy. This theory further assumes that labor and capital are complementary to each other.

Empirical Context

A report by the Intergovernmental Panel on Climate Change (2014) warned that global temperatures are expected to increase by an estimate of 4 °C by 2100 (World Bank

2012). Considering these projections, economists and policymakers are faced with the need to quantify the impact of weather patterns, specifically rising temperatures on economic activity. Nordhaus (2010) cites the significant effects of extreme weather events on the level of the US GDP. According to Dell et al. (2012), in their analysis of the relationship between temperatures and aggregate economic activity, hot countries tend to be poor, with national income falling 8.5% per degree Celsius in the world cross-section. With the recent interest in climate change, it is a matter of concern to understand the impact of the weather on all aspects of life. Colacito et al. (2019) estimated the effect of temperature on the growth rate of US GDP using a panel of the US states. From their estimates, they concluded that if the current trend in rising temperatures does not change, then a drop of economic growth by up to one third could occur. Further, in their estimation, they found that summer and fall exhibited opposite signs. Summer and fall had opposite effects on the US Gross State Product (GSP). This meant that rising temperatures during summer decreased economic growth as estimated by GSP and a significant rise during fall as the temperatures decreased. There has been a difficulty in concluding the general effect of weather patterns using annual data as each year presents different seasons. This heterogeneous effect can be dealt with by using more frequent data to represent the weather patterns.

In their inquiry, Linke et al. (2015) speculated that the future will get warmer, wetter, and wilder climates will be experienced. Ultimately, there is and still will be a surge of migrants and new wars. Intercommunity battles for resources increase conflicts and violence driven by calculation and political gain. According to the Food and Agriculture Organization of the United Nations (2019), increased competition for natural resources in Kenya has sparked escalated conflicts in some of the areas. Abidoye and Odusola (2015) examined the link between economic growth and climate change and found that the vulnerability of most African economies to climate change is of concern. A fair majority of the working population largely depend on informal employment in economic sectors that are sensitive to climate change (such as agriculture, forestry, energy, tourism, coastal, and water resources). Temperature was seen to have a negative impact on GDP growth where a 1 °C change in temperature would result in an inverse change in GDP growth by 0.67%. Given this, there is a need to manage the impact of climate change on Africa's economy to ensure developmental growth. In another article, Deryugina and Hsiang (2014) explored within-country variation in the United States and found that daily temperature above certain thresholds (15 °C and 30 °C) reduces the productivity level. In a related paper, Zivin and Neidell (2014) find that warmer temperatures reduce labor supply in the United States, thus providing an economic rationale for why climate change might affect economic activity in a developed economy. There has been a correlation between poverty and heat as suggested by Montesquieu and De Secondat (1748), who argue that excess heat made men slothful and dispirited.

Several other studies have focused on agriculture specifically and there is an evident inverse relationship between agricultural productivity and extreme weather occurrences although this is dependent on the crop type. Beyond agricultural constraints as a result of climate change, Awuor et al. (2008) found that floods lead to serious loss of life and property, which coastal towns such as Mombasa face as a result of climate change. Mombasa is a major contributor to Kenya's GDP through tourism, industries, imports, and exports and serves both Kenya and land-locked countries around it. Floods lead to loss of life, displacement of people, and destruction of infrastructure. Floods can occur at any time despite weather or climate patterns influencing when and where these floods occur (Smith 2002). Although drought affects more people than floods do, disease outbreaks such as malaria, typhoid, bilharzia, and dysentery have been seen to cripple labor productivity. Flood disasters are associated with the presence of flood hazards due to the nature of the terrain or flood vulnerability, which is attributed to poor regulation, poor land use, degradation of water catchment areas, poverty, population pressures, and settlement patterns (Opere 2013).

In a more recent research done in Kenya, Nyangena (2016) explored the relationship between GDP per capita, annual temperature changes, and annual rainfall and found that a unit change in temperature resulted in approximately 142 times change in GDP per capita arguing that temperature has a greater effect on GDP than rainfall. The empirical literature in Kenya revealed some inconsistencies with other bodies of literature that have sought out to explore the role of weather and climate changes in economic growth (Nyangena 2016). The findings of earlier studies revealed that temperature variability had an inverse relationship with economic growth (e.g., Colacito et al. 2019; Dell et al. 2012) whereas Nyangena (2016) found a positive relationship between temperature and economic growth. Nyangena (2016) determined the long-run relationship between economic growth and weather and used a vector error correction model to analyze the impact of weather variability on economic growth. On the other hand, this research aims to analyze the effect of weather variability on 13 different sectors in the Kenyan economy as opposed to the economy at an aggregate level. The sectors included in this research are: agriculture and forestry; mining and quarrying; manufacturing; electricity and water; construction; wholesale and retail trade; hotels and restaurants; transport and communication; financial intermediation; real estate, renting, and business services; public administration; education; and other services. Additionally, this chapter will also provide insight as to whether there is a long-run relationship between weather variability and output from the 13 sectors that contribute to Kenya's overall economic growth.

Interactions Between the Variables Used in This Research

The dependent variable in this research was sectoral output (measured using GDP per sector) focusing on the following sectors: agriculture and forestry; mining and quarrying; manufacturing; electricity and water; construction; wholesale and retail trade; hotels and restaurants; transport and communication; financial intermediation; real estate, renting and business services; public administration; education; and other services. The sectors were chosen based on availability of historical information. GDP per sector is the contribution that the sector has on overall GDP. The independent variables were temperature, rainfall, gross fixed capital formation, labor, and the business regulatory environment captured using the country policy and institutional assessment (CPIA) (Fig. 1).

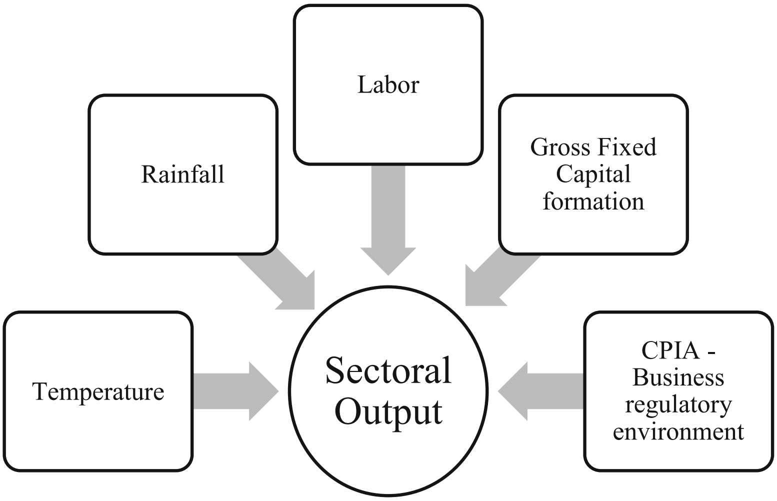

Fig. 1 Interactions between the variables used in this research

The Cobb–Douglas function drives the concept behind the variables chosen. Labor and capital should have a positive relationship with output, and in this case, the sectoral output is expected to have a positive relationship with gross capital formation because increased investments are expected to increase production and as such there would be more output, which is plowed back to investments and the cycle continues. The CPIA rating is expected to have a positive relationship with sectoral output where policy improvements would positively impact output growth. Labor is also expected to have a positive relationship with sectoral output because the labor force is key to increasing productivity up to a certain level. An increase in productivity due to labor just like capital formation should result in an increase in output, which would be eventually plowed back as investments, which could take the form of increased labor opportunities. The weather variables (rainfall and temperature) on the other hand are expected to have an inverse relationship with sectoral output should there be a significant increase or decrease. For example, in the case of agriculture, a significant increase or decrease in temperature and/or rainfall will affect agricultural yield, reducing production and in the long-run causing a decline in output, which is GDP per sector in this case.

Approach to Identify the Relationship Between Weather Variability and Sectoral Output

Data Collected

This research sought to determine the effect of temperature and rainfall on sectoral output in Kenya and further establish if there is a long-run relationship between temperature, rainfall, and sectoral output in Kenya. This research studied the sample overtime using past information, which made it possible to establish the direction and magnitude of the effect of the independent variables on the dependent variable.

According to the data availability on Kenya National Bureau of Statistics, the Kenyan economy has 13 economic sectors. The major industries include agriculture, forestry, fishing, mining, manufacturing, energy, tourism, and financial services. For this chapter, data on all 13 economic sectors over a period of 10 years, from 2008 to 2017 was used to establish the effect of weather variability on the economy. To capture the effects of weather variability of economic sectors in Kenya, the start year of the research was 2008 but due to the unavailability of the most recent data on weather in Kenya, this research was limited to the years 2008–2017. Weather is generally described using the following atmospheric conditions: Temperature, wind, precipitation, and sunlight. Being in the tropics (at the equator) precipitation is generally experienced as rainfall and as such, due to limited data, the variables used to measure weather variability in this chapter are rainfall and temperature over a period of 10 years from 2008 to 2017.

The data used was collected from secondary sources and comprised observations of variables over time with a cross-sectional dimension based on economic sectors. As such, panel data was used for this research. Variables used were temperature in degrees Celsius, rainfall in millimeters, GDP per sector in local currency, gross fixed capital formation in local currency, labor, and CPIA. The data for temperature in degrees Celsius, rainfall in millimeters were obtained from the World Bank Climate Change portal. Data for GDP per sector in local currency were obtained from the Kenya National Bureau of Statistics. Gross fixed capital formation data in local currency, which was measured as the annual net increase in physical assets was obtained from the World Bank Development Indicators. The data for labor, which measures the number of people employed was also obtained from the World Bank Development Indicators, while the CPIA data, which measures the implication of the legal, regulatory, and policy environments that help or hinder private businesses in investing, creating jobs, and becoming more productive was obtained from the World Bank Country Policy and Institutional Assessment database. All variables used for this research had an annual frequency.

Model on the Relationship Between Weather Variability and Sectoral Output

A panel data model was estimated and used to analyze the data. This model was used to provide information on the effect of temperature and rainfall on sectoral output in Kenya and was estimated using the fully modified ordinary least squares (FMOLS) method. All the variables were transformed into natural logarithms thus allowing the coefficient estimates to be interpreted as elasticities. The dependent variable of the model was GDP per sector (sectoral output) defined as the share that each sector contributes toward GDP. The independent variables were temperature measured in degrees Celsius and rainfall in millimeters. Additionally, following the Cobb-Douglas function of measuring productivity, the gross fixed capital formation was included to account for capital and labor force was used to account for human capital. The business regulatory environment was also captured using the country policy and institutional assessment (CPIA). Below is the econometric model:

$$lnGDP\ per\ sector_{it} = \beta_0 + \beta_1 lnCapital\ formation_{it} + \beta_2 lnLabor_{it} + \beta_3 lnTemp_{it} + \beta_4 lnRain_{it} + \beta_5 lnCPIA_{it} + \omega_{it}$$

Where: β_0 is the intercept, which is the same for all the sectors and over time. β_1 to β_5 are slope parameters. The subscript i refers to an individual sector and t refers to the years from 2008 to 2017. $\omega_{it} = \varepsilon_i + u_{it}$. ε_i measures the random deviation of each sector's intercept from the common intercept term β_0 and u_{it} is the residual term for sector i at time t. *Capital formation* is the net increase in physical assets, *Labor* captures the number of people employed, *Temp* captures temperature in degrees Celsius, *Rain* captures rainfall in millimeters, and *CPIA* captures the business regulatory environment as a rating (1 = low to 6 = high).

Procedure

Before investigating the existence of a long-run relationship between weather variability and sectoral output, a unit root test was carried out. Unit root tests are used to find out if a series of variables is stationary or nonstationary. When a series is stationary, the variables are time-invariant and are better suited for making forecasts. This research employed the Im, Peseran, and Shin (IPS) unit root test. Next, a test for the existence of a long-run relationship between weather variability and sectoral output using a cointegration test was carried out. A panel cointegration approach was employed and the principal idea was to investigate the existence of a long-run relationship among the nonstationary variables. Finally, a fully modified ordinary least squares (FMOLS) procedure was adopted to estimate the effect of weather variability on sectoral output. Pedroni (1996) brings forth the FMOLS as a solution to tackling non-exogeneity and serial correlation problems. Additionally, FMOLS addresses the problem of nonstationary variables as well as simultaneity biases.

Establishing the Relationship Between Weather Variability and Sectoral Output

Unit Root Test

In order to establish whether the distribution of the variables used in this research does not change with time (stationarity), unit root tests were carried out. The results in Table 1 are a result of conducting an Im, Pesaran, and Shin (IPS) panel unit root test at level, first difference, and second difference. When conducting a unit root test, the null hypothesis is the presence of a unit root and rejecting the null means that the variable is stationary. The null hypothesis is rejected when the p-value is smaller than

Table 1 Unit root test results

Variable	Level	First-order difference	Second-order difference
GDP per sector	−0.4362 (1.000)	−2.8004[a] (0.0001)	
Temperature	0.2327 (1.000)	−2.4535 (0.2990)	−2.3519[a] (0.0022)
Rainfall	−3.8568[a] (0.0000)		
Capital formation	−1.5808 (0.1887)	−3.2164[a] (0.0000)	
Labor	−0.8516 (0.9791)	−0.5463 (0.9995)	−3.0059[a] (0.0000)
CPIA	−2.3886[a] (0.0010)		

P-values in parenthesis
[a]Statistically significant at the 5% level of significance

Table 2 Panel cointegration results

Test	Level
Modified Phillips-Perron test	3.0714[a] (0.0011)
Phillips-Perron	1.9829[a] (0.0237)

P-values in parenthesis
[a]Statistically significant at the 5% level of significance

0.05 ($p < 0.05$). At level, the null hypothesis is rejected for rainfall and CPIA indicating stationarity. At first difference, the null hypothesis is rejected for GDP per sector and capital formation and finally, at second difference, the null hypothesis is rejected for temperature and labor.

Long-Run Relationship Between Temperature and Sectoral Output

Next, cointegration was tested. This test was used to find out if there exists a long-run relationship between sectoral output and temperature. Rainfall is not taken into account in this test as it is a stationary variable at level. The p-values in Table 2 are the values in parenthesis and are highlighted by an asterisk at a 95% confidence level. Given that the p-values of the cointegration tests are less than 0.05 ($p < 0.05$), the null hypothesis of no cointegration is rejected. This result indicates that there is a long-run relationship between sectoral output and temperature, which answers the research objective of establishing if there is a long-run relationship between weather variability and sectoral output in Kenya. The long-run relationship between the temperature and sectoral output supports the findings of Nyangena (2016) who found that weather and output in Kenya had a long-run relationship.

Effect of Weather Variability on Sectoral Output

After establishing the presence of a long-run relationship between sectoral output and temperature, a method known as fully modified ordinary least squares (OLS)

Table 3 Fully modified ordinary least squares results

Variable	Coefficient	P-value	Standard error
Temperature	−4.0229	0.7086	10.7312
Rainfall	0.1920	0.6976	0.4927
CPIA	0.7531	0.7624	2.4837
Capital formation	−0.8404	0.4746	1.1710
Labor	8.2220[a]	0.0102	3.1398

[a]Statistically significant at the 5% level of significance

was used to establish the relationship between weather variability and sectoral output. The results of the estimation are shown in Table 3.

The results in Table 3 show that there is a negative effect of temperature in degree Celsius on sectoral output, where a 1% increase in temperature leads to a 4.02% decrease in sectoral output holding all other factors constant. Regarding rainfall in millimeters, there is a positive relationship with sectoral output where a 1% increase in rainfall would result in a 0.19% increase in sectoral output holding all other factors constant. Colacito et al. (2019) also found an increase in temperature resulted in possible declines in economic growth. As seen in this chapter, there also exists an inverse relationship between temperature and sectoral output. Moreover, the inverse relationship between temperature and sectoral output is of a higher magnitude in comparison to the relationship between rainfall and sectoral output. This is consistent with the findings of Ochieng et al. (2016) who reported that temperature has a bigger effect on crop production in Kenya than rainfall. This chapter also supports the findings of Van-Passel et al. (2012) who argued that agricultural output is positively affected by rainfall when received on season and is good for overall economic performance. Even though this chapter found that rainfall has a positive effect on sectoral output, one should also keep in mind that continued heavy rain is likely to cause economic losses in Kenya as revealed by Ngecŭ and Mathu (1999) in their research. This research cannot particularly rule out this effect as it does not consider the seasonality of weather and the shocks therein.

The business regulatory environment as measured by the Country Policy and Institutional Assessment (CPIA) has a positive relationship with sectoral output where a 1% increase in the CPIA rating would result in an increase of sectoral output by 0.75% holding all other factors constant. The findings of this chapter also support the research carried out by Kimenyi et al. (2016) who reported that policy improvement would result in economic transformations and sustained economic growth in the sectors in Kenya.

Additionally, labor, which is the number of people employed, also has a positive relationship with sectoral output. A 1% increase in labor would result in an 8.22% increase in sectoral output holding all other factors constant. These results support the findings of Kimenyi et al. (2016) who found a positive correlation between human capital and productivity growth in Kenya. Further, they discuss the role of investment in education to improve the quality of human capital and spur rapid economic growth in the country.

Finally, capital formation and sectoral output have a negative relationship where a 1% increase in capital formation results in a 0.84% decrease in sectoral output holding all other factors constant. These results are different from the analysis carried out by Ongo et al. (2014) who find that technical progress and infrastructural development have a positive association with economic growth in the Economic and Monetary Community of Central Africa. Interestingly, the findings from Zeb (2013) indicate that the quality of capital falls as temperature increases and results in a drop in economic growth. With the exception of labor, all other variables in the model are not statistically significant. This indicates that weather variability in Kenya does not have a significant direct impact on sectoral output in the country. However, the annual nature of the data used in this research meant that the seasonal effects of weather variability on sectoral output were not captured, which may have led to the weather variables being statistically insignificant. Due to the unavailability of quarterly data (labor, gross fixed capital formation, and CPIA – business regulatory environment), this chapter was unable to take into account the seasonal effects of these variables.

Conclusion

The results from this chapter indicate the presence of a long-run relationship between sectoral output in Kenya and temperature. Furthermore, there is an inverse relationship between temperature and sectoral output, which shows that an increase in temperature will lead to a decrease in sectoral output in Kenya. On the other hand, this research finds a positive relationship between rainfall and sectoral output, which reveals that an increase in rainfall in the country is likely to lead to an increase in GDP per sector. Kenya's economy is highly reliant on the agricultural sector with most small-scale farmers relying on rain-fed farming. As such, an increase in consistent rainfall will lead to increased agricultural output as long as the rainfall is not in excess. Additionally, findings from this chapter show that the business regulatory environment as measured by the World Bank CPIA rating has a positive relationship with sectoral output. This implies that a better policy and institutional framework will lead to higher output in the various sectors in Kenya. The number of people employed also has a positive relationship with sectoral output. Gross fixed capital formation, which measures the annual net increase in physical assets has a negative relationship with GDP per sector in Kenya.

With the evidence gathered from this research, it can be concluded that weather variability has an economic effect on output from the different sectors in Kenya. This suggests that the Kenyan government needs to take a keen interest in understanding and addressing the effects of weather variability and in a broader picture, the effect of climate change on each sector of economy. Some of the sectors may bear more of the brunt due to their dependent nature on weather. However, none of the sectors in the Kenyan economy will be left unaffected due to the effects of changing weather patterns and in the long term, climate change. Therefore, the Kenyan government should ensure that it fully supports the National Adaptation Plan, which is supported by the Climate Change Act that was enacted into law in May 2016. Additional support and increased partnerships will also be required for Kenya to achieve its climate adaptation goals. For example, Kenya needs to actively take a broader perspective that encompasses other countries including those outside the African continent in its environmental conservation discussions. This is because the impact of climate change affect all countries across the globe. As much as temperature and rainfall levels in Kenya are not at extreme levels, there has been a notable change in the weather patterns and the effects are starting to be felt. Given this, Kenya should consider being more aggressive in its reforestation campaign throughout the country. This will help to remove excess carbon dioxide emissions from the atmosphere, thus reducing the severity of weather pattern changes and in the long-run, mitigate climate change. Further research could be carried out to investigate the effect of weather variability on the Kenyan economy using data with a higher frequency. This would help to factor in the effect of climatic seasons in the country on the economy.

Agro-ecological Lower Midland Zones IV and V in Kenya Using GIS and Remote Sensing for Climate-Smart Crop Management

49

Hilda Manzi and Joseph P. Gweyi-Onyango

Contents

Abstract

Food production in Kenya and Africa in recent past has experienced vagaries of weather fluctuations which ultimately have affected crop yield. Farming in Kenya is localized in specific Agro-ecological zones, hence understanding crop growth responses in particular regions is crucial in planning and management for purposes of accelerating adoption. A number of strategies for adoption and adaptation to changing weather patterns have been deployed yet only limited challenges have been partially addressed or managed. This chapter examines previous methods used in classifying agro-ecological zones and further provides additional insightful parameters that can be adopted to enable farmers understand and adapt better to the current

variable and unpredictable cropping seasons. The chapter scrutinizes past and current documented information on agro-ecological zonal valuations coupled with the use of earth observation components such as air temperature at surface, land surface temperature, evapotranspiration, soil, temperature, and soil and moisture content in order to better understand and effectively respond to new phenomena occurring as a result of climate change in the marginal agricultural areas. Significant variations in precipitation, ambient temperature, soil moisture content, and soil temperature become evident when earth observation data are used in evaluation of agro-ecological lower midland zones IV and V. The said variations cut across areas within the agro-ecological zones that have been allocated similar characteristics when assigning cropping seasons. The chapter summarizes the outcomes of various streams of contributions that have reported significant shifts or changes in rainfall and temperature patterns across Kenya and wider Eastern Africa region. The chapter highlights the need for re-evaluation of the agro-ecological zones based on the recent earth observation datasets in their diversity. The research emphasizes the use of multiple climate and soil-related parameters in understanding climate change in the other marginal areas of Kenya.

Introduction

Climate Change and Its Impacts in Lower Midland Agro-ecological Zones IV and V

The worrying trends and implication of the changing climatic patterns and extreme weather events have been previously documented (Donat et al. 2013; Schneider et al. 2018). One of the major concerns is the shift in weather patterns and its adverse effect on rain-fed agriculture. Previous work (Pearce 2000; Rosenzwerg, and le Parry 1994) have shown the vulnerability of most developing countries to climate change. Seo et al. (2009) evaluated the effects of climate variability in Africa and singled out the semi-arid areas as the most sensitive while the productive areas such as the high to medium wet zones becoming even more useful for agriculture. These researchers highlight the role that agro-ecological zones play to bring out the understanding of climate change and further emphasize the role of climate change on the impact on crops and livestock in light of changing economic value. They further observed that climate resilience is built more on net crop and livestock revenue combined rather than crop or livestock alone, particularly the African region. Mendelsohn (2008) links markets and places the largest economic impact of climate change upon agriculture. Furthermore, studies in developing countries have pointed to challenges in placing the economic value to agriculture due to lack of data on farm performance, as argued by Mendelsohn (2008). The author draws parallels from tropical and subtropical agriculture and is of the opinion that both regions are more sensitive to climate change compare to temperate zones and that the level of effect emanate more on climate scenarios at hand than agriculture practices or level of farming activities. In addition, the climate variability differs from one country to another and differences are also evident within regions in the countries (Mendelsohn 2008).

Kenya has experienced extreme rainfall events in every 3 years cycle on average based on the 1989–2011 analysis (Ndirangu et al. 2017). In the same period, severe droughts and changes in rainfall variability have become inevitable. These have severely affected farmers who depend on rain-fed agriculture and have eventually become victims of climate variability and extreme weather events. Furthermore, the global financial and economic crisis have made the situation worse through the disruption of agricultural supply chains and market, weakening the ability of the agricultural sector to address food security. Despite intervention in agriculture, crop, and livestock production system are still sensitive to drought and other extreme weather events especially in arid and semi-arid areas as indicated by Ndirangu et al. (2017). This confirms the existence of fragile local mechanism for coping and poor resilience to cushion against future climate change shocks. Ochieng (2015) discusses the impact of climate change on agricultural production and considers rainfall and temperature has having positive effects on the revenues of most crops. Fluctuation of temperature and rainfall in growing seasons is known to cause serious problems in normal plant processes, hence crop losses are inevitable. The findings by Ochieng (2015) stressed the significance of the longstanding effects of climate change in terms of temperature changes to have an adverse effect on crop production compared to interim effects. The impacts of temperature in this respect significantly override those of rainfall fluctuations. Fischer (2006) predicted that the global warming phenomenon would lead to higher temperatures and modify precipitation levels which to far extent have had an impact on the productivity of land suitable for agriculture. These are some of the current events being experienced in countries such as Kenya. He further concluded that the integration of agro-ecological zonal methodologies and socioeconomic models could provide right tools for land use planning and resource development.

Farming in most parts of Africa, Kenya included, revolves around agro-ecological zones. It is the *agro-ecological* zones as defined by FAO (1978) and improved by Jiitzold and Kutsch (2000) through the farm management guidelines that determine where crops can be suitably grown. In this agro-ecological zones, cropping seasons have been identified based on the length of growing periods. In addition, FAO (1978) defines agro-ecological zoning (AEZ) as the use of soil parameters, natural features, and climate characteristics to demarcate areas potential for agricultural production. The particular parameters used in the agro-ecological zoning and cropping pattern assign more focus on the climatic and soil, chemical, and physical parameters and their requirements by crops and on the management systems under which the crops are grown. Each zone has a similar definition to ensure its suitability to support certain functions. This kind of evaluation calls for certain recommendations designed to improve the existing land-use suitability situation, either through increasing advocacy for production or by barring use due to land degradation. Moreover, the studies on agro-ecological zoning put emphasis on the use of FAO classification of 1978 which looks at the ability of agricultural land to support crop production through length of growing period, temperature, and precipitation. According to FAO (1978), this length of growing period is understood to be the period where rainfall and stored soil moisture is greater than half of the evapotranspiration. This, therefore, simply means the longer the growing season, the more the plants to be planted, the longer the period for plant carbon fixation, and the higher the yields. Vrieling et al. (2013) indicate that the length of growing period is analyzed based on weather station data, which are unfortunately quite scarce in Africa or depend coarse rainfall satellite data that are not reliable. The findings reported by Vrieling et al. (2013) clearly show that there are high variability in length of growth period in arid and semi-arid areas. This is further confirmed by the high crop failure rate in the same regions.

Length of growth periods derived from earth observation data such as GIMMS Normalized Difference Vegetation Index generation 3 (NDVI3g) dataset provided useful information for mapping of farming system as well as study of climate variability. The other option for assessing the length of growing periods is documented elsewhere (De Beurs and Henebry 2010; White et al. 2009) and consider use of time-series remote sensing data. The remote sensing methods have been found to be convenient in providing useful information for understanding cropping patterns especially at the start and end of seasons. If such information is properly harnessed can provide early warning systems that can be leveraged on for efficient planning. Henricksen (1986) discussed the need for proper definition of agro-ecological zones in Africa. According to him, it would enhance the ease in collecting and updating agro-ecological data and further give a better latitude for proper definition of the cropping seasons.

The role of agro-ecological zone in defining the crop environment in Kenya, has been generated from the agro-climatic zones. An agro-ecological zone is therefore defined by its relevant agro-climatic factors, especially the moisture supply and differentiated as well by soil patterns. The aim is to provide a frame-work for the natural land use potential. The main zones are therefore differentiated by their ability to provide temperature and water requirements for the specific crops in that particular agro-ecological zone. This is related to the climatic yield potentials as calculated from the computer. Once these zones are established, they are comparatively run alongside the Braun's climatic zones of the precipitation/evaporation index as shown by Le Page et al. (2017). The comparability is expected to have variances due to the influence of the length and intensity of arid periods, a factor that has also to be considered. New agro-ecological zoning methodologies have been done and found to be effective in assessing crops against climate vulnerability (Le Page et al. 2017).

Climatic changes have caused drastic weather patterns over the years where more consideration other than length of the growing period are needed. The current length of growing periods are characterized by intensive precipitation whose distribution is poor while at the same time high temperatures are experienced in-between period of precipitation cessation. Inclusion of earth observation data, therefore, becomes very critical in understanding developing climate variability within the existing agro-ecological zones and thereafter necessitating technologies that can accommodate significant changes. Earth observation data and remote sensing technologies have improved and hence provide near real-time observations. Moreover, the placement of rain gauges which determine the precipitation data is sparse and may not reflect microclimatic changes that have occurred over the years as argued by Vrieling et al. (2013). The evaluation of agro-ecological zone focuses on changes in precipitation, temperatures, and soil characteristics which have necessitated the interpretation of changes in growing periods over the years using earth observation data. Furthermore, there has been a pressing need to adapt climate-smart crops for the various regions in Kenya. Coincidentally, climate-smart crop management in the twenty-first century is the new paradigm shift that may be panacea to majority of rain-fed smallholder farmers to cope with climate change. This chapter therefore calls for use of earth observation data such as soil surface moisture data, varied temperature parameters, varied precipitation parameters, and other relevant parameters that can enable the evaluation of cropping seasons based on gridded variation found within the agro-ecological zones from earth observation datasets.

Previous studies have shown that rainfall levels are bound to decrease, increase, or remain the same under most climate scenarios albeit with a lot of extremes in some scenarios, while the temperature are likely to increase. It is these impacts and implications of such reports that have necessitated the need to reevaluate the agro-ecological zonation and infer whether there any significant changes in the growing periods. Ayugi and Tan (2019) revealed a rise in temperature which might contribute to hydrological droughts in the arid and semi-arid areas in future. Additional information have pointed out the need to analyze for specific trends and thereafter characterize areas in terms of vulnerability to climate, particularly the semi-arid areas of Africa, Kenya included. King'uyu et al. (2000) noted significant changes over the surface temperature based on data collected in 71 stations for the period 1939–1992 in Eastern Africa. Unfortunately, geographical variability in nighttime temperature was difficult to interpret thereby calling for further research. Nsubuga and Rautenbach (2018) did a review of climate change and variability in Uganda and confirmed a growing trend in changes in temperature and rainfall and, moreso, in the Eastern Africa region where Kenya and Uganda lie. Hastenrath (2001) and Schreck and Semazzi (2004) have also done extensive work on climate change in East Africa and significantly provided information on changes in weather patterns over years. These reviews of scientific research findings have created a better understanding of the recent climate changes and variabilities in Kenya and provide further information for use in future research and adaptive actions.

The use of earth observation data in climate change monitoring cannot be overemphasized. Earth observation data have provided important insights into important parameters such as biological, physical, and chemical in its bid to address climate change needs and adaptation strategies (Guo et al. 2015). The capacity of earth observation data is advanced in terms of temporal and spatial scales. The complexity in the study of climate change in the aspects of atmosphere, oceans, and lands, make earth observation data an important option as stressed by Guo et al. (2015). The launch of various datasets by NASA and their availability to near real time open a huge platform for addressing climate change issues in Africa. The current chapter attempts to integrate a number of these options to give insights to climate-smart agricultural option in these fragile agro ecological zones IV and V with an aim of providing strong adaptation and adoption strategies to variable weather and cropping seasons.

This chapter focuses on the agro-ecological zones IV and V of the marginal lands of Tharaka-Nithi, Meru, Makueni, and Machakos counties that run along a similar agro-climatic belt in Eastern Kenya. These areas cover semi-arid region where most farmers depend on rain-fed agriculture for livelihood. These areas are characterized by crops as such green grams, sorghum, millet, and pigeon peas. Agro-ecological zones IV and V are classified as a Lower Midlands that are found in semi-arid areas (FAO 1996). According to FAO (1978), the various cropping patterns in the two rainy seasons are evaluated as having the following characteristics:- very short to short and very short cropping seasons, very short to short and very short to short cropping seasons, very short to very short to short cropping seasons, two very short cropping seasons, very uncertain and very short to short cropping season, and finally very uncertain and very short cropping season for Tharaka Nithi. Part of Meru that form part of the agro-climatic belt of Tharaka-Nithi have similar cropping pattern. Machakos' lower midlands zone V is also characterized by very short and very short to short cropping seasons, very short and very short cropping seasons, and finally very short to short and very short to short cropping seasons. Kitui, on the other hand, has very short to short and short to very short cropping seasons, very short and very short cropping seasons, very uncertain and short to short cropping seasons for both zones IV and V (Jiitzold and Kutsch 2000). The average rainfall and temperatures for Tharaka Nithi, Meru, Makueni, Kitui, and Machakos lower midland zones IV and V as documented by the farm management hand book of Kenya is illustrated in Table 1. Illustration of the these zones are also shown in Fig. 1.

Earth Observation Products in Climate Change Monitoring

Time average, soil moisture content underground, land surface skin temperature, multiyear monthly mean surface temperature, air temperature, total precipitation flux, total surface precipitation flux, total surface precipitation, precipitation rate, combined gauge precipitation, monthly precipitation, climatology rainfall flux, and monthly evapotranspiration for varied periods products were obtained from earth observation Geospatial Interactive Online Visualization and Analysis Infrastructure (GIOVANNI) NASA web portal. The products used were precipitation rates in mm/day with a spatial resolution of 0.25° for the period 1998–2019. Precipitation rates here refers to rainfall intensity. Another product used was amount of precipitation on monthly basis recorded as mm/day for the period 1998–2017 packaged as time average maps at 0.5° spatial resolution. Thirdly, soil moisture content underground at 0–10 cm, 10–40 cm, and 40–100 cm was also evaluated. The products were obtained from NOAH through the GLDAS model for the period 2000–2019. Alongside these, the soil temperature at 0–10 cm, 10–40 cm, and 40–100 cm was obtained from Atmospheric Infrared Sounder (AIRS)/National Oceanic and Atmospheric Administration (NOAA) products for the period 1998–2014 at 0.25° spatial resolution. Another temperature parameter examined was the products of air temperature at surface day time and night time as obtained from AIRS/STM for the period 2002–2016 at 1° spatial resolution. Further products on evapotranspiration from NLDAS/MOSO for the period 1998–2014 at 0.25° spatial resolution. The dataset used for this study are general time average maps for periods not less than 10 years to bring various phenomena of variation in the area of study. These phenomena are meant to provide current insight into climate change variability and influence in agro-ecological lower midland zones IV and V. The remote sensing product analyses were done using QGIS, Terrset software, and other GIS software. This was to get current status of the agro-ecological lower midland zones IV and V and whether there are any indications that can lead to change in cropping season and suitability of crops. Other products examined include time average products on amount and distribution of the precipitation as compared to studies done by Jiitzold

Table 1 Characterization of lower midland zone V based on cropping season, annual temperature, and annual average rainfall – Jatzold and Kutsch 2000)

Name of the county	Agro-ecological zones IV and V	Cropping season in the two rainy seasons	Annual mean temperature in ^{o}c	Annual average rainfall in mm

and Kutsch (2000) that are mostly used for national policy planning on cropping season in Kenya through the farm management guideline books.

Climate Variability in Agro-ecological Lower Midland Zones IV and V Soil, Air, and Land Surface Temperature Variations

This chapter gives a brief overview of air temperatures, land surface temperature, and multiyear land surface skin temperature daytime for the period 2000 to 2016 that depict an upward trend in temperature changes (Figs. 2 and 3, respectively) for zones IV and V. These areas that include parts of Makueni and Kitui show temperatures of between 26 °C and 31°C while Machakos, Tharaka, and parts of Meru have temperature ranges of 24–26°C. These temperatures changes compared closely with those earlier reported by Jiitzold and Kutsch (2000) (Table 1) with annual average temperature ranges of 22–24 °C for Machakos, Kitui, and Makueni indicating an increasing trend in temperature. Tharaka Nithi and parts of Meru temperature fluctuate between 24–26 °C and 22–24 °C, respectively. The trend of temperature

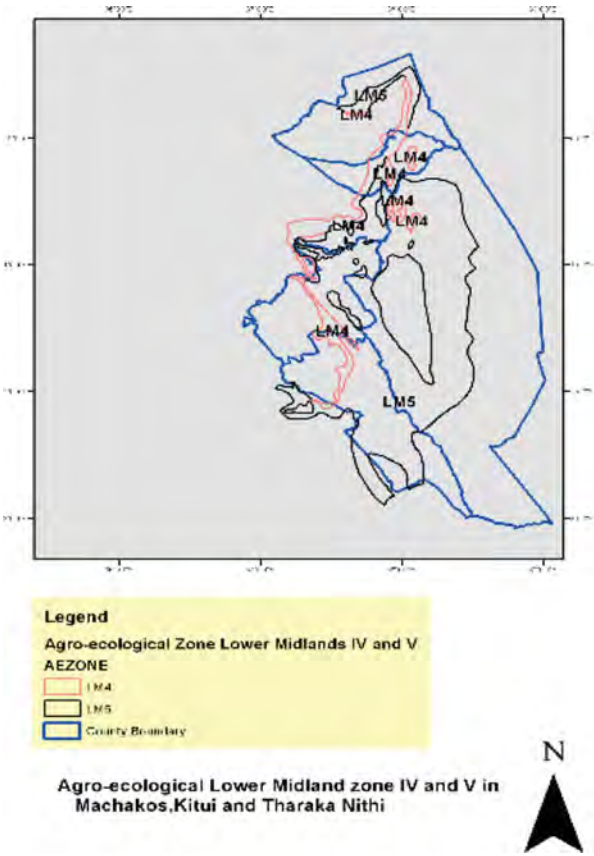

Fig. 1 Agro-ecological lower midland zone IV and V in Machakos, Kitui and Tharaka Nithi

variations confirms reports by previous studies (Nsubuga et al. 2014; Omondi et al. 2014), an indication of increase in temperature trends and variability over East Africa. The challenge of variations from one locality to another as highlighted by Omondi et al. (2014) may be solved through having gridded earth observations data. Earth observation data provide spatial resolution smaller compared to data collected from various in situ stations whose spatial resolutions are usually very wide due to unavailability of adequate and well-distributed weather or radar station in Kenya. There are pockets of temperature variations as shown on the time-average maps of air temperature for the period 2002–2016 which is a 14-years-period for both daytime and nighttime (Fig. 2). This is an indication that over the years, different areas within the agro-ecological zones of lower midland IV and V have experienced climate variability in terms of temperature changes. This may also imply that the length of growing periods of crops are different within the same zone. Vrieling et al. (2013) is of the opinion that the distribution of crop and farming systems go hand in hand with the length of growing period. They further note that length of growing period in Africa (Kenya included), have been determined by weather station data with poor spatial distribution.

Climate change over the years has been studied and confirmed to cause a fluctuation in the length of growing periods as shown by Gregory et al. (2005). Moreover, Ayugi and Tan (2019) brings out the importance of surface air temperature as one of the parameters to be considered and blends well with the current finding in regard to agro-ecological lower midland zone IV. Ayugi and Tan (2019) further highlights the significant role of this type of products in the assessment of climate change variability for interpretation of the overall climate state in Kenya. His observations depict a trend of increasing temperatures in the period between 1971 and 2010. Similar inferences are drawn from the earth observation climate products for air temperature at surface for the period 2002 to 2016 in the similar areas. The air temperature at surface (Fig. 2) varies significantly within the agro-ecologies of lower midland zones IV and V. These datasets if generally compared to data by Jiitzold and Kutsch (2000) in Table 1 are possible to infer that there is an increasing trend in temperature. Rise in temperatures were predicted to increase between 1 °C and 2.5 °C on average, with a predictive temperature change in 2020 being between 1 °C and 2 °C for 2030 and 2.5 °C for 2040 (Eitzinger et al. 2011). These predictions are likely to change crop suitability for various regions as further argued by Eitzinger et al. (2011) based on research that displays maps with changing suitability of tea growing area in Kenya. He further cautions that areas between 1400 and 2000 meters above

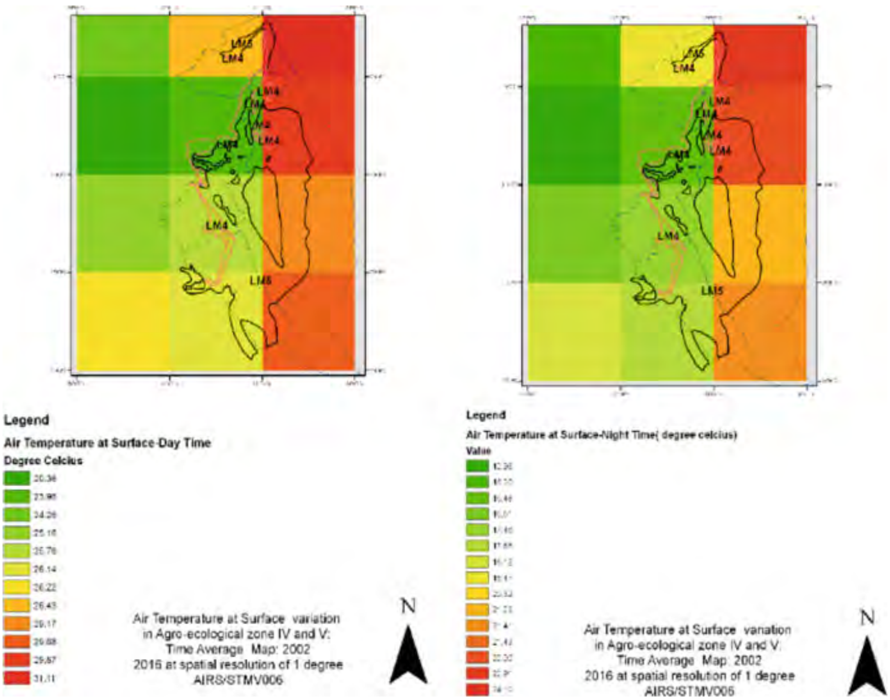

Fig. 2 Air temperature at surface variation in agro-ecological lower midland zone IV and V

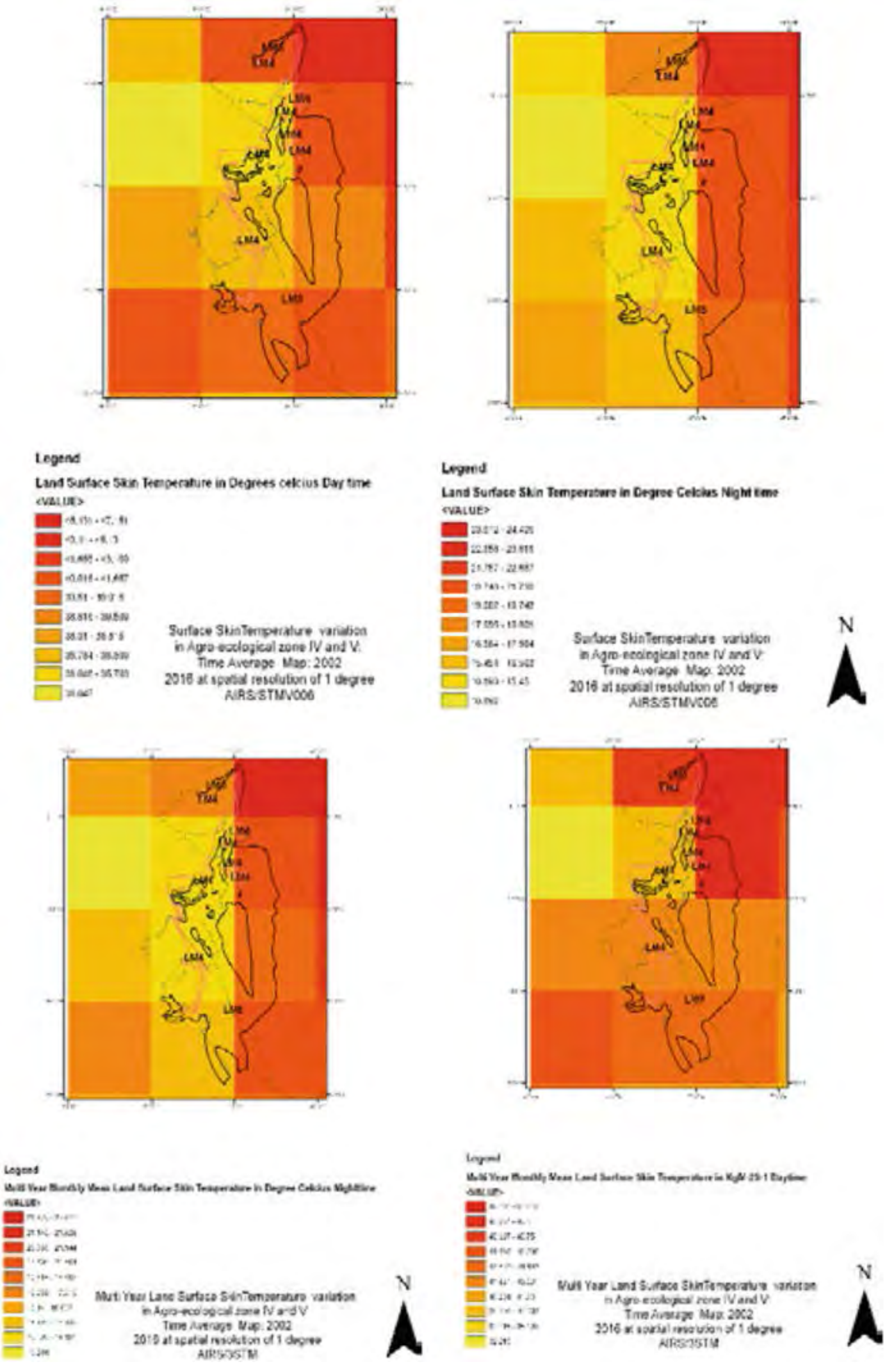

Fig. 3 Land surface skin temperature variations in agro-ecological lower midland zone IV and V

sea level are likely to be regions that will experience the highest changes in suitability for crops.

Additionally, this chapter made effort to deeply make observations on monthly Land surface skin temperatures for the period 2002–2016 at 1° spatial resolution to further improve on understanding of the analysis. Figure 3 shows significant variations within the agro-ecological lower midland zones IV and V. Such variability in land surface temperatures in any area is a manifestation of variation of vegetation responses to water stress (Sun 2009; Pinheiro et al. 2006). Land surface temperature has been confirmed to be a very important parameter for environmental as well as climate studies (Pinheiro et al. 2006). It is also important to note that currently, weather stations provide limited data on spatial patterns of temperatures over large areas as shown by Assiri (2017). This leaves interpretation of the land surface temperatures from satellite imagery a viable option. It would, therefore, be prudent to argue that land surface temperature is a key parameter in understanding crop water stress within any agro-ecological zone.

The significance of land surface temperatures in climate monitoring cannot be ruled out in the extreme weather event scenarios as reported by Sun (2009). Furthermore, Vlassova et al. (2014) emphasize land surface temperature as an important parameter in soil-vegetation transfer modeling in most terrestrial environments. This parameter becomes even more important in evaluating cropping seasons and assessment of length of growing periods in such areas. Time average maps of multi-year monthly daytime and nighttime land surface temperatures for the period 2002–2016 are also presented for agro-ecological zones IV and V (Fig. 3). Evidently, there are significant variations across the entire agro-ecological lower midlands zones IV and V area as also confirmed by the monthly daytime and nighttime temperatures for the same period. Assiri (2017) demonstrated high correlation between moderate resolution imaging spectroradiometer (MODIS) satellite nighttime land surface temperature which also had high correlation with station-based minimum temperatures as compared to the daytime land surface temperatures. The accuracy and effectiveness of MODIS land surface temperature was further corroborated by those of Kenawy et al. (2019). Apparently, Sun (2009) showed that land surface temperature uses/values to be quite wide and included but not limited to hazard prediction, water management in agriculture, crop management, in terms of crop stress monitoring and yield forecasting and nonrenewable resource management. In addition, the authors provide contribution to work done regarding assimilation of land surface temperatures in soil moisture monitoring through the surface energy balance assimilation scheme.

This chapter also makes observations on soil temperatures for 0–10 cm, 10–40 cm, and 40–100 cm for the period 1998–2014 at a spatial resolution of 0.25° since the focus of understanding agro-ecological zones currently suitable for certain crops and the cropping seasons. These products do not seem to show significant differences among the various soil depths (Fig. 4). This could probably be attributed to vegetation cover, an important element in thermal conditions of soils (Holmes et al. 2008). This condition has the ability to influence the vertical differentiation of soil temperatures as previously revealed by Skawina et al. (1999). What was striking is

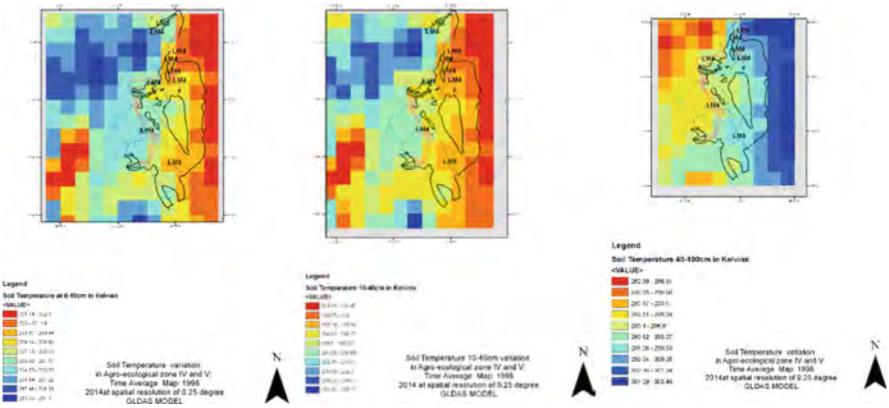

Fig. 4 Soil temperature variations in agro-ecological lower midland zone IV and V

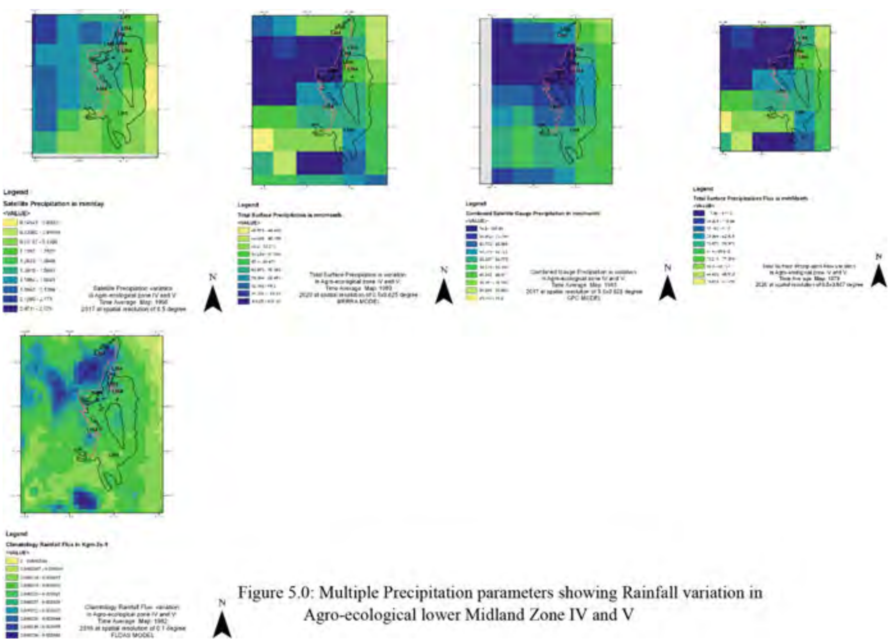

Fig. 5 Multiple precipitation parameters showing rainfall variation in agro-ecological lower midland zone IV and V

the significant variation identified within the agro-ecological lower midland zones IV and V with the soil temperatures varying across Makueni, Machakos, Tharaka Nithi all the way to the small parts of Meru, i.e., the ranges are 26.85–22.85, 20.85–24.85, 24.85–26.85, and 17.85–23.85, respectively, for all areas (see Fig. 5). These observations summarize quite significant and clear changes that have been taking place within the zones over a long period as result of climate variability and extreme weather events. Similar observations have been reported before by Buckman and Brady (1971) who stressed the significance of soil in agriculture since it is the medium upon which crops are grown. They confirm that significant chemical and biological reactions begin when certain temperatures are optimal in the soil media. Moreover, Skawina et al. (1999) demonstrated the significance of weather conditions on the thermal properties of soil. This, therefore, means that significant climate variability influence soil temperatures positively or negatively and thereby affecting crop growth.

Soil temperature parameters therefore become extremely important factors to consider in agro-ecological zone characterization as shown by studies of Osińska-Skotak (2007) who reported that soil temperatures were influenced by meteorological situations taking place. Onwuka (2018) confirms that soil temperatures are affected by environmental factors especially by controlling the heat on the soil surface and heat dissipated from the soil down the profile. The importance of soil temperature cannot be overemphasized in this chapter. Indeed Sabri et al. (2018) showed that biological processes such as seed germination, seedling emergence, plant root growth, and the availability of key nutrients are components dependent on soil temperature, moreso the transmission of water inside the plant. In addition, injuries in the plant tissue at root zone can occur as a result of fluctuation in temperatures (lower or higher) as attested by Decker (1955). This could imply that soil temperatures fluctuation could the reason for high soil-borne diseases due to injury of plant tissues. It could also be the explanation for high soil-borne disease incidences associated with climate change. Schollaert Uz et al. (2019) documents the role that remote sensing datasets can play in linking different climatic variability events to pest and disease incidences. In this chapter, the coupling of crop models to pest and diseases model together with climates are considered as new frontiers to enabling monitoring of pests and diseases outbreaks under extreme weather events for early preventative measures.

Precipitation Amount, Rate, and Soil Moisture Variations

Several earth observation products modeled for precipitation analysis were used in this chapter for understanding variations within the agro-ecological lower midland zones IV and V as shown in Fig. 5. The first product we considered was the average time maps for precipitation monthly for the period 1998–2017 (recorded in mm/day) at spatial resolution of 0.5°. This revealed variations in precipitation amounts within these areas. The amounts varied across the areas in consideration with Kitui and Makueni showing a range between 1.39 and 0.9 mm/day, while Machakaos had precipitation amounting to 1.59–1.89 mm/day and Tharaka Nithi and Meru exhibiting 1.39–1.89 mm/day and 1.26–1.59 mm/day, respectively. Another product of interest that observed was the total monthly surface precipitation in mm/day for a spatial resolution $0.5 \times 0.625°$ for the period 1980–2020. This product also showed significant variation within the agro-ecological lower midland zones IV and V where places like Makueni and Kitui showed precipitation amounts of 63.67–44.43 mm/month with small pockets showing higher precipitation amounts of 70.36–82.49 mm/month. Machakos area had rainfall ranges between 70.36 and 94.2 mm/month with some small areas to the North East experiencing precipitation amounts of 94.2–118.04 mm/month. Finally, Tharaka Nithi and parts of the drier Meru experienced precipitation amounts of 70.36–118.04 and 53.4–48.2 mm/month, respectively. The combined satellite gauge precipitation monthly in mm/month at spatial resolution of 0.5° for the period 1983–2017 also formed an interesting observation set. There were clear and interesting variations on precipitation amounts within the agro-ecological lower midland zones IV and V. This product specifically showed 49.17–62.72 mm/month for Makueni and Kitui, while for Machakos the precipitation ranges between 69.96 and 101.61 mm/month. Tharaka Nithi and Meru show precipitation amount of 59.77–101.61 mm/month with a small area to the northeast showing 41.51–49.17 mm/month. Finally, the time average maps of climatology of rainfall flux monthly for the period 1982–2016 at spatial resolution of 0.1° in $Kg/m^{-2}/s^{-1}$ was also observed. The observation pointed to the fact that substantial variations existed within the area of the agro-ecological lower midland zones IV and V. All products showed a significant rise in precipitation amount for areas, especially Makueni, Kitui, and Machakos. We observe that these areas have experienced gradual increase in rainfall amounts in some pockets, e.g., Machakos as compared to earlier reports by Jiitzold and Kutsch (2000), implying a rising trend. On the contrary, Makueni and Kitui areas seem to register a downward trend in precipitation (see Fig. 5 and Table 1). Over the years, these semi-arid regions have been described to be regions of limited precipitation (Slatyer and Mabbutt 1964). However, Managua (2011) had conflicting views, indicating a rise in rainfall for the period 2020–2050 for most parts of Kenya. These scenarios of high unprecedented rainfall are currently being experienced in Kenya.

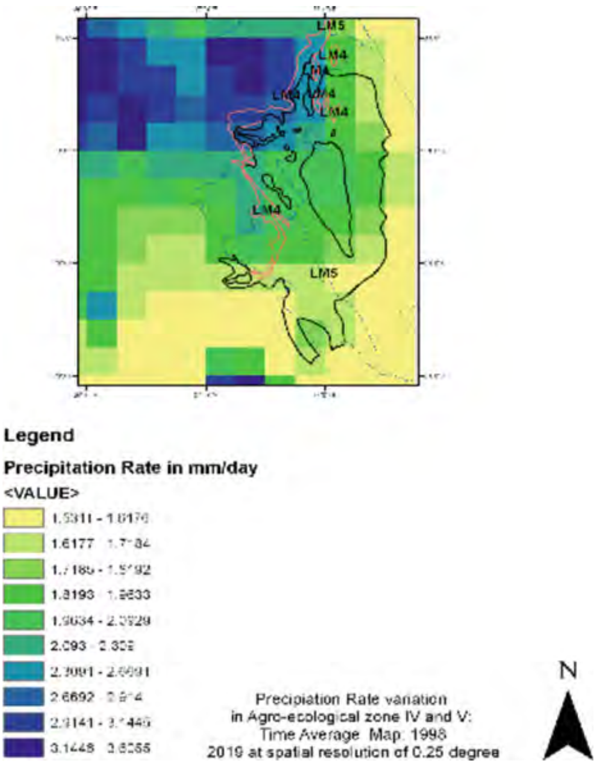
Precipitations in the marginal areas have been described to undergone considerable positive change, indicating trends of increasing rainfall amounts in some pockets. Other studies have reported conflicting (negative trends), indicating the failure to include the changing Indian Ocean weather patterns; − something that may affect climate data modeling along semi-arid regions as argued by Herrero et al. (2010). Vrieling et al. (2013) gave a comprehensive descriptive dataset on changes in weather patterns which showed an increasing trend in the dry period between the short and long rains and this has been happening at the expense of short rains. Interestingly, Elbasit et al. (2014) has also demonstrated that there is a good agreement between satellite Tropical Rainfall Measuring Mission (TRMM) 3B43 products and the monthly rain gauge information, confirming increasing trend in rainfall and the reliability on Tropical Rainfall Measuring Mission (TRMM) earth observation products for climate monitoring.

The variations observed and scenarios of higher precipitations in some part of the agro-ecological lower midlands zones IV and V call for future evaluation of the cropping season as well as the length of growth periods. The proper and reliable estimation of onset and cessation of precipitation is critical in rain-fed agriculture in the semi-arid areas as emphasized by Fiwa (2014). Incidentally, existing information shows that the relationship between precipitation onset, cessation, and length of growing period becomes very important in the planning of agricultural activities especially among smallholder farmers in Africa (Fiwa et al. 2014). In this chapter, therefore, we are of the opinion that there is an upward increase in precipitation in these marginal areas and but the absolute increase the precipitations have vast variability. Aming et al. (2014) also identified precipitation extremes and higher variabilities in arid and semi-arid parts of Africa, the findings which seem to be in line with our observations in these agro-ecological lower midland zones IV and V of Kenya. Fluctuation and variations in the rainfall have also been confirmed by Camberlin (2009) with indications showing serious variations from one weather station to another, especially in the long rains of East Africa. The growing developments in satellite-based rainfall assessments provide a cheaper alternative to rainfall data that is available for free online (Kumar and Reshmidevi 2013). The collection of rainfall data using passive or active remote sensing techniques has a potential to bring a more informed way of handling climate change in Africa and moreso Kenya with huge landmass represented by arid and semi-arid regions. These methods of rainfall data collection can be described as brightness temperature for passive method (Hengl et al. 2010) and attenuation of the radar power at several heights to estimate surface rain for the active method (Skolnik 1962; Meneghini et al. 1983; Hengl et al. 2010).

Rainfall intensity from earth observation data is known to show variations within the agro-ecological lower midland zones IV and V (Fig. 6). Higher precipitation rates are associated with areas of high precipitation as shown in Fig. 6. High precipitation rate is associated with runoff and hence low soil moisture content (Mutiga et al. 2013). This further affects the length of growing period and expected cropping seasons. Notably, high runoff is associated with low productivity of soil and causes severe risk in agriculture as result of climate hazard (Gatot et al. 2001). Furthermore, it is known that soils experiencing high runoff as result of high rainfall intensity are normally very low infertility due to the percolation of soil nutrients. Rainfall intensity monitoring in agro-ecological zone of marginal areas of Kenya is key since high level of runoff in the semi-arid areas are highly associated with precipitation rates as well as poor farming practices. Fiwa et al. (2014) asserts that rainfall intensity monitoring using weather satiation is a real challenge across Africa. Thies (2008) evaluated rainfall intensity data from satellite imagery differentiation techniques and concludes that they offer potential for improved rainfall rate. This allows for spatiotemporal near real-time information on rainfall distribution. This kind of data and techniques in Africa will definitely address the challenges facing climate-smart crop management under extreme weather events whenever they will be fully available.

Additional products considered included soil moisture content below the ground at 0–10 cm, 10–40 cm, and 40–100 cm, soil temperatures at 0–10 cm, 10–40 cm, and 40–100 cm, see (Fig. 7). These additional products provide information on moisture availability for the various crops within the agro-ecological lower midland zones IV

Fig. 6 Daily precipitation rate variation in agro-ecological lower midland zone IV and V



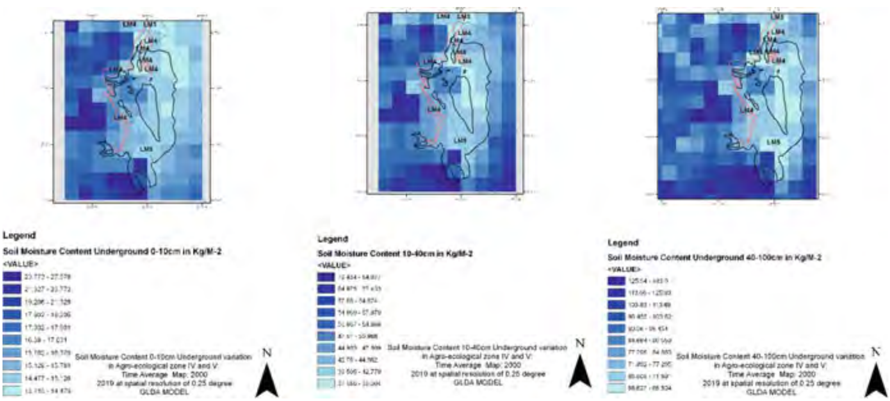


Fig. 7 Soil moisture content underground variations in agro-ecological lower midland zones IV and V

and V. This chapter makes a contribution on knowledge on increased variability in soil moisture content across the entire study area. This can be attributed to the verse variance in soil types and soil characterizes as well as canopy cover. This can also be related to the various changes in climatic;- soil related weather parameters. Other factors affecting soil moisture contents are human-induced activities that cause land degradation (FAO 2002). Degraded soils have very low water retention capacity hence low soil moisture content. The role that soil moisture content plays in crop development cannot be overemphasized. Every crop requires good soil moisture content to stimulate activities between the shoot and the root zone. Soil moisture contents are identified as key factor determining length of growth period which impact on cropping seasons and crop suitability in any agro-ecological zones.

Kamara and Jackson (1997) states that soil moisture is a better indicator of water availability to the crop than rainfall amount. Improved soil moisture management can only take place when analysis of soil moisture content are carried out and are well understood. Understanding soil moisture content scenarios assist in working toward high water retentions in the soil which eventual reduction in soil runoff in some cases. In semi-arid regions, the issue of soil moisture becomes very important since moisture stress in crop is one of the key determinants of crop failure. In other studies, Pellarin et al. (2020) has shown that soil moisture content can be used to infer precipitation using PrISM Model. This kind of modeling is said to provide useful information concerning crop yield estimates and irrigation demands over large areas. In his research, comparison made with weather station information showed that there was high correlation proving the significance and the role that soil moisture content below ground plays in understanding shifting precipitation patterns. Overall soil moisture content is vital in understanding cropping season, i.e., low soil moisture levels are indications of declining length of growing period for crops. The biggest challenge identified by this chapter is existence of many soil moisture algorithms and products that cannot be compared to other parameters such as precipitation as propounded by Pellarin et al. (2020). He further indicated the need for analysis that can integrate other parameters such as precipitation for the proper validation of satellite soil moisture and also system that can determine the relationship between different soil moisture products.

Evapotranspiration Variations

The other parameter that this chapter observed is evapotranspiration. The monthly evapotranspiration earth observation reported here are for the period 1998–2014 at spatial resolution of 1° and recorded in $\mathrm{Kgm}^{-2}\ \mathrm{s}^{-1}$ (see Fig. 8). The values indicated a variation in evapotranspiration across the agro-ecological lower midland zones IV and V area. There were no products for comparison with previous periods in order to understand any changes in evapotranspiration. Areas like Meru agro-ecological lower midland zones IV and V revealed higher evapotranspiration rates. This could be explained by high vegetation cover known to be in this region and high soil moisture content. Evapotranspiration is directly related to soil moisture content and

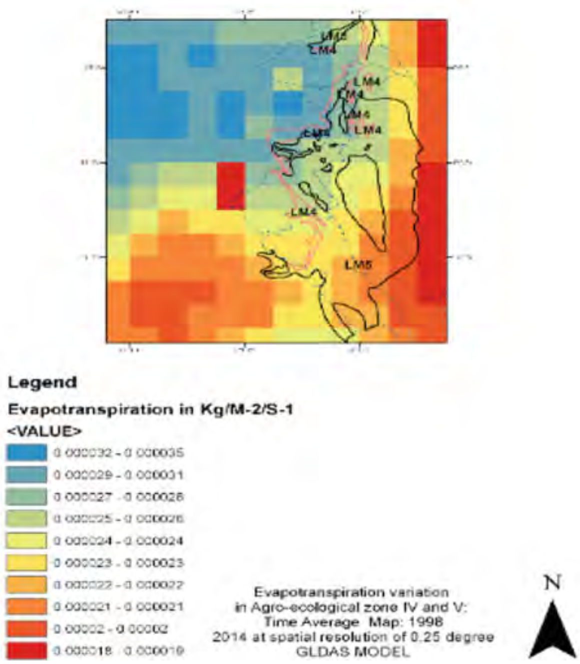

Fig. 8 Evapotranspiration variation in agro-ecological lower midland zone IV and V

atmospheric moisture demand (Fischer et al. 2008). Further Fisher et al. (2008) shows that soil moisture is as a result of precipitation while atmospheric moisture emanates from radiation that is controlled by surface and atmospheric temperatures.

Areas in Kitui and Makueni experience very low Evapotranspiration, which could also be due to low vegetation covers that are characteristic of these areas. These indicate that areas of high evapotranspiration rates are likely to have longer growing period. Table 1 classifies these areas and reveal that they have similar short cropping season as those with very low evapotranspiration rates. Evapotranspiration as shown by studies of Jiitzold and Kutsch (2000) shows variations in the length of growing periods which eventually determine the cropping seasons. In this case, the evapotranspiration employed statistical methods of Penman & McCulloch with albedo for green grass being 0.2; McCulloch (1965). This is not to imply its inadequacy but rather the need for improvement. Liou and Kar (2014) confirms that evapotranspiration at a global or regional scale can be done by combining surface parameters obtained from remote sensing data and surface meteorological variable and vegetation characteristics. Marshall and Funk (2014) describes evapotranspiration as an important component in the energy, water, and geochemical cycles that influence climate properties and further says that its interaction with drivers of climate change remain unexplored in Africa.

A combination of a number of parameters and variables in a climate change scenario is likely to improve evapotranspiration analysis and interpretation. This would further improve on the assessments of cropping seasons. Marshall and Funk (2014) in his discussion points out the usefulness of satellite imagery in representing important characteristics of evapotranspiration over Africa. Similar results have been reported by Dai (2010) who showed rising temperatures in Africa and a decreasing evapotranspiration as result of low precipitation and low soil moisture content. Satellite imagery products through available remote sensing techniques can enhance the availability of spatial and temporal datasets of Normalized Difference Vegetation Index (NDVI), Leaf Area Index (LAI), fraction of incidence sunlight that reflects, surface radiations, and radiometric surface temperatures that are indirectly related to evapotranspiration (Liou and Kar 2014). Further Henricksen (1986) present extensive report on the length of growing period model that was used that seem to work well in drought simulations in Africa. He pointed out the inability of the model to analyze moisture level below 1 month and the assumption of the model concerning runoff and deep percolation.

Contribution of GIS and Remote Sensing in Agro-ecological Zone Evaluations

The suitability of gridded climate indices in monitoring climatic variation is demonstrated in Donat et al. (2013) studies. The gridded climatic indices can enable near real-time monitoring of events as well as their placement for long-term use at both global and regional scales. Boitt et al. (2014) in his studies on the impact of climate change on agro-ecological zones and this chapter has made quite a number of inferences from their work regarding GIS and remote sensing. There are siginificant shifts in agro-ecological zones based on datasets analyzed and projections for future in 2050. These shifts and changes can be picked at apporoximately 1 km and significantly identified as “zone shift.” Boitt et al. (2014) further concluded that multivariate clustering under a GIS enviroment is a very informative tool for agro-ecological zone definition. Global agro-ecological zone module V is the latest model for defining crop suitability for various regions. This module utilizes various climate datasets such as number of rainy days; mean minimum, mean maximum temperature; diurnal temperature range; cloudiness; wind speed and vapor pressure (IIASA/FAO 2012). Among this climate dataset, soil parameters are accommodated extensively (IIASA/FAO 2012). Its use among African countries is still limited and therefore needs to be scaled for adoption to the benefit of smallholder farmer levels. Its adoption is generally challenged by the limited use of GIS and remote sensing datasets in most African countries (Rowland et al. 2007). This module could provide the new insights into understanding climate variability and its impact on cropping seasons. Its use in evaluating existing information on agro-ecological zones of lower midland IV and V is paramount.

Wango et al. (2018) explore the suitability of WorldClim dataset in climate analysis and monitoring in the advent of climate change. All previous studies highlighted the role of GIS and remote in transforming the understanding of climate variability, thereby successfully addressing the climate change issues in Kenya and

Africa at large. For example, Henricksen (1986) emphasize the use of satellite remote sensing to capture and monitor the climate variability occurring year after year. Another research by Bartoszek et al. (2015), for Poland, affirms the use of satellite data as useful source of temporal and spatial variability of information on climate. FAO (2017) in the report on review of remote sensing tools, products, and methodologies points out, the issues that Africa is facing, when it comes to improved crop production forecasting. The reports highlights the improvement in technologies related to remote sensing and the mode of communication which are at varying levels of development. Further, the reports mention the problems of various institutions, especially the government, to integrate and use effectively remote sensing products. This in the end has affected timely crop forecasting across the continent. Finally, there are readily available good products of early warning system that Africa should take advantage of since they are free.

Climate-Smart Crop Management

According to Mungai (2017), smallholder farmers in the East African region are facing unprecedented challenges in pursuit of increased production under increased climate change and variability. His work further gives highlights on the dire need for information on possible risk and viable management strategies. Information on risk stem from understanding the climate variability within the agro-ecological zones where farming is defined as discussed in previous sections of this chapter. Nsubuga and Rautenbach (2018) concluded that climate variability is bound to have considerable effects in terms of food availability, especially on the agriculture depended populations. They further point out that climatic variations and differences will continue to have a significant role in the geographic distribution of crop production. Understanding climate variations within agro-ecological zones and their influence on the soil environment is key in climate-smart crop management. The parameters selected in this chapter present time average maps that have shown increasing variations over years as result of climate change. Scaling down satellite imagery and remote sensing technologies for use by smallholder farmer presents one possible solution for the reduction of the impact of climate variability on food security. Previous studies have presented the challenges therein while highlighting various solutions that can be adopted. Nsubuga and Rautenbach (2018) in their reviews highlighted the importance of rainfall measurements in Uganda but failed to show a downward trend in rainfall amount yet there has been as shift precipitation rates as well as end and start of seasons. We looked at some of the climate-smart crop management practices that have been suggested and implemented. The chapter underpins the importance of climatic variability evaluation at agro-ecological zone level scaled down to farmers needs for successful climate-smart crop management. Food and Agriculture Organization (FAO) focus on climate-smart crop production pushes for crop production and practices that enable climate change and mitigation. In this view, different methods have been recommended and used. One of the approaches that has been advocated for is cropping systems which are believed to cushion farmers against climate change shocks. The other is the use of quality seeds and plantings adapted to the various environments. Sustainability and the resilience of a production system is believed to be achieved through improved crop varieties suited for a wide range of agro-ecosystem FAO (2013).

Changes in temperature, precipitation, assessment of evapotranspiration characteristics and soil temperature-moisture regimes necessitate for new frontiers in the management of crops through introduction of adoptable technologies. Report by FAO (2013) on climate-smart crop production pushes for agricultural systems that are very efficient in terms of inputs while at the same having less variability. This will enable sustainability through the stability in the outputs hence more resilient in nature and therefore able to cushion against climate change shock and long-term variability. On the other hand, climate-smart intervention by smallholder farmers cannot be ignored (Ullah et al. 2019). Even though most of the local coping strategies and mechanism may be weak as earlier mentioned, they can be strengthened by incorporating them in technology-based smart inventions.

Another adaptation for climate-smart agriculture is through crop modeling that focuses on building early warning monitoring systems that effectively alter the overall management of the crop in volatile climate environment (Ullah et al. 2019). In his studies, he highlights the use of weather data smart interventions that involve close monitoring of climate variability and relaying of information to relevant stakeholders. This is bound to improve further if implemented under an environment of well evaluated and monitored agro-ecological zoning. This means, the cropping seasons and length of growing period variations within agro-ecological zones will be factored in. The advent of weather data smart intervention and yield forecasting through crop modeling place the use of satellite imagery in products provision in crucial place. Weather data smart intervention cannot forget platforms of forecasting more frequently to the farmers. Stigter (2010) gave focus on the importance of such advisory services in his studies. Zuma-Netshiukhwi et al. (2016) in his study emphasizes on the need for agro-meteorological knowledge transfer or extension services to end-users such as farmers and other relevant stakeholders. Further, he discusses the need for downscaling of seasonal climate to lower resolutions that can address the farmers' needs. Abura (2017) argues that there is need for meteorological department to streamline climate advisory services to the locals so that livelihoods risk as result of climate change can be reduced. This can be done by training of agricultural extension officer who in most developing countries work hand in hand with the smallholder farmers.

Conclusion

This chapter concludes that variation within agro-ecological lower midland zones IV and V does exist and changes have been occurring over a long period of time. All the products from GIOVANNI NASA Earth data website have shown enormous variations. Secondly, earth observation products used alongside in situ information have the potential of improving agro-ecological zoning and the interpretation of the cropping season and crop suitability. Thirdly, climate studies that have relayed conclusive information on agro-ecological zones have focused more on rainfall with exclusion of more datasets that can provide more insight in terms of understanding climatic trends and cropping systems.

Fourthly, use of more varied datasets that focus on varied precipitation parameters, varied temperatures parameters, evapotranspiration, thermal conditions of soil, and soil moistures content are likely to improve on the understanding of length of growing period, hence enabling the adoptions of crop varieties that are climate-smart for particular regions. The low adoption of earth observation products and technologies in remote sensing poses a problem in the monitoring of climate variability in Africa. Effective assessment of length of growing periods from climate information for Africa need to be strengthened and improved through adoption of earth observation products alongside in situ surveillance. Finally, the climate-smart crop management must be considered to cut across the various sectors and not agriculture alone if successful implementation is to be achieved. Agricultural systems can achieve climate-smart objectives through continuous monitoring of activities being undertaken at the agro-ecological zones level since they form very important platforms of crop productions in Kenya. This study confirms that climate-smart crop management under extreme weather in Kenya is unavoidable. This management will stem from the adoptions of technologies, strategies, and policies that focus on climate monitoring, evaluation of exiting agro-ecological zones, and adoption of agro-ecosystems that can support sustainable agriculture. In addition, future studies on climate change impact on marginal areas should consider focusing on further reclassification of agro-ecological zones in Kenya and evaluation of cropping season using both satellite imagery and in situ information to compensate for challenges and gaps experienced in previous studies. This will assist smallholders' farmers in addressing the current challenges that they have as a result of climate variability. Soil moisture assessment and integration and its inter-comparison to other parameters still remain a challenge that needs to be addressed.

Abstract

This chapter addresses the use of partial least squares–structural equation modeling (PLS-SEM) to determine the requirements for an effective development of water resource management frameworks. The authors developed a quantitative approach using Smart-PLS version 3 to reveal the views of different experts based on their experiences in water-related adaptation to climate change in the Lake Victoria Basin (LVB) in Uganda. A sample size of 152 was computed from a population size of 245 across the districts of Buikwe, Jinja, Mukono, Kampala, and Wakiso. The chapter aimed to determine the relationship among the availability of legal, regulatory, and administrative frameworks, public water investment, price and demand management, information requirements, coordination structures, and analytical frameworks and how they influence the development of water resource management frameworks. The findings revealed that the availability of legal, regulatory, and administrative frameworks, public water investment, price and demand management, information requirements, and coordination structures had significant and positive effects on the development of water resource management frameworks. Public water investment had the highest path coefficient ($\beta = 0.387$ and $p = 0.000$), thus indicating that it has the greatest influence on the development of water resource management frameworks. The R^2 value of the model was 0.714, which means that the five exogenous latent constructs collectively explained 71.4% of the variance in the development. The chapter suggests putting special emphasis on public water investment to achieve an effective development of water resource management frameworks. These findings can support the practitioners and decision makers engaged in water-related adaptation to climate change within the LVB and beyond.

Climate change · Lake Victoria Basin · PLS-SEM · Water resource management frameworks

Introduction

Background

There is an increasing pressure on water resources in the Lake Victoria Basin (LVB) due to rapid population growth, increased urbanization and industrialization, uncontrolled environmental degradation, and pollution (Dauglas et al. 2014;

Bakibinga-ibembe et al. 2011). These pressures still remain as a big challenge to the sustainable management of water resources (Mongi et al. 2015). Moreover, the LVB remains to be an important water resource for five countries, namely, Uganda, Kenya, Tanzania, Rwanda, and Burundi. The LVB is the largest freshwater lake in Africa with a surface area of 68,800 km^2. It provides resources for fishing, agriculture, medicine, forestry, water transport, and other economic activities (Odongtoo et al. 2018). Its surrounding area is affected by increasing commercial activities and inadequate provision of sanitation services, among others (Okurut 2010; Wafula et al. 2014). These affect the landscape and water resources around the lake, making the water unsuitable for use.

According to Oyoo-Okoth et al. (2010), there is a combination of four analyzed heavy metals in the water samples of the LVB showing similar presence of heavy metal in the waters within the lake. This can be attributed to the fact that human activities, such as industrialization and agricultural practices, seriously contribute to the degradation and pollution of the environment, which adversely affect the water bodies, as noted by Devi et al. (2018). Increased human activities, such as poor land use, uncontrolled abstractions, and water pollution, greatly reduce the quantity and quality of the available water resources.

Globally, water resources are facing severe degradation due to pollution and inefficient water resource management strategies (Wang et al. 2015). It has been reported that water pollution causes approximately 14,000 deaths per day, mostly due to drinking water contamination caused by untreated sewage in developing countries (Devi et al. 2018). Rinawati et al. (2013) argued that these challenges create potential major threats to global biodiversity around water bodies, such as the LVB. The above authors further observed that this is true of the biodiversity around LVB as noted by Case (2006). The most recent statistics show that cities and small towns within the LVB are rapidly growing (Dauglas et al. 2014). The best examples of the growth pattern of towns and cities can be observed in Mwanza in Tanzania, Jinja and Port Bell in Uganda, and Kisumu in Kenya. Both population growth and urbanization have negative impacts on the quality and quantity of water resources. Some of these impacts include eutrophication and siltation, in addition to water pollution, as a result of increased runoff from bare lands as deforestation persists around the LVB (Ondieki 2015). Muhweezi (2014) also noted that biodiversity and ecosystem-specific goods and services around the LVB are likely to be adversely affected in the future by water pollution. It can be inferred that these challenges revolve around poor management of water resources. Failure to address such challenges will cause serious problem to the lives of many people who depend on the LVB.

Poor management of the scarce water resources can lead to climate change. The climate is continuously changing and is getting worse over time. Moreover, extreme weather conditions are occurring more frequently than before, thus negatively affecting the agricultural sector, consequently leading to food shortages. Farmers from different age groups acknowledge an increase in temperature, and they agree that the temperature is increasing with time (Mongi et al. 2015).

According to Leal et al. (2015), water is one of the essential resources for human being, and its availability has great impacts on the environmental, political, and economic situations. This means that water resources have to be managed well. Water resource management is the activity of planning, developing, distributing, and managing the optimum use of water resources (Okurut 2010). Ssozi et al. (2015) defined water resource management as the development of political, social, economic, and administrative systems to develop and manage water resources. According to the technical committee of the Global Water Partnership, Integrated Water Resources Management (IWRM) is a process that promotes the coordinated development and management of water, soil, and other related resources to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystem (ITU-T 2010).

Analytical Framework

Water resource management has been recently developed due to the improvement in water technology, natural events, economic developments, and changing social needs. The current trend in water management changed from technical to a combination of technical and sociopolitical perspectives (Demetropoulou et al. 2010). This led to an increase in stakeholders and public participation. It is therefore necessary to establish a framework to guide practitioners and managers in water resource management. For managers and decision makers to conduct good analysis, it is necessary to use analytical frameworks to promote logical thinking in a systematic manner.

Adaptation and ICT Frameworks

According to Akoh et al. (2011), the frameworks of Information and Communication Technology (ICTs) in mitigating climate change and adaptation are still relatively new. Frameworks on adaptation to climate change can be considered in three ways: first, to emphasize the potential of ICTs to reduce vulnerability to climate change by building resilience; second, to focus on delivering different types of information needed to achieve effective climate change adaptation; and third, to emphasize a disaster risk management framework focusing on the reduction of community vulnerabilities and management and recovery from emergencies as they arise.

According to the 1992 Dublin Conference on water and the Rio de Janeiro Summit on sustainable development (White 2013), the four key principles adopted were as follows: first, freshwater is a finite and vulnerable resource essential to life, development of irrigation, industrial and transport sector, and the environment; second, water development and management should be based on a participatory approach, involving users, planners, and policy makers at all levels; three, women play a central part in the provision, management, and safeguarding of water; and fourth, water has an economic value in all its competing uses and should be recognized as an economic good.

Objective

The objective of this chapter was to apply a PLS-SEM to evaluate the requirements for the development of water resource management framework in water-related adaptation to climate change in Uganda's side of the LVB.

Methods

In evaluating the requirements for the development of water resource management framework in water-related adaptation to climate change, PLS-SEM was used. The proposed model was analyzed in two different stages: first, the model was composed of measurement models that define the relationship between latent indicators and their manifest variables, and second, a structural model showing the relationship between the manifest variables. A total of 24 factors which were obtained from the literature review were named as the observed variables and were divided into six groups: availability of legal, regulatory, and administrative frameworks, analytical framework, public water investment, information requirements, coordination structures, and pricing and demand management. These six groups were called exogenous latent constructs. Thus, an effective water resource management framework is influenced by the six major constructs.

Study Hypotheses

Based on the objectives of the research, the hypothesized model was developed. Quantitative data to test the hypothesis was collected from experts in water resource sectors and was subjected to Smart-PLS test. Some of the hypotheses passed the test and were therefore accepted, whereas the others that failed the test were rejected. Hypothesis 1 (H1): Availability of legal, regulatory, and administrative frameworks has a significant and positive effect on the development of water resource management frameworks. Hypothesis 2 (H2): Analytical framework has a significant and positive effect on the development of water resource management frameworks. Hypothesis 3 (H3): Public water investment has a significant and positive effect on the development of water resource management frameworks. Hypothesis 4 (H4): Information requirements has a significant and positive effect on the development of water resource management frameworks. Hypothesis 5 (H5): Coordination structures has a significant and positive effect on the development of water resource management frameworks. Hypothesis 6 (H6): Pricing and demand management has a significant and positive effect on the development of water resource management frameworks. This hypothesis design was adapted from Shahid et al. (2018).

Data Collection

The data collection procedures involved three important phases. In the first phase, preliminary variables were obtained to formulate hypotheses using the materials in the review of literature, such as books, journals, and conference materials. In phase two, a pilot study was conducted to ensure consistency and completeness to help modify the questionnaire. Lastly, the questionnaire survey was conducted to obtain the opinion of the respondents. This study procedure was adapted from Shahid et al. (2018). Data collection was performed in the Buikwe, Jinja, Mukono, Kampala, and Wakiso districts in Uganda. The above districts were chosen based on the fact that those areas heavily depend on the LVB and at the same time were immensely affected by the decline in water resources. The key stakeholders that were engaged in this chapter included employees from the LVB Commission, the LV Fishery Organization, District Environmental Officers, District Forestry Officers, NEMA, Ministry of Water and Environment, National and Regional Policymaking and Communication Organs, and key community leaders. To calculate the sample size, Slovin's formula was used, $n = \frac{N}{1 + Ne^2}$, where n denotes the sample size, N denotes the population size, and e denotes the error margin. The population size of 245 was used with a confidence interval of 95% and error margin of 5%, generating a sample size of 152.

The questionnaire was composed of two sections. Section one consisted of the respondents' personal information. Section two consisted of variables appropriately grouped into six categories based on the nature of the measurements/constructs: availability of legal, regulatory, and administrative frameworks (LRA), analytical frameworks (AF), public water investment (PW), information requirements (IR), coordination structures (CS), and pricing and demand management. The questionnaires were administered to different stakeholders with an experience of more than 5 years in the water resource sector, such as executives, managers, water engineers, and IT officers. During the 4 months of study, valuable opinions from experts were obtained and incorporated in the model.

Data Analysis

The hypothesized structural model was analyzed using Smart-PLS version 3. Smart-PLS has advantages over other regression-based methods: First, it is capable of evaluating several latent constructs with various manifest variables and is considered as the best technique for multivariate analysis (Shahid et al. 2018). Second, it is suitable for evaluating the constructs when the sample size is less than 200 in comparison with other SEM software, such as AMOS, which require a sample size of more than 200. In this specific chapter, the sample size was 152 and therefore justifies the use of Smart-PLS. Smart-PLS involves a two-step procedure, namely, evaluation of the outer measurement model and evaluation of the inner structural model (Henseler et al. 2009).

Results and Discussion

Respondents' Profile

Table 1 shows the demographic information of the respondents. The respondents were selected from a wide range of professionals engaged in the water resource sector. About 61.8% of the interviewed experts were male. Majority of the interviewed individuals were in the middle age group (30–39 years) (34.9%), followed by the young age group (20–29 years) (31.6%), (40–49) years were 23.7%. Those aged 50 years and above only accounted for 9.9% of the total population. This research is part of a bigger study conducted to develop a water resource management ICT model in the LVB.

Table 1 Demographic information

Response item	Count	Percent
Gender Distribution		
Female	58	38.2
Male	94	61.8
Total	152	100.0
Age Group		
20–29 years	48	31.6
30–39 years	53	34.9
40–49 years	36	23.7
50–59 years	14	9.2
Above 59 years	1	0.7
Total	152	100.0
Qualification		
PhD	4	2.6
Masters	68	44.7
Bachelors	67	44.1
Diploma	13	8.6
Total	152	100.0
Designation		
Manager/Administrator	33	21.7
Staff/Employee	100	65.8
Systems Administrator	8	5.3
Client/Customer	1	0.7
Total	152	100.0

Demographic Information of the Respondents

In Table 1, the highest percentage (44.7%) of the respondents have acquired master's degree, followed by bachelor's degree (44.1%), diploma (8.6%), and PhD (2.6%). The highest category of workers (65.8%) was staff/employee, followed by managers/administrators (21.7%), system administrators (5.3%), and ICT technicians (6.6%).

The level of education, the designation, the age, and the sex have significant effects on the perception of a person with regard to information. Older people tend to have more experiences, whereas highly educated ones display more in-depth knowledge on the subject matter of research. A low level of education has an impact on the use and adoption of technologies. The designation status is related more to the skills in the management of water resources. This promoted trust on the outcome of this study.

Evaluation of Outer Measurement Model

Outer Loading

In order to determine whether what was hypothesized was in line with the collected data, PLS-SEM was employed. PLS-SEM is very suitable for theory building and for examining the complex relationship of the models. The outer measurement model was used to calculate the reliability, internal consistency, and validity of the observed variables together with the unobserved variables (Gabriel et al. 2016). Consistency evaluations were based on a single observed and construct reliability tests, whereas convergent validity and discriminant validity were used for validity assessment. The observed variables with an outer loading of at least 0.7 are acceptable and should therefore be retained, whereas those with values less than 0.7 should be dropped (Shahid et al. 2018; Smith et al. 2014). From Table 2, the outer loadings of the retained variables ranged between 0.819 and 0.917 which are more than 0.7 and

Table 2 Construct reliability and validity

Main constructs	Item	Outer loading	T-statistics	CR	AVE
Availability of legal, regulatory, and administrative Frameworks	LRA2	0.799	12.766	0.812	0.683
	LR3	0.853	16.156		
Coordination structures	CS2	0.773	10.034	0.839	0.724
	CS4	0.922	40.008		
Information requirements	IR1	0.890	34.942	0.886	0.796
	IR2	43.681	43.681		
Public water investments	PWI1	13.500	13.5	0.742	0.591
	PWI3	9.463	9.463		
Price and demand managements	PDM2	14.359	14.359	0.810	0.681
	PDM3	19.859	19.859		

therefore valid. The variables, namely, collection and allocation, reuse of waste water, and water resource management, were dropped since their outer loading were below 0.7. Composite reliability (CR) was used for internal consistency evaluation in the construct reliability.

Average Variance (AVE)

To establish convergent validity on the construct, average variance extracted (AVE) is normally used. It is the grand mean value of the squared loadings of the indicators associated with the construct and is the sum of the squared loadings divided by the number of indicators. An AVE value of at least 0.50 shows that the construct explains more than half of the variance of its indicators (Hair et al. 2011). As shown in Table 2, the AVE values are greater than 0.5; therefore, both their convergent validity and internal validity are acceptable for this measurement model. In Table 3, the cross-loading of all observed variables are greater than the inter-correlations of other constructs in the model. The Fornell–Larcker criterion is a very good approach for assessing discriminant validity. It compares the square root of the AVE values with the latent variable correlations. The square root of each construct's AVE should be greater than its highest correlation with any other construct (Shahid et al. 2018). Therefore, these findings confirmed the cross-loading assessment standards which provided acceptable validation for the discriminant validity of the measurement model.

Using the t-test approach, some of the items that measure each construct were either retained or dropped, depending on whether the t-values are more or less than 2.76. The t-values must be greater than 2.76 for it to be retained as a measure for the variable (Hair et al. 2013; Shadfar and Malekmohammadi 2013). In Table 2, all the t-values of the retained items in measuring each construct are greater than 2.76.

Table 3 Discriminant validity for water resource management frameworks

	LRA	*CS*	*IR*	*PDM*	*PDM*
Availability of legal, regulatory, and administrative frameworks (LRA)	0.827				
Coordination structures (CS)	0.615	0.851			
Information requirements(IR)	0.092	0.135	0.892		
Price and demand management (PDM)	0.532	0.575	0.072	0.825	
Public water investment (PWI)	0.029	0.067	0.308	0.054	0.769

Table 4 Path coefficient

Hypothesized path	Standardized β	P-values
Availability of legal, regulatory, and administrative frameworks	0.244	0.000
Coordination structures (CS)	0.206	0.001
Information requirements(IR)	0.335	0.000
Price and demand management (PDM)	0.211	0.000
Public water investment (PWI)	0.387	0.000

Estimation of Path Coefficients (b) and P-values

The significance of the hypotheses was tested by calculating the *beta (β)* values. The β values indicate the measure of the effect the variable has on the model. The higher the values, the stronger the effect, and it is always <1. As shown in Table 4, both the β *and* p values of every path in the hypothesized model were calculated.

In (H1), researchers hypothesized that availability of legal, regulatory, and administrative frameworks would significantly and positively influence the development of water resource management frameworks. The findings in Table 4 and Fig. 1 confirm that Availability of Legal, Regulatory, and Administrative Frameworks of water-related factor significantly influenced the development of water resource management frameworks ($\beta = 0.244, p < 0.000$). Hence, H1 was excellently confirmed. Furthermore, the findings from Table 4 and Fig. 1 hypothesized that the (H3) public water investment-related factor positively influenced the development of water resource management frameworks ($\beta = 0.387$, $p < 0.000$), showing that (H3) was effectively approved. Information requirements (IR) significantly and positively influenced the development of water resource management frameworks ($\beta = 0.335$, $p < 0.000$). Coordination structure (CS)-related factor was positive and significant ($\beta = 0.206, p < 0.001$), thus greatly supporting. The effect of price and demand management-related factor ($\beta = 0.211$ $p < 0.000$) was also confirmed, thereby supporting (H6). The greater the β coefficient, the stronger the effect of an exogenous latent construct on the endogenous latent construct. Analytical frameworks were dropped from the list because they failed both the t-test and the outer loading test.

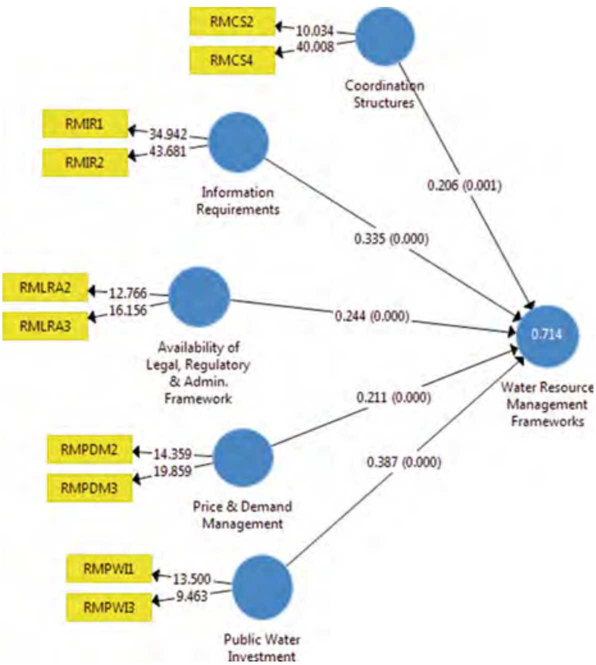

Fig. 1 The graphical representation of all path coefficients of the water resource management frameworks

The R^2 value of the model was 0.714, which means that the five exogenous latent constructs collectively explained 71.4% of the variance in the development of water resource management frameworks. The study suggests putting special emphasis on the public water investment factor to achieve an effective development of water resource management frameworks. These findings can support the practitioners and decision makers engaged in water-related adaptation to climate change within the LVB and beyond.

Limitation of the Study

The limitation and constraint of the chapter came from the fact that it was not possible to visit all the countries of the East African Community due to logistical constraints. This will be part of the future works when the current logistical constraints are solved.

Business Benefit

In accordance with the complete analysis of the measurement models and structural model, some of the hypotheses were statistically significant and hence were accepted, whereas the others failed the analysis. The results of this chapter support a richer and accurate picture of the factors influencing the development of effective water resource management frameworks. It is therefore important to consider the availability of legal, regulatory, and administrative frameworks, coordination structures, information requirements, price and demand management, and public water investment factors in the development of effective water resource management frameworks. The information obtained from this chapter will also enrich the body of knowledge that will benefit other researchers in the field of water resource management.

Conclusion, Recommendation, and Future Research

Conclusion

The key contribution of this chapter was the empirical identification of the constructs that can influence the development of effective water resource management frameworks and also the investigation of the fundamental issues affecting the constructs observed by water experts in the LVB. The results of the chapter revealed that availability of legal, regulatory, and administrative frameworks, coordination structures, information requirements, price and demand management, and public water investment had significant positive effects on the development of water resource management frameworks. This therefore suggests that emphasis should be put on the above variables. The final results of the partial least squares–structural equation modeling revealed that public water investment had the highest path coefficient ($\beta = 0.387$), thus indicating a major influence on the water resource management frameworks. Therefore, water resource managers should pay more attention to public water investment factors during the development of water resource management frameworks.

Recommendation

This chapter recommends that for a successful development of water resource management frameworks, emphasis should be put on availability of legal, regulatory, and administrative frameworks, coordination structures, information requirements, price and demand management, and public water investment. Since public water investment had the highest path coefficient ($\beta = 0.387$) with a major overall influence on the development of water resource management frameworks, more emphasis should be put on it.

Lesson Learned and Future Studies

This chapter revealed that majority of the people engaged in different activities around the LVB are unaware of the dangers posed by their economic activities. Moreover, the local leaders lack effective and efficient means of disseminating and sharing information on the LVB and the impact of human activities on ecosystems, biodiversity, and water resources.

Future Studies

The areas for further research may focus on the study of how effective water resource management frameworks influence the design of an effective water resource management ICT model for an integrated water resource management of the LVB .

51 Retracing Economic Impact of Climate Change Disasters in Africa: Case Study of Drought Episodes and Adaptation in Kenya

Mary Nthambi and Uche Dickson Ijioma

Contents

Abstract

Valuation studies have shown that drought occurrences have more severe economic impact compared to other natural disasters such as floods. In Kenya, drought has presented complex negative effects on farming communities. The main objective of this chapter is to analyze the economic impacts of drought and

identify appropriate climate change adaptation measures in Kenya. To achieve this objective, an empirical approach, combined with secondary data mined from World Bank Climate Knowledge Portal and FAOSTAT databases, has been used in three main steps. First, historical links between population size and land degradation, temperature and rainfall changes with drought events were established. Second, economic impacts of drought on selected economic indicators such as quantities of staple food crop, average food value production, number of undernourished people, gross domestic product, agriculture value added growth, and renewable water resources per annum in Kenya were evaluated. Third, different climate change adaptation measures among farmers in Makueni county were identified using focused group discussions and in-depth interviews, for which the use of bottom-up approach was used to elicit responses. Findings from the binary logistic regression model show a statistical relationship between drought events and a selected set of economic indicators. More specifically, drought events have led to increased use of pesticides, reduced access to credit for agriculture and the annual growth of gross domestic product. One of the main recommendations of this chapter is to involve farmers in designing and implementing community-based climate change adaptation measures, with support from other relevant stakeholders.

Keywords

Drought · Agriculture sector · Logistic regression · Climate adaptation · Kenya

Introduction

The agriculture sector in sub-Saharan Africa accounts for about 30% of the gross domestic product (GDP) and 40% exports in the region (Calzadilla et al. 2013). The sector is characterized by rainfed extensive crop and pastoral systems with low yields below potential (Amjath-Babu et al. 2016). The overreliance on rainfed systems has made the region prone to impacts of increasing temperatures, declining precipitation, changes in surface water run-off, and increased carbon dioxide (CO_2) (World Bank 2008). Low precipitation and high temperatures have reduced surface moisture content and increased evapotranspiration rates respectively causing soil degradation. Frequent weather-related disasters such as floods, droughts, tropical cyclones, and landslides have led to deaths and loss of livelihoods (Lumbroso 2017).

Drought is one of the most recurring climate change disasters for countries on the horn of Africa. This extreme weather event has occurred due to lack or inadequate precipitation leading to water shortage for plants, human, and animal consumption (Muller 2014; Maity et al. 2016). Its occurrence has been associated with global climate change, as there exist scientific evidence associating increased human activities with global climate change shocks such as floods and droughts (IPCC 2007). There are four types of droughts: meteorological (shortage in rainfall), hydrological (insufficient water in rivers and reservoirs), agricultural (inadequate soil moisture), and socioeconomic droughts (Maity et al. 2016).

In sub-Saharan Africa, droughts are common and their economic impacts in general have not been adequately studied. The reason behind this could be the complex nature of drought as it presents complex effects to lives on earth (Wang et al. 2014). Drought accounts for about 5% of the natural disasters but the losses that it causes account for about 30% of what is caused by other natural disasters (Wang et al. 2014). It aggravates water scarcity problem by affecting both surface and groundwater resources leading to reduced water supply, quality, and disruption of wetlands (Mishra and Singh 2011). When it persists for months or years, it causes conflicts between pastoral communities due to competition for the diminishing water and pasture resources (Uexkull 2014; Martin et al. 2016).

To demonstrate the economic impacts of drought, this chapter follows the framework by Freire-González et al. (2017). The authors establish many pathways and the drivers that contribute to the economic impacts of drought, which they classify into two categories: primary and secondary. The primary impacts of drought are those that affect economic agents such as industries, households, government, and the environment, while the secondary impacts lead to fires, desertification, and migration of people, as well as animals (Freire-González et al. 2017). Further, drought affects tangible assets such as land and vegetation cover differently from other natural disasters such as earthquakes, storms, or floods that affect buildings, machines, and other assets. In the long term, drought leads to soil degradation, damages to buildings due to soil sagging, as well as the ecosystems due to excessive groundwater abstractions without enough rainfall to replenish it (Freire-González et al. 2017). Drought leads to an increase in temperature causing excessive loss of water through evapotranspiration thus reducing water availability and quality. People are affected differently by drought depending on their geographical location (Freire-González et al. 2017). For example, the impact of drought on people in developing countries is more pronounced due to limited financial capacity to cope with effects such as malnutrition, starvation, increased pests and disease vectors such as malaria and dengue fever-causing mosquitoes (Freire-González et al. 2017), economic burden, and in extreme cases, death. Freire-González et al. (2017) framework focuses on how water scarcity caused by drought affects the households and the environment (Fig. 1).

It is important to focus on drought because it exacerbates the water scarcity situation, coupled with the fact that Africa is one of the driest continents in the world (Mishra 2014). Drought severely affects the water sector in many parts of SSA region, and the impact of the drought on the sector negatively affects the economy.

Some of the effects of drought on the agricultural productivity are also tabulated (Table 1), and the resulting socioeconomic impacts. The analysis gives a broad picture of the effects of drought on the agricultural productivity and the social aspects of the farmers. In some regions of America, the costs relating the effects of drought on the crop and livestock sectors among households have been quantified. For instance, Craft et al. (2017) carried out a study in Kentucky, USA, and reported a reduction in livestocks and hay produced, estimated at a cost of $143.4 due to

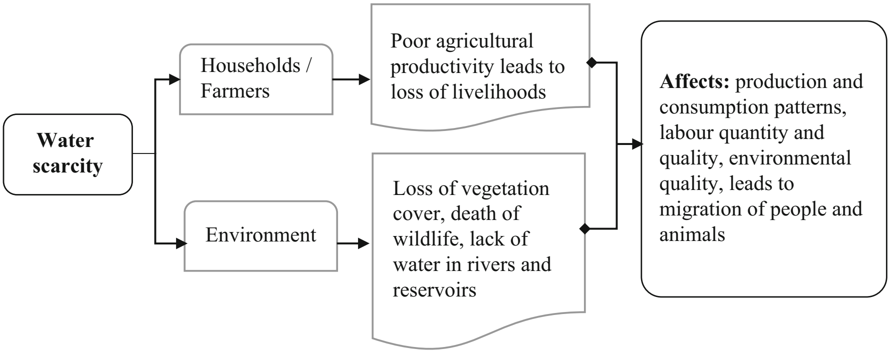

Fig. 1 Impacts of water scarcity caused by drought on households and environment (Adapted from Freire-González et al. 2017)

Table 1 Impacts of drought on agricultural productivity and resulting socioeconomic impacts

Description	Impacts on productivity	Socio-economic effects
Cropping systems	Shift planting and harvesting dates	High market food prices
	Partial or total crop failure	Starvation and malnutrition
	Decreased crop yields	Decrease in farmers' income
Livestock	Decrease in forage from grasslands	Conflicts over pasture
	Increased livestock deaths	Decrease in household income
	Decrease in the quality of meat and milk	From livestock sales
Soil properties and soil health	Insufficient soil moisture for plant growth	Loss of vegetation cover
	Death of soil micro-organisms	Desertification
Hydrological cycle	Reduced water levels in rivers and reservoirs or no water at all	Increase in water prices
	Water scarcity	Conflict over scarce water and pasture resources

water shortage caused by drought. However, the quantitative analysis of the impacts of drought on livestock and crop production in SSA has not yet been estimated due to paucity of available data and research capacity. In the context of SSA, a general qualitative analysis based on previous studies such as Wang et al. (2014), Kusangaya et al. (2014), and Adams et al. (1998) is used in this chapter to draw a close context.

Climate Change Adaptation Measures in the Agriculture Sector of Sub-Saharan Africa

Climate change adaptation is one of the coping strategies supported by the United Nations Framework Convention on Climate Change (UNFCCC) to help developing countries, to reduce the negative effects of climate change (UNFCC 2015;

Deressa et al. 2009). Countries in sub-Saharan Africa express their adaptation needs in a policy document known as the Intended Nationally Determined Contributions (INDCs) (UNFCC 2015). The implementation of the INDCs is supported by several stakeholders such as government institutions, non-governmental organizations (NGOs), donor organizations, the World Bank, and the United Nations Environmental Programs involved in environment and climate change adaptation implementation in SSA region. These organizations have so far supported adaptation strategies in the agriculture sector such as small-scale irrigation of crop in areas where rains have failed, crop and livestock diversification, changes in planting dates, use of soil and water conservation techniques, namely terracing, mulching, and organic manure application (Nthambi et al. 2021; Bryan et al. 2013; Calzadilla et al. 2013; Francisco et al. 2010). Previous research has treated climate change adaptation measures in agriculture as a private good because this only involves individual farmers' adapting to the situation to reduce the local impacts of climate change (Lavoro 2010; Hasson et al. 2010). The effectiveness of these adaptation measures depends on the amount of resources available to support the adaptation process. Adaptation measures can, however, be categorized into two classes: autonomous and anticipatory (public). Autonomous adaptation measures are adjustments to respond to climate variability such as (rainfall) by individual farmers. This could be adopting suitable cropping types, changes in planting dates, and investment in irrigation technologies among other strategies (Calzadilla et al. 2013).

Anticipatory (public) adaptation is a planned measure to respond to climate change which is based on a public policy characterized by acceptability, flexibility, and net benefits (Dinar et al. 2008, c.f. Calzadilla et al. 2013). There are already existing studies from different countries in SSA region that have suggested autonomous adaptation measures (Alemayehu and Bewket (2017); Gebrehiwot and van der Veen (2013); Tessema et al. (2013); Deressa et al. (2011); Amdu (2010)). However, there are limited studies that have sought to address the anticipatory (public) climate change adaptation approach from both a scientific and public policy perspective.

Methodology

Study Area

Kenya is one of the SSA countries in the East African region. It covers an area of 581,309 km^2, which consists of 98.1% land and 1.9% water mass (GoK 2010). The agro-ecological zone distribution map of Kenya is shown in Fig. 2a, and this map identifies four main climate zones including humid, subhumid, semi-arid, and arid regions within the administrative map of Kenya. About 82% of the land mass represents arid and semi-arid areas (ASALs) (Kabubo-Mariara 2009; Rosenzweig et al. 2004), which are naturally prone to drought events. In Kenya, most

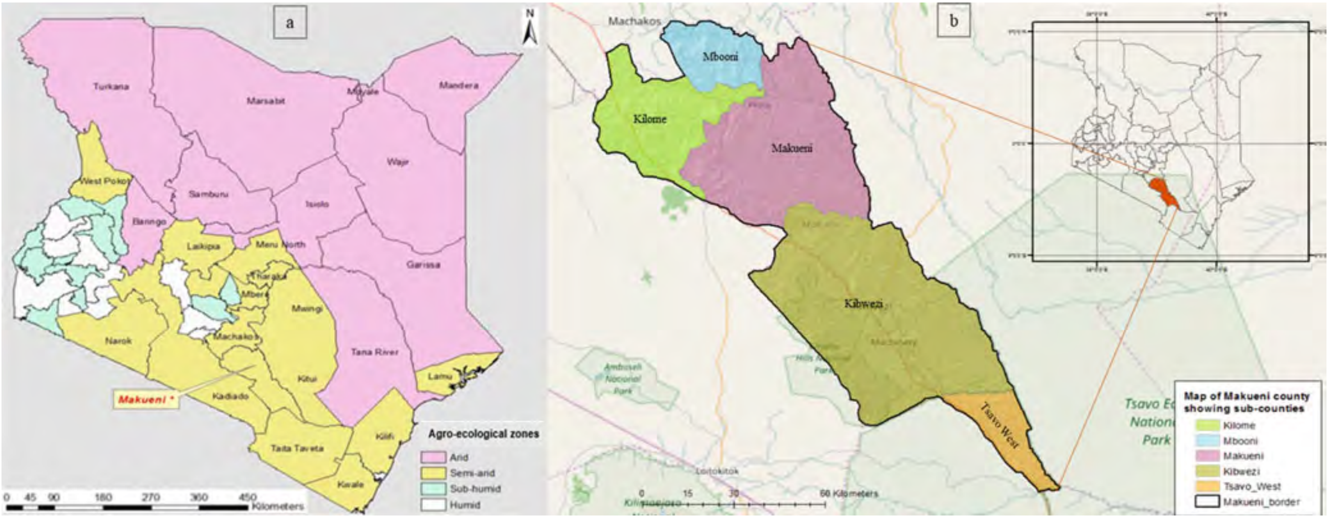

Fig. 2 Map of Kenya showing (**a**) the distribution of agro-ecological zones across the counties and (**b**) the sub-counties in Makueni, the case area in Kenya

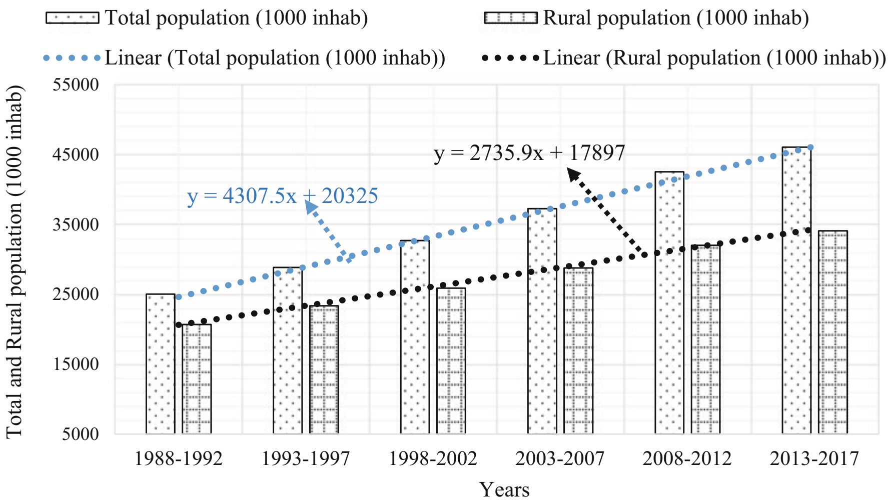

Fig. 3 Total and rural population (1000 inhabitants) between 1988 and 2017 in Kenya (Data source: FAOSTAT 2017)

households found in the ASAL region have limited financial capability to respond to weather shocks such as the severe drought events (Ng'ang'a et al. 2016).

One of the counties in the ASALs region of Kenya in focus is Makueni County. It is situated in the eastern part of Kenya and lies between Latitudes 1° 35′ and 3° 00″ South and Longitudes 37° 10′ E and 38° 30′ E. It covers an area of 8034.7 km^2 (GoK 2013) I has four sub-counties (Fig. 2b). Households in Makueni County hold a base area of 1.58 hectares which is more in comparison to the national household land holding size of 0.97 hectares. The area experiences a bimodal rainfall pattern of between 300 mm and 1200 mm/annum (GoK 2013). The County's average temperature ranges between 20.2 °C and 35.8 °C (SACRED AFRICA 2011). It is prone to frequent droughts which are caused by inadequate rainfall leading to loss of fodder and food crop productivity. The drought events affect crop farming in the lower areas of the County making the communities living there to take a shift from crop production to animal production (GoK 2013).

One of the main drivers of climate change in Kenya is land degradation resulting from unsustainable land use practices due to a growing population. Land degradation occurs mainly due to the excessive conversion of woodlands into agricultural and settlement areas to cater for the increasing demand for food and shelter among households (Shadeed and Lange 2010). The estimated population in Kenya is approximately 46 million people out of which 34 million people live in rural areas (FAOSTAT 2017). Since the late 1980s, there has been an increasing population trend in the rural areas and the total number of inhabitants in Kenya (Fig. 3). The increase in rural population (Fig. 3) means an increasing dependence on agricultural activities to sustain the daily livelihood of the rural populace.

Muriuki et al. (2011) argue that the population growth in Kenya over the years has led to the massive movement of people from humid and sub-humid areas to arid and semi-arid areas. Resulting land degradation from these migrations has partly contributed to increased temperature and drought frequencies in Kenya since has potential to cause an interruption to the hydrological and ecosystem cycles.

Methods

The selected data mined from databases of the World Bank and the UN FAO websites to evaluate the impact of drought consisted of climate indicators (temperature and rainfall values), population size, average food value, number of undernourished persons, renewable water resources, agriculture value added annual percentage growth, pesticide use, producer prices (US dollars), credit to agriculture (US dollars), and annual % growth of GDP for a period of over 20 years. The time series trend analyses of rainfall, temperature, population size, average food value, number of undernourished persons, renewable water resources, and agriculture value added annual percentage growth were done. Logistic regression model of the economic indicators (pesticide use, producer prices (US dollars), credit to agriculture (US dollars), and annual percentage growth of GDP) datasets were implemented in STATA to demonstrate the relationship between drought events and the selected variables. A binary coding approach was adopted to separate the years when drought events occurred which were coded as 1 and 0 otherwise. The binary logit model estimates the relationship between drought and several other independent variables. The model is applied to variables which are within $(0\ldots1)$ and $(-\infty\ldots\infty)$ and is expressed in eqs. 1, 2 and 3 as specified in Bera et al. (2020).

$$c = \beta_0 + \beta_k x_k \tag{1}$$

$$c = log_e[\frac{P}{1-P}] = logit(P) \tag{2}$$

where P represents the probability of a drought event causing an impact to the agriculture sector. c represents the logit(P) and it is related to the independent variables. β_0 denotes the constant value, β_{k} represents the coeficient estimates for the x factors. x_k represents selected indicators that explain the dependent variable. In terms of the probability that drought events influence the independent variables, the model can be formulated as follows:

$$P = \frac{\exp(\beta_0 + \beta_k x_k)}{(1 + \exp(\beta_0 + \beta_k x_k))} \tag{3}$$

To demonstrate the willingness of smallholder farmers to be involved in an appropriate anticipatory climate change adaptation strategy, focused group discussions were conducted among three population groups in Makueni County. The population consisted of farmer groups, NGOs dealing with agriculture and environmental issues in each of the agro-ecological zones, and government institutions charged with the responsibility of food security and environmental protection. The selection of these three populations was guided by the Agricultural Sector Development Strategy (ASDS) 2009–2020. Six focused group discussions were conducted with six registered farmer groups (a total of 190 farmers; 60 males and 130 females) between February and March 2015. The semi-structured interviews consisted of 17 key informants from the NGOs and government institutions which were used to supplement the information obtained from the smallholder farmers in the focus group discussions. In both cases, farmers and officials of NGOs and government institutions were asked to identify different adaptation measures based on the status quo then.

Results and Discussion

Drought Identification and Historical Trend Analysis

Drought Episodes

The meteorological drought is responsible for hydrological and agricultural droughts types in Kenya. However, a successful integrated water resources management can help prevent the socioeconomic drought caused by the two droughts types. The socioeconomic drought is driven by factors of demand and supply of crop and livestock products (AMS 1997). The meteorological drought events in Kenya recorded were experienced between 1991–2, 1992–3, 1995–6, 1998–2000, 2004, 2006, 2008–9 (Ochieng et al. 2016), 2010–11, 2014–15, and 2016–17 (Reliefweb 2017). These episodes affected the agriculture sector and posed a risk on the food production systems. They caused an imbalance in the production and consumption patterns, which are very important components of food security (Kogan et al. 2013; Li et al. 2009; Tubiello et al. 2007). Previous studies in Kenya show that the agriculture sector is adversely affected by drought events leading to water scarcity, food insecurity, and conflict among pastoral communities (Muriuki et al. 2011). In some cases, people, livestock, and wildlife have lost their lives through starvation (Ombis 2013). The most recent instances occurred on February 10, 2017, and the government of Kenya responded by declaring drought a national disaster. This is because 2.7 million people faced the risk of starvation and about 23 out of a total of its 47 Counties were alarm areas, requiring urgent food and water aid (Reliefweb 2017). The declaration simply means high opportunity costs of other sectoral developments would be lost in pursuing food and cash transfers to the affected people in areas such as the Southeast, coastal lowlands, and the northern parts of the country. Although these impacts of drought are real in Kenya, there are limited scientific documentation to evaluate the impact of drought due to paucity of data. Moreso, there is limited literature which have studied the frequent droughts and linked them to the historical changes in the rainfall and temperature trends in the area.

Rainfall Trends

Over the past decades, scientists have carried out studies demonstrating how rainfall variability and increase in temperature have affected the agriculture sector and/or have a likelihood of causing catastrophes in the future. In East Africa, the annual rainfall amounts have declined considerably since the 1990s thus marking the region with frequent severe droughts between 2004–2005, 2009–2011 (Bloszies and Forman 2015) and 2014–2017 (Reliefweb 2017). The severe droughts have caused failures in rainfed crop production systems leading to food insecurity, famine, and political instability in most parts of northern Kenya, and other countries on the horn of Africa such as Ethiopia, southern Sudan (Bloszies and Forman 2015), and Somalia. Kenya has two main rainy seasons between January to May and October to December and a dry season from June to August. However, since the 1960s the amounts of rainfall received have reduced and are expected to reduce in the coming years. Trend analysis of data from World Bank (2017) database demonstrates a declining trend of precipitation and a high variability of rainfall characterized by extreme highs and lows over the past 55 years (Fig. 4).

A Kolmogorov-Smirnov (K-S) on the rainfall data from 1961 to 2016 indicates a normal distribution of rainfall. However, a Mann-Kendall (MK) statistic test at 95% and 99% indicate significant annual and seasonal variations of rainfall. The changes in seasonal and annual variations represent a reducing rainfall trend (Fig. 4). The trendline in the illustration indicates decreasing rainfall trend (see blue dotted linear) over time. A further decline may be expected if the diagram does not take into account the years of El Niño/Southern Oscillation (ENSO) rains which represent a climate change shock. For instance, the El Niño rains caused massive flooding and

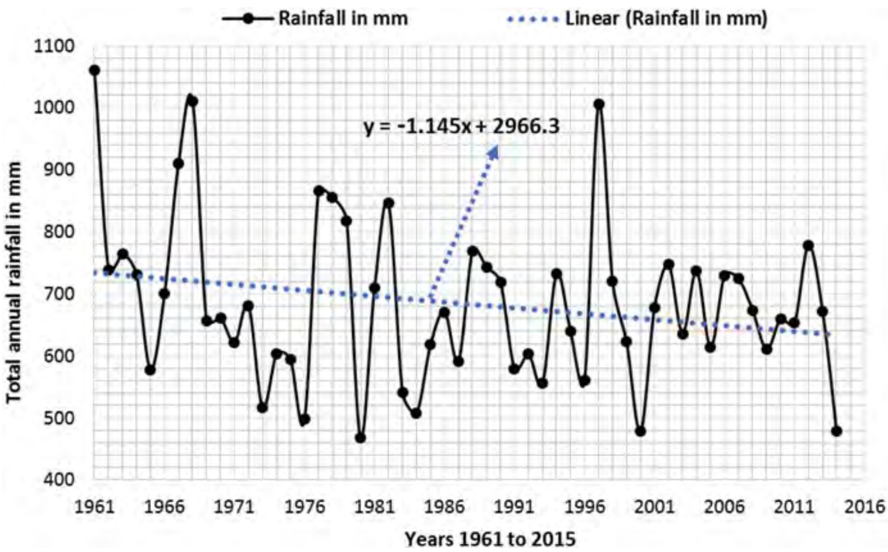

Fig. 4 Total annual rainfall in mm between 1961 and 2014 in Kenya (Data source: World Bank 2017)

mudslides in 1998 (Bloszies and Forman 2015). The severe floods in 1998 caused deaths, extensive damage to infrastructure leaving many households isolated and displaced (FAO 1998). If the years of El Niño rains are excluded from Fig. 4, the rainfall trend would probably be expected to decrease further.

Temperature Trends

Since the 1960s the mean annual temperature in Kenya has increased by 1.0 °C at a mean rate 0.21 °C per decade. The increase is higher between March and May (0.29 °C) and low between June and September (0.19 °C) per decade (World Bank 2017). In the last 55 years, trend analysis of temperature data from the World Bank (2017) has increased by 1.1 °C. The increase in temperature affect the agriculture sector as the soil organic matter is depleted leading to degradation (Kirschbaum 1995). Soil degradation affects crop growth, and causes poor production yield. This is because there is a high correlation between soil organic carbon pool and climate (Kirschbaum 1995). The increase in temperature leads to an increase in humidity in the atmosphere due to high evapotranspiration rates (Tian and Yang 2017). The analysis of the temperature time series of Kenya is illustrated in Fig. 5. The result of the trend in the temperature changes is expected to increase further as shown by the trend (blue dotted linear line) line. The temperature increase in Kenya explains the local warming and drying of the country which has manifested in the form of frequent severe drought events since the 1990s.

Global warming has been associated with increased drought frequencies over the last five decades in Kenya. Yin et al. (2014) argue that the dry to very dry areas have doubled in the world due to effect of rising temperature. In Kenya, it is evident that

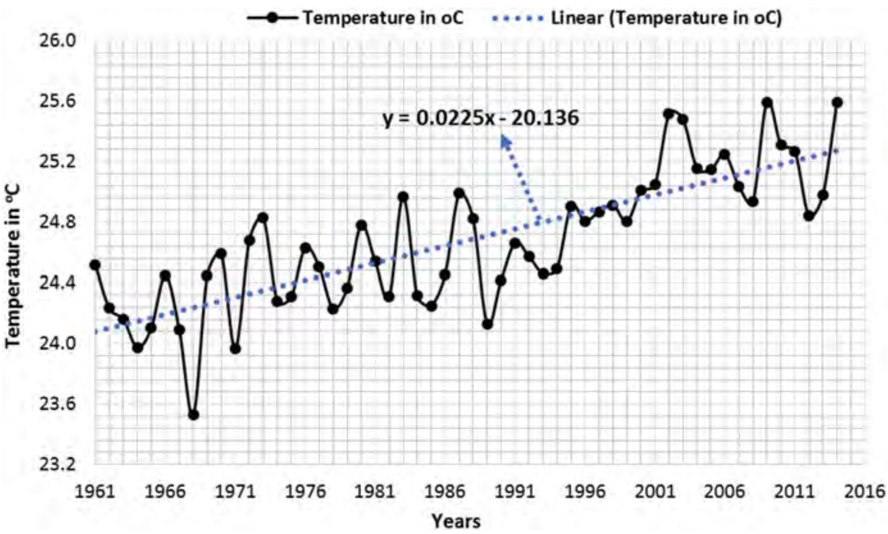

Fig. 5 Mean annual temperature between 1961 and 2014 in Kenya (Data source: World Bank 2017)

the temperature increase has led to further drying in many parts of the arid and semi-arid region, for example, in the south-east, coastal areas, and northern parts of the country. This has increased the cases of land-related conflicts, as viable agricultural crop lands encroach into meadows meant for animals of pastoralists who graze in these areas (Reliefweb 2017).

Evaluation of Economic Impacts of Drought on the Agriculture Sector in Kenya

Impact of Drought on Maize Production

The impact of the global climate change has been linked to the negative effects of economies, governance structures, and communities (Linke et al. 2015). Therefore, many developing economies and poor communities that depend on the agricultural produce can be badly affected due to the change. For instance, maize is one of the staple food crop in Kenya and contributes significantly toward food security (MALF 2017). The dwindling trend in its production since the 1990s can be attributed to severe droughts, especially during periods of drought episodes. To illustrate this, the trend in the annual percent change of maize yields corresponding to periods of drought between 1991 and 2014 declined (blue dotted trend line) (Fig. 6). The annual percentage changes in maize production were positive for the years when the drought events of 1991, 1993, 1998, 2008, and 2011 occurred. They became negative in 1992, 1995, 2004, 2010, and 2014 and zero for drought event of 1996.

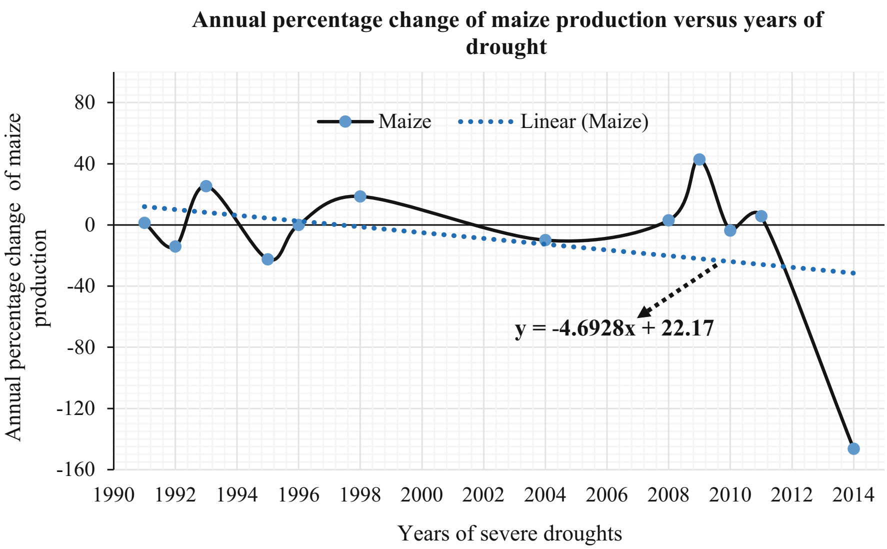

Fig. 6 Annual percentage change in maize production between 1991 and 2014 in Kenya (Data source: FAOSTAT 2017)

During these drought events there were low maize yields and this led to increase in maize prices and higher demand for substitute food types such as rice, wheat, and root crops among others. The increased demand in the substitute food crop for the staple maize, forced the prices of these crop to go higher.

Impact of Drought on the Average Food Value Production

Drought affects the average value of food production expressed in dollars per capita. Average value of food production is a country-wide measure of the absolute economic size of the food production sector (Land Portal 2018). The relationship between rainfalls and average food value revealed that there were drought events between 1991–1998 and 2008–2013. During this period, the average food value in dollars per capita followed a declining trend (Fig. 7). The average food value indicator is estimated over 3 years moving average to reduce the impacts of production errors resulting from complexities that occur due to disparities in major food stocks (Land Portal 2018). The two-person moving average curve (blue dotted curve) in Fig. 7 smoothens the short-term fluctuations in the average food value and shows an increasing or decreasing trend in the long term.

Impact of Drought on the Number of Undernourished People

The agriculture sector in Kenya provides means of livelihood to more than 80% of the population (Faostat 2019). The population of undernourished people between 1990 and 2016 remained relatively high corresponding to the period of drought episodes in the country. These numbers of people are estimated to be in danger of calorie inadequacy and are under hunger threat (World Hunger Education Service 2016). They are thus at a risk of malnourishment. The analysis of the data revealed that the number of

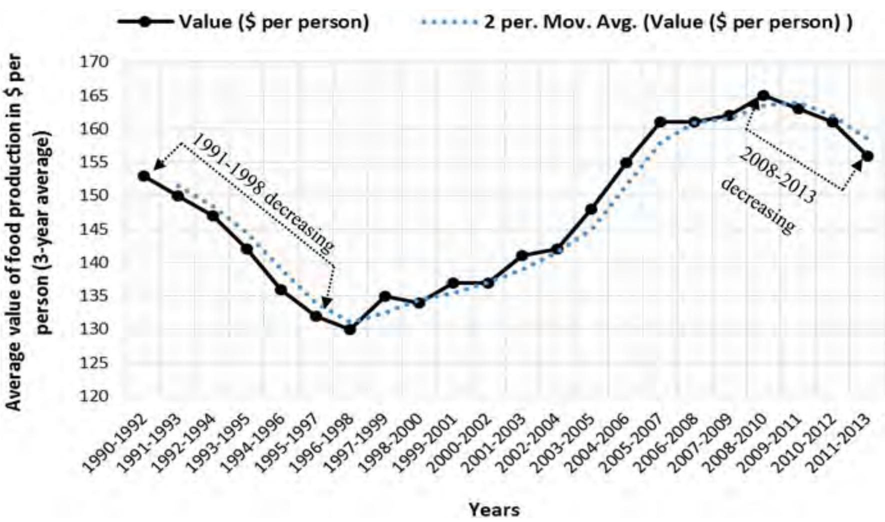

Fig. 7 Average value of food production in dollars per person (3 – year average) in Kenya (Data source: FAOSTAT 2017)

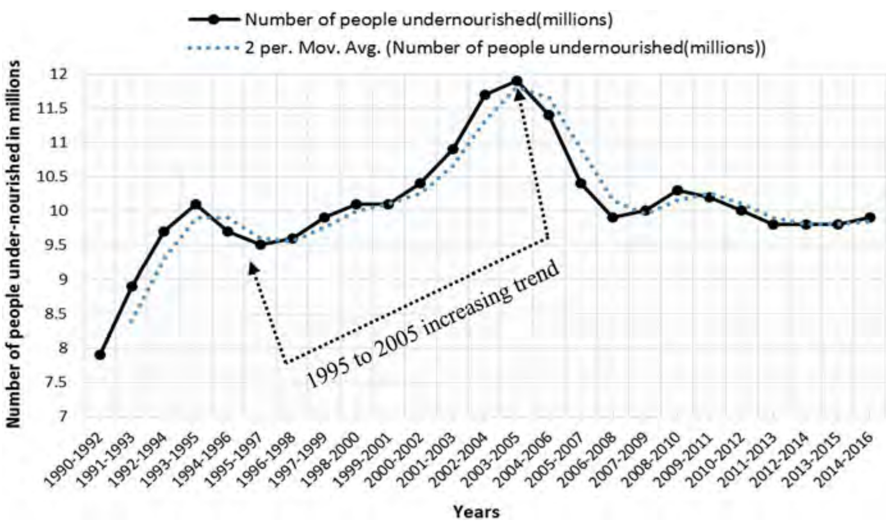

Fig. 8 Number of undernourished people in millions (three-years average) in Kenya (Data source: FAOSTAT 2017)

undernourished people has been fluctuating, but relatively increasing in number, as shown in the trend plot (Fig. 8). For instance, between 1995 and 2005 there is a noticeable increase in the number of people under the threat of hunger in Kenya due to the 11 drought events that occurred between 1995 and 2005. The implication of this fact is that frequent severe drought events can be a threat to the Sustainable Development Goal (SDG 2) of the United Nations on the eradication of hunger and malnourishment because drought limits food availability to the people.

Thus, the number of undernourished people in Kenya have remained high regardless of efforts to meet SDG 2 of ensuring zero (0) hunger. Ensuring zero (0) means ending hunger by achieving food security through access to the right amounts and quality of food from sustainable agricultural practices. To understand the relationship between food and drought, or hunger and water scarcity can be correlated as common phenomena (Loewenberg 2014). This is due to overreliance on rain-fed agriculture which is highly vulnerable to the frequent severe droughts in Kenya. An estimated 75% of the population in the country derive their livelihoods from crop and livestock production (Loewenberg 2014), half of whom survive on less than a dollar a day. People who live on less than a dollar a day to meet their food and water needs are said to be poor (Nthambi et al. 2021; Loewenberg 2014).

Impact of Drought on the Gross Domestic Product (GDP)

The agriculture sector contributes approximately 25.9% to the GDP in employment and in providing food to local communities in Kenya (Ochieng et al. 2016). This means that the impact of drought on the agriculture sector is likely to affect the national GDP. Data from the World Bank (2017) show that agriculture, value-added annual % growth values are negative during the years of drought in Kenya. For example, the annual % growth for the valued added in agriculture 1991 (−1%), 1992

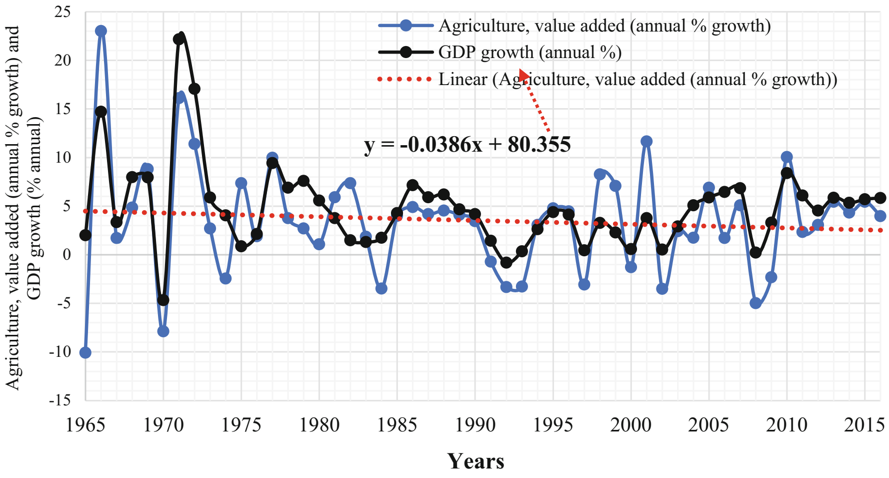

Fig. 9 Agriculture, value added annual % growth versus GDP annual % growth between 1965 and 2016 in Kenya (Data source: World Bank 2017)

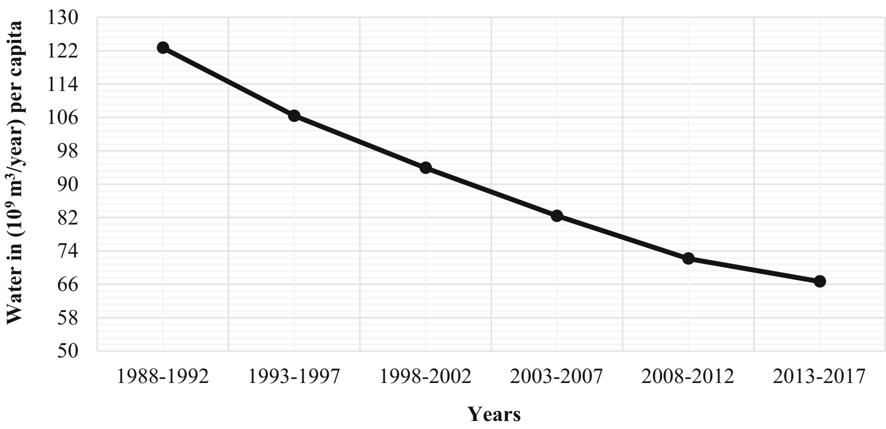

Fig. 10 Total renewable water resources in m^3 per capita in Kenya (Data source: FAOSTAT 2017)

(−3%), 1993 (−3%), 2008 (−5%), and 2009 (−2%) (Fig. 9). The agriculture, value-added annual % growth describes the net value output of the agriculture sector obtained by summing up all the outputs minus intermediate inputs. When agriculture, value-added annual % growth curve is compared with that of the GDP % annual growth in Kenya for the period between 1965 and 2016, the curves behave similarly. That is, as agriculture, annual % growth increases, the GDP annual growth % also increases and vice versa (Fig. 9). These trends suggest that the agriculture sector correlates linearly to the GDP. This means that the impact of drought on the agriculture sector will lead to negative value-added annual % growth, which in turn leads to the reduction of the GDP annual growth %.

Impact of Drought on Water Security

Kenya is water-scarce and has only about 3–4% of its land cover composed of wetlands. The country experiences loss of wetlands estimated at 7% per annum due to the expansion of land for crop and livestock production (Böhme et al. 2016). Therefore, severe droughts have led to decline in surface and groundwater recharge. The total renewable water resources per capita per year between 1988 and 2017 have followed a declining trend (Fig. 10). Total renewable water resources are internal and external water resources (both surface water and groundwater) generated through the hydrological cycle (FAO 2016). The internal water resources are generated through endogenous precipitation while external water resources are the resources that enter the country through the transboundary flow from external surface and groundwater resources (FAO 2016). With the total renewable water resource being finite and the population continuing to grow, the water consumption per capita will dwindle. The drought events will have very harsh impact on the population. Hence, alternative water sources and conservation techniques are required to supplement the deficits caused by the drought.

Statistical Analysis of Drought Impact on Selected Economic Indicators

Table 2 shows the descriptive statistics of the dataset obtained from FAOSTAT 2019, consisting of some economic indicators used in the binary logit regression model. These indicators represent independent variables that were hypothesized to be influenced by drought in the agriculture sector. The producer prices represent the average cost of producing a ton of maize – the staple food crop per annum. The annual growth of GDP (%) is the macroeconomic indicator representing the status of the economy in which agriculture, forestry, and fisheries are major contributors. Credit to agriculture represents the average amounts of loans that producers in the agriculture sector, forestry and fisheries, household producers, cooperatives, and agro-businesses have borrowed from private/commercial banking sectors per year (FAOSTAT 2019) to support agricultural production.

Regression results (Table 3) show that pesticide use has a positive relationship with drought events while the coefficient estimates of producer prices, number of undernourished persons, GDP, and credit to agriculture have a negative relationship with drought events.

Table 2 Descriptive statistics of economic indicators influenced by drought from 1991 to 2016

Economic indicators	Mean	Standard deviation
Pesticide use in tons	0.44	0.26
Producer prices (US dollars)	224.38	84.39
Number of under-nourished persons	10.15	0.86
Annual growth in gross domestic product (%)	7.59	12.023
Credit to agriculture (US dollars)	387.69	273.61

Table 3 Summary of the results of the binary logit regression model

Choice (drought/no drought)	Coefficient	Std. Err	z	P > |z|	95% Conf. Interval	
Pesticide use	9.787	2.956	3.31	0.001***	3.993	15.580
Producer price	−0.024	0.0131	−1.85	0.064	−0.050	0.001
Undernourished	−1.467	0.9917	−1.48	0.139	−3.411	0.476

Credit resources	−0.013	0.0047	−2.73	0.006**	−0.022	−0.004
Constant	−1979.512	11.857	−166.94	0.000	−2002.8	−1956.3
Number of observations	26					
Wald $chi^2(5)$	158.7					
Prob > chi^2	0.000					
Log likelihood	−12.659					

Pesticide use has a positive coefficient of variation and significant relationship with drought events. Increasing drought episodes means increased use of pesticides to control disease causing pests and vectors.

During drought events, soil moisture reduces the level of pesticide uptake. Moisture-deficient crops attract insects as such crops are unable to produce metabolites that prevent them from being susceptible to pest attacks (Yihdego et al. 2018). The annual growth percent of GDP is negative and statistically significant to drought events. Drought decreases food availability leading to decline in agriculture value added %. During drought events, farmers' ability to borrow money to support agricultural inputs declines as collateral for loans in form of farm assets becomes less available and valuable.

Identified Climate Change Adaptation Measures in Makueni County

Autonomous Climate Change Adaptation Measures

Makueni county has pilot private ponds already in place that are owned by a few households (Fig. 11a, b). Water accumulates in the ponds during the rainy season, and the farmers use it to irrigate the farm and/or fish farming. A standard water pond

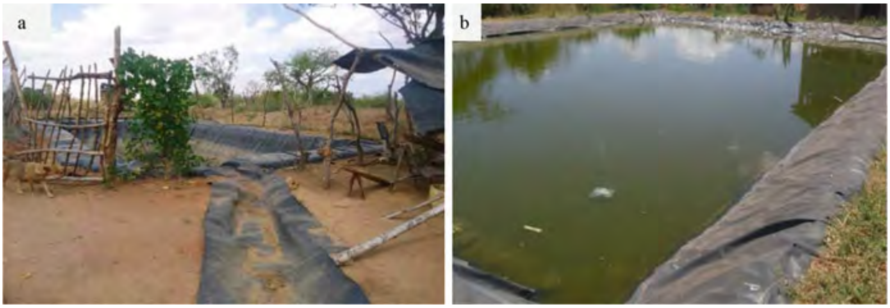

Fig. 11 Water ponds for harvesting during rainwater (**a**) dry season and (**b**) filled pond in the rainy season (Photos taken by Mary)

Fig. 12 An example of a household owned water pond for irrigating a kales/vegetable garden showing (**b**) drip and (**c**) furrow irrigation (Photos taken by Mary)

holds a minimum of 200,000 L of water and can be used by an individual farmer to farm an acre of maize and vegetables for approximately three seasons (Fig. 12). However, the disadvantage of this adaptation measure is that most farmers are unable to purchase the polythene sheet used as an inner lining of the water pond because it is costly (KES 70,000 exchange rate @ 103.2270 KES = 1 USD as at June 2015). The plastic layer is used to prevent the harvested rainwater from permeating into the groundwater. However, these water ponds can be a health hazard and that can lead to the drowning of livestock and children if not well guarded, as well as act as a breeding ground for malaria-causing mosquitoes.

Anticipatory Climate Change Adaptation Measures

Anticipatory climate change adaptation coping strategies to climate change are those public adaptation measures provided to the rural communities through the support of organized groups such as the farmer networks/groups, NGOs, and government institutions. These measures are in most cases capital intensive and might require highly skilled technical input to put them in place. A universal set of community-based water projects suggested include boreholes, earth dams, shallow wells, water tanks, subsurface, and sand storage dams. The communities chose a sand storage dam as the best option because of the following reasons; (1) it is the world's cheapest way of providing rainwater to communities in arid and semi-arid areas, (2), a sand storage dam creates an indigenous, reliable, clean water supply up to about 1000 people, (3), water sinks through the sand to the bedrock preventing it from evaporation and pollution as compared to water in shallow wells, and (4) it saves farmers a lot of stress regarding land disputes since it is constructed along seasonal rivers which are owned by the government and (5) sand storage dam reduces the risk of flooding and increases chances of water availability during the dry seasons. A sand dam is constructed across a shallow riverbed such as an ephemeral stream and water is extracted using pumps. An example of sand dam is shown in the following photograph (Fig. 13).

A subsurface sand dam is an underground facility that can be used as an alternative to the surface dams. It has some advantages over the conventional surface

Fig. 13 A sand storage dam construction in Makueni County during the dry season (Photo taken by Mary)

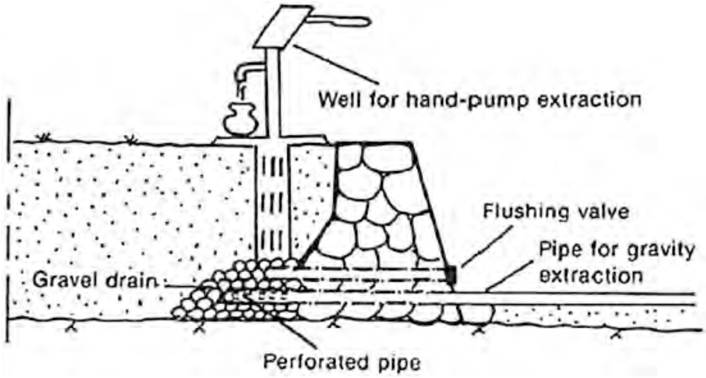

Fig. 14 Cross-section of water extraction from a sand-storage dam (modified from Hanson and Nilsson 1986)

dam because it prevents excessive loss of water through evaporation and does not support the breeding of vectors such as malaria-causing mosquitoes on it. However, the subsurface dam is constructed below the ground level to tap from the flowing groundwater in the natural aquifers. It also has enhanced surface permeability to cause faster infiltration of rainwater to the groundwater during the rainy season. The sand-storage dam stores water in the sand which accumulates naturally behind a dam wall (Onder and Yilmaz 2005). The wall constructed across the seasonal river should be tight and stable to withstand the pressure of running water downstream. The riverbanks of the sand storage dam ought to be protected from erosion on sloppy areas and the dam bottom (Nilsson 1988). According to Hanson and Nilsson (1986), the extraction of the water from the sand storage dam can either be through pumping or gravity. The use of gravity means a drain is placed at the reservoir bottom in the upstream direction of the sand storage dam or a pipe downstream as shown in Fig. 14. The construction of a sand storage dam has four stages: the first stage deals with the capacity of the dam. It is described by the height of the dam wall to be constructed and the quantity of water it is expected to hold.

The second stage involves a careful selection of a proper water pumping mechanism and how to incorporate it into the sand storage dam design. The third step involves the protection of the dam banks through the planting of trees on the sloppy areas both downstream and upstream of the river where the sand storage dam is constructed. The fourth stage involves a careful selection of the donor (management structure) to support the construction of the wall and one that would organize the farmers who will be involved in the construction process. The loss of benefit accruing from the choice of management structure in the area has been fully documented in Nthambi et al. (2021). Farmers should be involved in the four phases and the actual construction process of the selected climate adaptation measure. Other forms of participation can be accounted through contribution of labor time or cash for the purchase of raw materials.

Conclusions

The frequent severe drought events in SSA region have heavily affected the growth of the agriculture sector, forcing crop and livestock farmers to work under very dry conditions in countries such as Kenya. In this chapter, the impacts of drought on the economy of Kenya were discussed, and a possible climate change adaptation measures demonstrated using a case study area in one of the counties. The findings can be summarized in three main ways. First, the analyzed climate indicators revealed frequent drought episodes, which have led to direct and indirect economic impacts on the agriculture sector and the economy. The analysis shows drought events have a positive relationship with pesticide use and negative relationship with credit resources, producer prices, number of undernourished people, and annual percentage growth of gross domestic product (GDP). Again, drought events negatively affect the number of undernourished people as the quantities of crop yields, for example, maize as the staple food crop in Kenya reduces. During the years of drought events, the agriculture value added % growth declines reducing the annual GDP. Producers and households' access to credit resources reduce during drought episodes. The amount of water from renewable water resources also declines due to decreasing rainfall amounts causing water scarcity.

Second, farmers and households can adapt to the negative impacts of drought using either autonomous or anticipatory climate adaptation measures. The major concern is the dryness that comes with drought events, and given the arid and semi-arid nature in most parts of Kenya, rainwater harvesting in sand dams would be the most suitable adaptation measure to reduce the impact of drought. Generally, farmers in the area prefer a sand dam over water ponds or boreholes. However, the lack of financial support hamper farmers' desire to execute this type of anticipatory climate change adaptation measure.

Third, from a methodological perspective, the use of available secondary data to avail important literature required for climate change research in SSA region was promoted. It demonstrates a simple way of relating climate variables with economic indicators using existing qualitative and quantitative approaches. In terms of determining suitable climate change adaptation measures, we consulted stakeholders to suggest the adaptation measures and propose a practical approach to implement them.

Two main recommendations were suggested in this chapter. First, the Kenya National Adaptation Plan (NCCAP) 2015–2030 highlights financing as one of the limitations in the mainstream of climate change adaptation in the water sector. The country is keen on providing adequate water management strategies that can ameliorate the water scarcity problem caused by drought events. We established the involvement of stakeholders to participate in constructing sand dams to harvest rainwater across seasonal rivers. Thus, the NCCAP, 2015–2030 should integrate community participation strategy to provide local materials such as water, sand, and stones or cash when possible, as a way for farmers to partially finance the provision of adaptation measures for sustainable water harvesting techniques. A bottom-top approach to adaptation measure is necessary to understanding farmers' willingness to take part in adaptation projects such as the construction of a sand dam in the SSA region.

The National Drought Management Authority (NDMA) in Kenya, charged with the responsibility to identify risks, end drought emergencies, and ensure adaptation for sustainable livelihoods, should encourage farmers to form community-based organizations. NDMA should also encourage farmers to form farmer networks/groups and register them under the Self-help Association Bill (2015) to provide legal protection to farmers who wish to participate in sand storage dam construction. Membership of community-based organization would encourage collective action efforts that enhance trust among farmers thus strengthening stakeholders' participation in community adaptation projects. Government institutions and non-governmental organizations should work with farmer networks to ensure adaptation measures are implemented in a way that is acceptable to the communities that benefit from them.

Rural Farmers' Approach to Drought Adaptation: Lessons from Crop Farmers in Ghana

52

Hillary Dumba, Jones Abrefa Danquah, and Ari Pappinen

Contents

Abstract

Sub-Saharan Africa is considered to be highly vulnerable to climate change-related disasters particularly drought. Farmers in Ghana have learnt to co-exist with it by resorting to various approaches. This study sheds light on farmers' adaptation to drought in Ghana. The cross-sectional survey design was used to

collect data from a random sample of 326 farmers and six purposively selected lead farmers from six farming communities. Questionnaire and in-depth interviews were used for data collection. The data were analyzed using descriptive and inferential statistics. The study revealed a significant variation between locations and use of drought adaptation approaches. The study showed that the most common drought adaptation measures comprise locating farms on riverine areas, drought monitoring, formation of farm-based organizations for dissemination of climate information, application of agro-chemicals, changing planting dates, cultivating different crops, integrating crop and livestock production, changing the location of crops, diversifying from farm to non-farm income-generating activities, and cultivation of early maturing crops. Therefore, it was recommended, among other things, that Non-Governmental Organizations (NGOs) should assist the government to construct small-scale irrigation facilities and provide drought-resistant crops to further boost the capacity of farming communities in Ghana.

Rural Communities · Subsistence Farmers · Drought · Adaptive Capacity

Introduction

Climate change has occurred and still occurring. Among all climate change-induced disasters, drought is the costliest and most devastating climatic disaster that imposes untold adverse consequences on human activities. Its recurrent occurrence is associated with high level of vulnerability among farming households (Makoka 2008; United Nations 2010). It severely affects agriculture in rural areas as well as trade and food security in both developed and developing economies of the world. Drought is particularly hazardous to communities which depend on agriculture for livelihood (Diaz et al. 2016). Incidence of drought is prevalent in Ghana, with the 1983 being the severest and most destructive in the history of the country (Owusu and Waylen 2009). Drought conditions impose consequences on crop yield and food security (Van de Giesen et al. 2010). Previous report indicated that persistent drought conditions affected all investments in the agricultural sector in the country. Unreliable rainfall, prolonged droughts, coupled with high temperatures have severely affected sustainable agriculture in the country (Armah et al. 2011; Dietz et al. 2013). Ajzen's (1985) theory of planned behavior argues that individuals perform certain planned actions known as behaviors in response to the achievement of a target. Given the serious problems posed by drought to agriculture in Ghana, farmers practice adaptation to overcome or reduce the resultant vulnerability.

Families whose livelihoods depend on farming activities need a variety of adaptation strategies to mitigate the harmful impacts of climate change and. This will help them to maintain their livelihoods (Uddin et al. 2014). Adaptation serves as the means to mitigate a system's vulnerability to hazardous events. Adaptation reflects farmer's adaptive capacity. It is a process through which a society makes better adjustments and changes in order to adapt to an unforeseen situation in the future (Smit and Wandel 2006; United Nations Framework Convention on Climate Change (UNFCCC) 2011). Adaptation refers to the process of adjustment to the actual or expected climate, its variability, and concomitant effects (Intergovernmental Panel on Climate Change (IPCC) 2014; Quandt and Kimathi 2016). It is a means to build a system's capacity, resilience, and to adjust to the impact of climate change with the ultimate aim of reducing vulnerability. It is a process through which a society makes better adjustments and changes in order to cope with an unforeseen situation in the future (Smit and Wandel 2006). It may involve adjustments in technologies, lifestyles, infrastructure, ecosystem-based approaches, basic public health measures, and livelihood diversifications to reduce vulnerability (IPCC 2014). It may also serve as means to optimizing the potential benefits of climate change. Numerous studies have examined farmers' adaptation to climate change in different locations and contexts (Mabe et al. 2014; Obayelu et al. 2014; Shongwe et al. 2014). However, these studies are not only predominantly quantitative but also based broadly on farmers' adaptation to climate change. Farmers' adaptation to climate change is dependent upon specific climate change events and hence, may differ from one climatic event to another. The measures that farmers employ to adapt to other climate change events may differ from strategies employed to adapt to drought. Therefore, a clear understanding of farmers' adaptation to drought is desirable for designing and implementing appropriate drought adaptation strategies to enhance sustainable agriculture in Ghana. The study will expand theoretical knowledge and understanding of drought adaptation planning. Specifically, the study will shed more light on farmers' planned behavior towards drought. This will provide the necessary information and reference material for other researchers and drought management policy-makers. The study also explored only farmers' views on the use of both on-farms and off-farm measures to combat drought.

Study Areas

Three agro-ecological locations, namely, Wa West (Savannah zone), Nkoranza North (Transitional zone), and Wassa East (Forest zone) of Ghana were chosen as the sites for this study (Fig. 1). Evidence indicates that rain-fed agriculture constitutes the main livelihood activity in the selected agro-ecological locations. For instance, crop farming (96.1%) is the major activity undertaken by households in the Wassa East District while most households (97.2%) in the Wa West District are engaged in crop farming as the main economic activity. Similarly, almost all agricultural households (98.5%) in the Nkoranza North District are involved in crop farming (Ghana Statistical Service 2013, 2014).

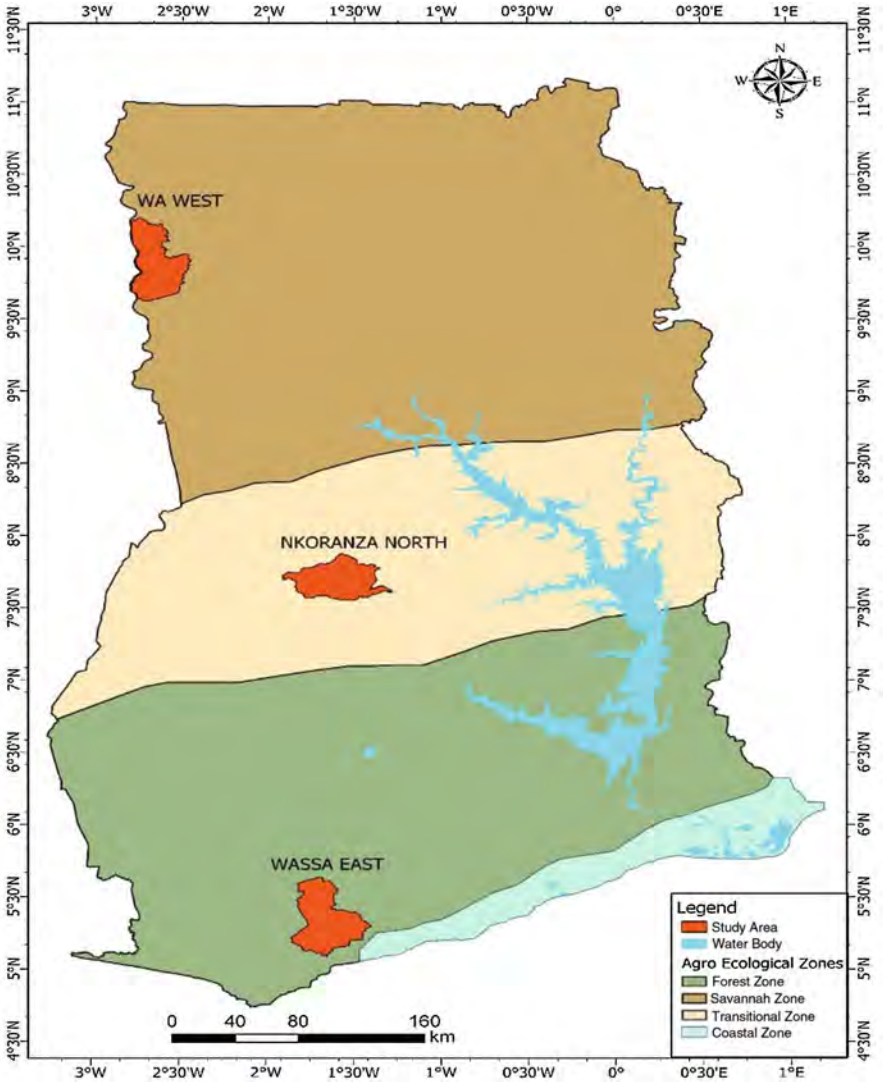

Fig. 1 Map of selected agro-ecological locations

Data Collection and Sampling Procedure

The study employed cross-sectional survey design because it has some practical advantages over longitudinal and experimental designs. Cross-sectional design helps to capture large factual numeric and descriptive data from a large sample that represents a wide target population on a one-shot basis (Bhattacherjee 2012). Out of a total population of 1765 household farmers, 326 participants were randomly selected using Yamane's (1967) formula. In generally, farming is a male-dominated activity in Ghana (Food and Agriculture Organization (FAO) 2012). However, harvesting, processing, and marketing is usually done by the female. Traditionally, the head of each household in these study areas is a male. However, in the absence of a male head the de facto female heads or de jure household heads were interviewed (See, Danquah 2015). Both qualitative and quantitative data were collected using structured questionnaire and in-depth interview guide.

Data Processing and Analysis

The first step in the process of analyzing qualitative data was data transcription. The tape recordings were listened to several times so as to get a complete sense of the data. All the transcribed data was categorized into patterns by following the guidelines prescribed by Miles and Huberman (1994) (cited in Cohen et al. 2011). Five points scale Likert estimation was used to assess or rate farmers' perception to sets of constraints to drought adaptation. The Likert scale ranging from "*Strongly Disagree (5)" to "Strongly Agree (1)".* We also employed Pearson Chi-Square Test Statistic Tool in the analyses. This helped to compare farmers' adaptation practices across the three selected agro-ecological zones. In addition, Phi and Crammer's V were generated as measures of contingency coefficient to explore the strength of the association between the agro-ecological zones and farmers' adaptation strategies (Prematunga 2012). Problem Confrontation Index (PCI) was used as modified procedure adopted from Elias (2015) and Talukder (2014), and was computed as follows:

$$PCI = [5(P_{SA}) + 4(P_A) + 3(P_N) + 2(P_D) + (P_{SD})]$$

Where:

P_{SD} = Frequency of farmers who rated the problem as strongly disagree
P_D = Frequency of farmers who rated the problem as disagree
P_N = Frequency of farmers who rated the problem as not sure
P_A = Frequency of farmers who rated the problem as agree
P_{SA} = Frequency of farmers who rate the problem as strongly agree

Results and Discussion

Farm Household Characteristics and Adaptation Capacity

We asked participants to indicate their level of formal education, age, years of schooling, farming experience, farm size, landholding, household size, and dependents (Fig. 2). The proportion of farmers in the Forest agro-ecological zone who obtained middle school education (9.51%.) is less than the proportion of farmers in Transitional agro-ecological zone with middle school education (13.80%). This

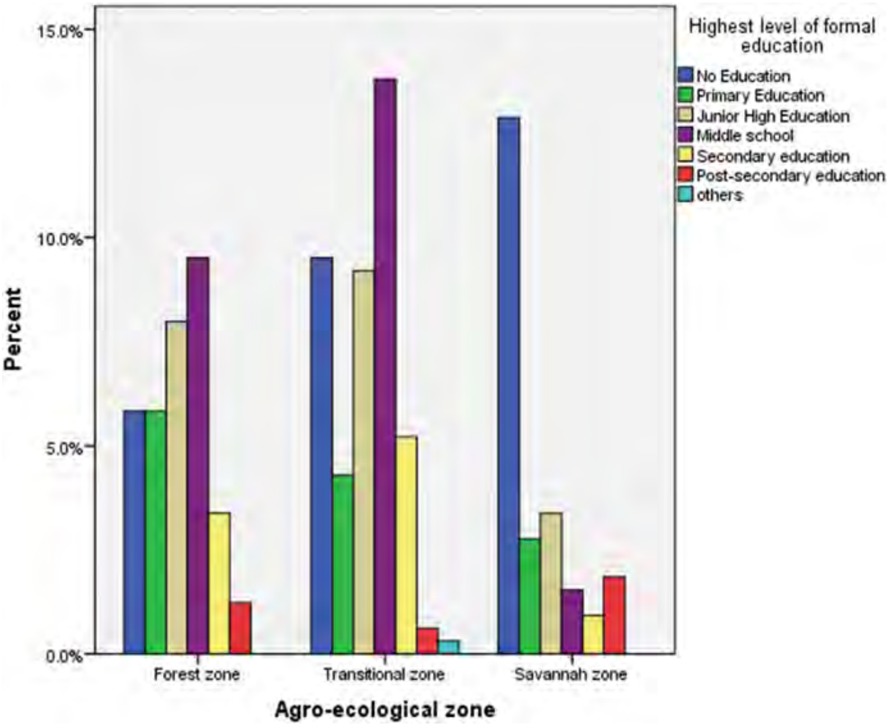

Fig. 2 Farmers' level of education across agro-ecological zones

implies that most farmers in the Forest and Transitional zones had completed middle school compared to their farming counterparts in the Savannah zone where majority (12.88%) had no education.

The educational background of farmers presupposes that these farmers would have knowledge and understanding of climatic events as well as climate change adaptation. According to Apata, (2011), education among farmers can promote climate change adaptation. Similarly, other empirical evidence from a study conducted by Abdul-Razak and Kruse (2017) indicated that farmers with formal education had high adaptive capacity while farmers without formal education had low adaptive capacity to cope with climate change and variabilities

The minimum age of the farmers was 18 years while the maximum age was 87 years (Table 1). The mean age of the farmers was 43.9 years (Mean = 43.99, SD = 14.12). Similarly, the result as shown in Table 1 is indicative that the participants have been farming for almost 19 years (Mean = 18.96, SD = 13.45). Thus, the average farming experience is 18.96 years while the minimum and maximum years of farming experience are 1 year and 76 years, respectively. Farming experience contribute to the level of knowledge on climate change adaptation and risk management (Montle and Teweldemedhin 2014). It is also clear from the results that the selected farmers had an average of 6.83 acres (Mean = 6.83, SD = 6.80).

Table 1 Descriptive statistics of farm household characteristics

Variable	*N*	Min	Max	Mean	SD
Age (in years)	326	18.00	87.00	43.99	14.12
Years of schooling	326	0.00	22.00	6.89	4.79
Farming experience (in years)	326	1.00	76.00	18.96	13.45
Farm size (in acres)	326	1.00	55.00	6.83	6.80
Landholding size (in acres)	326	2.00	250.00	13.77	16.66
Household size	326	1.00	25.00	6.37	3.56
Number of dependents	326	0.00	10.00	2.83	2.08

Moreover, farmers had 1.0 acre and 55.0 acres as minimum and maximum farm size, respectively. It was revealed that most of the farmers who had large farms cultivated both cash and food crops. For instance, most farmers in the Forest zone planted vast acres of cocoa whereas some farmers in the Transitional zone cultivated cashew plants on large scale. The results show that farmers' farm estate landholding ranged from at least 2.0 acres to a maximum of 250 acres, with average landholding of 13.77 acres. This implies that access to land to undertake agricultural activities may not constitute a problem to the rural farmers (see, e.g., Kassaga and Kotey 2001).

The minimum and maximum household size were 1 and 25 persons, respectively. The average household size was found to be six (Mean = 6.37, SD = 3.56) and the number of dependents in households ranged from zero to a maximum of 10. Households had about three dependents on the average (Mean = 2.83, SD = 2.08). Household size constitutes labor endowment of the farm household and it is an integration part of on-farm labor provision in smallholder farming systems (Deressa et al. 2009).

Constraints to Drought Adaptation

Farmers may have knowledge and information on drought adaptation. However, these farmers may not be capable of adapting to drought because certain factors that can hinder their adaptation behavior (see, e.g., Ajzen 1987, 2006). The results highlight that there are several challenges that confront farmers. It is evident from the results shown in Table 2 that a majority of 261 farmers (85.3%) agreed that shortage of water for irrigation is problem that confronts their capacity to cope with the impacts of drought on their farming activities. The associated PCI indicates that shortage of water for irrigation ranks first among all the problems that farmers face. This situation can be attributed to the absence of major water sources coupled with reduced precipitation in the selected agro-ecological zones (Owusu and Waylen 2009). The shortage of water poses a challenge to farmers who would have otherwise wished to irrigate their farms during episodes of drought. This confirms results of a study by Abid et al. (2015) that shortage of water for irrigation is challenge that limits farmers adaptation to drought. Furthermore, the results indicate that out of the

Table 2 Constraints to farmers adaptation to drought

Farmers' responses ($N = 326$)												
	Strongly disagree		Disagree		Not sure		Agree		Strongly agree			
Constraints to adaptation	*n*	%	*N*	%	*n*	%	*N*	%	*n*	%	[a]PCI	Rank

NB: [a]Problem Confrontation Index (PCI)

326 respondents, a majority of 85.3% farmers agreed that unavailability of financial resources serve as a constraint to their effort to adapt to drought (Table 2). This was ranked as the 2nd problem that confronts their capacity to adapt to drought. Lack of finance has been cited as the common problem that considerably hampers most farmers from adopting improved varieties of seed to combat drought (Fisher et al. 2015; Pardoe et al. 2016). High cost of agricultural inputs was rated or ranked 3rd and Inadequate labor force 4th by the farm household heads within the three ecological zones the study was conducted. However, farmers were least concern about access to land for their farming activities. This was ranked 9th on the list of factors influencing farm household ability to adapt to drought in the study area. Invariable, it was expected that extension education and information to weather forecast should feature prominently on top of the ranking, but turned out otherwise. Lack of agriculture extension services and climate base information in the form of weather forecast have been cited as the policy constraints to adaptation strategies of smallholder farmer in the tropics, particularly in sub-Saharan Africa including Ghana (Naab et al. 2019).

Determinants of Adoption of Drought Adaptation Measures

This section focuses on the presentation and discussion of main results on farmers' adoption or non-adoption of various drought adaptation measures. It also discusses farmers' socio-demographic factors as determinants of drought adaptation strategies. Table 3 presents the results with respect to farmers' drought adaptation across the three agro-ecological locations in Ghana. The application of agro-chemicals as a drought adaptation measure is significantly associated with agro-ecological locations as shown by the ($\chi^2 = 43.98$: DF $= 2$, $N = 326$), $p < 0.001$). It is indicative from the results that majority of farmers (90.7%) in Nkoranza North in the Transitional zone applied agro-chemical compared to farmers in the Daboase and Wechaiu (54.5% and 63.2%, respectively) who adapted to drought through the application of agro-chemicals. Most crop farmers in Daboase in the Transitional zone adopted the application of agro-chemicals compared to other farmers in the Forest zone because the Forest oxysol soil has higher moisture holding capacity and fertility and therefore more capable of supporting crop production. On the whole, the study reveals that most farmers (72.1%) in the selected study areas adopted application of agro-chemicals as measure to adapt to drought. This finding is consistent with results of previous studies that applying both organic and inorganic fertilizer on farmlands is a method of mitigating low crop yield associated with unreliable rainfall pattern and prolonged dry spell (Kurothe et al. 2014; Kloos and Renaud 2014; Pardoe et al. 2016).

The results as shown in Table 3 indicate that majority of farmers in Daboase in the Forest zone do not resort to migration as a drought adaptation measure. Out of the 110 farmers in the Forest zone who participated in the survey, an overwhelming majority of 101 (91.8%) did not employ migration while only nine farmers (8.2%) resorted to migration as a measure to reduce their vulnerability to drought.

Table 3 Adaptation measures across agro-ecological zones ($N = 326$)

Adaptation Measures	Agroecological Zones						Over all adoption	χ^2	ρ-value	Phi
	Forest($n = 110$)		Transitional ($n = 140$)		Savannah($n = 76$)

Moreover, out of the 140 farmers in Nkoranza North in the Transitional zone that participated in the study, it was found that a greater proportion of farmers (67.1%) did not adopt migration as drought adaptation measure. Thus, migration is not a common drought adaptation strategy in the Forest as well as the Transitional zones of Ghana. This contradicts findings of Yang et al. (2015) that migration is the commonest drought adaptation strategy among farmers in the Ningxia Hui Autonomous Region of North-western China. Most farmers in the Forest and Transitional zones of Ghana do not adapt to drought through migration because there are various livelihood options and crop diversification strategies that assist them to adapt to the hardships imposed by drought (Asante et al. 2017). For instance, various artisanal activities, trading or business ventures, seeking employment in craft and cottage industries, and other sources of off-farm income generating abound in the forest belt of Ghana and hence, most farmers in this area do not over dependent on rain-fed agriculture. However, there are more cases of migration among farmers in Wechaiu in the Transitional zone compared to farmers in Daboase in the Forest zone (see Derbile et al. 2016). This is because some farmers in the Forest zone migrated either from the Savannah zone, Transitional zone, or neighboring communities in Cote d' Ivoire to undertake cocoa cultivation since the rainfall pattern in the Forest is more favorable to farming activities (Jarawura 2013).

The results suggest that farmers in the Savannah zone are more likely to adapt to drought and rainfall variability through migration to other places compared to farmers in the Forest and Transitional zones of Ghana. This collaborate the findings Van der Geest (2011) and Jarawura (2013), that rainfall variability and climate change slightly account for the out-migration of farmers from the three northern regions to Brong Regions of Ghana. When there are drought conditions some farmers migrate to other areas to engage in other livelihood activities. There is a statistical highly significant relationship between agro-ecological zones and farmers' adoption of migration as a drought adaptation measure ($\chi^2 = 63$: DF = 2; $N = 326$; $p < 0.001$).

Migration among farmers is dependent on agro-ecological location. The phi value (0.44) indicates that is a positive significant moderate difference between farmers' migration patterns and agro-ecological zones. This is because the severity of drought differs from one agro-ecological zone to another (Adepetu and Berthe 2007).

The results indicated that out of the 110 farmers interviewed in Daboase in the Forest zone, 89.1% were nonadopters of soil moisture conservation practices as an adaptation strategy. However, relatively small proportion of the farmers (10.9%) in this zone adopted soil conservation practices. Similarly, nonadopters were 66.4% and 63.2% in Transitional and Savannah zones respectively. Collectively, across all the ecological zones studied out of 326 farmers interviewed only 87 farmers employed soil conservation measures. This represents a total of 26.7% farmers.

Moreover, it was revealed that only 53 (16.3%) out of the 326 farmers in the three agro-ecological zones cultivated some sort of drought-tolerant crops as drought adaptation measure. The results show that most farmers in the agro-ecological location do not cultivate crops that are drought-resistant. Only a small proportion of farmers in the various agro-ecological zones indicated that they cultivated some crops that are resistant to drought conditions. Farmers non-adoption of drought-resistant crop varieties can be attributed to the fact that most farmers in Ghana do not have access to drought-tolerant crops. This contradicts the results of previous works by Udmale et al. (2014) that rural farmers widely cultivate less water intensive and drought tolerant crops as adaptation options to drought.

The results show that a majority of 264 farmers (81.0%) out of the 326 farmers in the three agro-ecological zones adopted the cultivation of early maturing crops as a measure to adapt to drought. The adoption of early maturing crops is highly dependent upon agro-ecological zone. Most farmers in the Savannah and Transitional zones cultivate early maturing crops compared to the proportion of farmers in the Forest zone who cultivate early maturing. The results of this current study corroborate the findings of various previous studies (Bawakyillenuo et al. 2016; Pardoe et al. 2016) that farmers resort to the cultivation of early maturing crops as a climate change adaptation strategy.

The study also revealed that farmers have been adapting to drought by integrating both farming and non-farming activities as similarly found by a previous study by Balama et al. (2013). From the results out of the 326 farmers, a little over half (50.6%) diversified from farm to non-farm income generating activities in order to adapt to the impact of drought. Majority of farmers (59.2%) who diversified farm to non-farm income generating activities were located in Wechaiu in the Savannah zone.

The study further indicated that most farmers (56.4%) integrated livestock production with crop production as drought adaptation measure. This is because farmers seek solace in livestock rearing when their crops fail as a result of drought. Farmers do experience decline in crop productivity as a result of drought. Therefore, they have seen the need to engage in livestock rearing to augment their farming activities. Similarly, Balama et al. (2013**)** has found that local farmers in Kilombero District of Tanzania integrated crop farming into livestock production as a climate change adaptation strategy. The results in Table 3 indicate that most farmers in Wechaiu in the Savannah zone (61.8%) as well as those in the Transitional zones (60.0%) integrated livestock rearing with crop production compared to farmers in the Forest zone (48.2). This confirms results of a study by Bawakyillenuo et al. (2016) that integrating livestock rearing into crop production is common climate change adaptation method being adopted by farmers in rural Savannah zone of northern Ghana. This is because the vegetation and climatic features within the Savannah and Transitional zones are more favorable to livestock rearing compared to the Forest zone. However, this is not significant ($\chi^2 = 4.68$: DF = 2, $N = 326$; $p > 0.05$).

There is moderate significant association between the proportion of farmers who employed water harvesting practices and agro-ecological zone ($\chi^2 = 14.87$; DF = 2; $N = 326$, $p < 0.001$). A majority of farmers (93.6%) in the Transitional zone and farmers in Savannah (75.0%) employed water harvesting practices as drought adaption measure compared to number of farmers in the Forest zone (82.7%) who did not employ water harvesting practices to combat drought. Most farmers in the Savannah and Transitional zones experienced severe drought conditions and acute water shortage than farmers in the Forest zone (Armah et al. 2011). This in keeping with the fact that farmers in the Savannah and Transitional zones need to harvest rainwater and store it for domestic use and animal consumption as well. However, farmers in the Forest may have unimpeded access to riverine water supply throughout the year due to high level of precipitation (Armah et al. 2011).

The results show strong relationship between change in farm sizes and agro-ecological zones ($\chi^2 = 12.89$; DF $= 2$; $N = 326, p < 0.001$). Variation in farm size as a drought adaptation strategy is dependent upon agro-ecological location. The proportion of farmers who change their farm sizes as drought adaptation mechanism varies across the agro-ecological zones (sensu, Hansen et al. 2004). The settler farmers in the Transitional zone have fixed portions of land for farming, whereas the native farmers have most of their land occupied by cashew plantation. Hence, such farmers may find it difficult to increase their farm size. Farmers in the Savannah zone may not even change their farm sizes because fertile lands are limited in supply. Hence, farmers are fixated to the same parcel of land. Moreover, the farmers may find it unrewarding and time-consuming to clear new parcel of land for cultivation in the midst of unpredictable and scanty rainfalls. However, majority of farmers 84 (60.0%) in Daboase in the Forest zone stated that they changed their farm sizes in order to deal with the impacts of drought. Finally, the results indicate that out of the 140 farmers in Nkoranza North in the Transitional zone, 70.0% in this zone adopted drought monitoring as drought adaptation strategy, particularly constant listen to weather news on radio and TV stations on daily basis. During an interview in the Transitional zone, a male farmer indicated that:

> *I always listen to 'weather man' on FM radio in order to know the on-set of rains before I even begin to prepare for farming. Sometimes before I go to farm, I have to listen to 'weather man' to know whether it would rain on that day or not* (Male farmer, Transitional zone).

Similarly, a majority of 45 farmers (59.2%) in the Savannah zone indicated that they employed drought monitoring as a tool for preparing for impending drought conditions and to improve their resilience to drought vulnerability. The plurality of radio stations as well as the availability of agricultural extension officers in the study areas provide easy access to weather information. Hence, most farmers continually monitor weather and climatic conditions before they plant their crops. Regarding drought monitoring, a lead farmer in the Savannah zone hinted during an interview schedule that:

> *We do not sow arbitrarily in this area. We usually 'study' the weather pattern to predict the arrival of rains before sowing seeds* (Male lead farmer, Savannah zone).

However, majority of 69 farmers, representing 62.7% of the 110 farmers who participated in the survey in the Forest zone did not practice drought monitoring. The climatic conditions in this zone is quite conducive for agriculture. The farmers in this zone hardly experience severe drought that lasts long as compared to farmers in the Savannah and Transitional zones Moreover, the soil in the Forest zone holds moisture. Hence, farmers in this zone do not really have to monitor the rainfall pattern as farmers in the Savannah and Transitional zones would do. Overall, more than half of farmers (56.4%) practice drought monitoring. This shows that drought monitoring is mostly being practiced by farmers as a method of adapting to drought in the selected agro-ecological zones. This confirms the results of a study by Pardoe et al. (2016) that farmers "follow the rain" until they are well-convinced that the rain would not fail them before they sow their seeds. It is obvious that drought monitoring is highly statistically and significantly related to agro-ecological zones ($\chi^2 = 27.15$: DF $= 2$, $N = 326$; $p < 0.001$). This is because various agro-ecological zones have different amount of precipitation and soil moisture content to support farming activities. The phi value (0.30) indicates that there is a moderate significant relationship between drought monitoring and agro-ecological zones. Therefore, the decision of a farmer to monitor and time drought would depend upon a particular zone where he is located. Rather than employing only scientific and orthodox strategies to adapt to drought, the study also revealed that the farmers also employ prayers and supplications as means to adapt to drought conditions. They offer supplications to Him so that He would cause the rain to fall. This could be so because farmers have sociocultural perception about climate change and drought. Some farmers attribute the occurrence of climate and drought to the intention of God and other deities (Jarawura 2013). Hence, farmers combine both spiritual and scientific means to adapt to drought.

> *Traditionally, we usually call on deities to intercede for us to get the rains. We go round the community to pour libation asking the gods of the land to cause rains to fall. And if it rains, we thank them [gods] by making animal sacrifice.* (Male farmer, savannah zone). *During droughts, we throw a challenge to the gods of the land to let it rain to prove the that they are living gods* (Male farmer, Transitional zone).

In conclusion, farmers employed both scientific and unscientific methods to adapt to drought in the selected agro-ecological locations in Ghana. The study reveals that drought adaption measures differ significantly among farmers in the Forest, Transitional and Savannah zones of Ghana. This finding is in harmony with results of various studies (Jarawura 2014; Abid et al. 2015; Bawakyillenuo et al. 2016) that climate and drought adaptation strategies are numerous and their implementation differs from place to place. This is because farmers' knowledge of drought adaption and their adaptive capacities as well as rainfall and soil properties differ from place to place. Therefore, farmers in various geographical locations would adapt to drought by adopting different mechanisms. However, the most commonly adopted drought adaptation measures comprise application of agro-chemicals, changing of planting date, cultivating different crops, integration of crop and livestock production, changing the location of crop on yearly basis, diversifying from farm to non-farm income generation activities, cultivation of early maturing crops, and drought monitoring.

Conclusions

Farmers' adaptation to drought differs across various agro-ecological locations in Ghana and they adapt to drought by employing mixed adaptation strategies. The most commonly used drought adaptation strategies include application of agro-chemicals, changing planting dates, cultivation of different crops, changing location of crops, cultivation of early maturing crops, diversification to non-farm activities, integrating crops and livestock production, as well as drought monitoring. Moreover, farmers' choice of specific drought adaptation strategies is a determinant of various factors. Farmers' ecological location acts as the major significant determinant of their adoption of all the eight drought adaptation measures. Finally, farmers with access to credit facilities and extension services are more likely to adopt farm-based drought adaptation measures and less likely to diversify to non-farming activities. Ministry of Food Agriculture (MoFA) and the National Disaster Management Organization should provide drought relief measures and safety net programs for vulnerable smallholder farmers. This also calls for the introduction and implementation of crop insurance schemes where farmers would be given the opportunity to indemnify their crops against possible loss associated with drought. As a matter of mitigating farmers' vulnerability to drought, both governmental organizations such as MoFA and National Climate Research Institute, and other non-governmental organizations should help develop, introduce, and implement affordable drought adaptation technologies in farming communities. The introduction and cultivation of drought-resistant crops, water harvesting, and conservative agriculture practices should be promoted among farmers in the country.

Abstract

Climate change impacts a natural and human system on the entire globe. Climate-related extreme weather such as drought, floods, and heat waves alters the ecosystems that society depends on. Climate, land, energy, and water systems (CLEWS) are a critical aspect of high importance on resource availability, distribution, and interconnection. The nexus provides a set of guidelines to South Africa that aims on creating a level playing field for all sectors while achieving the aims of the SDGs that are cross-sectoral and multilevel approaches to climate change. The nexus expressed three domains that included resources, governance, and security. It integrated a smart climate resilient with inclusion of the governance and involvement of the stakeholders. Recognition of spatial and sector interdependencies should inform policies, investment and institutional for enhancing nexus security and climate change towards making transition green carbon deals. The nexus offers an integrated approach that analyzes the trade-offs and synergies between the different sectors in order to maximize the efficiency of using the resources that adapt institutional and optimum policy arrangements. Economic transformation and creation of employment through green economy is one of the COP26 green deal agendas in curbing the carbon emissions (green house emission, industrial processes, fuel combustion, and fugitive emissions) as mitigation to climate change, which is cost-effective and economically efficient. The future climate change policy in the developing countries is likely to be both promoted by climate technology transfer and public-private cooperation (cross-sector partnership) through the technology mechanism of the nexus and inclusion of the gender.

Adaptation · CLEWS · Climate change · Climate technology · Ecosystem · Green economy · Policy · Resilience · SDGs · Nexus

Introduction

Green revolution, disruption of the natural resources and social-economic impact are becoming increasingly in Industry 4.0 (Fourth Industrial Revolution-41R). The is due to enhancement of the adaptive capacity for the complex global challenges in advanced nexus approach to the sustainable management of climate change, land use, water, energy, and food. This serve the paradigmatically that was isolated and understanding of the interrelation of the WEF, human well-being, resilient ecosystem, climate change that coexists within the planetary boundaries. The shift in society disruption legion of unfortunate solution to an environment or development challenges that end up creating new, unforeseen problems and dilemma (Newell et al. 2019; Matheri et al. 2020). The nexus describes the interconnections and interdependencies between the land, water, energy, and food (LWEF) sectors. These interdependencies of the LWEF securities have received growing attention in the past years by researchers and policy-makers. Lack of understanding of the nexus has been described as a major global economic challenge by the World Economic Forum. This put forward the nexus approach as a fundamental shift for sustainable development (Hassan et al. 2018). A review on the LWEF and land utilization needs to be addressed on policy-making and decision-making concerning the nexus framework and climate change. This bridges the gap between science and policy in the implementation of nexus. More importantly, the nexus can also support achieving the United Nations Sustainable Development Goals (SDGs), 2030 Agenda, because of its close relation to three SDGs: SDG2 “zero hunger,” SDG6 “clean water and sanitation for all,” SDG7 “affordable and clean energy,” and SDG13 “climate action” (Tashtoush et al. 2012).

The nexus is expressed into three domains that include resources, governance, and security. The domain requires inclusion of the policy and institution expertise, natural resources use, environmental science, and engineering expertise for the mutual perspective of multiple decision-making, solution, and resource recovery (Scott et al. 2015, 2018). The priorities areas for climate change include decarbonization of the economy, digitization, decentralization of the production, transition of 100% renewable energy, carbon taxation (tax the polluters not people), access to sustainable finance, assist small island and least developing countries, support people affected by climate change, increase accessibility and availability of the jobs and livelihood, nature-based solutions, stronger commitments by the major emitters, and commitments to achieve carbon neutrality by 2050 (United Nation (UN) 2020). The focus is placed on implementation of the nexus concepts with a smart climate resilient on nexus regional dialogue programs by United Nations (UN) bodies, World Bank, GIZ, European Union (EU), Africa Union (AU), Middle East and North Africa (MENA), and World Economic Forum among others.

Paris Agreement on Climate Change

Climate change results in disruption of national economies that affect the countries, communities, living standards, and flora and fauna. With likely shift of the climate zones, long-term, changes of the rainfall patterns, and raising of the temperature, climate change shock is expected to increase frequency putting pressure in energy, food, water supply, and competition of land ownership in unaffected areas (Stocker et al. 2013; Carter and Gulati 2014). The historic Paris agreement provides countries with strong global climate change response by keeping the temperature rise below 2–1.5 °C. It encourages parties and stakeholders to reduce the impacts of the climate change (ambition and implementation to ensure highest mitigation and adaptation efforts by all parties with building climate resilience).

The intergovernmental climate change panels have recorded the following:

- 1901–2010: Warm oceans and diminishing snows and ice by 1.07 million km^2 with rise of the sea levels by 19 cm
- 1880–2012: Increase of the temperature by 0.85 °C due to warmer climate
- 1990 to date: Global emission of the CO_2 that has increased by 50%

The agreement solidifies international cooperation on investment of a low-emission economy (green economy) that contains transparency framework, mutual trust, and confidence. Industry 4.0 is overseeing the scalable, affordable solutions that are more resilient to the economy and mostly helping the developing countries toward the low-carbon economy. Major technologies and institutions will see a shift of containing and ensuring that global warming does not exceed the threshold. SDG 13 defines the commitment by strengthening resilience and adaptive capacity; integrating climate change strategies, policies, and planning; creating awareness on adaptation, mitigation, and impact reduction; and implementing meaningful mitigation again and transparency through UNFCCC (United Nation Framework Convention on Climate Change) framework and inclusion of the marginalized communities and planning and management (SDGs, UN 2019). The impact of the climate change will be amplified through interdependence and interconnection among the resources, land, water, energy, and food.

Climate-Land-Water-Energy-Food Nexus

The global web of mutual interlinkages defines the climate-land-water-energy-food nexus on societal changes that drive growth and demand. The ongoing disruption of the environment is likely to alter the accessibility or availability of land, energy, water, and food that is central to climate change policies and natural resource management (Markantonis et al. 2019). Holistic and integrated approaches to resource planning and management have been largely embraced by decision-makers and stakeholders although the benefits of the nexus approach may appear obvious to its advocates. The nexus is related to integrated management, consumption, economic resources, policy, security, and approach. The nexus concept needs to be approached beyond the research and development domain.

The WEF nexus has emerged as a useful disruption in Industry 4.0 in understanding multiple interdependencies that coexist between land use, water, energy, food, and climate change. It is a multidisciplinary that cuts across both state and non-state sectors. The WEF has potential to unlock groundbreaking solutions to complex problems with appropriate models and climate change mitigation. The is expressed as National Development Plans (NDP) and United Nations Sustainable Development Goals (SDG) that are emerging in the international agenda at the World Economic Forum on understanding the link between use of resources in providing universal basic rights and climate protection (Seeliger et al. 2018). This was welcomed by the Conference of Parties (COP) by the UNFCCC on

Fig. 1 The water-energy-food nexus concept. Source: IW: LEARN, Germany 2014

enhancement of climate technologies' development and knowledge transfer through the technology mechanisms of greater public-private cooperation (cross-sector partnerships). This is through the action on climate and SDGs, climate technology, education, youth, gender, having open-source information and intellectual properties, climate finance, adaptation and resilience, and capacity building (Forsyth 2007; Forsyth 2005; COP25 2019a, b). Figure 1 shows the WEF nexus concept.

The nexus can provide technology, innovation, and analytical framework by complementing design principles and new policy perspectives for the CLEWS' security policy. Building future planned actions on nexus needs advanced research and development (R&D) such as cost action and Horizon 2020. The role of the WEF nexus is gaining increasing attention in the region from developing countries, which is a partner in the Nexus Regional Dialogues Programme (NRDP) with an aim to create an enabling environment that drives implementation and cross-sectoral engagement of nexus investment projects. The intention is to provide decision-makers with prospects where the theory of the nexus concept has been made operational.

The C40 cities program seeks to build and identify opportunities and build evidence benefits of climate action synergies within the climate, water, and energy nexus. C40 cities have built a platform of networks, adaptation, communications, finance, and other programs on taking bold climate actions that are healthier and more sustainable to resilient cities (C40 2020).

Specific to Agenda 2030, 4 of the 17 SDGs are directly related to the food, water, and energy sectors (Tashtoush et al. 2012; United Nation (UN) 2015):

- SDG 2 (Zero Hunger): End hunger, achieve improved nutrition and food security, and promote sustainable agriculture.
- SDG 6 (Clean Water and Sanitation): Ensure availability and sustainable management of sanitation and water for all.
- SDG 7 (Affordable and Clean Energy): Ensure access to reliable, affordable, sustainable, and modern energy for all.
- SDG 13 (Climate Action): Taking action to combat climate change and the impacts.

Although these four goals directly relate to the individual areas of climate change, water, energy, and food security, progress in 12 of the 17 SDGs is directly related to the sustainable use of resources. Some goals cannot be achieved without a holistic view of the nexus.

Energy Security and Pursuit of Water, Food, and Earth System Resilience

Energy security exists where there is uninterrupted availability of energy sources and distribution at an affordable price to the consumers. With frequent power rationing (load shedding) in many African countries that ranges in hours, this remains a dream in achieving adequate energy production, stable tariffs, relax policies on independent power production (IPP), political stability, intelligent distribution of energy, green buildings, smart metering, energy auction, bidding and pricing, self-driving cars, electronic cars, energy storage, smart cars, high-speed trains, next-generation GPS devices, autonomous vehicles, gyroscopic vehicles, smart roads, hyperloops, micromobility, intelligent electric vehicle networks, etc. All of this lies on policies and politics.

The food challenges from energy perspectives include increasing food cooling systems; energy-intensive farm operations; local food chains that is minimizing transport energy; extended crop seasons; artificial intelligence and blockchain technology on food tracking systems; use of remote sensing technology (i.e., drone use for mapping, irrigation, and spraying) to monitor food production, spraying and irrigation; use of hydroponic and aeroponics for urban farming; use of drone to monitor crop production and pest controls; use of robotics technology in farming; and use of artificial intelligence in detecting crop diseases at an early state which all needs intensive use of energy and technology literacy.

The water challenges from energy perspectives include energy intensive of desalination, water reuse, rising demand for carbon-free energy systems, climate change raises water needs of energy, water allocation to energy generation, water capture from atmosphere (humid ambient air) using solar-powered devices, and

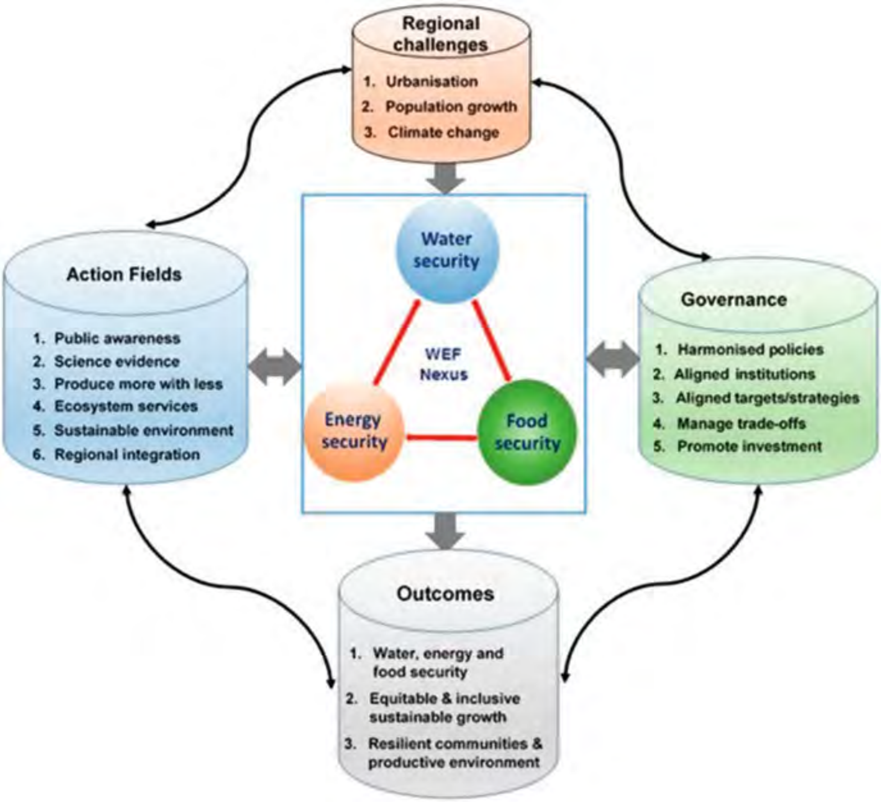

Fig. 2 Conceptual framework of the regional water-energy-food nexus action plan

decentralized wastewater treatment (online wastewater treatment and monitoring using sensors).

The future of transportation lies on our behavior, culture, taboos, and way of life. How often one drives the vehicles, the mode of transport we take, the types of fuels we use, an investment in public transportation, compensation due to shift and investment on green energy (green funding), congestion charges, and more vehicle-pooling and ride-hailing services justify dependence toward zero emission and thus mitigation to climate change. Figure 2 shows the conceptual framework of the water-energy-food action plan (Nhamo et al. 2018; Chirisa and Bandauko 2015).

Reliable Integrated Waste Management and Nexus

The populace development, urbanization, economic advancement, and improvement in expectations for everyday comforts in disruption of Industry 4.0 (4IR) have increased the amount of the waste generation in the cities and reintroduction of the emerging contaminants into waste streams. These wastes pose sanitary, health hazard, and environmental risks. These contaminants end up in water bodies and landfills, prompting to pollution of the entire environment, thus putting a high strain on social, economic, health sector, and climate change. Tackling integrated waste management disruption and energy security requires stipulated regulation and policies that coordinate waste administration frameworks. The future of digital disruption and transformation of industrial platform, energy-water-food generation lies on the decarbonation, decentralization, electrification, and digitalization (sustainable industrialization and diversification in the digital era). Technologies in the era of digital transformation are becoming commercially viable to the integrated systems and services that enable sustainable management and efficient integrated waste management (IWM), energy production, and use. Reliable IWM and data provide an all-inclusive resource for a critical, comprehensive, and informative evaluation of IWM options in all integrated waste management programs. Optimized programmed operations using predictive analytics (i.e., convectional and AI modelling), big data, blockchain, e-citizens, fintech, and data mining are the fundamental apparatuses generally used to assess the policy impact and technology of savvy arrangements, just as to design the most ideal approaches to move from current to more intelligent urban areas. There are several obstacles confronting municipal solid waste management within the cities. Some of such obstacles are interrelation of urbanization and economic growth; change of living standards that causes complexity of the waste stream; overstretching of the superannuated infrastructure; lack of location and facilities to expedite waste separation at source; Intelligent Network Infrastructure (tracking collectors, IoT bins, automated recycler with incentive to users, available recycle plants); and integrated waste management technologies that are handy and costly compared to landfilling and composting. Detachment of waste at the source and embracing zero waste financial motivation urge a family to diminish squander.

The organic waste can be changed over to vitality utilizing waste to vitality elective courses that incorporate transformation, gasification, combustion, pyrolysis and liquefaction, organic procedures, aging, hydrolysis, and anaerobic assimilation for biogas and biomethane creation. An investigation waste quantification to assess the sustainability, characterization to assess the composition, and anaerobic digestion to assess the amount and quality of energy (CH_4) generated by the City of Johannesburg were carried by a team of researchers (University of Johannesburg). The outcomes indicated that 1,444,772 tons per annum of local waste were created in the city of six million residents consistently as announced by the City of Johannesburg (CoJ), South Africa Pikitup (2017). Littering alone costs the city 5.7 million dollars every year, while illicit dumping costs another 6.2 million dollars for each annum. Organic waste can be changed over to vitality utilizing waste or vitality elective courses that incorporate transformation, gasification, combustion, pyrolysis and liquefaction, organic procedures, aging, hydrolysis, fermentation, and anaerobic assimilation for biogas and biomethane creation. Recyclable squander (paper/paperboards, plastics, and glass) was the second biggest part 12%, 19%, and 9%, respectively (Matheri et al. 2018a, b; Matheri 2016, 2020; Fig. 3).

The generated biomasses had potential of the alternative clean fuel production to meet the energy security and climate change mitigation. The physiochemical properties of the biomass showed the energy value equivalent to natural gas. The generated energy will contribute to a reliable, affordable, carbon-neutral, sustainable

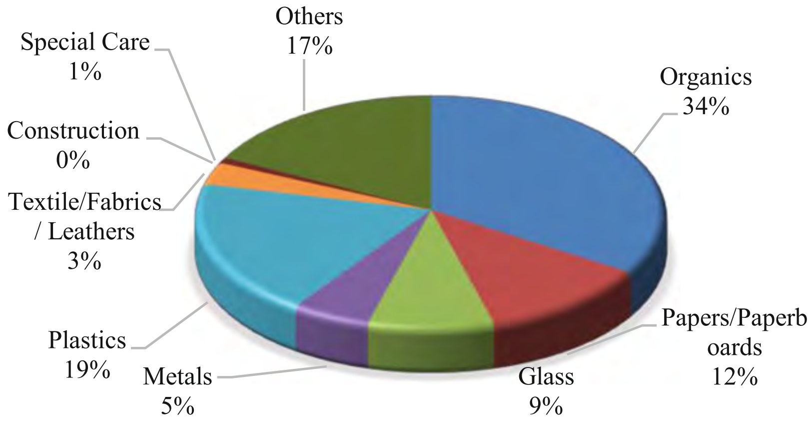

Fig. 3 Quantification of waste generated by the City of Johannesburg, South Africa

form of modern energy. This will help in the development of the conservation of biodiversity, waste management, poverty eradication, and adequate waste to energy recovery management strategies and improve living standards of the citizens (Matheri 2016). The energy system disruption will assist to bridge the gap in the implementation of the SDGs and fourth industrial revolution. The high number of plastic calls for the introduction of the bioplastics to protect the flora and fauna. This adds up pressure on the added value recycling and reduction of waste to landfills. The climate change future policy in developing countries is likely to be both promoted by climate technology transfer and public-private cooperation (cross-sector partnership) through the technology mechanism of the nexus and inclusion of the gender.

Water Security and Pursuit of Energy, Food, and Earth System Resilience

Water is inseparably linked to food and energy production. The interdependence of energy on water is seen in transport, extraction, power generation, irrigation of biofuel crops, processing of fossil fuels, fuel cells, energy storage, etc. (Birol 2012). The emerging issues are cultivated on the regions that are facing adoption of the appropriate water management policies, water scarcity, and approaches fostering the allocation and sustainable use of resources while promoting economic growth. Due to human activities and availability of the water resources, Africa is one of the most vulnerable regions. In order to maximize the efficiency of using the resources, nexus is offering an integrated approach that analyzes the synergies and trade-offs between different sectors whereas adapting optimum institutional and policy arrangements (Markantonis et al. 2019). Lifecycle approaches are widely used by the industry for the assessment of the risk water management. The absence of lifecycle database to complement developing countries' databases is a challenging issue that extensively improved the national accounting system. More positive economic opportunities are created in desalination technologies, smart metering, leak detection (prevent water loss), online water treatment, sensor technology in parameters detection, and smart use of ecosystems to collect and store water and carbon. Water security encourages the population to increase capacity of sustainable water access with adequate quality and quantities for human well-being, sustaining livelihoods and socioeconomic development. This ensures the protection against water-borne diseases, emerging contaminants, and water-related disasters by preserving a climate with peaceful ecosystems and political stability (Hassan et al. 2018; Matheri 2020; UN Water 2013).

The food challenges from water perspectives include raises irrigation demands, diminishing institutional that influences the irrigation schemes, groundwater pumped variables, production shifts poleward, higher elevation, water and wastewater treatment and reuse of the resources (Scott et al. 2018). The energy challenges from water perspectives include low water footprint solar PV and wind, dry cooled thermogeneration, water footprint of multiple energy portfolios, energy generation degrades water quality, energy generation from water resources (hydropower, fuel cells, anaerobic digestion), and energy storage (Scott et al. 2018). Construction of the decentralized solar-powered desalination systems in the dry areas will be one of the game changer deployments of the sustainable technology solution in disadvantaged communities in developing countries. This helps bring millions of liters and address perennial water shortage and thus reduction of water-borne diseases.

Water Pricing

Water pricing currently is often underestimated which is fundamentally of importance in the economic issues that affect the implementation of the nexus on water use. Water pricing is an economic instrument which efficiency depends on the designed and implementation of the WEF nexus framework and investment. This is with regard to the policy choice, economic pursuit, realities, environmental, social, opportunity cost, and cultural cost. Developing countries' adaptation of the EU members' states law and policies on water pricing is one of the key goals in sustainable development (Markantonis et al. 2019).

Food Security and Pursuit of Water, Energy, and Earth System Resilience

Food production needs energy, productive land, and water to grow crops, process food, and maintain livestock. Organic fraction of waste can also be put into value by converting and generating energy via anaerobic digestion and fermentation processes, while other technologies go more to gasification and direct combustion to generate energy and organic fertilizers (Matheri 2020). Such bidirectional links are complicated by the specific external factors that modify the chemical and physical characteristics and composition of water flows. Food consumption (changing dietary habits) and generation of the food waste have large effects on the nexus. This is yet to be accounted in SDGs and cannot be treated with isolation from one another and alternative in the attainable chosen pathways in the water and food systems. Food security exists when everyone, at all times, has economic and physical access to adequate nutritious, safe, and sufficient food that meets their specific dietary preference and needs for an healthy and active life (Hassan et al. 2018). The water challenges from food perspectives include land degradation (salinization), water use, wastewater use for food production, supplemental irrigation of rainfed land, high water footprint of agriculture, and ensuring water allocation to irrigation. The energy challenges from food perspectives include mitigate hydropower-farming trade-offs, energy intensification of agriculture, energy intensification of the biofuel production and food transport, and competition between energy production and food security. One of the futures of food in climate change is podcast on the plant-based meat change to counteract the intensive use of energy.

Biophysical and Biogeochemical Land-Climate Systems

The evidence of the land cover matters and climate systems is on early paleoclimate model studies and impacts on human-induced deforestation at margined regions. Changes from land conditions due to human activities affect the global climate change. This is driven by changes in emission removals of the GHGs (e.g., CH_4, CO_2, N_2O) by biogeochemical effects. Any land redistribution and local changes on the water vapor and energy between the land and atmosphere influence the biophysical effects on regional climate. The terrestrial biosphere interacts with oceans through influx of nutrients, carbon cycle, water, and particles. This interaction affects crop yield, frequency heat waves, intensive heat waves, rainfall, and air quality. Land has net sources of 441% of the CH_4 emission between 2006 and 2017. IPCC has established GHG inventories and earth system models (ESM) on deforestation and afforestation as to reduce the anthropogenic CO_2 emission. This combines biophysical and biogeochemical processes to the land-climate system processes. IPCC reports that about one-quarter of 2030 mitigation pledges by countries in initial nationally determined contributions (NDCs) under Paris Agreement is expected to come from land-based mitigation (Jia et al. 2019). Some of the mitigation responses have a response option on technical potential for >3 $GtCO_{2\text{-eq}}$ $year^{-1}$ by 2050 through reduction of the carbon dioxide. These technical aspects include afforestation, waste to energy (bioenergy), wastewater recycle, and carbon capture and storage (carbon dioxide removal-CDR). The estimate includes sustainability and cost consideration with social-economic consideration on the climate changes or non-GHG climate forcing. Rising CO_2 concentration limits stomatal opening of the moisture content in the soil, thus reducing transpiration (land-based water cycle/ hydrological on climate change). This increases the aerosol levels, declines surface winds, and increases solar radiation to the ground. The impact of the climate-related extremes on land includes the disruption of the water-energy-food production and supply chain, alteration of the ecosystems, hydrological cycle, surface temperature, atmosphere composition, morbidity and mortality, and damages of the infrastructure and settlements and human health. Advanced knowledge and optimization of the mitigation and adaptation with coordination of the sustainable land use and management across all sectors are required to achieve better livelihood, food security, energy security, and water security and improve human health, biodiversity, quality of the local environment, and equitable sustainable development. This is through the modification of the regional and global climate change, seasonal and annual climate variation, extreme weather, and human activities on the land, e.g., deforestation, afforestation, and forest management. Incorporating land-climate processes into climate projection allows emotional intelligence and artificial intelligence to take shape through understanding land's response to climate action and better quantify the potential of land-based response options for the mitigation of climate change (Jia et al. 2019).

Nexus Contributions to Job Market

When developing or implementing a nexus, approaches with regard to minimization of high transaction costs should be an added value in economic measurement. Furthermore, energy and water generation and distribution have high characteristics of being monopolized in the developing countries. This creates merits and demerits to the end users. In general, the CLEWS' nexus has great potential to create new job opportunities and improving living standards in the developing countries. There is a higher need to accelerate the process of the WEF management of emergence of new employment opportunities. Investment of the research and development and implementations on nexus approaches could induce a positive economic effect through job creation. Other disrupted sectors should further be redeveloped, attracting additional meaningful investments and producing new employments within a nexus framework of policies and governance, auditing, and monitoring. Governments have the biggest role to play in the nexus implementation either by making relevant policies or providing funding that subsidizes new technologies and contributes to the welfare of society and enrichment of the emerging market gap.

Carbon Tax

Developing countries' economic transformation and creation of employment through green economy and digitalization will be one of the COP26 green deal agendas. This is with the transition of the national development goals (NDG) 2030 and transition of the low-carbon economy and sustainable development goals as per the economic partnership agreement between the European Union (EU) and developing countries. The commitment through policy-making is paramount in the carbon taxation. The carbon tax is levied on carbon content of fuels (energy and transport sector) and carbon emission trading in the form of carbon pricing (CO_2 equivalent tax/pollution tax). The tax offers potentially cost-effective means of the reduction of the greenhouse gas emissions by shifting the cost from society to companies that create the emissions (the more the emission, the more the cost). South Africa has spearheaded the developing countries in the carbon tax 2019 (carbon tax act No.15 of 2019) meant to curb the carbon emissions (green house emission, industrial processes, fuel combustion, and fugitive emissions) as mitigation to climate change, which is cost-effective and economically efficient. The cost of the impact of climate change to food pricing, water, infrastructure, health, conflict, and disasters tends to shift to polluters (global economy shifts toward lower carbon economy). The impact of crop disease and rainfall changes, extreme storms and drought, and temperature changes has shift changes in food prices and food security. This has direct impact on the carbon taxation (Republic of South Africa ZA 2019).

Data-Driven Nexus

It is a big challenge to relatively obtain national data for the nexus. Small numbers of bodies (e.g., IRENA. World Bank, IEA, UN) share production, transformation, and consumption data. This remains a key challenge in the mitigation of climate change. Examples os data include water evaporations rates from hydro-powers, flood controls or irrigation, water requirement in energy production and food production, mixed SI units on the data presentations, pattern use of water with regard to locations. Data gap is even larger if fully life cycle of the technology is considered (Ferroukhi et al. 2015).

Matters concerning the big data in nexus' availability and accessibility should be of high priority in policy-making. Nexus is based on a holistic environmental and economic perspective, which should use reliable, consistent, and comprehensive data. It is also imperative that data source across the nexus sectors is comparable in terms of resolution and accuracy. Efficiency in implementation of the nexus is dependent on high-accuracy economic databases that support sustainability. Research and development, scientific institutions, and stakeholders can initiate the collection of open data, in order to build a sustainable database for analyzing the nexus. This can add value and be generated only through workable partnerships between the private-public sector, NGOs, knowledge institutes, and local and regional stakeholders (Markantonis et al. 2019).

Industry 4.0 in Nexus and Climate Resilient

The nexus pillars of sustainable development need to be explored in the numerical modelling (i.e., economic modelling; kinetic modelling; life cycle assessment (LCA); WEF modelling; multi-criteria decision analysis (MCDA); CLEWS' modelling; resource flow; network analysis; remote sensing, geospatial, and hydrologic models; finance models; climate models; material and energy models; land-use models; institutional analysis; environmental management; indicator models; social science and integration models; system analysis) (Albrecht et al. 2018). The climate change estimation is based on the sparse station coverage, particularly on scrutiny of

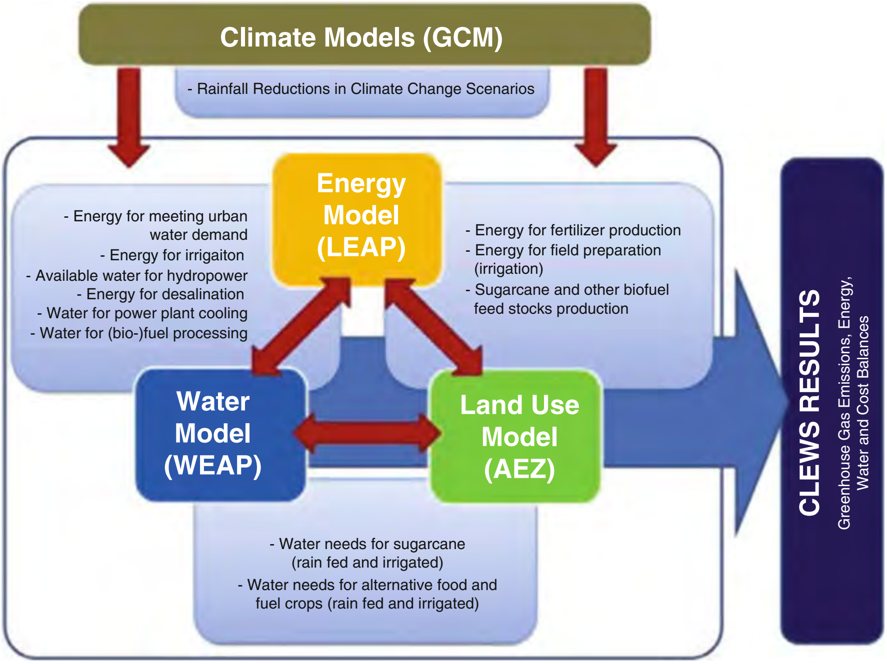

Fig. 4 The CLEWS' framework founded upon the LEAP, WEAP, AEZ, and GCM models

GDP data. Lack of transparency in data sources and collection methods, lack of details on methods of aggression, and lack of metadata have led to differences between GDP estimates, adjustment to historical data, nonrandom errors, and inhomogeneity in time series. Good quality data is paramount to reliable physical and economic modelling of the nexus and climate sector (Conway et al. 2015). Climate, land, energy, and water systems (CLEWS) are integrated. The CLEWS' resource assessment and interlinkages with new paradigms are presented in Fig. 4 (Howells et al. 2013; Welsch et al. 2014).

The CLEWS serve as highlights and dynamics that overlook the system approach to sustainable development. The CLEWS' framework is developed by integrating the LEAP (energy), WEAP (water), GCM (general circulation model, climate), and AEZ (agroecological zoning, land) to produce the GHG emissions, water, and energy balance. The model outcome exercises policy development and resource assessment approach through linking existing single-resource modelling tools (Howells et al. 2013; World Bank Group (WBG) 2016).

Modelling of the Water-Energy-Food-Land-Climate Nexus

The climate-water-energy-food-land are indirectly and directly interlinking. Nexus unique assessment and monitoring is based on indicators and interlinkages to better

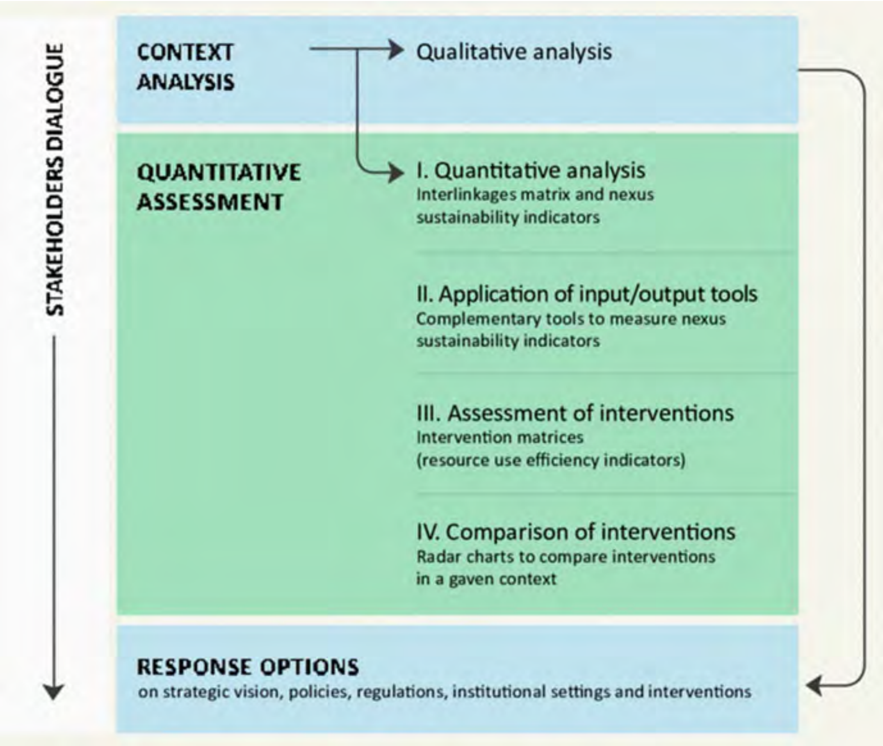

Fig. 5 FAO component of the nexus assessment

understand the potential synergies and trade-offs. Quantification and characterization are mostly needed in decision-making. Nexus modelling and framework are classified as (Hassan et al. 2018; Bizikova et al. 2013):

- Type of models: quantitative analysis models, simulation models, and integrated models
- Geographical scale in addressing intercountry levels

Figure 5 indicates the components of the nexus assessment (Hassan et al. 2018).

For example, assuming change in water (ΔW), reduces freshwater availability and create shift in energy (ΔE) with limiting cooling power that leads to load shedding (power rationing) and water scrubber thus increase shift of climate change (ΔC) and land use. The interlinkages are unique and can go to any directions. The 20 interlinkages are summarized below:

- Water: WL, WF, WE, WC
- Energy: WL, EF, EC, EW
- Land: LF. LW, LC, LE

- Food: FE, FE, FL, FC
- Climate: CF, CW, CE, CL

The analysis of the interlinkages can be analyzed well by the use of artificial intelligence tools (e.g., artificial neural network, ANN), statistical tools (e.g., multi-criteria decision analysis (MCDA)), and conventional modelling concepts. The nexus pathways can be restructured in the first to fourth order. Similar nexus can be constructed with fourth-order interlinkages for the whole nexus making it 120 (Laspidou et al. 2018). The multicentric approach will add complexity with interconnection, trade-offs, and drives on nexus assessments (Simpson and Jewitt 2019).

Adaptation of Climate Change Technology Transfer in Developing Countries

Currently, combating anthropogenic climate change in developing countries is carried out through the transfer of environmentally sound technologies (EST). This is a widely recognized priority for global environmental policy. Climate change technology transfer and policy analytics are of high success factors underlying collaboration between private and public sectors in developing countries. Climate change future policies in developing countries are likely to both be promoted by climate technology transfer and public-private cooperation (cross-sector partnership) through the technology mechanism of the water-energy-food nexus and inclusion of the gender. Building partnership mechanisms can reduce cost and increase local clean development mechanisms (CDM). The difficulties in achieving the CDM include first a sidelined investment by investors on diversifying a project away from cheap forms of climate change mitigation by increasing cost and broader development outcomes. Second, the technology dividends are uncertain and often reflect on preference of host government or deliberative processes involving the stakeholders. Third, green climate fund shortage or project investment guidelines combine production cost, human capacity, and innovator multidisciplinary. Overcoming the barrier allows the smart climate-resilient and efficient integrated energy-water-food nexus system in a developing country: Industry 4.0 with climate change friendly investment to proceed quicker and implement the development dividend (Forsyth 2007). The costs of climate technology transfer and increase local representation in establishing the development dividend can be reduced by cross-sector partnerships (CSPs). CSPs can comprise of orthodox public-private partnerships, where governments make contracts with a private-sector company in order to provide Intelligent Network Infrastructure or services more efficient than the state (Forsyth 2005, 2007). Climate change policy and technology transfer minimize the transaction costs, strengthen the collaboration, build capacity, increase public trust and accountability, and enhance environmental governance under the climate change convention and application of the CDM (Forsyth 2005; COP25 2019b).

Nexus and Research Gap

The concept of the nexus has been received in the business, academics, and policy sectors with a few implemented projects on the ground. The major discussion is how to implement and shift from the ideal concept of the theory based on practice and policies. The nexus methodology emphasis on water-food is majorly researched on hydrological, ecological, and agronomic integrated models and analysis with limited focus on the governance issues of the resources. Versatile methodology to quantify the interlinkages between the WEF and climate change is required. Improving the formulating existing methodology and practices is of high priority to advancing the adoption of the nexus approach. Lack of the reliable data (big data/open source) in the digitalization, electrification, decentralization, and decarbonation world (fourth industrial revolution, Industry 4.0) is a major barrier toward implementation of the WEF nexus approach. Lack of the reliable comprehensive analytic tools is another highlighted concern. Development of critical soft skills (sciences/social/business, STEM) in integrated software and online platform is helpful in addressing the potential synergies and trade-offs in the nexus. Convectional models and AI-based models' development is of a big challenge, and a big question is how nexus and climate change interact and are quantified. In providing important strategies for the SDGs, the integrated models and managements for developing countries is enhanced.

Climate change on the WEF is another critical aspect of high importance on resource availability, distribution, and interconnection to the WEF. How does climate change affect the nexus? What are the impacts of climate change to the nexus? Which agent of change needs to be implemented in WEF NEXUS? Is there political good will in the addressing climate change? What are the governance and policy coordination in place? These fundamental aspects can be addressed based on smart climate-resilient and efficient climate change adaptation, international commitment, corporation and stewardship, new and refurbished green infrastructure projects, green funding, reward and awarding the environmental champions, and payment for ecosystem services (Hassan et al. 2018). The methodological challenge, supports, and opportunities that are associated with robust quantification of the WEF nexus are indicated in Fig. 6 (Chang et al. 2016):

Analytics Framework

The nexus provides a set of guidelines that aims in creating a great and equal level playing field for all sectors while achieving the aims of the SDGs that are multilevel approach and cross-sectoral to climate change. This comprises of six categories (Hoff et al. 2019):

- Nexus framing creates specific understanding on key issues from that which explores the interlinkages between the different sectors and resources.

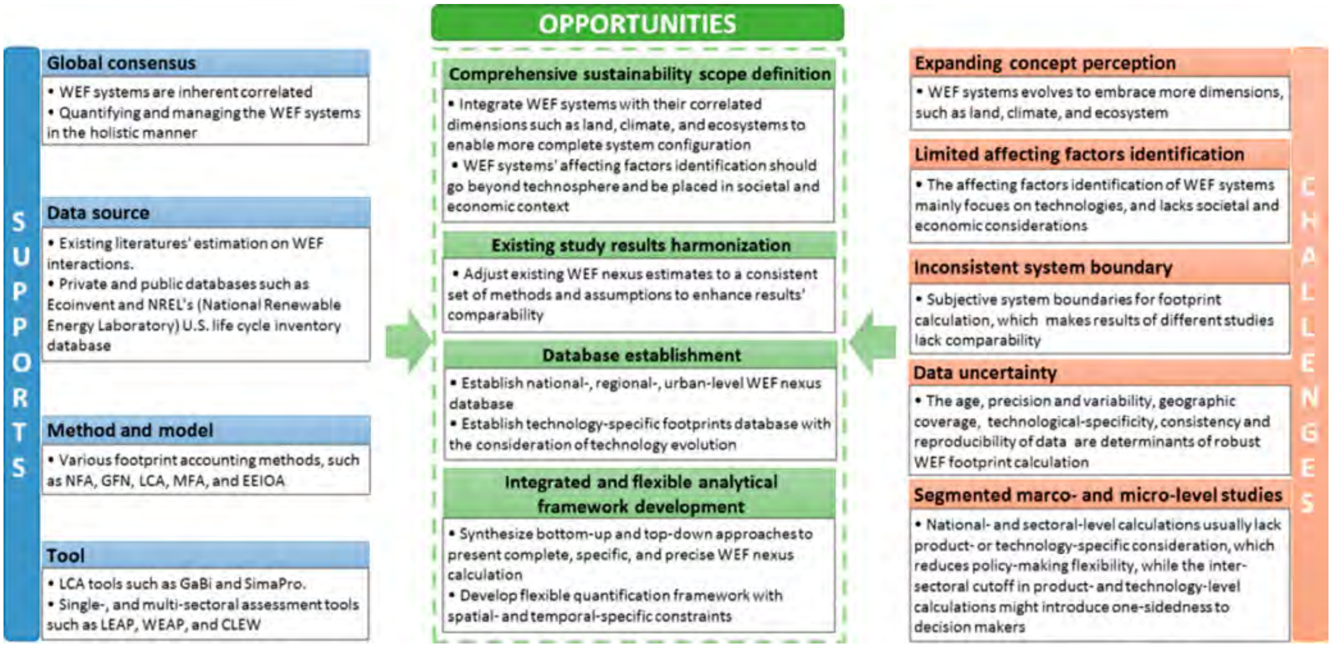

Fig. 6 Methodological challenge, supports, and opportunities that are associated with robust quantification of the WEF nexus

- Nexus opportunities create a category on how to identify a new approach and adding values in context by improving cross resources productivity, reducing resources and environmental degradation, reducing human insecurities/unemployment/poverty, and increasing climate resilience.
- Technical and economic nexus (nexus savings) assesses possible potential benefits from implementation of nexus approaches through multifunctioning production systems, cross resources, and cross-sector recycling.
- Stakeholders' involvement specifies different types and levels of stakeholders involved in the nexus, e.g., private-public sectors and civil society in overseeing the implementations.
- Conditions' framework addresses factors such as policies, technical solution, scalability, initialization, bridging mechanisms, integration of SDGs and NDGs, and innovations (start-ups, incubation, and entrepreneurship).
- Monitoring and evaluation (M&E) serves as an indicator for the required data for implementation of the nexus. This is because it is dynamic objectives, composition of stakeholders, and processes.

The overall methodology of the WEF nexus management approach is performed in three steps (see Fig. 7): (1) overview characterization (identifying and quantifying the connectivity between nexuses), (2) integrated models and analysis (climate-land-energy-water) of the nexus system, and (3) performing future management scenarios to help policy and decision-making (Tashtoush et al. 2012).

The nexus framework is seconded by the holistic resources planning showed in Fig. 8 (Kulat et al. 2019).

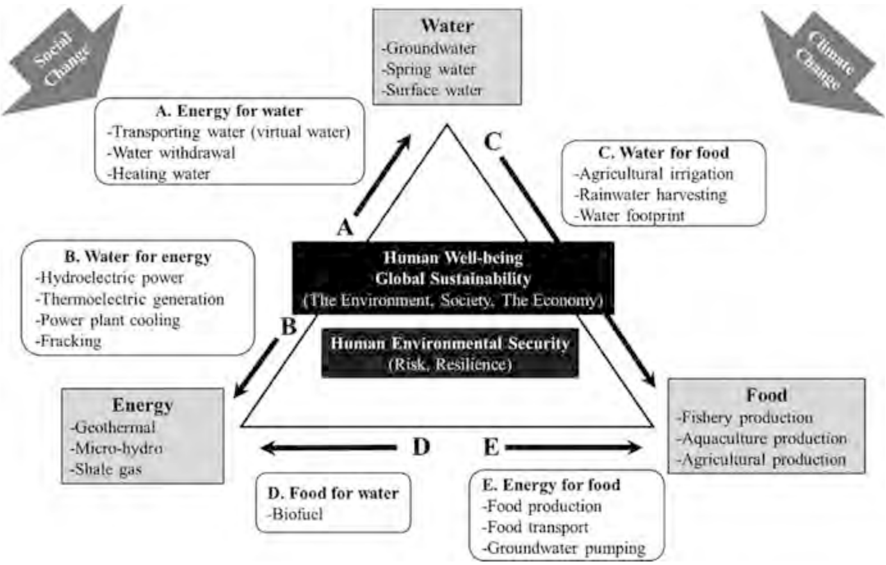

Fig. 7 Water-energy-food nexus analytics framework

Nexus Securities and Environmental Protection

Climate change intensifies high competition and trade-offs between the WEF resources. The potential impact of the climate change is manifested by rise in temperature, more energy demand, and more water demand. Urbanization and population increase (industrialization) account for the 75% of the energy consumption and emission of the 75% of the greenhouse gases (GHGs). This creates high opportunities for the decentralization, decarbonization, and digitalization systems that improve the resource efficiency and implementation of the nexus approached. Suitable adaptation of the climate change demands efficient use of water, energy, and food resources to fight against vulnerability. Figure 9 illustrates the conceptual

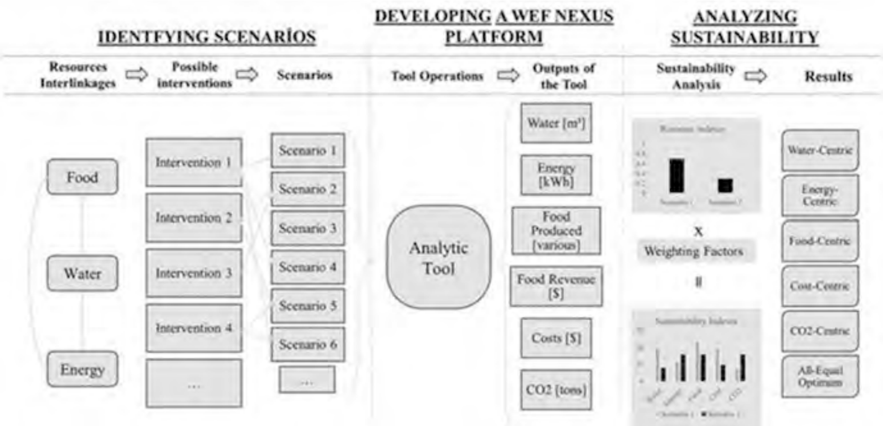

Fig. 8 Holistic water-energy-food nexus resources planning

Fig. 9 Conceptual framework of the water-food-energy nexus and climate change integration

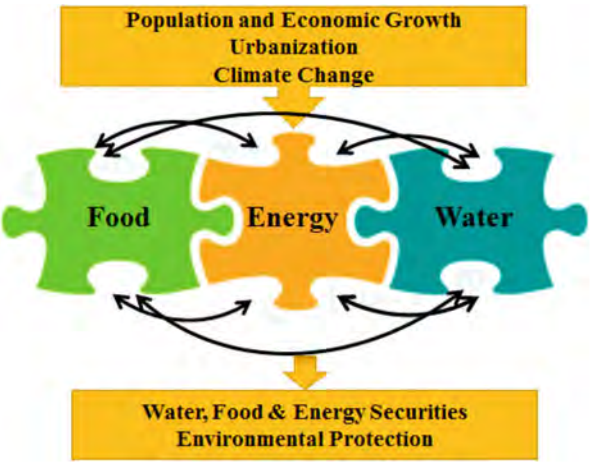

diagram of the WEF nexus with link between the WEF and climate change integration (Tashtoush et al. 2012).

The global emission of carbon dioxide has increased with almost 50% since 1990. The SDGs and NDGs cannot be achieved without addressing the climate emergence (SDGs, UN 2019). The region that is vulnerable to climate change encourages to adapt measures that are implementable and have surety of the WEF security. Enhancing efficiency of small-scale water supply systems and consolidated small services helps reduce vulnerability to climate change of the systems (policy initiative to adapt the climate change in water sector); collaboration in data collection and analysis to mitigation of climate change are key to sustainability of the WEF nexus. Adaptation of the climate change can be improved by building ecological networks that connect ecological to local governments, thus improving decision-making. Spatial equilibrium models seek to optimize resource allocation in various scales, thus providing realistic estimates of the value and into accounting alternative use of the disrupting technology. WEF nexus needs to be integrated to a smart climate resilient with inclusion of the governance and stakeholders. This serves as a comprehensive tool in decision-making toward sustainable resources in climate change (Volk 2014; Daher and Mohtar 2015). Recognition of spatial and sector interdependencies should inform policies, investment, and institutions for enhancing WEF security and climate change (Conway et al. 2015).

Policy and Governance (Coordination and Collaboration) for Climate Change

Climate gas (GHG) emissions and climate risks in countries are not only city government's concerns but also rural government oversight concerns (climate governance). The drivers, consequences, and dynamics of climate change cut across jurisdictional boundaries that require collaboration and coordination of governance across nongovernment and government sectors. Climate change governance is within broader political and social-economic context negotiable with Conference of the Parties (COP) to the UNFCCC (Romero-Lankao et al. 2018). Strategies, policies, and plans provide guidelines and framework for practical coordination and collaboration on CLEWS. Overarching climate change policies integrate the practical collaboration and giving timeline to the policies and their inclusion of climate changes and nexus. Persistence of these strategies recognized a gap in governance (policies and planning). The emphases on a formal model of contract may disincentivize regular collaboration and not only the barrier to cross-sector collaboration and coordination but budge and financial agreements. The issues of the regional security (power imbalance) are a sector interest overriding the climate change agenda. The integrations of the national-level strategies, planning, policies, and age and gender inclusion encourage action on climate change (Pardoe et al. 2018). Increase policy synergies among transformative investments that require a holistic approach with process innovation that fueled a higher level of nonhuman and human capital. Formation of the transboundary with globalized decision-makers

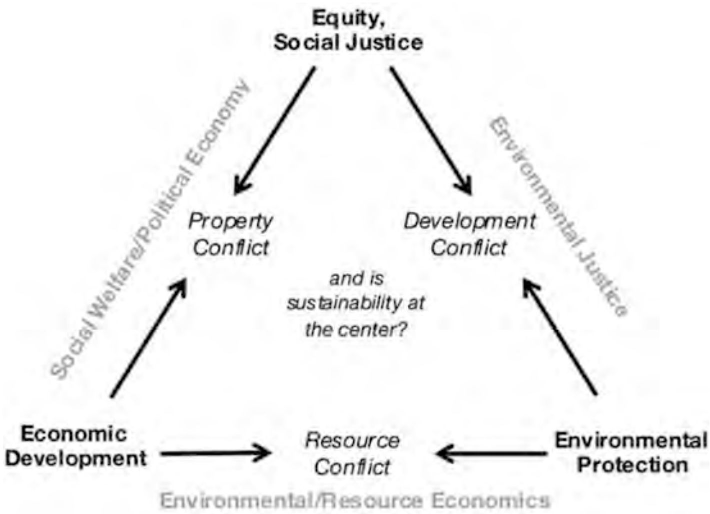

Fig. 10 Three fundamentals of planning

creates integration and enhances benefits through the climate-land and WEF nexus and equitable distribution. Creation and promotion of the gender equality environment enhances the nexus investments and implementations with enhanced family wealth that widens skills and knowledge (Mishra et al. 2019; RES4 Africa Foundation 2018). Collaborative, informed decision-making and equitable needs in transformation response of the climate change as well as fundamentals of the legal framework, leadership, land-use regime, land ownership, energy use, food production and distribution, public participation, information sharing, financial resources, growth, and ethos shape the climate change governance (Romero-Lankao et al. 2018). The three fundamentals of planning are presented in Fig. 9. It consists of the development conflict, resources, and property with three broad political/social institutions to manage environmental justice, regulation, environmental economics, and social welfare (Campbell 2013; Fig. 10).

Despite deficiency, state, government, provinces, municipalities, counties, and nongovernmental and governmental action on addressing climate change the jurisdiction over many dimensions of adaptation and mitigations reside on financial and technical capability and policies that hold greatest potential to create legitimate and effective response strategies (Romero-Lankao et al. 2018).

Equity, Climate Change, and Environmental Justice

Major cities are characterized by socioeconomics of different diversifications that are often accompanied with the stratification on gender, race, professional classes, cultures, age, ethnicity, and ability. This gives rise to endure climate stresses and minimize climate risks. Lower social class, disadvantages in the community, hazard prone areas, ethnics, and racial minorities increase their susceptibility to the impact of climate change and reduce their capacity to adapt (Rosenzweig et al. 2015).

Climate change vulnerability is driven by (1) resource influence by social characteristics, (2) ineffective planning and absence of community engagement due to governance and institutional weaknesses, (3) failure of the urban developers in providing accessibility to critical infrastructures and services, and (4) occupational health that leads to physical exposure at different levels. As the climate event such as drought in prone areas becomes more frequent and intense, this can increase the scale and depth of poverty overall. Gender inequality is pervasive and cuts across to disability, income, and literacy that in turn contribute to differential consequences of climate change. Mobilization of the resources increases environmental justice, and equity of climate change requires participation of the locals, international bodies in involvement of the nontraditional resources, finance civil society, public-private sector, monitoring and evaluation, and principles of transparency (Reckien et al. 2018). Figure 11 indicates the interconnected benefits and dimensions of inclusive climate action.

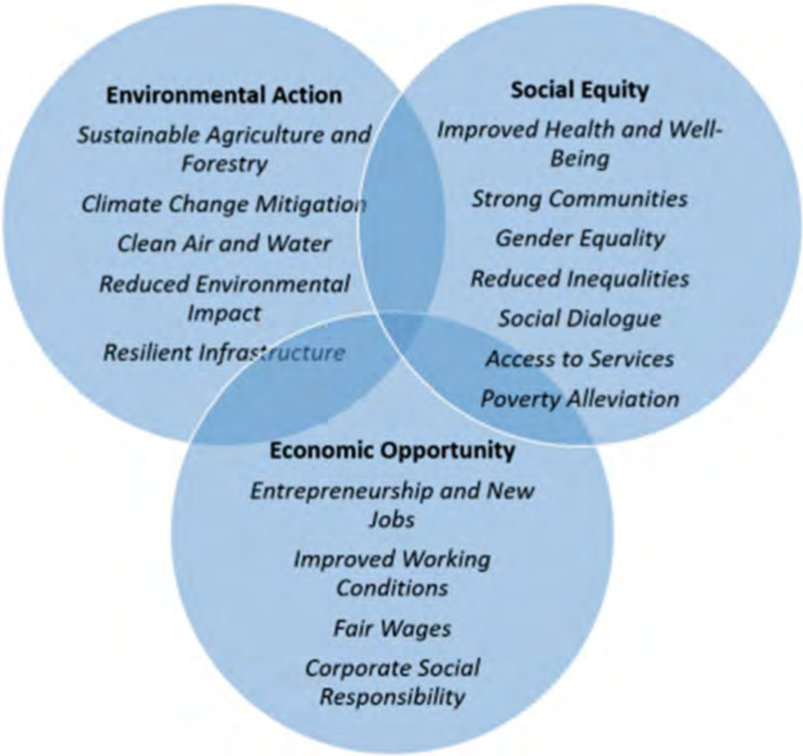

Fig. 11 Interconnected benefits and dimensions of inclusive climate action (Reckien et al. 2018)

The primary goal in achieving environmental justice and equity in climate change is for the urban climate policies to foster human beings, economic and sustainable social development, social capital, access to land, security tenure, risk reduction infrastructure, access to CLEWS; integrate community and stakeholders, in decision-making; adjust climate change policies by ensuring resilience and equity goals; and develop a periodic monitoring and evaluation using fair indicators and progress measurement, resilience objective and feasibility, equitable resources, budgetary transparency, resource allocation scheme, and equitable resilience outcomes (Rosenzweig et al. 2015; Reckien et al. 2018).

Conclusion and Recommendations

The CLEWS nexus is a concept of integration that accesses the resources such as water, food, and energy that are inextricably dependent and linked to one another and have a strong interaction with the environment and climate change. The interlinkages exist between nexuses that manifest in providing exploring opportunities that explore the disruption, policies, and alternatives for increasing the use of resources and sustainable resources management and minimizing the environmental impacts. The nexus and climate resilience offer great opportunities that integrate and manage the disruptive technology in a more sustainable manner by promoting local and regional cooperation and peace; harmonizing the policies, legislation, and strategies; creating proper resource coordination; improving resilience; and reducing vulnerability to attainment of the region integration in-line with SDGs. The impact of the climate-related extreme on land includes the disruption of the water-energy-food production and supply chain, alteration of the ecosystems, morbidity and mortality, and damages of the infrastructure, settlements, and human health. Advanced knowledge and optimization of the mitigation and adaptation with coordination of the sustainable land use and management across all sectors are required to achieve better livelihood, food security, energy security, and water security improve human health, biodiversity, quality of the local environment, and equitable sustainable development. Climate action future policy in developing countries is likely to be promoted by climate technology transfer and public-private cooperation (cross-sector partnership) through the technology mechanism of the water-energy-food nexus and inclusion of the gender. Building partnership mechanisms can reduce cost and increase local clean development mechanisms (CDM). Agenda 2030 sustainable development, Paris agreement, and national development policies are alignments to advance climate-resilient development and green deal that enhance stainable future.

Recommendations arising include:

1. Great investments into nexus with strong collaboration of the multidisciplinary.
2. Governments should work together to achieve green circular economy with smart and intelligent novel solutions.
3. SDGs 17 need to be widely explored and policies clarified.

4. Development of new tools to investigate the interconnection of the WEF nexus with land and climate change.
5. Research and development should be enhanced before decision-makings on sustainability and efficiency.
6. Better understanding is required of the trade-offs between nexus and ecosystems.
7. It is important to take action of the spatial reach of intersectoral interdependencies (pricing, control instruments, and command) and effects in the multi-level governance systems to ensure appropriate participation by affected sectors and stakeholders.
8. Data shortages should be reduced by encouraging open-source digitalized systems with capacity building support on sustainable monitoring and data management systems.
9. Introduction and enhancement of the existing free trade movement on the borders will enhance reaching the SGDs more than expected.
10. Use of the artificial intelligence solutions (nexus and climate change digitalization) on WEF and land and climate change applicability in decision support management, i.e., machine/deep learning, blockchain, remote sensing, IoT, big data, etc.
11. Introduction of the climate change coding (code for climate change and nexus) will enhance early data analytics and action (action toward digitalization, digital earth).
12. Enhanced, efficiency and accessibility of the green climate funding will enable preparation, implementation, and strategic workstreams of national determined contributors and adaptation-related elements of the Paris Agreement. The mechanism will minimize and address loss and damages associated with climate change impacts of developing countries' parties.

Abstract

Climate change has been viewed to result from anthropogenic human activities that have significantly altered the Nitrogen (N) cycle and carbon cycles, increasing the risks of global warming and pollution. A key cause of global warming is the increase in greenhouse gas emissions including methane, nitrous oxide, and carbon among others. The context of this chapter is based on a comprehensive desktop review on published scientific papers on climate change, greenhouse emissions, agricultural fertilizer use, modeling and projections of greenhouse gases emissions. Interestingly, sub-Saharan Africa (SSA) has the least emissions of the greenhouses gases accounting for only 7% of the total world's emissions, implying that there is overall very little contribution yet it has the highest regional burden concerning climate change impacts. However, the values could be extremely higher than this due to lack of proper estimation and measurement tools in the region and therefore, caution needs to be taken early enough to avoid taking the trend currently experienced in developed nations. In SSA, agricultural production is the leading sector in emissions of N compound to the atmosphere followed by energy and transportation. The greatest challenge lies in the management of the two systems to ensure sufficiency in food production using more bioenergy hence less pollution. Integrating livestock and cropping systems is one strategy that can reduce methane emissions. Additionally, developing fertilizer use policy to improve management of fertilizer and organic manure have been potentially considered as effective in reducing the effects of agriculture activities on climate change and hence the main focus of the current chapter.

Modeling · Pollution · Environment · Mitigation · Nitrous oxide · Carbon dioxide · Methane

Introduction

Globally, agriculture is the main contributor to greenhouse gases emissions (GHG) that is estimated to be between 10% and 20% of the total anthropogenic GHG emissions (Allen et al. 2020). From a baseline scenario, it is projected that GHG emissions from agriculture will be 1.7 gigatonnes by 2050. The GHG concentration especially CO_2 has increased by 40% since preindustrial times due to fossil fuels burning and also land-use changes. Current arable land cultivation practices have raised a great concern on the increase of GHG to the atmosphere. In sub-Saharan Africa, the effects are quite crucial but diverse as it has been associated with the variations of the season (rainy and dry) (Awazi and Tchamba 2019). As a result, this has significantly impacted the level of productivity, leading to food insecurity in this region. According to the US Environmental Protection Agency in 2010, the agricultural sector is the leading source of global GHG and accounts for 53% of carbon dioxide CO_2 emissions (Ronaghi et al. 2018). The distribution of CO_2 emissions is

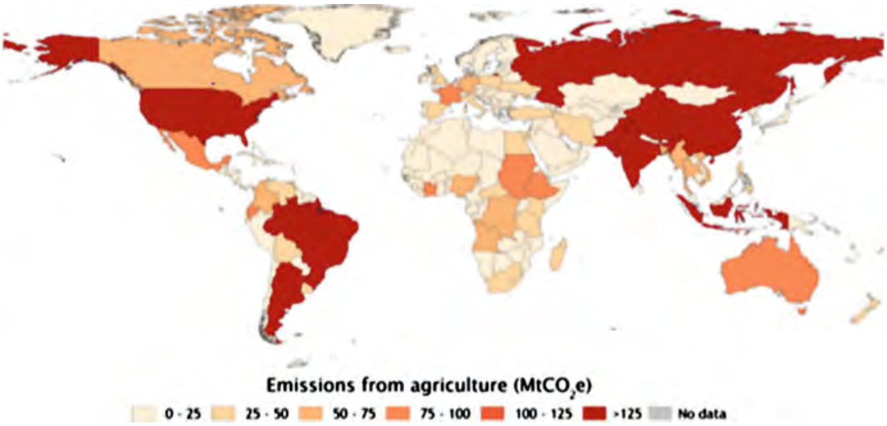

Fig. 1 Showing contribution of agriculture to GHG emission in global perspective. (Adapted from Malaka 2017)

globally spread as shown in Fig. 1, with most of sub-Saharan African countries emitting in the ranges of 0–75 $MtCO_2e$.

The main four sources of emissions from the agricultural sector include cropland soil management, rice cultivation, ruminant livestock enteric fermentation, and livestock manure management (Beach et al. 2015). According to Tongwane and Moeletsi (2018), half of Africa's total agricultural emissions were from enteric fermentation in 214 which signifies how great this source is. The GHG emissions in sub-Saharan Africa are estimated using Intergovernmental Panel on Climate Change guidelines in various subsystems of agriculture including crop production, animal manures, and methane emissions from livestock.

The main GHG fluxes from agricultural land include nitrous oxide (N_2O), carbon dioxide (CO_2), and methane (CH_4). The emissions of these gases (CH_4) and (N_2O) in agricultural land have increased by 17% from 1990 to 2005 globally (Popp et al. 2010). It is also anticipated that the GHG emissions will increase soon due to modern land-use changes that the sub-Saharan Africa region has adopted (Popp et al. 2010). Although the fluxes are anticipated to be high, there are various uncertainties in the estimates provided due to large insufficient temporal and spatial representation of emissions from agricultural soils (Mwanake et al. 2019). In SSA, these changes have significantly impacted the climatic patterns leading to more extended droughts and excessive rainfall that does not support agricultural productivity at the field level. Furthermore, organic soils are important sources of GHG emissions with about 35 thousand Giga grams of CO_2 as of 2010 demonstrated in SSA (Malaka 2017). Though there is no clear quantification data, there no doubt that there are some emissions from due to lack of management of crop residues since most of the agricultural waste in the land is openly burned or left free for livestock grazing. The burning of savannas and grassland fires that is common with the sub-Saharan African region is another greater contributors to GHG emissions (Malaka 2017). Due to this huge contribution of GHG emissions to the ecosystems, agriculture becomes an integral part that SSA and the whole globe should focus on to stabilize the emissions and save the current and future generations from the devastating effects of climate change. Therefore, this chapter will explore several available options and strategies that have the potential of mitigating GHG emissions from agriculture and minimize the impact of climate change.

The Approach Used

To acquire information of this chapter, we used the Google Scholar search engine to identify relevant peer-reviewed research articles published in high impact journals. A total of 53 articles were used that ranged from experimental, reviews, and policy papers. Keywords used in Google Scholar search engine were sub-Saharan Africa, GHG, emissions, management of emissions from the agriculture sector, climate change, agricultural sectors, management, agricultural systems, modeling, emissions, and global warming. The chapter focused broadly on various methods that have been suggested by the global panel, policies, and guidelines of the Intergovernmental Panel on climate change.

Key Strategies for Reducing Greenhouse Gases Emissions and Mitigation of Climate Change

Adopting Improved Nutrient Management in the Agricultural Lands

In sub-Saharan Africa, there is a problem of declining nutrient levels in cultivatable land which is due to poor nutrient management among the farmers. Most of the farmers lack the know-how on efficient use of the available fertilizers with minimal N loss but with improved crop yield (Galloway et al. 2003). To achieve this, farmers should be enlightened through policies and extension on various ways of fertilizer use that minimize the extent of nutrient loss to the environment that contribute to emissions of gases such as nitrous oxide (Huang et al. 2019). Improvement of nutrient use efficiency has a high potential of minimizing the N_2O emissions from cropland that are generally generated by the soil microbes from the surplus of N and indirect emissions from carbon dioxide from fertilizer companies (Galloway et al. 2003). Some of the recommended practices that farmers can adopt lie in the 4 R principle, which entails the use of the right source (fertilizer with higher efficiency), right rate, right timing, and right placement as expounded by Cassman et al. (2003). The proper placements of these fertilizers lead to fewer losses since there is a concomitant improvement in the plant uptake through making nutrients more accessible by the roots hence restricting available pathways for emissions. An important viable option for reducing losses is by reducing nitrification. Use of nitrification inhibitors for the case of nitrogen use is a promising strategy that has the huge potential of slowing the release processes that contribute to the formation of N_2O emissions (Coskun et al. 2017). Use of improved crop varieties with higher N uptake and use efficiencies will lead to a reduction in the nutrient loss since such crop idiotypes fully utilize the applied and available nutrient for use hence less losses in the form of GHG emissions (Sanz-Cobena et al. 2017).

Improved nutrient management is considered a better and viable strategy to overcome the challenges associated with the impacts of climate change in crop and food insecurities. According to García-Marco et al. (2016), adopting improved agronomic practices can lead to higher yields and promote the generation of more carbon that can be used to increase the soil carbon storage hence fewer losses to the environment. Some of the practices suggested by García-Marco et al. (2016) are extending crop rotations, use of improved varieties as mentioned earlier in this text, and using mixed cropping with perennial crops that will result to more carbon storage underground.

Emissions of GHG can also be reduced through practicing intensive cropping systems that minimize overreliance of pesticides and other agricultural inputs and consequently reduce the extent of emissions to the environment (Hoekman and Broch 2018). Besides, farmers/growers can use the cover crops that provide additional carbon to the soil and may help in extracting the available unused N by the next crops hence resulting to reduction of N_2O emissions (Oberthür et al. 2019). Use of Global Positioning Systems (GPS) guidance and variable rate technology are useful in applying inputs and hence allowing farmers to optimize nutrients with consequent less GHG emissions. In addition, the use of slow-release fertilizers such as prilled urea can be an efficient way of reducing N_2O emissions from cropland. Moreover, the use of biofertilizer has been advocated as an alternative to the more soluble and more reactive N sources as documented by excellent reviews by Ntinyari and Gweyi-Onyango (2018). Locally available nitrification inhibitors can also be useful in reducing the amount GHG from applied fertilizers to cropping systems. Soil pH management is also critical towards the management of N_2O emissions from the soil. Furthermore, the influence of pH on N_2O emissions more profound in soils that have high nitrate levels. According to the existing literature, pH contributes between 3 and 10 folds in incidences denitrification (Šimek and Cooper 2002). However, the good news is that use of liming in management of pH is something feasible among many farmers within sub-Saharan Africa if given fertilizer subsidies. Liming is a good option since is technically feasible and is affordable at a small scale levels. Nutrient use models are other useful tools in quantifying emissions from respective farms through the nutrient budget methods. These tools are key in estimating farm emissions by considering key components of nutrients inputs and nutrient outputs in given farms. In this case, it can be used to make a rough estimate of the amount of inputs required for specific crops to help in the reduction of emissions. Another option is the use and application of the soil systems budgets which record all the nutrient transformation related to emissions, for example, leaching, denitrification, and ammonia volatilization. This points to the fact that modeling tools are essential in linking the soil nutrients as well as a proxy resource for nutrient management and economic benefits to farmers.

Organic soils also need to be properly managed as they have the highest accumulation of carbon over the years. Avoiding row crops and tubers and deep ploughing using heavy machinery has been pointed out as one of the strategies that reduce the emissions of N_2O and CO_2 (Smith et al. 2008). In sub-Saharan

Africa, a large fraction of the arable land has been degraded due to soil erosion, loss of organic matter, acidification, and other processes. These have to a greater extent affected the potential of the soil in holding/storing of carbon (Smith et al. 2008). Therefore, there is need for reclaiming land by application of organic substrates like manures, biosolids, reducing tillage, and leaving crop residues in the soils. With these practices in the farm, high nitrogen use efficiency is anticipated and this will minimize the emissions of N_2O.

Proper Management of Residue and Adoption of Appropriate Tillage Methods

Advancing methods of weed control and machinery used in farming systems is another available way of reducing N_2O emissions from the soils. This is explained by the fact that soil disturbances tend to stimulate the soil carbon loss through enhanced erosion that result in soil carbon loss. However, the tillage method is dependent on the climatic conditions of the soils, considering that some reduced tillage options may have great effects of N_2O emissions from cropland (Feng et al. 2018). In tillage systems where growers/farmers retain crop residues, they tend to increase the soil carb since these residues act as precursors of soil organic matter which is a main store of carbon in soils. Mostly in the case where paddy crop growing is practiced, it has been found that no-tillage has a significant decrease in methane CH_4 emissions. Furthermore, recycling of crop residues has been reported to be of help in preventing the release and/or deposition of aerosols and GHGs that are generated during burning (Feng et al. 2018). Biomass burning is always thought to be a key contributory factor to climate change since it releases methane in notable amounts. This is a common practice in Kano plains in Western Kenya under rice production. This implies that there is a need to manage fire concerning biomass burning in agricultural fields. Reducing biomass burning will also go a long way in minimizing the emissions of hydrocarbons and reactive nitrogen emissions that react to form tropospheric ozone (Leng et al. 2019). This is explained by the fact that smoke composes of aerosols which can have either warming or cooling effects of the atmosphere, hence directly or indirectly contributing to climate change. In this light, reducing the frequency of or the intensity of fires will contribute to landscape carbon density in soil and biomass. To minimize the emissions, mitigation of the radiant forcing is expected to entail fire suppression strategies such as reducing fuel load through vegetation management and also burning of biomass at the time of year when CH_4 and N_2O are less emitted (Leng et al. 2019).

Crop rotation is advocated since it has given beneficial outcome through improving the quality of soils, with reported overall increment of as much 50% in terms of organic carbon into soils (Paustian et al. 2019). This practice creates resilience in cropping systems and helps the world to be able to combat climate change effects and hence can be a better option for SSA, where this is practiced already in noticeable scale. Through this approach, it is possible to sequester carbon for long-term storage of the atmospheric carbon. In this regard, this alternative offers the best solution to counter the greenhouse gases emissions in the ecosystem. In addition, more yields are obtained from the cropping systems, which helps reduce the direct impacts of climate-related contributions to food insecurity. In soil management, there is also a need to bring in low-cost inhibitors that regulate nitrogen processes in the soils. However, this requires knowledge on the sources of the GHG using various soil microbial process that can help to bring mitigation of the same on board. Diversifying on the crop rotations will also provide another strategy to minimize GHG emissions from agriculture in SSA. Diversification of crops helps in improving the productivity in the different and diverse agro-ecosystems in SSA and also lower the carbon footprint. The choice of these crops can be guided depending on the ecological requirements in various growing zones within the region. Another option in minimizing emissions is through intensifying rotations in cropping systems through fallowing. Fallowing promotes nitrogen mineralization hence increasing available nitrogen for use by crops and minimize the amount of organic matter hence less carbon is stored in the soils. Most of the farmers prefer burning of various crop residues in their farms which contributes to climate change in various ways. It contributes to releases of GHGs like CH_4 and also generates hydrocarbon and reactive nitrogen emissions that react to for tropospheric zones. Burning also destroys existing grass and also blackens the soil spoiling its quality and ability to sequester carbon. As a mitigation practice, farmers should rescue the frequency and the extent of fires for less CH_4 and N_2O emissions (Smith et al. 2008).

Introduction of Carbon-Sequestrating Grass Species

Introduction of improved grasses that have a high level of production or with adaptations to C allocation to deeper roots has a great potential of increasing the soil carbon (Yang et al. 2019). For instance, using deep-rooted grasses in savannas has been associated with increased rates of carbon accrual hence less is emitted to the atmosphere. Cultivating of legumes into grazing lands has also been associated with the promotion of soil C storage and perhaps reduces N_2O emissions (Garnett et al. 2017). Grasses also act as cover crops that have long-term potential for reducing GHG emissions through agriculture that comes from agricultural activities. The grasses have the potential of absorbing and retaining stored carbon in the soil. The roots and shoots of cover crops feed bacteria, fungi, and earthworms and other soil organisms that have a significant contribution to the soil carbon levels over time. In the land that is left fallow, there is a need to convert the lands to grassland to sequester more carbon and create a balance of the carbon in the soils for a longer period. The most beneficial aspects of grassland are that they can stay longer without ploughing hence reducing emissions of N_2O from the soils. In grasslands, intensity grazing has an influence on the density of the grasses and allocation of carbon into the grass fields. It has been reported that carbon accrual on optimally grazed land has been often greater compared to ungrazed grasslands. Also, irrigation of grasslands has also high promotion of the soil carbon gains. Also alleviating deficiencies of nutrients in grassland through use of fertilizer or other organic amendments will promote carbon soil storage (Smith et al. 2008).

Livestock and Manure Management Strategies in SSA

Livestock, specifically ruminants such as cattle and sheep, are important sources of CH_4 estimated to 18% of the global anthropogenic of this gas. In Table 1, there is a high chance of methane emissions that are more prevalent in the year 2000 compared with those likely to be there in the year 2030. These percentages represent a great share that needs to be mitigated using possible strategies that are available to the local farmers (Swamy and Bhattacharya 2006). According to the current statistics, the current population of livestock is anticipated to increase in 2030 based on the projections with sub-Saharan Africa, leading in the population as demonstrated in Fig. 2 (Herrero et al. 2008). This means that there is a need to come up with strategies for minimizing CH_4 from livestock systems. Some of the mitigation practices that can be used to reduce CH_4 emissions from livestock rearing include but not limited to improving the feeding practices. Feeding animals with more concentrates other than forages has been reported to reduce the rate of.

CH_4 for reducing. Other practices that can be used to minimize the level of CH_4 emissions are adding oils to the diet, as this is key in improving pasture quality since it improved animal productivity that reduces the proportion of energy lost as CH_4. A high intake of protein feeds is also associated with reduced N_2O emissions to the environment.

Another strategy of managing livestock methane emissions is the use of specific agents and dietary additives that can have the ability to suppress methanogenesis process. Some of the additives include Ionophores antibiotics that can minimize methane emissions in the livestock systems (Gibson 2002). Halogenated compounds inhibit methanogenic bacteria and their effects although they can have reduced feed intake. These have not yet been used extensively in SSA and have a huge potential of adopting. The bovine somatotropin (bST) and hormonal growth implants do not specifically suppress CH_4 formation, but by improving animal performance they can reduce emissions per kilogram of animal product (Cerri 2010), which is also another viable option. Adoption of longer-term management changes and animal breeding will enhance reduction of methane output per kilogram of an animal. With improved animal production efficiency, there are reduced lifetime emissions (Wall et al. 2010). Supplements can also be used in reducing methane emission in the livestock. Some of the supplements include oils, fats, tannins, probiotics, and marine algae. It has been reported that methane abetment between 10% and 25% is possible when feeding ruminants dietary oils. Also, plant secondary compounds like condensed tannins have proved to reduce methane production by 13–16% through curbing the process of methanogens.

Other available methane suppressers that are used in combating protozoal infections. Specialized proteins targeting methane-producing microbes will also constitute an effective alternative towards the management of emission from livestock. Moreover, plant saponins that occur naturally in many of the existing plant families have the potential to reduce methane and can be effective in the current measure towards minimizing the concentration of GHG in the atmosphere. Enteric methane emissions can be reduced through manipulation of the microbial communities in the

stomach of ruminants. This can be done through injecting/administering specific vaccines, drugs, or supplements that contribute to the reduction of methane. Other methods inlcude; biological methods can be adopted to reduce the ability of the livestock to reduce methane production in domesticated animals. For instance, the virus that attacks microbes in the rumen of the ruminants can be used to ensure animals produce less GHG. Methanotrophs which are microbes can also be introduced in the animals to help in the breakdown of produced into other wastes. The bovine somatotropin and hormonal growth implants is also a possible option but it does not suppress methane formation but rather improved the general performance of animals hence minimizing the intensity of GHG.

Manure management should be given priority as it is associated with significant amounts of N_2O and CH_4 during storage. However, the magnitude of the emissions varies depending on the structure. World over, there are no well-defined measures and policies of manure use and management since most of the grazing is done in open fields. For manure stored in lagoons or tanks, methane emissions can be minimized by covering or cooling of the sources. Other preliminary information has also suggested that covering manure heaps can significantly reduce N_2O emissions (Dennehy et al. 2017). In addition, emissions from manure can be curtailed by altering feeding practices and also precision application when it comes to cropland. Methane digesters/anaerobic digester can also be used as an alternative strategy to the reduction of GHG although it is expensive to install. This is since maintaining anaerobic digester requires basic knowledge in wastewater and electrical generation hence high investment costs that can be managed by respective governments. Adopting anaerobic digestion offers an excellent strategy towards the reduction of the CH_4 and CO_2 to the ecosystem. The process offers natural existing bacteria that decompose organic matter resulting in biogas (Wang et al. 2017). In return, the biogas can be used to burn fuel and reduce emissions of GHG from fossils. Other practices that need to be put into consideration include:

- Application placement (e.g., slurry injection)
- Application timing
- Application amounts (e.g., controlled rate systems)
- Export of manure (from the agricultural system)

GHG models can be developed at whole-farm level approaches to help in mitigation of various emissions specifically from daily farms. The advantage of using models in dairy farms is their ability to simulate calculations of CH_4 and N_2O emissions although the models may considerably vary but they give information on the current and future trends upon application of given measures.

Following the Intergovernmental Panel on Climate Change standard emission factors, it is confirmed that nitrogen deposited from urine and feces is converted to nitrous oxide twice the rate from the fertilizers used in farms. From the projections done for 2050, it is shown clearly that that in open pasture method, if no mitigation is put into practice, there is a possibility of having 25% increment on the emissions. In open field grazing strategy, the farmers can use chemical nitrification inhibitors as a way of preventing the transformation of the nitrogen is excreted in urine and feces to nitrous oxide. The other option is the introduction of biological nitrification, for example, use of the Brachiaria grass that has been reported to generate almost zero N_2O emissions. Therefore, this a grass that the breeders can focus on to have the particular trait transferred in mostly grown grasses in pastures fields (Fig. 3).

Use of methane digesters is another excellent successful strategy for consideration in SSA but will require government intervention especially in extending facilities from e large to small scale farmers to be able to encourage innovation. The respective governments should come into a collaboration to develop the most cost-effective technologies and this can be achieved through funded programs by innovators. In addition, there is a need to have programs that will enable early detection and remediation of leakages from digesters. The collected manure can also be used to make biogas which provides an additional source of renewable energy hence has higher chances of reducing GHG emissions. This is an economical method since it will save the farmers from using fossil fuels in cooking since they can generate power from their farms. It is also feasible to acidify slurry produced mostly in the zero-grazing sectors to enhance to reduce conversion and formation of methane.

Adopting Bioenergy as GHG Emission Reduction Strategy

Crops and residues have high potential as sources of feedstocks for energy as a replacement of fossil fuels. Many of the materials that have been proposed for bioenergy role are grain, crop residue, cellulosic crops, and various tree species (Haberl et al. 2012). The advantage of these products is that they can be burned directly but later processed to generate fuel liquid. Although this process also produces CO_2, it is associated with the original CO_2 from the atmosphere for the process of photosynthesis hence displaces the CO_2 that could be produced from fossils. The

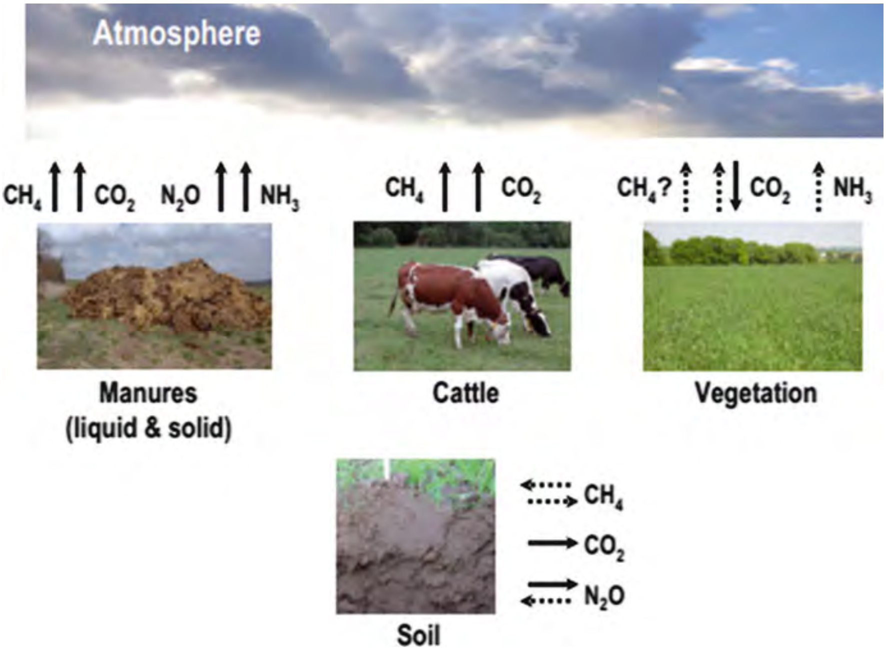

Fig. 3 Greenhouse gas and ammonia fluxes in the main compartments of a mixed crop-dairy system. (Adapted from Novak and Fiorelli 2010)

energy used in growing and processing the feedstock of bioenergy has a net benefit to the atmospheric CO_2 (Eloka-Eboka et al. 2019). The existing interaction of an expanding bioenergy sector land use and other ecosystems services such as food production has not been exploited potentially; for instance, through assessment modeling, sub-Saharan Africa has been listed as one of the promising regions for bioenergy. It is estimated that in 2050, 65% of the expected agricultural energy emissions will arise from farm energy use. In this regard, there is a need to reduce the amount of farm energy used from fossil to nonfossil use. Mitigation on the use of diesel fuels by tractors and other heavy equipment will be an effective move but requires transitions to hydrogen power that comes from solar and wind power. Also, battery-powered equipment and synthetic carbon-based fields will provide an alternative strategy. Use of these kinds of renewable energy in farms where mechanization is highly practiced will help in mitigating 85% of the total emissions from the synthesis of nitrogen fertilizers. Considering bioenergy as an option of mitigating GHG and saving our planet from climate change impacts, there is a need to make major transitions that are essential in exploiting the great potential of this particular source of energy (Smith et al. 2008). Bioenergy or use of biofuels implies a decrease in the dependence on fossil fuels and chemicals. The energy supplied from the use of plant-based fuels has the potential of decreasing GHG flow to the atmospheres. The biofuels will enable GHG mitigation through three key factors that include lower and competitive prices compared to fossil energy sources, ease in their production since the plants are grown during the entire year, and ecological and economic benefits of biofuels due to their environmentally friendly nature. Through these strategies, it will be efficient in mitigation of climate change effects in sub-Saharan Africa, though this will take longer to be achieved compared to other considered options.

Reduction of GHG Through Genetic Selection of Animals

Dairy is being one of the highest emitters of GHG to the atmosphere that requires critical strategies right from the selection of the best animals to reduce methane production. More focus should be put forward on the selection of cows that have less production of CH4 per unit according to Table 2. The impact of increasing genetic potential of the production stock is to increase the daily live weight gain of livestock for meat production or by nutrition hence leading to reduction of methane product per unity of the product. However, faster growth for slaughter implies that more feed will be needed to meet the required weight within a short time (de Haas et al. 2017). Therefore, this also means that the genetic selection has also to consider the type of grasses that can meet the requirements of such animals within the set time.

A high growth genotype leads to low emissions hence providing a promising measure towards mitigation of the climate change as a result of concentration in the atmosphere (Martinez-Fernandez et al. 2018). In addition, the use of environmentally fit genotypes is fundamental to increasing efficiency of converting feed to beef. In an experiment conducted in a farm in Northern Territory, methane production was lower by 31% in per tonne of the weaned weight within a given time because of a genetic characteristic of animals that can be weaned early to reduce the total emissions in the livestock sector (Mottet et al. 2017).

Adopting to Isotopic Tracers in the Agricultural Field

Stable isotopes that do not emit radiation such as nitrogen-15 and carbon 13 on small experimental fields are good options. This method allows then to analyze the efficiency of the crops to consume nitrogen and the accumulation of carbon in the soils. For instance, nitrogen-15 technique is widely used by scientist to track and advise farmers on the amount of chemical fertilizer/manure needed by the plants as one of the ways to reduce increased emissions to the ecosystems (Slaets et al. 2016). Nitrogen-15 isotopic techniques can also be used by scientist to identify the sources of nitrous oxide in production and this forms an important pathway of reducing the emission of the gas to the atmosphere. Therefore, this technique has the potential of measuring the impact of climate and provides a way of mitigation.

Carbon-13 has also been used in the assessment of the soil quality by identifying the content of organic sources of carbon in the soil. This is also a crucial favor in promoting the optimal application of the agricultural practices hence reducing GHG emission. Stable isotope can also be essential in the generation of information on

GHG production and transport within a soil ecosystem. Importantly, stable isotopes have the potential of studying how GHG exchange with soils and atmosphere. This information is useful to enable researchers to understand the pathways of GHG, as well as the magnitude, as well as the magnitude is hence given rational recommendations (Zhu et al. 2019). However, this method is expensive and local farmers cannot afford to use to make various estimates. Therefore, the use of experimental reference sites can be useful in giving recommendations over a geographical position with similar activities.

Management of Emissions in Rice by Adoption of Efficient Varieties

Rice production in flooded or paddy rice contributes to at least 10% of global agriculture production. There are various suggestions that have high technical potential to mitigate rice emissions and that many of the options have a high potential of giving economic gains through yields and reduce the amount of water used in irrigation. Focusing on yield increase will give a promising measure towards reducing emission in rice production per unit area (Saha et al. 2018). This is in agreement with the FAO's forecast that increasing the rate of yield in paddy will also contribute to emission reduction in rice. Removing rice straws from paddies before reflooding to reduce methane production is also advised as one of the practices that farmers can embrace. The straws may be used for Bioenergy production (Joint 2018). Reducing the rate of flooding will reduce methane-producing bacteria where farmers can draw water down during the middle of the growing seasons. Another option is the beeding for rice varaities with lower emmissions of methane in the systems. Experiments in other regions such as China and Japan have shown that drawdown can reduce methane emissions by up to 90% (Müller et al. 2016). Use of the system of Rice Intensification that aims at reducing irrigation water at farm-scale is also an adaptable technique that farmers can use to minimize methane emissions in their rice fields. In rice irrigation, farmers should be advised to reduce the duration of flooding to minimize the populations of the methane-producing bacteria. In this regard, rice can be planted in a dry field other than flooding them and also they can reduce water during the middle days of the growing season. Breeding of lower methane rice will be another strategy that researchers should focus on to introduce both upland and lowland rice-growing irrigation systems. Water management in irrigation through the expanding area on irrigation could be more effective in increased carbon storage in the soils. Draining of agricultural fields in humid regions will help in suppressing N_2O emission through improved aeration in soils. This strategy has been used in other regions such as China and Japan since it also increases yield and saves on irrigation water hence can also be adopted for the sub-Saharan Africa region.

Development of Flexible Technology-Forcing Regulations

The GHG emissions are strong issues that need to be regulated by the governments more so in sub-Saharan Africa counties where the governments have not invested much on controlling emissions due to their low-income capabilities. This is since if this issue remains a voluntary service, most of the individuals are not likely to take it as seriously as it is taken globally (Inglesi-Lotz and Dogan 2018). Therefore, there is a need to have flexible regulations that are designed to spur the technological development for the needed change. For instance, in case of fertilizer use, countries should develop regulatory systems that are similar to those developed in the United States or other places to increase the fuel efficiency of fleets of time (Nyamoga and Solberg 2019). Also, fertilizer manufacturers and importers will be required to sell fertilizers with increased efficiencies. Fertilizers regulation needed to be brought into consideration, for instance, the manufacturer should be barred from releasing any fertilizer product that does not have a coat to enhance its slow release and minimize N_2O emissions in cropping systems.

Minimizing Enteric Fermentation and Food Wastes

Enteric fermentation has the highest accountability of emissions from agriculture. It is part of the digestive systems of herbivorous animals that have a large four-compartment stomach with a complex microbial environment that enables it to digest complex carbohydrates. The process of digestion produced methane as a byproduct hence contributing to its accumulation in the atmosphere. In this regard when animals are kept for long, the more they produce methane, and therefore, this should be shortened and ensure the levels of methane per production unit are minimal (Owen and Silver 2015). The three main existing options to mitigate this kind of fermentation and emissions are

1. Improving the quality and digestibility of feed
2. Providing supplements and additives and reduce methane
3. Optimizing the health and reproductive capacity of the herds

Food and Agriculture Organization (FAO) has approximated that food wastes contribute to almost a third of the world's GHG. This is more so in sub-Saharan Africa due to the culture of people holding a social gathering with several types of edibles available hence providing a wide range of choice. These foods are potential sources of GHG emissions with key gases produced being carbon dioxide, methane, nitrous oxide, and hydrofluorocarbons especially in countries without any existing policies on food loss and waste management (Capone et al. 2016). This calls for the development of a monitoring framework for developing countries especially in sub-Saharan countries through installing simple tools that can be used in the traceability of GHG emissions. According to the Intergovernmental Panel on Climate Change (IPCC), the lowering of food wastes will help in reducing the rate of GHG emissions and concentration in the environment. In this regard, there is a requirement for the respective government to come up with policies and campaign to enlighten the locals on the need to reduce their food wastes as one of the factors for environmental sustainability and to alleviate the serious threats of climate change that are currently experienced (Edenhofer et al. 2011).

Use of Biochar to Minimize GHG Emissions

Biochar is an organic material rich in carbon that is produced by the heating of biomass in the limited supply of oxygen. It is mainly produced as an additive to soils to improve nutrient retentions and carbon storage. In recent research, there has been growing interest in the use of biochar as an amendment to improve soil health, decrease net N_2O emissions and methane, and to store carbon in the soils. Biochar has been recognized as one of the possible materials to enhance reduction of CO2 concentration in the environment. The advantage of biochar is sufficiently used to reduce GHG emission in the atmosphere for a prolonged time. It also allows a net reduction on the emissions in the entire lifecycle including both direct and indirect land uses (Kumar et al. 2020. It has been documented that biochar has the potential of reducing anthropogenic CO2 in the atmosphere by 12%. Biochar has a low degradation process which helps in increasing its potential to store more carbon in the soils compared to other materials.

Compositing of Solid Manure Before Applying to Crop Fields

In many organic systems, composting of solid manure before applying to the field is encouraged. This method offers the advantage of producing a more stable product, free of weeds and toxins and easier to spread in the cropping systems. Through compositing it is subjects manure to the aerobic composition at temperatures of around 60 °C. Since this method requires frequent turning of the heaps, the method makes it more vulnerable for NH_3 losses; however, after application to the cropping fields, there are minimal losses since remaining N is mainly bound organically (Kumar et al. 2020). The mechanical turning of the composted manure is associated with lower N_2O and CH_4 compared to the anaerobic method; hence, this should be considered for the whole management systems right from manure storage to supplication to soils in the fields. It has been estimated that compositing lowers N_2O and CH_4 emissions; although significant amounts of CO_2 are emitted during the composting process, it is not considered as a net source of CO_2 in the entire agricultural chain. In addition, since composted manure is less degradable than fresh manure, application of this is a greater source of carbon storage in the soil and thus reduces the rate of CO_2 emissions. The rapid incorporation of manure in the soils as an improved technique of application is associated with fewer emissions and is more cost-effective (Joint 2018). This kind of incorporation should be done during the first hours after application. Through this method, a significant N_2O emissions in the soils will be reduced. Farmers should also consider using farmyard manure over liquid slurry for reduced GHG emissions.

In crop production as agriculture, subsystem offers various mitigation of greenhouse gases specifically the CO_2 and N_2O that are main gases in this level. The limitation of net CO_2 can be achieved through increasing the rate of carbon storage to soils or by the plant. This is achieved through slowing return of stored carbon into the atmosphere via mineralization (Stanton et al. 2018). Most importantly, N_2O mitigation should focus specifically on improving the nitrogen use efficiency of crops since N_2O is generated from the soils. In crop production, farmers should also avoid compacting during tillage since this may increase N_2O emission due to the conducive environment created for anaerobic zones within the soil structures. During the incorporation of plant, farmers should be advised to use plant contents with low N content since high N content in the tissue will trigger mineralization and denitrification that can alleviate the levels of N_2O emissions. Tackling the interlinked problems on land degradation, climate change mitigation is a promising strategy that can produce promising results for both farmers and government (Zerhusen et al. 2019).

Integrated Farming Systems

The integrated farming system is another way to reduce GHG emission and promotes the fight against climate change. The integrated systems are based on nuclear techniques that have been put into practice in some counties within sub-Saharan Africa including Kenya and Uganda. The practices are aiming at maximizing the recycling of nutrients that are found in animal manure and crop residues. This will ensure there is a reduction in the chemical fertilizers use and this will enhance the reduction of GHG from agricultural land (Stanton et al. 2018). This is a practical strategy since farmers can recycle nutrients as livestock mainly feeds on herbs and grasses that are excreted in form of manure then farmers can collect the manure and apply in fields, which is a way of returning many nutrients into the soil as illustrated in Fig. 4.

This strategy is feasible and practically possible in sub-Saharan Africa since it has been applied in other regions and does not require high investment but rather involves a set of regulations and extension to enlighten farmers on the benefits of

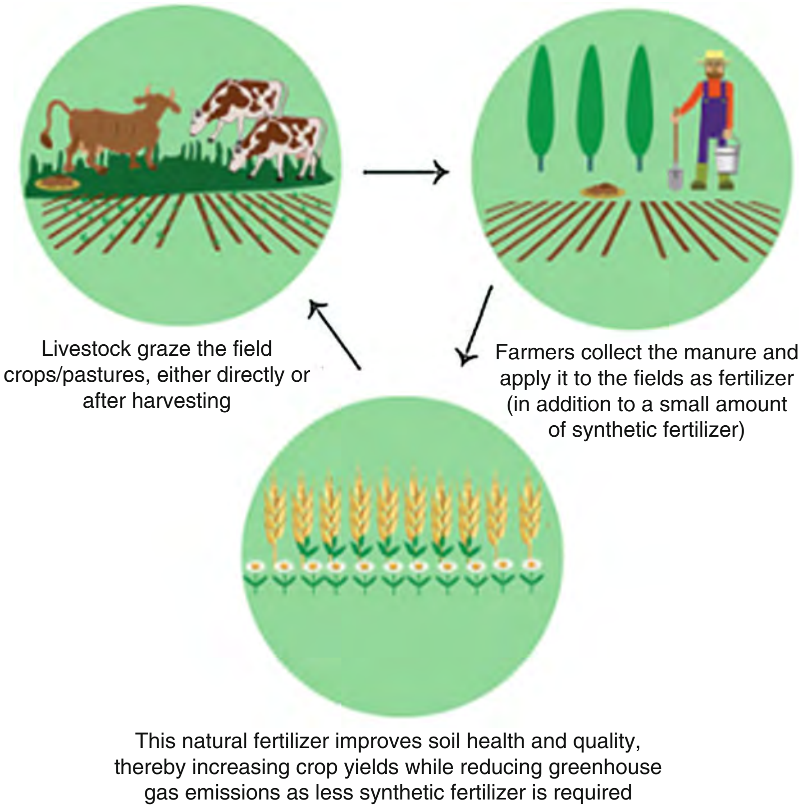

Fig. 4 Illustration of how an integrated system can reduce greenhouse gas emissions. (Adapted from Garnett 2011)

this process. Integrated cropping–livestock practices have been used in Brazil and have given a successful out management plan in the use of land more efficiently. As a result, the GHG emission from urine and dung was reported to reduce by 89% from respective farms. Polyculture is another agronomic practice that can be used to mitigate emissions of GHG and help in combating the adverse effects of climate change. Polyculture entails growing of multiple crops in the same space to increase local biodiversity and increase the soil carbon. Agroforestry is another agronomic practice that can be encouraged as a strategy to minimize GHG emission in agriculture. This practice entails integrating crops or livestock and trees either for timber, firewood, or any other wood products. The agroforestry provides buffer strips in the riparian land as well as increasing carbon stock in the soils since they increase carbon sequestration hence emissions of CO_2 to the atmosphere (Garnett 2011). Changes in consumption habits have substantial effects on the reduction of GHG emissions. Therefore, this calls for addressing how our food from agriculture is distributed across a supply chain. In particular, many of the environmental bodies have a recommended reduction of consumption of meat and other dairy products to enhance the reduction of GHG emissions from agricultural production. This implies that if consumers can adhere to this strategy and focus on well-grown crop products will have a significant effect on the overall concentration of GHG in the atmospheres. How this requires policy regulations and consumers' willingness to adapt to this kind of change. Although it is difficult to some communities that rear livestock as the main agricultural activity, they could be advised to minimize meat consumption, which may be from 5 to 2 days a week.

Barriers to Mitigation GHG Emission and Climate Change in Sub-Saharan Africa

Although there are various opportunities to combat GHG emissions and reduce impacts of climate in Africa, there are key barriers that may hinder adoption and achievement of these goals. There is a challenge on lack of awareness among the farmers on the bottom line impacts of climate change and causes that emanate from their cropping-livestock systems. A great population of the farmers in sub-Saharan Africa are not aware of the existing option, either high or low cost. This is since there is less focus on the ground level to address the issue; in this regard mitigation of GHG and reducing the impact of climate change more focus on starting ground level for the change to experience. Moreso, there is the existence of unsureness about the practicality of the available measure among the leaders and activist of climate change actions; hence, less awareness has been created to date. There is also the existence of complex interactions as farmers do not know the bottom line of the unintended consequences on the complexity of interaction during the adoption of what is believed to make a change to GHG emissions from agriculture (Mehra et al. 2018). Regulations and policies are also other barriers towards adoption and application of the existing measure. Some of the verification and regulation are quite expensive, and the fact that sub-Saharan Africa is a low-income region confirms the weight of the barrier. In addition, new regulatory regimes may require structuring the existing regulation before the implementation of proper governing policies.

Adopting some of the options may be against the social norms of the culture with diverse cultures being dominant in sub-Saharan Africa. For instance, manure management may be viewed as a dirty practice by some communities or religious beliefs hence making its management difficult. Besides, most farmers may fear loss aversion and may be adamant towards investing on best practices as advised by regulators. The existing extension services have the challenge of meeting farmers need and they create doubt on bits of advice they receive from them. Also, the government is slow in making clear on the role of extension officer and to what extent do they need to give communal seminars on critical issues such as climate change and GHG emissions (Allen et al. 2020). Development and transfer of technologies is another underlying barrier in the management of GHG emissions and mitigation of climate change. This is due to limited human and institutional capabilities to enhance proper dissemination of new information. Technological barriers exist in the limitation of generating and applying the developed solution to handle the problem. Technologies development and transfer remain crucial components for sustainable increase of productivity and mitigation of climate effects. Ecological barriers exist because mitigation potential in agriculture subsystems is mainly site-specific even within the same cropping systems. The limited resources in Sub-Saharan Africa pauses an ecological barrier towrads management of GHG and climate changes impacts. The frequent drought in Africa may limit the exact measurement and application of the mitigation measures at the farm level. In addition, due to high levels of poverty in the region, there is a likelihood that affording good equipment for mitigation will be hard hence have to rely on donors from other regions.

Need for More Research

Mitigation of GHG emissions is a critical area that currently requires a lot of investment in research, because these gases are complex and emitted from day to day activities that men perform to earn a daily living. Due to the adverse effects, they are causing damage to our ecosystems; identification of scientifically proven measures and option needs to be analyzed and scrutinized keenly through research. The researcher should focus more on agriculture although other sectors such as transport, energy, and industrialization have an equivalent measure. Although several measures have been documented to curb and minimize the rate of emissions, there is a need to have additional measures and strongly emphasize on their adoption through policy regulations. The research should focus on both generating new technologies and management systems with lower emission rates. Therefore, this requires the collaboration of governments in the sub-Saharan each to generate funds that can motivate and facilitate scientists in agricultural discipline to focus more on GHG about to actual quantification of the emissions as well as documenting available measures in the current context. Generation of more knowledge through research will provide cost-benefit analysis concepts to help in the assessment of the trade-off in the climate change mitigation options (Garnett 2011). The discoveries through research will enhance the provision of information and rationale on taking actions to mitigate GHG emissions. In addition, it will form a basis on informing decision-makers and policymakers in the whole system.

Conclusions

In the light of adverse climate change effects being experienced in sub-Saharan countries currently, several opportunities to mitigate GHG in agriculture exist and can be realized through overcoming several barriers. There is a need to assign mitigation measures on the key causes of climate change hence more emphasis on greenhouse gases emitted from agriculture. The key GHGs – CO_2, N_2O, and CH_4 – are not only produced in the farm setting but other sectors including energy, transport, and industries have a significant contribution. However, more potential lies in the agricultural sector that is widely spread in major regions of sub-Saharan Africa. Critical elements that require proper management are livestock systems and crop production that have shown to have the highest emission of the main GHG to the ecosystems. Therefore, to protect and improve the quality of our planet, there is a need to apply measures including manure management, improved fertilizer use efficiency, genetic selection of animals with less methane emission, minimizing enteric fermentation and floodwaters in agriculture and dairy subsystems. Developments of feasible and technological solutions to minimize GHG at small scale level, adopting bioenergy, growing of grass species with carbon sequestration effects, integrating crop-livestock system, and managing emission in paddy rice trough proper use of irrigation water and biochar application among others. Putting all measures discussed in the current chapter will help reduce the impacts of climate change in sub-Saharan and improve the quality of air and environment health in general. Regardless of several feasible options existing to mitigate GHG emissions and climate change in agriculture, to achieve these measures, there is a need for collaborative efforts between governments and the locals to carry out the required ground activities. There is the existence of certain barriers that limit the potential of management. Some of these barriers include policy and regulation, inadequate human and institutional capabilities, unstructured extension services, fear of loss aversion among farmers, and absence of platforms for disseminating new technologies. For any of the above-discussed measure, decision-makers need to make a consideration to the extent to which it moves away or closer to making the environment safer and still maintaining sustainable agricultural production with less GHG emissions.

Abstract

Although Climate Change is a global phenomenon, the impact in Africa is anticipated to be greater than in many other parts of the world. This expectation is supported by many factors, including the relatively low shock tolerance of many African countries and the relatively high percentage of African workers engaged in the agricultural sector. High-income countries are increasingly turning their focus to climate change adaptation, and Artificial

Intelligence (AI) is a critical tool in those efforts. Algorithms using AI are making better predictions on the short- and long-term effects of climate change, including predictions related to weather patterns, floods and droughts, and human migration patterns. It is not clear, however, that Africa is (or will be) maximally benefitting from those AI tools, particularly since they are largely developed by highly developed countries using data sets that are specific to those same countries. It is therefore important to characterize the efforts underway to use AI in a way that specifically benefits Africa in climate change adaptation. These efforts include projects undertaken physically in Africa as well as those that have Africa as their focus. In exploring AI projects in or about Africa, this chapter also looks at the sufficiency of such efforts and the variety of approaches taken by researchers working with AI to address climate change in Africa.

Africa · Climate change · Artificial intelligence · Algorithms · Data · Adaptation · Migration

Introduction

The deepest roots of climate change begin with the second industrial revolution and the widespread adoption of fossil fuel-based machinery. As the world enters the fourth industrial revolution, the adoption of advanced technologies such as artificial intelligence (AI) introduces complex challenges and opportunities for the now-inevitable and as-yet-undetermined issues of climate change. This chapter explores those challenges and opportunities, and whether or to what extent the fourth industrial revolution will enhance Africa's ability to cope with climate change.

Technologies associated with the fourth industrial revolution (4IR) include blockchain, the Internet of things (IoT), artificial intelligence, cloud computing, quantum computing, advanced wireless communications, and 3D printing, among others. Although these technologies are, at times and in various ways, interrelated, this chapter focuses mainly on AI and the impact that it will have on Africa's ability to cope with climate change. This focus is not, however, meant to imply that other 4IR technologies will not be important. Indeed, some technologies such as the widespread connectivity of sensors that accompany the development of IoT will likely have substantial positive impact on the ability of African nations to gather useful data. An example of this is Upepo Technologies, described below, that is using IoT devices to monitor water distribution points throughout Kenya. Other technologies may have mixed or negative impact: cryptocurrencies based on blockchain technology have so far increased the amount of energy used worldwide by computers, and advanced communications technologies are projected to account for 20% of global energy demand by 2025 (The Guardian 2017). Any increase in energy demand has a negative effect on climate change. Surely these technologies will continue to evolve, and Africans' ability to predict their ultimate impacts is limited.

AI has probably been postulated for longer than any other 4IR technology, but has remained impractical until the recent decade. Although a variety of forms of AI are known and being pursued in various contexts and by various private- and public-sector stakeholders, this chapter is largely confined to discussing AI as a tool for processing large amounts of data and improving predictions from those data.

Predictive algorithms using AI are available to entrepreneurs using two main pathways. The first is by using and adapting widely available open source algorithms. Many of the global technology companies have released suites of AI tools on open source licenses, including Google, Microsoft, and IBM. The alternative pathway is to develop, test, and train novel algorithms. Examples of companies following each of these pathways, as well as combinations thereof, can be readily identified, particularly (but not exclusively) in the high technology hubs of Lagos, Nairobi, and Johannesburg.

Developing the algorithms is, however, only one part of a larger process of integrating AI into products and processes. Effective predictive algorithms using AI rely on three main components: fast computers, large datasets, and abundant human labor (The Economist 2020). The need for fast computers is obvious, and suitable computing power is relatively abundantly available, even if Africa is perpetually and conspicuously absent from international lists of supercomputers (TOP500.org 2019). Human labor is needed in order to label data, as AI algorithms require accurately labelled data in order to learn and increase the accuracy of predictions. Africa has an abundance of labor, including large numbers of unemployed or underemployed youth that have sufficient computer skills, and is therefore ideally positioned for performing this task. For example, Samasource is a data annotation provider with a major presence in Kenya and Uganda. Using a hybrid structure involving both for-profit and nonprofit entities, Samasource provides data labelling services for Fortune 500 companies employing AI systems, while simultaneously seeking to reduce poverty through job creation.

This leaves three factors that are particularly interesting in the African context: the availability of sufficiently large datasets, the suitability of the algorithms themselves; and the creativity of developers, entrepreneurs, and others in applying AI in the creation of new products, services, and solutions. The three factors of interest are interrelated, and it is difficult to assess any one factor in isolation. AI is a multi-purpose tool, but the output of any given AI product is as much or more dependent upon the dataset as on the specific AI algorithm. Regardless of the algorithms, the availability of high quality, locally relevant datasets is likely to be extremely important for AI to be of any use to the fight against climate change. Furthermore, since the bulk of AI development has so far been from outside the African continent, the creativity and effort of developers and their collaborators are also critical to the contribution of AI. Accordingly, the second (datasets) and third (applications) factors are the subject of this chapter.

Part I of this chapter introduced the topic and framed the research question. Part II broadly and briefly review the state of AI research and development in Africa, as well as global AI research that is relevant or targeted at Africa. Part III narrows the focus and explore African AI products and research that are specific to the issues of Climate Change. Such issues include weather prediction, agriculture, floods and drought, and human migration. The chapter concludes in Part IV, with a look at particular challenges and potential future applications of AI in the area of climate change.

Scoping AI in Africa

It is easy to get the impression that there is little or no activity in AI research and development in Africa. In report after report, African countries are either characterized as poorly performing or are complete absent from the analysis. African governments score very low in their perceived readiness to "take advantage of the benefits of AI in their operations and delivery of public services" (Oxford Insights International Development Research Centre 2019). In that global index, no African government ranked within the top 50 governments. In a broader index covering 54 countries over seven factors (Talent, Infrastructure, Operating Environment, Research, Development, Government Strategy and Commercial Ventures), all six African countries that were part of the study ranked in the bottom quartile (Tortoise Intelligence 2019). In an even broader analysis using different datasets to "comprehensively assess the state of AI R&D activities around the world," the African region was ranked at or near the bottom of nearly every measure and ranking (Perrault et al. 2019). This included measurements such as AI papers published and cited, AI-focused patents, conferences, and technical performance. The picture painted by these global indices is one of virtually no activity and a gloomy outlook for future activity.

As is often the case, however, the global indices are not necessarily good measures of activity on the African continent. Activities by African governments and certain other entities are often not reported or described online. Activities in the private sector may be minimal when compared to activity levels in developed countries, but the comparison is not particularly useful. As shown by the examples provided below, the R&D that is carried out is meaningful and a significant part of the overall research environment on the continent.

African-hosted conferences on AI showcase African-led and Africa-focused AI R&D and demonstrate the breadth of such work. The Deep Learning Indaba, which began in 2017, is such an example; devoted entirely to African AI R&D, it has doubled attendance each of the following 2 years. The yearly event has created great interest, and in 2018, 13 mini-conferences (referred to as "IndabaX" conferences) were held in as many countries in Africa. Such conferences are important for the normal reasons, but also because African researchers have particular difficulties attending AI conferences in other parts of the world. African nationals are routinely denied visas to attend international conferences (Knight 2019). The challenges faced by African nationals is significant enough that the International Conference on Learning Representations, a major AI conference, elected to hold the 2020 conference in Africa. This decision was intended to enable greater African participation (Johnson 2018).

Meanwhile, global technology companies are turning some of the focus of their AI R&D on Africa. Google opened an AI development laboratory in Ghana in 2019. Microsoft published a whitepaper focusing on the importance of AI research in Africa (Microsoft Access Partnership University of Pretoria 2018). A significant body of technological developments have been produced by IBM researchers at the IBM laboratory in Nairobi (Weldemariam et al. 2020). Motivations for global technology companies to work in Africa include, among others, the reduction of bias by increasing diversity in the researchers and the context in which they work (Adeoye 2019).

Case Studies of General Applications of AI in Africa

Academic and private sector AI researchers in Africa seek to apply AI to a wide variety of topics, some of which are directly relevant to climate change, and others are relevant insomuch as they advance the general state of AI. A particularly important topic is bioinformatics and genomics (Diallo et al. 2019). Significant biodiversity exists on the African continent, and much of it is understudied relative to other regions (Campbell and Tishkoff 2008). The application of AI algorithms, with its ability to analyze large datasets, is particularly appropriate in the area of genomics. Even where the work is not specifically addressing issues directly related to climate change, a better understanding of bioinformatics and genomics will support biodiversity and our ability to encourage genetic resistance to environmental shocks.

Another topic of interest to African AI researchers is farming. The importance and vulnerability of farming on the African continent cannot be overstated. More than 50% of the entire African workforce is employed in agriculture, yet most of that activity is at the subsistence level (Alliance for a Green Revolution in Africa (AGRA) 2014). Approximately 80% of all farms in Sub-Saharan Africa are smallholder farms where 175 million people are directly employed. Modern farming methods such as large-scale mechanized harvesting, irrigation, and crop rotation are less common, meaning that African agriculture is more susceptible to weather and labor shocks. Traditional African crops are under threat from global seed companies seeking to dominate the African market (Scoones and Thompson 2011). Deforestation and overgrazing threaten African soil, but productive farmland is targeted by foreign governments and companies seeking new resources to enhance food security (The World Bank 2014).

It is anticipated that predictive analytics, aided by machine learning, will significantly improve overall output by the African farming sector (Alliance for a Green Revolution in Africa (AGRA) 2014). The cornerstone of successful AI is sufficient data, and in this area, Africa is relatively well positioned. Datasets pertaining to agriculture are available from a variety of sources, as the subject of African agriculture has been of intense interest to both local and international stakeholders for many decades. These datasets include actual measurement data as well as predictive or extrapolative datasets, as well as combinations thereof (African Soil Information Service). Improving the quantity and quality of data, and encouraging wider and more effective use of Big Data, is the focus of research by Patrick MacSharry at the Carnegie Mellon University campus in Kigali, Rwanda. Numerous other academic researchers are also contributing to the push toward effective incorporation of data science in African agriculture.

Successful agriculture requires more than land, seeds, and suitable weather. Crop diseases and infestations of plant pests are significant threats to global agriculture and are particularly dangerous to agriculture in Africa. For example, invasions of the desert locust can last for up to a decade, and can cause widespread food shortages of catastrophic proportions (Lecoq 2003). Similarly, strains of wheat rust such as ug99, which originated in Uganda, are considered a global threat as well as a threat to African agriculture (Aydoğdu and Boyraz 2012). An ability to diagnose crop diseases is therefore critical, and local and global technology industries have taken notice. Mobile phone applications that allow farmers to diagnose crop disease or identify the presence of crop pests are proliferating (Nzouankeu 2019). Considering that many plant diseases and crop pests are highly geographically specific, local development of technology solutions to these problems is a prerequisite to their success, and the African technology industry is beginning to address this need.

Looking beyond agriculture, financial institutions in Africa are not often at the forefront of widespread introduction and adoption of technology. Notwithstanding the success of mobile banking (which more properly attributes success to the fact that it originated from the telecom industry rather than the banking industry), traditional financial institutions have been slow to adopt technologies such as online banking. This is not necessarily only due to resistance within the African banking sector, but is also due to the relatively low level of access to technology by banking customers. Nevertheless, nearly every industry sector in Africa is affected by the availability (or absence) of credit and the presence (or absence) of financial institutions. Financial technologies, referred to as "fintech," are a particularly active area of the incorporation of AI into products and services. A common use of AI in fintech is in the determination of creditworthiness. Although not discussed here, it is worth noting that such applications have been criticized for a variety of reasons, ranging from data protection issues to exacerbation of inequality (Johnson et al. 2019). Traditional and nontraditional banking institutions can make use of larger datasets from a broader list of sources in order to determine the risk of extending credit to individual or institutional customers. This is particularly useful in a region where formal credit histories are relatively rare or based on very limited data. Another fintech product that is gaining traction with African financial institutions is the use of AI to evaluate customer behavior. Behavior analysis can be used to improve predictions of suitable financial products, thus allowing institutions to focus their marketing efforts and improve efficiencies.

Raising capital to support product development and market expansion is a necessary component of the modern technology industry. There is significant evidence that success at attracting investor attention in Africa is due to a variety of factors, including some factors that are not related to the quality or appropriateness of the technology (Peacock and Mungai 2019). Nevertheless, some African startups have raised significant capital for the application of AI to agriculture, fintech, and mobility solutions, among other uses of AI. In South Africa, Aerobotics is a company that is developing a digital platform for using AI to interpret data gathered by drones and satellites. The data interpretation algorithms are targeted at detecting plant pests and diseases. Apollo Agriculture is a Kenyan company using AI to interpret satellite data, soil data, farmer behavior, and crop yield models. The data interpretation algorithms allow the company to offer farmers customized financing as well as customized seed and fertilizer packages (Nanalyze 2019).

In view of the above examples and others not mentioned, there is clearly activity in AI R&D in Africa. It may be that the activity is minimal when compared with that of developed countries, but there is a very high level of interest in AI technologies by governments, academia, and the private sector, and activity levels will surely increase with time.

Having reviewed the general state of AI R&D in Africa, and having established that there is ongoing interest and activity in applying AI to a variety of fields, this chapter now turns to the specific application of AI to climate change.

Review of African AI Focusing on Climate Change Issues

By 2050, it is widely expected that hundreds of millions of people in developing countries will have left their homes as a result of climate change – a mass displacement that will make already-precarious populations more vulnerable and impose heavy burdens on the communities that absorb them. Unfortunately, the world has barely begun to prepare for this impending crisis.

According to the World Politics Review, those displaced by climate change are neither true refugees nor traditional migrants, and thus occupy an ambiguous position under international law. Consequently, the world needs to agree on how to classify environmental migrants, as well as what their rights are. It also needs to strengthen its capacity to manage these mass migrations, without weakening existing international regimes for refugees and migrants (Patrick 2020).

Similarly, international organizations, such as the United Nations, as well as industry and social society are exploring technological solutions including the development of tools and technologies that leverage data sources from radio content, social media, mobile phones and satellite imagery, and technology toolkits. These toolkits can enhance decision-making by providing real-time situational awareness for project and policy implementation. The trend is moving towards a converging of exponential technologies (AI, robotics, drones, sensors, and networks). Although there is growing criticism of this trend toward 'technologizing of care', which can conflict with the centrality of the humanitarian principles, these technologies, in particular AI, have the potential to help Africa to be better prepared to thwart the effects of climate change, both through mitigation and adaptation.

In light of this, this section examines the use of AI that is being (or could be) used in Africa for any aspect of climate change such as weather prediction, agriculture, human migration, floods and droughts. These projects could be undertaken physically in Africa as well as in those countries that have Africa as their focus, and those that can be adapted to Africa. It assumes a broader definition of AI which includes the use of "software (and possibly also hardware) systems designed by humans that, given a complex goal, act in the physical or digital dimension by perceiving their environment through data acquisition, interpreting the collected" (European

Commission High-Level Expert Group on Artificial Intelligence 2018). It examines how a combination of technologies work together, including geospatial technologies, converging technologies such as robotic responders, swarm technology, and aerial drones which may also rely on geospatial data. Further, it also examines AI-driven platforms that crowdsource first-hand experiential data from those on the ground, and how these technologies could potentially transform disaster relief methods in Africa. Finally, it examines the issue of mobile connectivity and wireless networking trends and how improving these can give a newfound narrative power to those most in need. Although some of the projects examined in this section do not directly address climate change, per se, they may address other environmental concerns that are relevant to climate change.

Geospatial Technologies

Africa has seen a steady increase in multi-stakeholder geospatial initiatives in recent years and these include those sponsored by the UN agencies, Public Private Partnerships, and initiatives led by international organizations and industry, especially global technology companies such as Google and Vodafone.

UN Agencies

The UN, in particular its data science arm, the Global Pulse, has been working to support African governments to achieve the U.N. 2030 Agenda for Sustainable Development. The Global Pulse, working from its Kampala Lab in Uganda, has led the work to develop numerous toolkits that consolidate it as an important technical arm of the UN network (Pulse Lab Kampala 2018). These pieces of software are a key in informing the SDGs through big data, data science and artificial intelligence because they aggregate, anonymize, combine, analyze, and visualize data. During 2016 and 2017 the Lab has both created brand-new toolkits and adapted previously developed ones for new projects. This has been part of a bigger project under which, between 2016 and 2017, the Pulse Lab Kampala worked with various UN agencies and development partners in Uganda and the region to test, explore and develop 17 innovation projects. The Lab also furthered the development of tools and technologies that leverage data sources from radio content, social media, mobile phones and satellite imagery, and created technology toolkits. These toolkits can enhance decision-making by providing real-time situational awareness for project and policy implementation (Pulse Lab Kampala 2018).

The Pulse's projects sit in the current global policy shift which emphasizes technological tools as opposed to their application to improving knowledge about climate change. This is even reflected in the secondary school geography curriculum which has seen an introduction of GSI in some African countries (Cox et al. 2014). This shift is borne from the premise that geospatial technologies, synergetic applications of remote sensing, and geographical information systems, offer versatile cross-scale tools to study long term climate changes, and their impacts on social- and ecological systems.

According to the UN World Data Forum, the U.N. 2030 Agenda for Sustainable Development requires countries to be chiefly responsible for collecting information and monitoring progress towards achieving economic, social, and environmental sustainability (United Nations World Data Forum 2018). For instance, the UN World Data Forum has held sessions to enable the sharing of sound Earth Observation (EO) methods, tools, and technologies, as well as national use cases of effective integration of EO and geospatial data products with traditional and other relevant information sources in support of the Sustainable Development Goals (SDGs), targets, and indicators, and for informed decision-making. Some of the technologies discussed at such forms include the African Regional Data Cube, aimed to enable greater use of EO and geospatial data for sustainable development (Anderson et al. 2017).

To strengthen its work at policy level in this area, in 2019, the UN Pulse has been engaging African AI experts to lead efforts to draft a Code of Ethics for the use of AI-supported systems in humanitarian and development contexts (International Telecommunication Union 2019). Once developed, the Code may be used as guidance for the work at Global Pulse and at other UN organizations deploying AI for social good and to ensure the deployment of such technologies is both ethical and human rights respecting.

Public-Private Partnerships
Similarly, the private sector has been working with governments on data science projects that leverage data for AI applications in humanitarian contexts. For instance, the Vodafone Foundation pioneered a program in Ghana to use aggregated anonymized data to help the government track and control epidemics to prevent widespread outbreaks (Vodafone 2018). The program, dubbed as one of the first of its kind globally, tracks and analyzes real-time trends in population movement. The program demonstrates the use of big data in situations directly relevant to climate change. The Ghana initiative is a good example of a multistakeholder approach to technology deployment for humanitarian ends as it is not only supported by Vodafone Ghana but also the Flowminder Foundation, an NGO that provides insights, tools and capacity-strengthening to governments as well as international agencies and NGOs (GhanaWeb 2019).

The South Africa company Aerobotics, mentioned above, operates a public private partnership that utilizes aerial imagery and machine learning algorithms to solve specific problems across some industries including insurance and agriculture. In May 2019, Aerobotics signed an agreement with Agri SA to offer free service for all South African farmers (Lukhanyu 2019). Drones are used to track tree health and size, using multispectral, high resolution imagery. The project also enables farmers to identify areas needing attention from historical satellite health data, and inspect these in the field using a mobile app. The Aerobotics project is supported by the South African Department of Environmental Affairs (DEA) which works with the Committee on Spatial Information (CSI) and the broader GIS community to define the data architecture, systems, standards, policies and processes for a fully integrated and effective spatial data infrastructure for the country. The Environmental Geographical Information Systems (E-GIS) webpage provides access to baseline environmental geospatial data, map services, printable maps and relevant documents to users of geospatial technology, government, and the public (Department of Environmental Affairs South Africa 2016).

Another example, also out of South Africa, applies machine learning to the issue of air quality prediction (Chiwewe and Ditsela 2016). Stemming from the Green Horizons initiative, IBM researchers partnered with Chinese government researchers for the purpose of building air quality prediction software. In Johannesburg, the work is to adapt the air quality prediction software to the local context. The Green Horizon's system harnesses historical and real time data about weather, air quality, topography, and traffic reports to build predictions about air quality. The project's South Africa lead, Tapiwa Chiwewe, says that the task is to tweak the software to local particularities. For instance, Johannesburg does not have the dense network of air quality monitoring stations (eight stations compared to 35). Chiwewe and the team of researchers sought to 'teach' the software to work with more sparse data and to use intermediate fixes to make up for the lack of data.

The Private Sector, and Converging Exponential Technologies

International Organizations & Global Technology Companies

Globally, converging exponential technologies (AI, robotics, drones, sensors, networks) are transforming the future of disaster relief (Diamandis 2019). African stakeholders have been experimenting with these technologies in a variety of contexts. These efforts have been led by international organizations such as Omdena and Element AI, working with local African NGOs like R365 and the Nigerian NGO Renewable Africa (Adewumi 2020). Academic institutions and global technology companies such as Google also play a part in this work, which span the R&D process as well as prototyping and implementation. For example, the Canadian based Element AI has African-focused projects that support the use of robots for humanitarian purposes. Their intention is to develop human-machine collaborations that build up a trusted relationship with AI products and services already available. Two further examples are illustrative. Atlas AI, a Silicon Valley public benefit corporation, has teamed with the Alliance for a Green Revolution in Africa (AGRA), to apply predictive analytics and machine learning to help process numerous datasets in an effort to improve smallholding farming output (AGRA 2019). Pennsylvania State University developed, deployed, and continue to upgrade PlantVillage, a mobile application that uses an AI tool to diagnose crop diseases in Africa (Penn State 2019).

Global initiatives inspired by Kenya's Ushahidi are emerging that leverage AI, crowd sourced intelligence, and cutting-edge visualizations to optimize crisis response (Starbird 2012). Such projects include One Concern (2020), which employs AI in analytical disaster assessment and damage estimates. Crowdsourced intelligence (which includes predictive crisis mapping and AI-powered responses) is used in response to both natural disasters and humanitarian disasters. An open-source crisis-mapping software developed by Ushahidi is used for real-time mining of social media, news articles, and geo-tagged, time-stamped data from countless sources (Meier 2012). As mobile connectivity and abundant sensors converge with AI-mined crowd intelligence, real-time awareness will only multiply in speed and scale (Diamandis 2019).

Other organizations are using similar crowdsourcing technologies to address different challenges, but such technologies are also helpful in understanding agricultural and other environment concerns. IBM's Hello Tractor is an open source mobile platform that enables farmers to access tractor services on demand (Assefa 2018). By using technology integrated from partners like the IoT companies Aeris and CalAmp, the platform can tell when a tractor is turned on and how far it travels. By using the platform, over the next 5 years, through a public-private partnership, John Deere plans to deploy 10,000 tractors in Nigeria, selling them to contractors who then rent them out to small farmers (Peters 2018). Considering that climate change is expected to increase uncertainty in the long-term viability of agricultural land, the availability of tractors for rent will be critical as a means for improving flexibility of farmers.

Another organization using AI-based crowdsourcing solutions to climate-related or climate-relevant challenges is Omdena, which sources ideas to respond to local challenges. Several of Omdena's projects are worth discussion. Under one of its challenges, 34 collaborators working together with the UN Refugee Agency (UNHCR) built several AI and machine learning solutions to predict forced displacement, violent conflicts, and climate change effects in Somalia (Omdena 2019). Their community of AI experts and data scientists have developed several solutions to predict climate change and forced displacement in Somalia, where millions of people are forced to leave their current area of residence due to natural and man-made disasters such as droughts, floods, and violent conflicts. This is a holistic project under which Omdena's challenge partner, UNHCR, provides assistance and protection for those who are forcibly displaced inside of Somalia. The findings will help UNHCR improve speed and efficiency of responses to such disruptions.

In a second project, Omdena's collaborators analyze conflict data to build a hot zone representation, which predicts the most dangerous locations and the highest fatalities (Omdena 2019). The machine learning model can help to optimize the allocation of utility personnel to handle incidents. A promising application of this technology is to leverage satellite images to assess the environmental impact of forced displacement and conflict by comparing the weekly Vegetation Health Index with human displacement data.

Omdena's projects are also focused on increasing the adoption of renewable energy, an important component of climate change mitigation. In Nigeria, Omdena's AI community built an interactive map showing the top Nigerian regions for solar power instalments (Adewumi 2020). The solutions will provide helpful insights for government and policy makers to make decisions on where to allocate resources in the most effective way. In a country where more than 100 million people lack stable access to electricity, renewable energy must be a major part of any environmentally friendly solution. The Omdena community generated a variety of outputs, including a grid coverage analysis and machine-learning-driven heatmaps to identify sites that are most suitable for solar panel installation. Along with an interactive map listing the top Nigerian regions in terms of demand for electricity, such tools are helpful for those seeking to survey and validate locations before installing solar panels. This will enable data-driven investments and policy-making and potentially impact the lives of many people in Nigeria.

A particularly forward-looking initiative is the Microsoft AI for Earth grant program. One of the recipients of the grant is Upepo Technology, a Kenyan company that plans to use the grant in a water monitoring project. The company is deploying a large network of IoT devices, and employing AI algorithms to analyze the data from sensors monitoring reservoirs, boreholes, water kiosks, individual taps, and other water points. Considering the substantial impact that climate change has on issues pertaining to water – particularly by changing the patterns of precipitation – an enhanced ability to monitor water usage, wastage, and storage will greatly benefit the ability to deal with climate change impacts.

University Activity

African universities and academic institutions are also setting up AI technology-based projects to tackle environmental issues, including Makerere University in Uganda and Carnegie Mellon University in Kigali, which was the first to offer a Master of Science Degree in Electrical and Computer Engineering with hands-on courses which include machine learning, robotics, and the internet of things (Carnegie Mellon University Africa). A few such projects are discussed below.

AirQo

The Makerere University Artificial Intelligence Research Group (AIR Lab) specializes in the application of artificial intelligence and data science to challenges common in the developing world. AIR Lab received support from the Pulse Lab to set up AirQo – an air quality data monitoring, analysis and modelling platform in East Africa meant to achieve clean air for all African cities through leveraging data (Nabatte 2019). AirQo is deploying a growing network of low-cost air quality monitors. Using machine learning and artificial intelligence to collect and analyze data, the project makes air quality predictions useful in raising awareness and informing policy decisions. Future research plans include the development and deployment of machine learning methodology to analyze air pollution data from Kampala, in order to determine the source of the pollution and to aid the design of mitigating interventions.

WIMEA-ICT

WIMEA-ICT is a combined research and capacity building project that seeks to improve weather information management in the entire East Africa region by development of ICT-based solutions (Norwegian Agency for Development Cooperation [NORAD] 2013). Funded by the Norwegian Agency for Development Cooperation (Norad) under the NORHED (Norwegian Programme for Capacity Development in Higher Education and Research for Development) scheme, the project is a cooperation between Makerere University in Uganda, Dar es Salaam Institute of Technology (DIT) in Tanzania, the University of Juba in South Sudan, and the Geophysical Institute of the University of Bergen.

The project recognizes the wide-ranging importance of weather data and the problems that result when weather predictions are inaccurate. Although project documentation does not specify the use of AI, among the five components of the project at least one is ideal for incorporation of AI: development of numerical weather prediction models specifically designed for the East African context.

The Potential of AI

It is not difficult to identify a long list of research projects that focus on various climate change issues in Africa. Many such projects include analyses of large datasets that would, seemingly, be ideal for analysis by AI algorithms. For example, Petja et al. (2004) describe an analysis of South African regional weather data dating from 1900 onward and satellite data dating from 1985 onward. The data are used to monitor regional climate and vegetation variations over time. In another example, Hagenlocher et al. (2014) describe the combination of numerous datasets to develop a cumulative climate change impact indicator. Applied to sub-Saharan Africa, the authors identified, evaluated, and mapped 19 hotspots that exhibited the most severe climate changes. In research out of Stanford University, Burke and Lobell (2017) demonstrated the importance of high-resolution satellite imagery data to estimate and understand yield variation among smallholder African farmers. This understanding generates various potential capabilities including the inexpensive measurement of the impact of specific interventions, the broader characterization of the source and magnitude of yield gaps, and the development of financial products aimed at African smallholders.

Although the immediately foregoing examples, and many other studies, do not specifically mention the use of AI, it is clear that large interrelated datasets are of vital importance to many different areas of research relevant to climate change. There is significant room for AI to be used by researchers to improve methodologies involving analysis of weather and other data (Rasp et al. 2018).

Challenges and Future Applications

Development of advanced technologies typically encounters challenges, and AI technologies and applications with a focus on climate change are no exception. Besides the typical challenges of developing AI products and services, Africa presents unique challenges both technological and political/ethical.

Scope of the Problem

Technologies powered by machine learning (ML) algorithms, including those discussed herein that aid climate analysis (Huntingford et al. 2019), have advanced dramatically, triggering breakthroughs in other research sectors. Although a considerable number of isolated Earth System features have been analyzed with ML techniques, more generic application to understand better the full climate system has not occurred, and the technology to do so may be quite far from the current state of development. At this stage of development, Artificial intelligence (AI) can be used to analyze smaller systems and provide enhanced warnings of approaching weather features, including extreme events. ML and AI can aid in understanding and improving existing data and simulations, as it has done in other systems (Huntingford et al. 2019). For instance, Airbus Defence and Space is using TensorFlow, the open-source set of AI tools from Google, to extract information from satellite images and offer valuable insights to customers. In a similar manner, AI can be used to detect and analyze isolated Earth System features and climate patterns, especially with the latest release of TensorFlow Quantum which enables a faster prototyping of ML models. Nevertheless, modeling the entire global climate remains challenging, and predictions from such models vary at all scales. Until the computational power and models have been refined to enable accurate global predictions, the need remains for smaller scale models. Local modeling requires context specific data and algorithms, so efforts toward development of Africa-specific climate change models must continue to be encouraged.

Ethical Issues of Predicting Climate Change Impacts

AI algorithms are well suited to analyze large datasets and detect patterns, so they are naturally well suited for looking at patterns of large-scale human movement and the data that might be associated with such movement (Beduschi 2020). For example, it is postulated that economic data such as GDP growth, along with trends in other data such as population growth and weather data (which might indicate food security issues), can be used to predict future large-scale human migration (Nyoni 2017). Accuracy of the predictions can be increased by incorporating real-time data points, such as announcements by government central banks, military actions, and weather observations.

Assuming there is a reasonable level of accuracy, predicting the location or the country most likely to suffer the next crisis of human migration has both remedial and prophylactic uses (TEDx Talks 2016). Humanitarian organizations can begin preparations for dealing with the crisis, and intergovernmental financial institutions can consider policy measures to ease debt burdens or encourage growth. Local and national governments of the yet-to-be affected regions can take measures to calm tensions and address the issues that cause migration. As useful as such predictions may be, this use case raises extreme ethical issues, for example by encouraging international efforts (including both active and passive efforts) to promote regime change where a specific government's policies appear to be leading to a future migratory crisis. Additionally, a prediction of a future migratory crisis may be a self-fulfilling prophecy, by increasing tension among the population and reducing investor confidence in the economy. The good intentions of those developing the technology, in this case, may increase the likelihood of the humanitarian disasters that they are seeking to ease.

Data Inadequacies

Apart from ethical issues, the development of AI for combating climate change in Africa may be severely hampered by a lack of data. The concept of a digital divide is many decades old, and documentation of the digital divide separating Africa from other regions is well established (Karar 2019). The modern-day extension of this concept is that of a data divide (Castro 2014), also referred to as a data desert or data poverty. First recognized with respect to certain populations in developed countries, the data divide is a problem in Africa and with respect to climate change for a variety of reasons. Historical weather data is less extensive in Africa compared with other parts of the world (Dinku 2018). Current data is also less extensive, as there are fewer weather satellites monitoring Africa than other regions and ground-based sensing is also less extensive (Dinku et al. 2011).

Even where there is historical climate data, those data may be inaccessible – for example, because African governments and their weather agencies are increasingly seeking to commercialize the data, or because the data are not digitized (Nordling 2019). In this context, the issue of a data divide is complex and is indicative of an uneven power dynamic. As with many other areas, Africa engages the rest of the world from a disadvantaged position, and the unbalanced power of the relationship may negatively affect the outcome. Whereas monetizing data is a common practice in developed countries, because African nations need significant help in building the infrastructure for collecting data, they are expected to willingly release the data. A data commons, in which climate data is readily available for all to use, is vitally important to help climate scientists and other interested parties understand the impacts of climate change in Africa. Nevertheless, the desire of data holders to seek ways of monetizing their data is understandable.

The concept of Africa as a data desert may, therefore, be unfairly characterizing the true situation. Rather than an absence of data, as the desert analogy implies, it is probably more accurate to say that data are present but not as readily available or easily searchable. As mentioned previously, African government websites may lack updated data (Ndongmo 2016), but this does not mean that they are not collecting the data. Open data portals are present in a few countries but have not become mainstream methods for governments to disseminate datasets. In some cases, governments generate revenue by selling datasets, and therefore have little incentive to making them available on an open platform. Efforts at increasing the volume of data collected about Africa should take into account these issues.

Regardless of the causes of the data divide, there is no doubt that insufficient data is important in Africa's ability to adapt to climate change. Climate change does not affect all geographical locations equally (United States Environmental Protection Agency (USEPA) 2017). As the global average temperature rises, and sea levels rise, average temperatures in some areas may decline. Overall rainfall may increase or decrease in any particular location, depending on a variety of factors. Extremes in precipitation and temperatures will also be in homogeneously affected. These variations would be less problematic if data were gathered with uniform consistency in all locations, but as mentioned previously, data collection in Africa is less consistent and less thorough. The result of this situation is likely to be less accurate predictions of the effects of climate change in Africa compared with other regions. Less accurate predictions may mean that local and international decision makers are unable to adequately prepare for the impacts of climate change.

Whether due to inefficient dissemination or to a fundamental lack of collection, or to some other reasons, the lack of available data has severe implications for the use of AI in adapting to climate change. Without sufficient data, AI algorithms are substantially less accurate and useful (West and Allen 2018). The trend in Africa, however, appears to be shifting toward a wider availability of data and a greater effort toward utilizing all available tools, including AI, in addressing climate change issues.

Conclusions

Some countries are serious in their look toward the future. For example, Ethiopia launched its first observatory satellite into space in 2019. The 70-kg remote sensing satellite is to be used for agricultural, climate, mining and environmental observations, allowing the Horn of Africa to collect data and improve its ability to plan for changing weather patterns for example. The satellite will operate from space around 700 km above the surface of earth. Developments in Ethiopia follow the introduction by the African Union of an African space policy, which calls for the development of a continental outer-space program and the adoption of a framework to use satellite communication for economic progress. Clearly, efforts such as this are forward thinking and will help the continent to address the lack of data that hampers the use of AI to address issues of climate change.

The problems of climate change are global, but Africa is likely to suffer to a greater degree compared with other regions. Scientists and policymakers in Africa need every available tool to help the continent adapt to the changes, but should always keep in mind the severity and scale of the problem. Notwithstanding the benefits that AI clearly brings, or promises to bring, in the efforts to adapt to climate change, it is clear that the fourth industrial revolution cannot fix what the second industrial revolution started.

Abstract

This chapter investigates extreme rainfall events that caused flood during summer months of June–September 2010–2014. The aim is to determine the impact of horizontal moisture flux divergence (HMFD) and vertical wind shear on forecasting extreme rainfall events over Nigeria. Wind divergence and convective available potential energy (CAPE) were also examined to ascertain their threshold values during the events. The data used include rainfall observation from 40 synoptic stations across Nigeria, reanalyzed datasets from ECMWF at 0.125° × 0.125° resolution and the Tropical Rainfall Measuring Mission (TRMM) dataset at resolution of 0.25° × 0.25°. The ECMWF datasets for the selected days were employed to derive the moisture flux divergence, wind shear, and wind convergence. The derived meteorological parameters and the CAPE were spatially analyzed and superimposed on the precipitation obtained from the satellite data. The mean moisture flux and CAPE for some northern Nigerian stations were also plotted for 3 days prior to and 3 days after the storm. The result showed that HMFD and CAPE increased few days before the storm and peak on the day of the storms, and then declined afterwards. HMFD values above 1.0×10^{-6} g kg^{-1} s^{-1} is capable of producing substantial amount of rainfall mostly above 50 mm while wind shear has a much weaker impact on higher rainfall amount than moisture availability. CAPE above 1000 Jkg^{-1} and 1500 Jk^{-1} are favorable for convection over the southern and northern Nigeria, respectively. The study recommends quantitative analysis of moisture flux as a valuable short-term severe storm predictor and should be considered in the prediction of extreme rainfall.

Mesoscale convective system · Moisture flux divergence · Wind shear · Extreme rainfall · Flood

Introduction

Human-induced climate change has increased the amount of water vapor in the atmosphere and has caused adverse effects on different regions, ecosystems, and economies across the world (Nwankwoala 2015). These effects depend not only on the sensitivity of populace to climate change but also on their ability to adapt to risks and changes associated with it. Since the atmospheric moisture budget plays an important role in the hydrology of a particular region, the changing weather patterns caused by climate change has increased the incidences of extreme rainfall events (Roshani et al. 2012; Weisman et al. 1988). Rainfall variability associated with climate change has impacted socioeconomic activities such as agriculture, food security, water resources management, health sector, hydroelectric power generation, and dam management among others in Nigeria (Bello 2010). Most of the negative effects of rainfall variability are on agriculture since majority of farmers in the country depend on rain-fed agriculture for livelihood (IPCC 2014; Lawal et al. 2016). Levels of adaptation of farmers in Nigeria to climate change is low, due to lack of adequate education, assets, information, and income (Madu 2016), and consequently agriculture is more vulnerable to climate change impact. Rainfall over Nigeria is mostly from the West African Monsoon systems (WAMS) (Diatta and Fink 2014), and agriculture is an important sector of economy of the country which is highly dependent on the WAMS (Raj et al. 2019). Studies have shown that the complexity of the atmospheric dynamics that generate rainfall, temporal and spatial variation of its scale made it difficult to understand and model. Also, the required parameters to predict it are usually complex even for a short-term period (Sumi et al. 2012). Majority of the results of studies conducted on extreme precipitation events over Nigeria showed that there have been some notable increase in intensity of rainfall extremes which usually claim many lives and properties (Okorie 2015).

In recent times, incidences of large storms have become more frequent with increased intensity, especially the occurrences of high rainfall in form of intense single-day events causing devastating flood (Enete 2014). However, short-range forecasting of these flood occurrences has been a great challenge. Studies have also shown that the distinctive property of West African monsoon flow is that there is seasonal, monthly, and daily variability in its moisture content mainly in the lowest 1 km of the atmosphere (Omotosho and Abiodun 2007). Furthermore, the intensity and duration of extreme rainfall are majorly dependent on the adequacy of moisture carried by the moist southwesterly flow from the South Atlantic Ocean. Studies have also shown that the daily variability of moisture advection mechanisms is responsible for the changes in the intensity and amount of rainfall (Omotosho et al. 2000). Couvreux et al. (2010) noted that at low level, daily moisture transport takes place with periodic northward advection of moisture flux that has 3–5 days frequency. A study conducted by Bechtold et al. (2004) also showed that large-scale thunderstorms in form of Mesoscale Convective Systems (MCSs) are formed over West Africa when there is constant supply of low-level moisture. The action of synoptic scale intensification of the St. Helena high pressure system over the South Atlantic Ocean is majorly responsible for moisture divergence into West Africa. Similarly, in a numerical study of moisture build-up and rainfall done by Omotosho and Abiodun (2007), it was reported that the rainfall amount does not depend on the monsoon flow alone but majorly on the sufficiency and the variability of its moisture content. Other studies have also examined the influence and interaction of different scales of motion such as African Easterly Jet (AEJ), Tropical Easterly Jet (TEJ), and African Easterly Waves (AEW) on the formation of MCSs (Nicholson 2013). These studies focused mainly on the scale interactions responsible for seasonal variability in weather pattern during northern summer (Janicot et al. 2011). They, however, did not consider in detail the quantity of daily moisture advection responsible for these rainfall extremes. The main focus of this chapter is to contribute to the understanding of the impact of moisture flux on the rainfall amount. Hence, it is necessary to study extreme precipitation events and diagnose the signatures of the meteorological parameters peculiar to such events. Studying this may enhance the assessment of the manner in which extreme rainfall events evolve and therefore provide a short-term early warning method to forecasters. It will also assist in understanding the evolution of some derived meteorological parameters such as the moisture flux which determines the quantity of rainfall and the wind shear which determines the life span of the storm (Weisman et al. 1988). Thorough understanding of these parameters will aid reliable short-term flood forecast. The usefulness of horizontal moisture flux at or near the earth's surface as a thunderstorm predictor has been recognized throughout various studies (Beckman 1990). Apart from the availability of moisture, sustenance of MCSs also requires a certain magnitude of vertical wind shear to produce a stronger and longer-lived system (Weisman and Rotunno 2004). Observational and numerical studies have revealed that horizontal winds and their vertical structures have important impacts on convective development; to buttress this point, Omotosho (1987) noted that thunderstorms occur, most frequently, in association with low-level wind shears below the AEJ (surface to 700 hPa) ranging from -20 to -5 s^{-1} and for mid troposphere (700–400 hPa) in the range of 0 to $10s^{-1}$. Despite the importance of wind shear, its effect on MCS has not been treated explicitly over Nigeria.

Most climate prediction models do not perform well in prediction of extreme rainfall events over West Africa because of their low resolution (Nyakwada 2004), the nature of parameterization schemes employed in the model, scarcity of real-time data, and mostly due to the convective nature of West African rainfall, hence the forecast of extreme rainfall event is a major challenge to forecasters in West Africa. The aim of this chapter is therefore to determine the impact of moisture flux, vertical wind shear, and other derived meteorological parameters such as wind divergence and convective available potential energy (CAPE) on MCSs during extreme rainfall events over Nigeria. Therefore, the study investigates the spatiotemporal variability of moisture flux that feeds into MCSs and its impacts on the occurrences of high impact rainfall. The objective is to assess the threshold values of derived meteorological parameters responsible for isolated cases of extreme precipitation in order to enhance its predictability and contribute to the understanding of the impact of moisture flux on the amount of precipitation. This research makes use of a synergistic approach involving the moisture flux divergence, wind shear analysis below and above the AEJ, and CAPE. The spatial distribution of these derived parameters is considered, with a focus on understanding their contribution to the formation and sustenance of MCSs during extreme rainfall events. This chapter will be a useful guide for further investigations into accurate prediction of high impact rainfall that can result into flood events using moisture flux analysis.

Description of the Study Area and Methodology

Study Area

Nigeria is situated between latitudes 4° and 14°N and longitudes 2° and 15°E and falls within the tropics. It shares borders with Niger in the north, Chad in the northeast, Benin in the west, Cameroon in the east, and its coast in the south borders the Gulf of Guinea on the South Atlantic Ocean. Precipitation is received mainly

Fig. 1 Map of Nigeria showing the whole country as study area and spatial distribution of Nigerian Meteorological Agency synoptic stations used in this chapter

during the northern hemispheric summer, which is referred to as the wet seasons. Moist southwesterly winds from the South Atlantic Ocean prevail during the summer while dry northeasterlies from the Sahara desert are dominant in the winter which is the dry season (Fig. 1).

The confluence zone between both wind systems is the Inter-tropical Discontinuity (ITD). The surface location of the ITD significantly accounts for rainfall interannual variability in the country (Nicholson 2009). The ITD fluctuates seasonally during the northern summer over West Africa and migrates northward from its winter position of 4°N to its northernmost position of about 22°N (Fig. 2). The amount of rainfall experienced by different areas depends on the position of the ITD. Most of the convective rainfall follows the south-north-south displacement of the ITD (Sultan and Janicot 2003).

Data

Daily data for selected days of heavy rainfall was obtained from the European Centre for Medium-Range Weather Forecast's (ECMWF) ERA-INTERIM dataset on a gridded point of 0.125° × 0.125° and pressure levels of 1000, 850, 700, 400, and 200 hPa for the summer months of June–September 2010–2014. The daily datasets

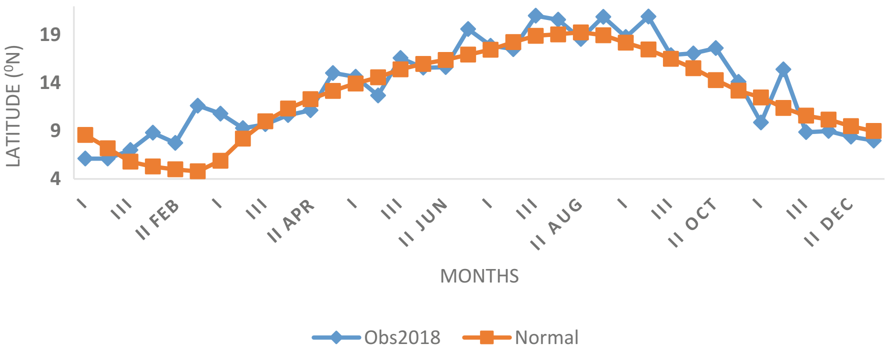

Fig. 2 Decadal latitudinal positions of the ITD in 2018 and its climatological mean over Nigeria. (Source: NiMet Climate Review Bulletin 2018)

are convective available potential energy (CAPE), specific humidity, zonal (U), meridional (V) winds, and divergence. Daily-accumulated rainfall was obtained from Tropical Rainfall Measuring Mission (TRMM) dataset, at a resolution of 0.25° × 0.25°. Observed rainfall for the months of June–September 2010–2014 was obtained from the Nigerian Meteorological Agency (NiMet) from 40 synoptic stations over Nigeria as shown in Fig. 1 to validate the TRMM dataset. Days of unusually high amount of rainfall during the months of June–September were selected from 2010 to 2014.

Research Methodology

Derived meteorological parameters such as moisture flux, CAPE, vertical wind shear, monsoon depth, the strengths of AEJ and TEJ were evaluated on these specific days to ascertain the characteristics of atmospheric dynamics during the occurrences of extreme rainfall events. The monsoon depth, the strengths of AEJ and TEJ are obtained by plotting the vertical wind profile using the U component of wind. The atmospheric dynamics of these events were diagnosed to find out the significant threshold of moisture flux, CAPE, vertical wind shear, monsoon depth, the strengths of AEJ and TEJ that may possibly be responsible for such unusually high amount of rainfall. Convective days were compared to a non-convective day to determine the difference in the characteristics of the atmospheric dynamics. Observationally, while there were occurrences of thunderstorms with heavy rainfall on convective days, none occurred on non-convective days. Ten weather events that produce rainfall above 50 mm were also selected for four meteorological stations over the northern region from 2010 to 2014. The mean of derived parameters such as moisture flux and CAPE 3 days prior and after the rainfall events are calculated to assess their characteristics during the period. (12.00°N, 8.59°E), Maiduguri (11.83 N, 13.15°E), Sokoto (13.01° N, 5.25°E), and Yelwa (10.83°N, 4.74°E) were chosen, because according to Omotosho (1985), about 90% of rainfall over these stations is attributed to MCSs.

Computation of Horizontal Moisture Flux and Wind Shear

Horizontal moisture flux is computed by the following formula.

Using U and V components of wind,

$$\nabla.\mathrm{V} = \frac{\partial \mathbf{u}}{\partial \mathbf{x}} + \frac{\partial \mathbf{v}}{\partial \mathbf{y}} \tag{1}$$

where ∇. V = Divergence

Horizontal moisture flux divergence (HMFD) fields were derived from the specific humidity and components of the wind for the surface and 850 hPa by using the following formula:

$$\mathrm{HMF} = -\left(\boldsymbol{U}\frac{\partial \mathbf{q}}{\partial \mathbf{x}} + \boldsymbol{V}\frac{\partial \mathbf{q}}{\partial \mathbf{y}}\right) + \mathrm{q}\left(\frac{\partial \mathbf{u}}{\partial \mathbf{x}} + \frac{\partial \mathbf{v}}{\partial \mathbf{y}}\right) \tag{2}$$

where:

$$\left(\boldsymbol{U}\frac{\partial \mathbf{q}}{\partial \mathbf{x}} + \boldsymbol{V}\frac{\partial \mathbf{q}}{\partial \mathbf{y}}\right) \text{ is the Advection term}$$

$$\left(\mathrm{q}\frac{\partial \mathbf{u}}{\partial \mathbf{x}} + \frac{\partial \mathbf{v}}{\partial \mathbf{y}}\right) \text{ is the divergence term}$$

where (q) is the specific humidity, (u) and (v) are zonal and meridional wind speed components of q, u and v; the advection term represents the horizontal advection of specific humidity, while the divergence term denotes the product of the specific humidity and horizontal mass convergence. $\frac{\partial}{\partial \mathbf{x}}$ and $\frac{\partial}{\partial \mathbf{y}}$ show the horizontal variation of atmospheric quantities such as specific humidity and wind. The first term in the moisture flux (MF) equation is moisture advection. This term incorporates changes of the moisture field with time or the flux of the moisture field. The moisture advection term, similar to the mass divergence term, incorporates into MF the effects of moisture availability on convection. The second term, mass convergence term incorporates moisture accumulation by multiplying the wind convergence, which is the rate at which the air itself is pooling, by the moisture content of the air (mixing ratio). The mass convergence term is usually the dominant term, and observations have shown that the moisture advection term can significantly contribute to the development and subsequent intensification of storms. By combining the effects of mass convergence as a low-level forcing mechanism with moisture availability, moisture flux incorporates most of the ingredients necessary for convection (Roshani et al. 2012).

Vertical wind shear (U_S) was calculated using the zonal component of wind at 1000, 700, 400, and 200 hPa levels. The vertical wind shear (U_S) is defined as:

$$\mathrm{U_S} = \frac{\mathbf{du}}{\mathbf{dz}}\mathrm{S}^{-1} \tag{3}$$

The vertical wind shear at the lower, mid, and upper troposphere using the formula (Omotosho 1987):

$$U_{S\,(L)} = U_{700} - U_{surface} \quad (4)$$

$$U_{S\,(M)} = U_{400} - U_{700} \quad (5)$$

$$U_{S\,(U)} = U_{200} - U_{400} \quad (6)$$

where:

$U_{S\,(L)}$ = Wind shear at lower troposphere
$U_{S\,(M)}$ = Wind shear at mid troposphere
$U_{S\,(U)}$ = Wind shear at upper troposphere

Rainfall events that produced rainfall above 50 mm were also selected for four meteorological stations over the northern Nigerian region from 2010 to 2014. The mean of derived moisture flux and CAPE 3 days prior and after the rainfall events were calculated to assess their characteristics during the period. Kano (12.00°N, 8.59°E), Maiduguri (11.83°N, 13.15°E), Sokoto (13.01°N, 5.25°E), and Yelwa (10.83°N, 4.74°E) were chosen, because according to Omotosho (1985), about 90% of rainfall over these stations is attributed to MCSs.

Result

Convective Days

Moisture Flux Analysis

The study presents the analysis of rainfall events that took place from the first to third July 2014 over most parts of the country. The intense rainfall observed led to flooding which resulted into loss of lives and properties. The TRMM rainfall analysis over the country from first to third as shown by Fig. 3a–c depicted the widespread rainfall across the country during the period. Rainfall amount of 71.5, 104, and 117 mm was observed on the first to third day, respectively, over Eket (4.65°N, 7.94°E), a coastal city in the southeastern part of the country. The horizontal moisture flux divergence (HMFD) analysis indicated that divergence of moisture at the surface was from the South Atlantic Ocean for the 3 days considered. Figure 4a–c showed that the values of HMFD ranged from 0.10 to 1.05×10^{-6}g kg^{-1} s^{-1} on the first day with slight reduction on the second day to 0.85×10^{-6} g kg^{-1} s^{-1} while the maximum value of HMFD on the third day was up to 1.25×10^{-6} g kg^{-1} s^{-1}. This analysis showed that higher the amount of moisture supplied to the storm, the higher the amount of precipitation. The analysis at 850 hPa level as shown by Fig. 5a–c depicted that area of moisture divergence shifted from the coast to mainly over the high grounds of Jos, Mambilla plateaus, and other high

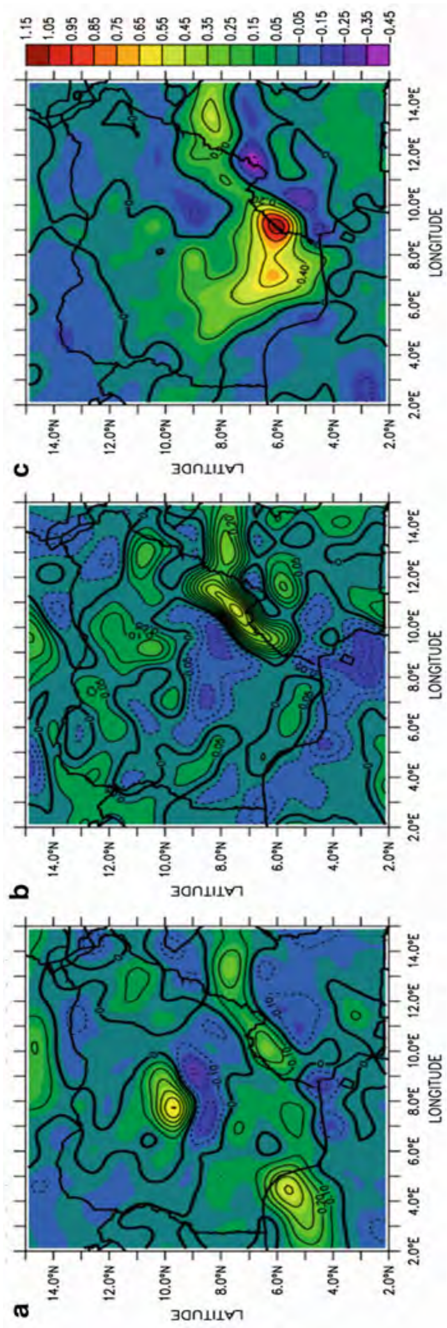

Fig. 5 (**a–c**) Spatial distribution of horizontal moisture flux divergence (HMFD) at the 850 hPa for 1–3 July 2014 (conversely, dotted lines indicate moisture convergence)

grounds across the country. Values of HMFD ranged from 0.01 to 0.55×10^{-6}g kg^{-1} s^{-1} on the first and second day and increased to 1.15×10^{-6}g kg^{-1} s^{-1} on the third day. It was observed that close to the divergence areas were areas of strong convergence, which coincided with areas of highest precipitation.

Wind Divergence Analysis

Figures 6a–c and 7a–c showed the observed rainfall distribution over the country was maximum along the coastal areas and some inland cities of the southwest, e.g., at Shaki (8.35°N, 5.47°E) on the first day, strong wind divergence at 200 hPa level exactly over this area enhanced the lower tropospheric wind convergence. This is consistent with Nicholson (2009) which stated that strong upper-level divergence is associated with strong upward motion and severe convective storms; in contrast, upper-level convergence usually indicates downward motion, which is a sign of decaying convection. Due to this strong divergence at the upper level, convection became vigorous and vertical transport of moisture was enhanced from the lower troposphere. However, Fig. 5b shows that along the coast, convergence was observed at the surface with corresponding divergence at 200 hPa with little amount of rainfall; this may also be attributed to insufficient moisture as shown by the moisture flux analysis. Similarly, over the western parts of the country, wind divergence was at the surface with corresponding convergence at 200 hPa, hence less precipitation was observed.

Vertical Wind Shear

The wind shear analysis, Fig. 8a–c showed that the low-level wind shear $Us_{(L)}$ ranged between -4 s^{-1} and -14 s^{-1} across the country. These values agreed with Omotosho (1987) who showed that thunderstorms occur most frequently in association with low-level shears, below the African Easterly Jet (i.e., surface to 700 hPa) with values within $-20 \sim < Us_{(L)} \sim < -5$ s^{-1}. Areas with precipitation value above 50 mm have values of $Us_{(L)}$ of -14 s^{-1} and above. However, some areas with $Us_{(L)}$ of -14 s^{-1} did not record any rainfall, this may be attributed to wind divergence observed at the surface or inadequate moisture supply (Grist and Nicholson, 2001). The value of $Us_{(L)}$ ranges from -8 to -4 s^{-1} over the southwest on the first and second day and up to -12 s^{-1} on the third day. Considerable amount of rainfall observed over these regions coincided with areas with adequate moisture flux convergence on the first and third day. According to Rotunno et al. (1988) and Weisman et al. (1988), vertical wind shear is important in the formation of organized long-lived convection; however, very strong horizontal wind shear can inhibit the growth of cumulus clouds by blowing away the parts of the cloud containing the best developed precipitation particle and thereby preventing the process of precipitation (Rickenbach et al. 2002). Figure 8a–c showed that the value of mid-level wind shear $Us_{(U)}$ over the country ranges between 0 and 2 s^{-1} except on the second day where the value of W_SU over western parts is between 0 and -10s^{-1}. It is noteworthy that moderately sheared environment is important for sustaining MCSs during extreme rainfall event (Figs. 9 and 10).

Wind Vector at 850 hPa

Figure 11a–c showed that there was continuous moisture supply from the Atlantic Ocean throughout the rainfall events. Moist southwesterly winds convergence that was observed along the southwest coast on the first day produced significant amount of rainfall over Lagos (6.52°N, 3.37°E) and Lokoja (7.80°N, 6.73°E) axis. The wind flow from south to north remained steady from the day 1 and 2. Although over the northern parts, the wind direction indicated northeasterly flow on day 3, but sufficient residual moisture has already accumulated over the country up to the northern areas before the occurrence of a more widespread and heavy rainfall on the third day as shown by Fig. (11a–b). On the third day, over the southeastern parts, there was a well-organized deep monsoon flow from the Gulf of Guinea feeding into a vortex over the inland area of the southeastern parts of the country. The advected moisture depth was enough to maintain the active system over the southeastern axis as shown by the HMFD analysis. A total rainfall of 292.5 mm was recorded round Eket (4.65° N, 7.94°E), the vicinity of the vortex.

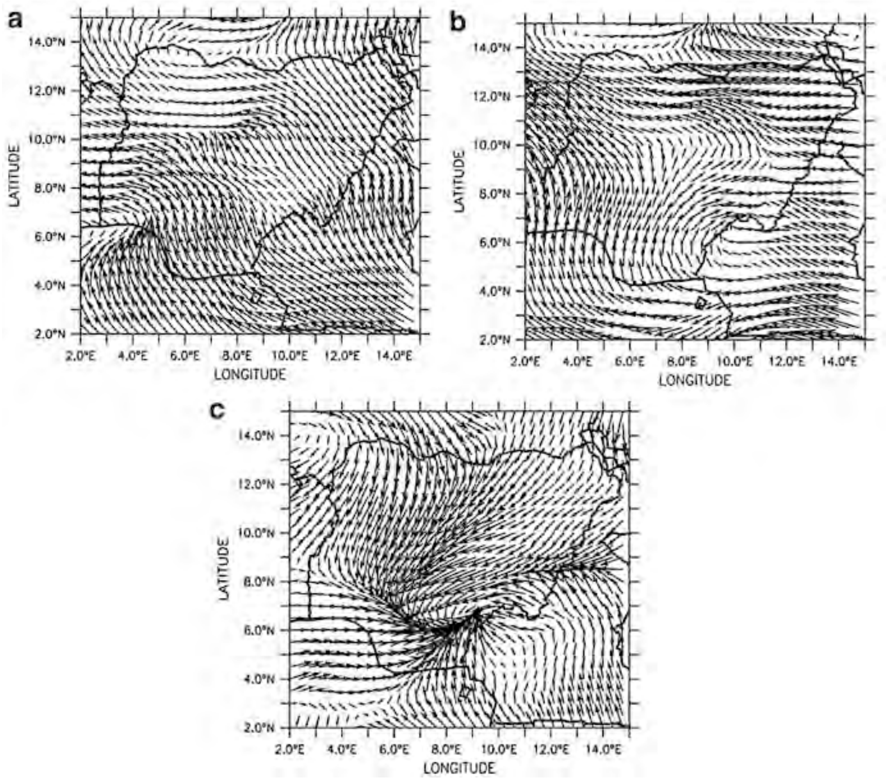

Fig. 11 (**a**–**c**): Spatial distribution of wind vector at 850 hPa for 1–3 July 2014

Convective Available Potential Energy (CAPE)

CAPE is an energy-based measure of atmospheric stability; it is a very important index in the forecasting of rainfall over Nigeria (Olaniyan et al. 2015). Figure 12a–c showed that the CAPE up to 2900 Jkg^{-1} was observed over the northeast and central parts in the first and second day; however, not much precipitation was recorded. This may also be attributed to insufficient moisture as shown by Fig. 4a–b. Over the southwest, CAPE value of 1600 Jkg^{-1} and 2400 Jkg^{-1} was observed on the first day and the second day, respectively, but due to reduction in moisture flux on the second day, rainfall reduction was observed compared to the first day. Over the southeastern parts, the CAPE values vary from 800 JKg^{-1} to 1600 JKg^{-1} and 1000–1500 Jkg^{-1} on the first and second day, respectively, while on the third day, the value ranged from 1000 JKg^{-1} to 1500 JKg^{-1}, and the highest amount of rainfall was observed on the third day. Over the northern parts, CAPE values favorable for convection ranges between 1000 and 2800 Jkg^{-1} on the first day, while it is 600–3000 Jkg^{-1} on the second day though no rainfall was observed on this day due to reduced moisture flux. On the third day, the CAPE value was 2500 Jkg^{-1} and peaked to 4000 Jkg^{-1}, higher rainfall was observed due to abundant moisture over this area indicating a deep layer of moisture to fuel the MCSs. A consistent pattern of CAPE was observed throughout the rainfall events, CAPE increases from coastal to the northern parts of Nigeria and the higher the CAPE, the higher the intensity of storm, provided moisture is sufficient.

Vertical Wind Profile (AEJ, TEJ, and Monsoon Depth)

Figure 13a–c showed the extent of the moist southwesterly winds, the strength of the AEJ and the TEJ over the south and northern regions, and their mean position over the whole country, respectively, from the first to third of July. The zonal wind at the surface was westerly with speed of about 2, 6, and 5 ms^{-1}, respectively, over the south of 9°N, north of 9°N, and the entire country. The first and second days indicated lower moisture depth at 900 hPa compared to 950 hPa on the third day (Fig. 13c). The AEJ was located at about 700 hPa with a mean speed of 12, 10, and 8 ms^{-1} for the first, second, and third day, respectively, while the speed of TEJ was 18, 12, and 13 ms^{-1}, respectively, for the 3 days over the entire country. Thermodynamically, the AEJ is often responsible for advection of both sensible heat and latent energy into regions where severe thunderstorms are formed. TEJ is responsible for enhancing upper level divergence, which in turn encourages vertical motion and lower level convergence (Nicholson et al. 2012). Therefore, the strength of the jets and the availability of adequate moisture support these extreme rainfall events.

Non-convective Day

Generally, the atmosphere was stable on this day; most stations in the country reported no rainfall. Analysis of a non-convective day was done to evaluate the

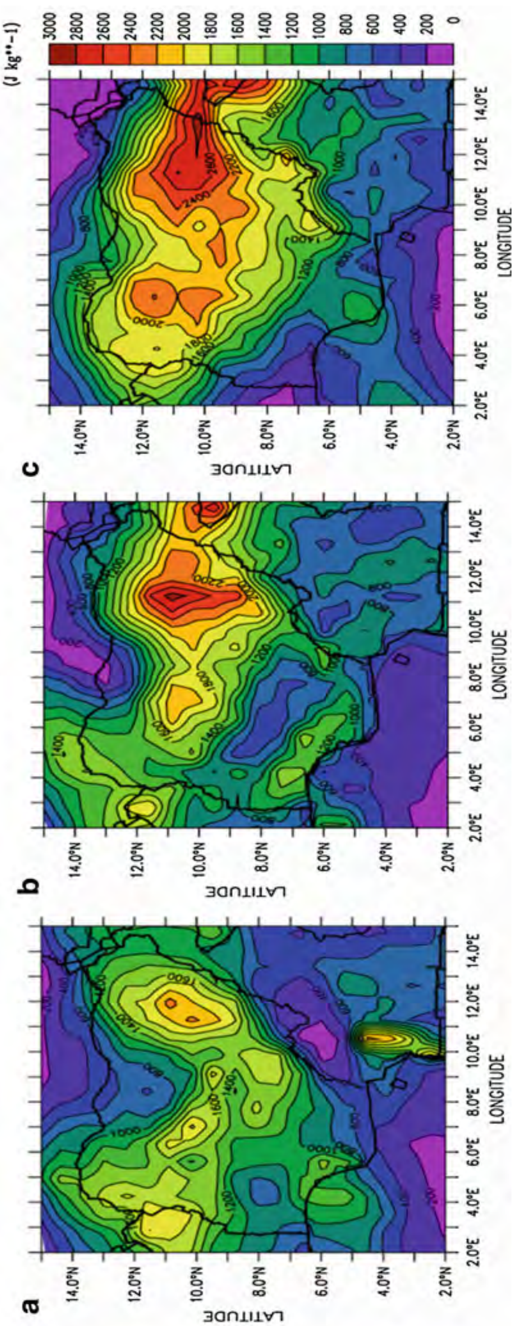

Fig. 12 (**a**–**c**): Spatial distribution of CAPE over Nigeria for 1–3 July 2014

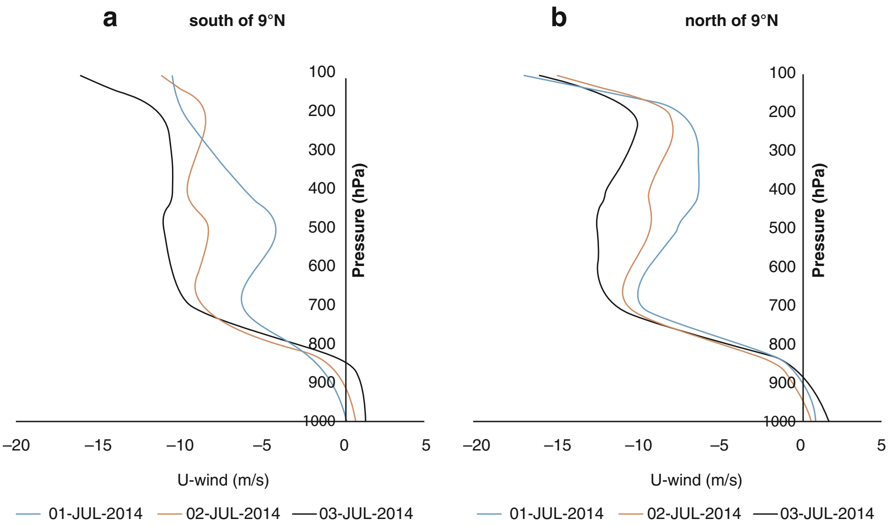

Fig. 13 (**a**–**c**) Vertical wind profiles (in m/s) averaged over (**a**) south of 9°N, (**b**) north of 9°N, and (**c**) the entire Nigeria for 1–3 July 2014. Days 1, 2, and 3 are indicated in blue, red, and gray lines, respectively

difference in the behavior of the convective parameters in order to identify the reason for the observed stability in the atmosphere on the day.

Divergence Analysis

Figure 14a, b shows that over the southwestern parts of the country, convergence was observed at the surface and also at 200 hPa, and hence vertical motion was

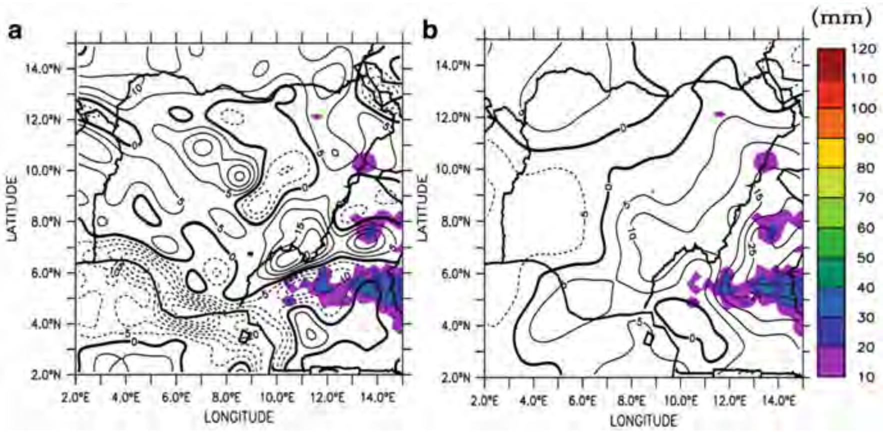

Fig. 14 Spatial distribution of rainfall (color; mm) and wind divergence at (**a**) 1000 hPa (**b**) 200 hPa level (contour; s^{-1}) for 27 August 2014 (dotted lines indicate convergence)

suppressed; this may be due to widespread subsidence prominent during this period caused by reduced sea surface temperature and the ridging effect of the south Atlantic high pressure system over the St. Helena. This period is usually referred to as the little dry season. However, over some parts of the central region and the southeastern coast, convergence was observed at the surface while there was corresponding divergence at 200 hPa, but no rainfall was observed; this may be due to lack of sufficient moisture as shown by the HMFD (as shown in the next section) analysis. The rest of the country was prevailed by convergence at 200 hPa while divergence was observed at the surface. These features could suppress vertical transport of moisture.

Moisture Flux Analysis

The HMFD analysis at the surface in Fig. 15a shows that less moisture was available at the surface and 850 hpa level. Moisture flux diverging from the Atlantic Ocean at the surface over the southwest coast was almost negligible, while over the south-eastern part extended from the coast even to the inland has values ranging from 0.10 to 0.55×10^{-6} kg/gs^{-1}. Although wind convergence is present at the surface with corresponding divergence at 200 hPa, moisture may not be sufficient as shown in Fig. 14b, hence no rainfall is observed over the country.

Vertical Wind Shear Analysis

Figure 16a–c shows that $U_{S(L)}$ values ranged between 0 s^{-1} and -12 s^{-1}. The value of $U_{S(M)}$ across the country ranged from 0 s^{-1} to -8 s^{-1}, zero value was observed over the central state, while the value of $U_{S(U)}$ ranged from -8 s^{-1} to -18 s^{-1}as shown in Fig. 15a–c. Although this range is conducive for storm initiation, provided other conditions such as moisture availability, lower level convergence, and upper level divergence are met; otherwise, convection may be suppressed.

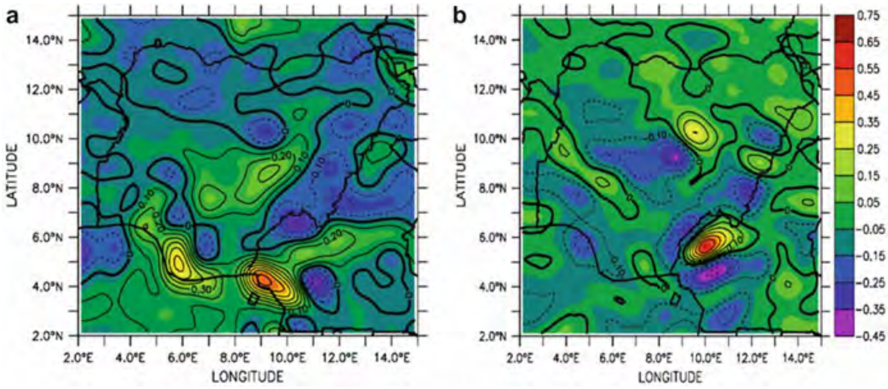

Fig. 15 (**a** and **b**) Spatial distribution of horizontal moisture flux divergence (HMFD) at the surface (1000 hPa) and 850 hPa for 27 August 2014 (conversely, dotted lines indicate moisture convergence)

Wind Vector

The wind vector analysis shown in Fig. 17 depicted the prevalence of southwesterly wind from the Atlantic Ocean, but no rainfall was over the country; this was confirmed by insufficient moisture as shown in the moisture flux analysis of Fig. 15a, b despite the fact that the entire country was prevailed by southwesterly winds, and no rainfall was recorded across the country. According to Omotosho and Abiodun (2007), little or no precipitation is observed below a certain limit of atmospheric moisture.

Convective Available Potential Energy (CAPE)

Figure 18 shows that the CAPE across the country ranges between 200 Jkg^{-1} in the south and 1200 Jkg^{-1} over the north; this is an indication of less potential energy to support convection, and for this particular day, moisture was also not sufficient to support rainfall as shown by HMFD analysis (Fig. 15a, b).

Mean HMFD and CAPE at the Surface, Three Days Prior and Three Days After Storm Events

Ten weather events that produce rainfall above 50 mm were selected for four meteorological stations over the northern Nigeria from 2010 to 2014. The mean of derived parameters for selected days namely, horizontal moisture flux divergence (HMFD) and CAPE were evaluated 3 days before and 3 days after the storm over the northern stations of Kano (12.00°N, 8.59°E), Maiduguri (11.83 N, 13.15°E), Sokoto (13.01°N, 5.25°E), and Yelwa (10.83°N, 4.74°E) depicted in Figs. 19a, b, 20a, b, 21a, b, and 22a, b, respectively. On these figures, horizontal axes represent days; with 0 representing the day of the stormy events while negative and positive values (day) represent, respectively, 3 days prior and 3 days after the storm. Generally,

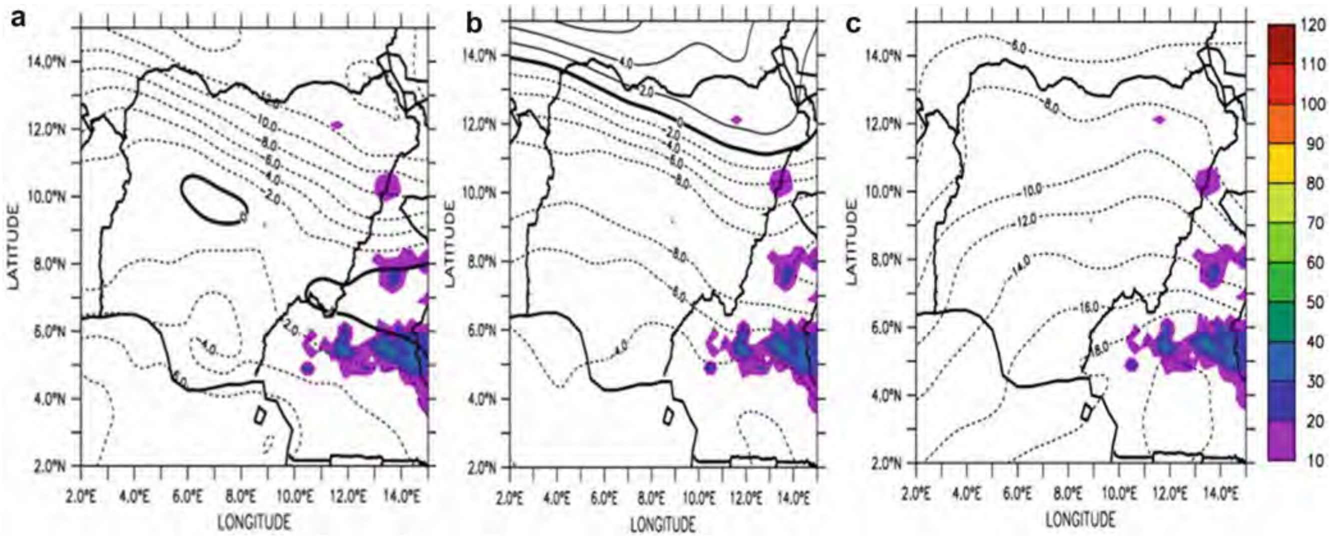

Fig. 16 (**a**–**c**) Spatial distribution of low-level wind shear: (**a**) 700–1000 hPa ($_{L)}$), (**b**) 400–700 ($U_{S(M)}$), and (**c**) 200–400 hPa ($U_{S(U)}$) level (contour; s^{-1}) and TRMM precipitation (color; mm) for 27 August 2014

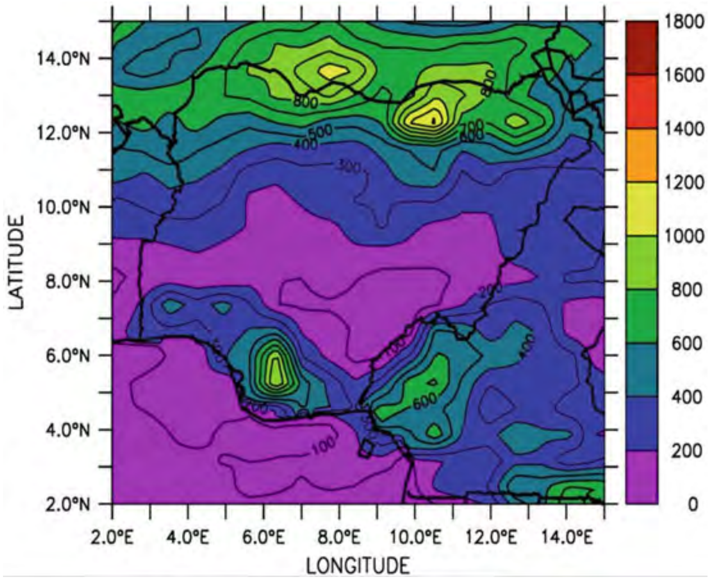

Fig. 18 Spatial distribution of CAPE over Nigeria for 27 August 2014

moisture divergence from the Atlantic Ocean accumulates prior to the storm, reaches climax on the day of the rainfall event, and starts declining after the storm (Panel (a) of Figs. 19, 20, 21, and 22). The mean HMFD was highest on day 0 which is day of the rainstorm. This is depicted by negative moisture flux and afterwards it gradually decreased after the storm. The analysis showed that extreme rainfall events are characterized by significant moisture flux divergence prior to storm events. Panel

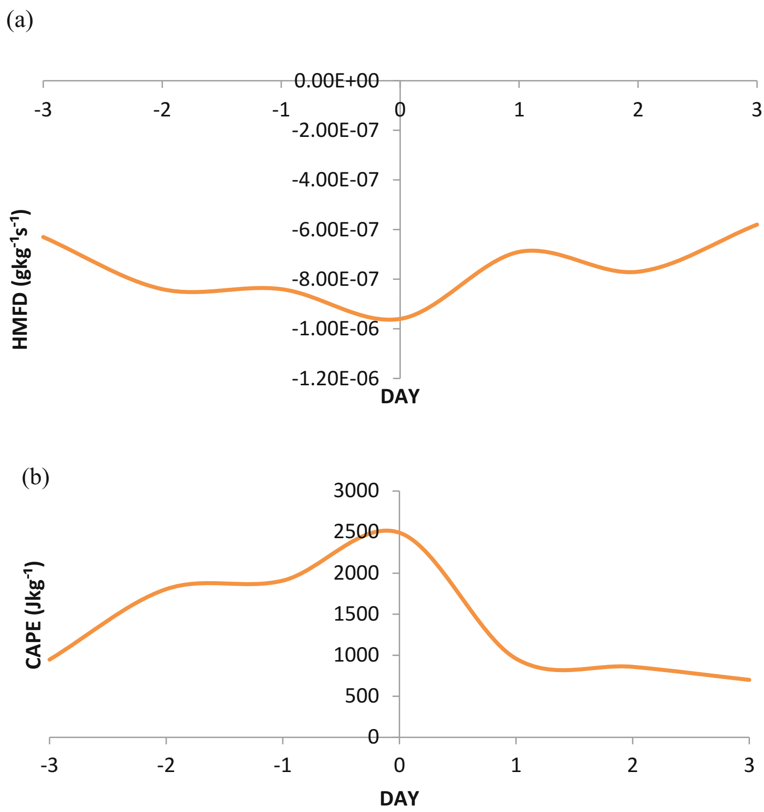

Fig. 19 (**a** and **b**) Derived meteorological parameters at surface over Kano (3 days before and 3 days after extreme rainfall events from June to September 2010–2014) for (**a**) mean HMFD and (**b**) CAPE

(b) of Figs. 19, 20, 21, and 22 also showed a similar pattern for the mean CAPE analysis.

Table 1 shows the mean CAPE on day 0, which ranges from 2416 Jkg^{-1} to 2954 Jkg^{-1} with the highest over Sokoto.

Conclusion

This chapter identified and examined a set of severe widespread rainfall that produced flood events over different parts of Nigeria. The result showed that moisture, convective instability, vertical wind shear, and lifting mechanisms all contributed to these events, but most importantly, the moisture influx. The quantity of rainfall over a given area can be related to the magnitude of the lower tropospheric moisture flux. The study also showed that the transfer of moisture flux in the low layer is mainly from the South Atlantic Ocean, and the higher the moisture flux diverged from the

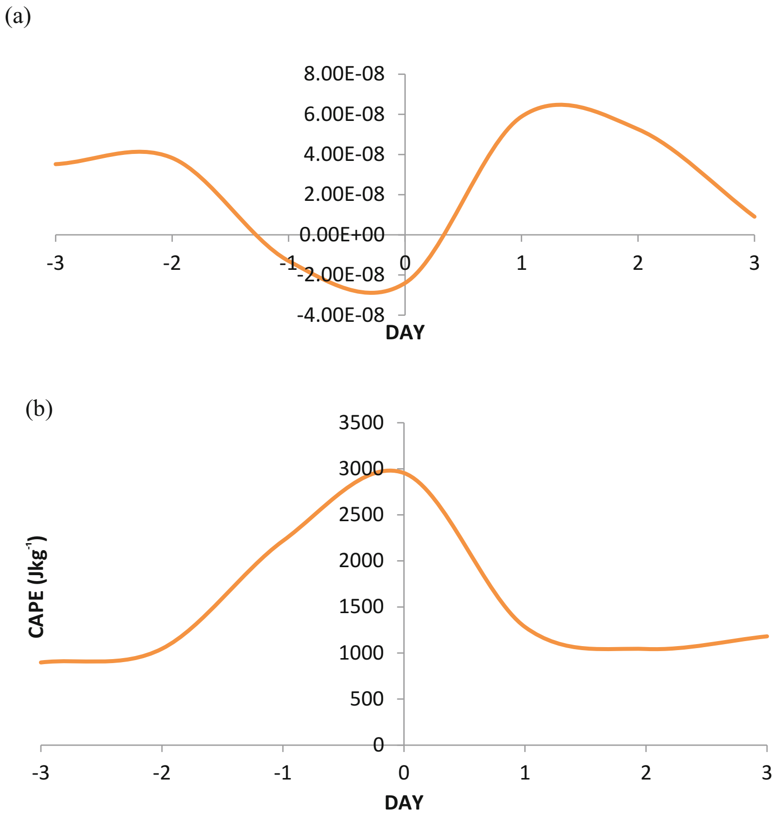

Fig. 20 (**a** and **b**) Derived meteorological parameters at surface Sokoto (3 days before and 3 days after the storm for extreme events from June to September 2010–2014) for (**a**) mean moisture flux divergence and (**b**) CAPE. Negative values in moisture flux analysis indicate convergence while positive values indicate divergence

Atlantic Ocean, the higher the amount of rainfall. The result also indicated that low-level convergence that corresponds with upper-level divergence encourages vertical transport of moisture while low-level divergence and upper-level convergence results in subsidence. At the surface, the value of moisture flux divergence ranges between 0.05 and 1.15×10^{-6}gkg^{-1} s^{-1} at the vicinity of areas where considerable amount of precipitation of above 50 mm were observed. They are mostly located westward of moisture divergence zone. This gives a good indication of where flood is most likely. Moisture flux divergence value ranged from 1.0 to 2.0×10^{-6} gkg^{-1} s^{-1} at 850 hpa around the areas with substantial amount of rainfall in its vicinity, the high grounds of the southwest, Jos, Mambila, Adamawa plateaus, and Cameroonian mountain are good source of moisture divergence at 850 hPa, and hence theses area can be referred to as fertile ground for convection (Hodges and Thorncroft 1997; Akinsanola and Ogunjobi 2014). The wind shear below the AEJ ($U_{S(L)}$) over

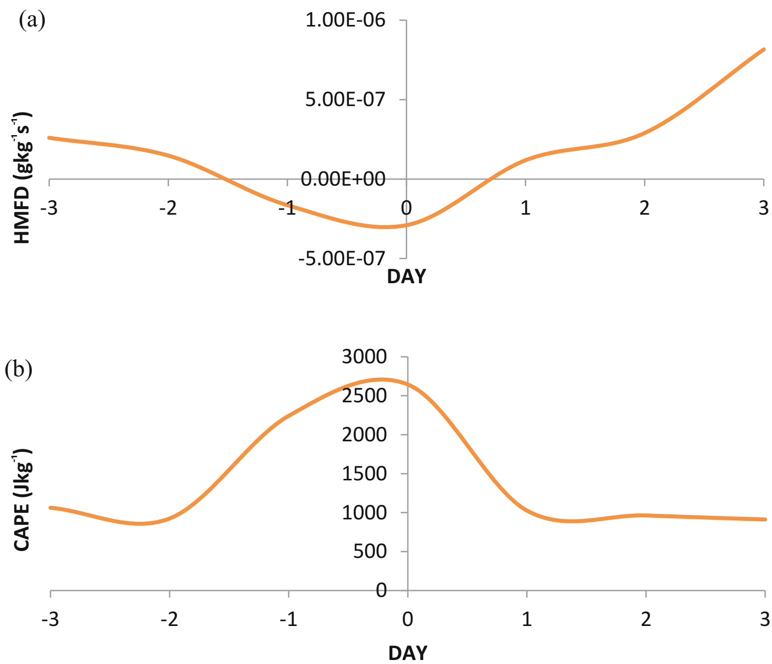

Fig. 21 (**a** and **b**) Derived meteorological parameters at surface over Maiduguri (3 days before and 3 days after extreme rainfall events from June to September 2010–2014) for (**a**) mean moisture flux divergence and (**b**) CAPE. Negative values in moisture flux analysis indicate convergence while positive values indicate divergence

the region of intense precipitation ranges between -8 and -12 ms^{-1}. At mid-troposphere ($U_{S(M)}$), wind shear value ranged from 2 s^{-1} to -8 s^{-1}, while at upper level ($U_{S(U)}$), the values ranged between 0 and 12 s^{-1}. Most of the result of $U_{S(L)}$ were in agreement with Omotosho (1987) on the value of wind shear necessary for the initiation and sustenance of MCSs.

The CAPE analysis indicated that potential energy equal or greater than 1500 Jkg^{-1} favored convection over the northern parts, while CAPE value equal or greater 1000 Jkg^{-1} was able to trigger convective activities over the southern parts. The result also showed that extreme rainfall also depends on convective available potential energy CAPE, and the higher the CAPE, the more intense was the rainfall, provided moisture was sufficient. Similarly, rainfall observed at a particular area varies according to the amount of moisture flux advected by the monsoon winds into the area. The mean moisture flux and CAPE analysis for extreme storm events over selected cities in northern Nigeria indicated that there is always an increase in the value of moisture flux and CAPE 3 days prior to storm occurrences. This can be a good indicator for forecasting extreme rainfall events. Table 1 shows the peak values of mean CAPE and moisture flux over the selected northern Nigerian stations. The result also shows that sufficient CAPE and wind

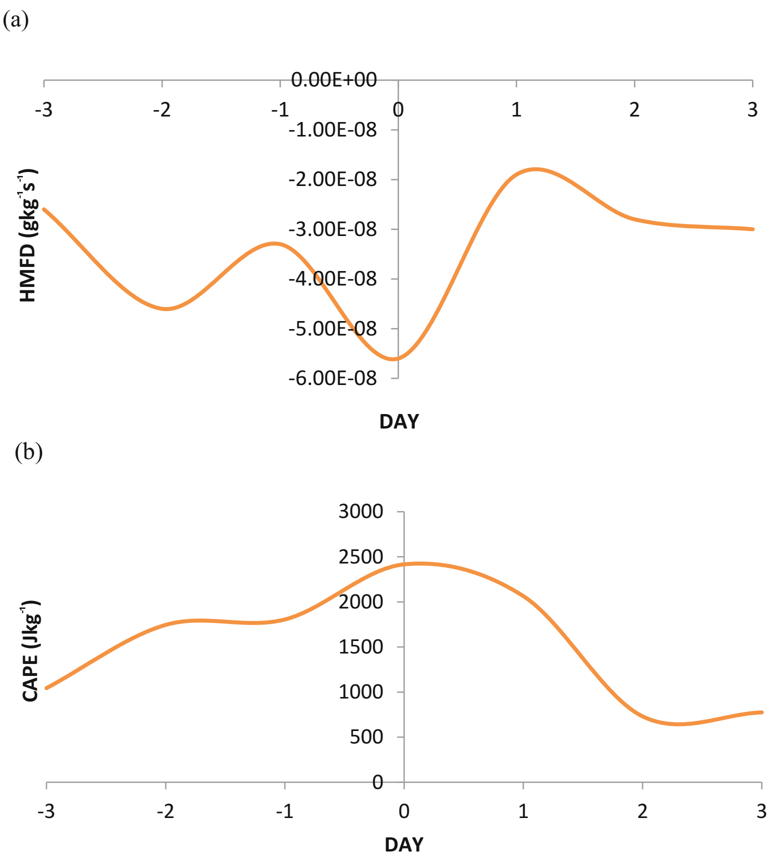

Fig. 22 (**a** and **b**) Derived meteorological parameters at surface over Yelwa (3 days before and 3 days after extreme rainfall events from June to September 2010–2014) for (**a**) mean moisture HMFD and (**b**) CAPE

Table 1 Peak values of mean derived meteorological parameters at the surface HMFD and CAPE over Kano, Maiduguri, Sokoto, and Yelwa for JJAS (2010–2014)

STATIONS	HMFD ($gKg^{-1}\ s^{-1}$)	CAPE (Jkg^{-1})
KANO	−9.60E-07	2492
MAIDUGURI	−2.90E-07	2644
SOKOTO	−2.40E-08	2954
YELWA	−5.60E-08	2416

shear is not enough for convection, it is necessary to have sufficient amount of moisture for initiation and sustenance of the storm throughout its life. These observed pattern of wind flow at the surface and 850 hPa, the CAPE and HMFD when sighted on the forecast charts may be good indicators for forecasting extreme rainfall and the likelihood of flood events which will help in early preparedness and prevention of the worst impacts of such extreme events on lives and properties.

A further study of moisture flux and wind shear is recommended using different operational models and more network of stations as this will give a better perception of impact of moisture flux on spatial rainfall variability across the country. Forecasting precipitation amount is a challenging task for forecasters, therefore adequate study of the criteria such as moisture flux, wind shear, and CAPE will increase the understanding of extreme rainfall events; though there will always be variability in the values of meteorological parameters, sound understanding of forecast models, learning how to analyze the situation using the appropriate tools, and knowing how to apply these tools will give the best chance of predicting extreme events and issuing timely warnings.

Plastic Pollution and Climate Change: Role of Bioremediation as a Tool to Achieving Sustainability

57

S. A. Idowu, D. J. Arotupin, and S. O. Oladejo

Contents

Abstract

Pollution from post-consumer plastics is a growing global environmental challenge whose negative impacts are exacerbating climate change. Plastics are stable, durable, and hydrophobic. They possess high molecular weight, complex three-dimensional structure, and are not readily available to be used as substrate by biological agents such as microorganisms and enzymes. Polyethylene terephthalate (PET) is one of the examples of petrochemical-based plastics. PET is a strong, clear, and light-weight plastic with global usage in the production of bottles.

https://doi.org/10.1007/978-3-030-45106-6_102

Technological innovation, policy formulation, advocacy and sensitization, change in consumption pattern, and bioremediation are some of the approaches that are currently being used to mitigate environmental pollution from post-consumer PET bottles. The ubiquitous property of microorganisms and their ability to survive in almost every environment, including very extreme ones, make them good candidate for biodegradation. Bioremediation is simply defined as engineered or enhanced biodegradation. This review discusses the potential of bioremediation as sustainable and environment-friendly tool to clean up post-consumer PET bottles that already accumulate on land, in soil, and in water bodies.

Keywords

Bioremediation · Plastic · Pollution · Climate change · Biodegradation

Introduction

Plastic is a group of substances with wide global usages and applications as a consumer product. Plastic possesses characteristic cheap price, light weight, and disposable nature which make them the substance of choice in the manufacturing industry. However, plastic pollution is a growing global environmental challenge to aquatic, celestial, and terrestrial organisms including man. The current increasing global human population and technological developments are among the major factors contributing to increasing significant snowballing quantity of plastic waste that is generated annually. This increase exacerbates environmental pollution due to unsustainable methods of disposal of post-consumer (or used) plastics. Accumulation of post-consumer plastics on the surface of the earth including those that are buried in the earth is a serious threat to environmental safety and human health. In general, plastics possess characteristic stable, durable, and hydrophobic nature. They possess high molecular weight, complex three-dimensional structure, and are not readily available to be used as a substrate by many biological agents such as microorganisms and enzymes (Arutchelvi et al. 2008; Kale et al. 2015). As a result of the above, plastics accumulate over a very long period of time. (Kenny et al. 2008) reported that an efficient decomposition of plastic takes about 1,000 years.

Polyethylene Terephthalate (PET): A Typical Plastic

Polyethylene terephthalate (PET) is one of the examples of petrochemical-based plastics. PET is a thermoplastic polyester (Hosseini et al. 2005). It is a strong, clear, and light weight plastic with global usage in the production of bottles. The PET bottles are used for packaging drinks, other food products, and pharmaceuticals. In the field of engineering, PET is being used as alternative or replacement for metals like aluminum, steel, and other metals in the manufacture of precision moldings for office appliances, domestic appliances, and electrical and electronic devices (Hosseini et al. 2005; Tanasupawat et al. 2016; Yoshida et al. 2016). Polyethylene

Fig. 1 Typical example of a bottle made from polyethylene terephthalate (PET). (Source: https://www.shutterstock.com/image-photo/top-view-empty-plastic-bottle-isolated-572688928)

terephthalate is a polyester (polymer) produced by polymerization reaction. The reaction involves two monomers, namely terephthalic acid (TPA) and ethylene glycol (EG) according to (Kale et al. 2015). A typical example of bottle made of PET is presented in Fig. 1 below.

The presence of aromatic groups in the PET molecule makes PET nondegradable under normal condition according to the report of (Hosseini et al. 2005). The biological degradation of PET was thought to be limited to only a few fungal species and as a result biodegradation was earlier considered as not yet a remediation strategy for PET (Tanasupawat et al. 2016).

Plastic Waste and Environmental Pollution

The traditional methods (such as burning in the open field) used to dispose of post-consumer plastics, especially in developing countries, is a global environmental concern. Smoke, containing dioxins, furans, mercury, and polychlorinated biphenyls which are injurious to health and the environment, is released into the atmosphere during open burning of plastics, thereby leading to air pollution which consequently contributes to climate change (Webb et al. 2013). In addition, most post-consumer PET bottles end up in landfills where they persist and occupy huge land space, thereby impairing soil fertility with subsequent negative impact on agricultural practice (Chan 2016; Kale et al. 2015). Some post-consumer PET bottles are burnt in open fire during which they release carbon dioxide (CO_2) and dioxins into the atmosphere, also exacerbating environmental pollution and climate change (Kenny et al. 2008; Tanasupawat et al. 2016). Increasing efforts are being made globally to address environmental pollution from PET wastes. Other toxic and hazardous pollutants from plastic wastes are highlighted in the report of (Webb et al. 2013).

Measures and approaches that are currently being used to mitigate plastic pollution include the following:

- Technological innovations (e.g., bioplastics)
- Policies (e.g., ban of single-use plastics and green shopping)
- Change in consumption pattern and different "Rs" including r*eduction, reuse,* and *recycling* of post-consumer plastics
- Advocacy/sensitization (e.g., The 2018 World Environment Day with the theme "*Plastic Pollution"*).
- Bioremediation (Gnanavel et al. 2012; Hadad et al. 2005; Hosseini et al. 2005; Ron and Eugene 2014; Sardrood et al. 2013; Yoshida et al. 2016)

It is practically impossible to totally eradicate the use of plastics for domestic and industrial uses, neither is it possible not to generate post-consumer plastics due to vast properties of plastics that make them suitable for various domestic and industrial uses. This therefore means that wastes from post-consumer plastics will be generated continually as long as man exists on earth. This waste is projected to increase with the increasing global human population.

Several approaches have been identified to mitigate environmental pollution from post-consumer plastics. However, two of the approaches are majorly relevant to this discourse. The first is a total removal of PET bottles which constitute environmental nuisance. This can be achieved through sustainable clearing of PET bottles that have been used and dumped, mostly in indiscriminate manner, from the surface of the earth or from water bodies. The second approach is replacing plastics of non-biological origin with plastics that are made from biological agents. The latter are commonly referred to as bioplastics. Bioplastics are produced or synthesized from biomass or renewable resources according to the report of (Sardrood et al. 2013). They have been identified to be more readily available for bioremediation than nonbioplastics, thereby preventing accumulation on the environment for a very long period of time. Technology is involved in the production of bioplastics to harness the biomass and other raw materials that are employed in the production. This special type of technological process that involves biological agent is called biotechnology (Sardrood et al. 2013). Detailed discussion of types of biotechnology and the processes involved in each of the types are beyond the scope of this chapter.

Technological advancements and scientific researches toward development and improvement on bioplastics are growing globally. This biotechnology will help to produce plastics that will be readily available for easy degradation by microorganisms, thereby proving solution to environmental and climatic problems that are associated with accumulation of post-consumer plastics. As this biotechnology develops to gain worldwide popularity and acceptance to displace nonbioplastics in circulation, it is important to provide suitable sustainable approach to get rid of post-consumer plastics, particularly PET bottles that are already exacerbating environmental pollution and climate change. A biological approach will be appropriate for this remediation as it is usually environment friendly (Gnanavel et al. 2012; Hosseini et al. 2005). The interesting ability of microorganisms to survive in almost every environment including very extreme ones together with their ubiquitous property makes them a good candidate for bioremediation. Bioremediation is a form of biotechnology which involves engineering. This essence of engineering the process is to enhance the capacity of the microorganisms being used and to make the process faster (Borasiya and Shah 2007; Hadad et al. 2005).

Climate Change

Climate change (natural and human induced) is real. Industrialization and human desire for development and better living, which are carried out sometime in an unsustainable way, affect the environment and natural resources negatively, thereby exacerbating climate change. The realization of this challenge by the General Assembly of the United Nations gave birth to establishment of Brundtland Commission. The Commission in their report tagged *Our Common Future* and submitted to the UN General Assembly in 1987, and identified that both environment and development are inseparable, nevertheless sustainable development must be encouraged in every human development as a means of saving the earth. This development, described popularly as sustainable development, embraces and encourages development that equally promotes economy, social, and environmental developments without prejudice to any of the three members (Burton 1987). Any development whose economic, environmental, and social benefits are not equally addressed is unsustainable and this was part of the recommendation of the commission. Unsustainable consumption of PET bottles is a potential economic, social, and environmental problem that can increase climate change.

Bioremediation

According to (Baggot 1993; Boopathy 2000) in (Sardrood et al. 2013), bioremediation is a process of using living organisms or biological processes to clean up contaminated environments by exploiting and harnessing metabolic abilities of microorganisms to convert contaminants into harmless products by mineralization, generation of carbon (IV) oxide and water, or by conversion into microbial biomass. Bioremediation as evolving environmental biotechnology uses microorganisms in the degradation process and can be optimized to achieve better result (Borasiya and Shah 2007). Some of the numerous applications of bioremediation include cleanup of ground water, sludges, lagoons, and process-waste stream (Boopathy 2000). Practically, bioremediation has been used on a large-scale application in cleanup of oil spill from Exxon in Prince William Sound, Alaska (Kenny et al. 2008). Some of the advantages of bioremediation have been reported (Boopathy 2000; Sardrood et al. 2013).

Microorganisms have the ability to break the molecular chains in polymers like the PET through degradation. Degradation is one of the many processes involved in bioremediation (Sardrood et al. 2013), this means that a biodegradation activity may not result into total bioremediation. The break in molecular chains during biodegradation leads to decrease in the total length of macromolecules that make the polymer and the degree of polymerization (Fig. 3) as contained in the report of (Hosseini et al. 2005).

In Situ and Ex Situ Bioremediation

One of the advantages of bioremediation in management and treatment of wastes is that the process can be carried out at site of contamination or somewhere away from site of contamination. Based on the above, bioremediation can be classified as in situ bioremediation and ex situ bioremediation. The former involves treatment of the contaminated material within the site where contamination or pollution has occurred, while ex situ technique of bioremediation involves physical removal of the contaminant or pollutant from the site of pollution for treatment (Boopathy 2000). In situ bioremediation is usually used in cleanup of oil spills. However, in treating pollutants such as post-consumer PET bottles, ex situ bioremediation may be used.

Organisms Involved in Bioremediation

Bioremediation involves the use of microorganisms in the remediation process. Pollution from post-consumer plastics can be noticed in the air, on land, and in water bodies such as sea and oceans. The natural ability of microorganisms to degrade hydrocarbons, though at a relatively slow rate, makes them suitable candidates for bioremediation. What scientists do is to simply optimize and harness the natural potential of such microorganisms through biotechnology. (Ron and Eugene 2014; Sardrood et al. 2013) highlight how certain species of microorganisms were used to clean oil spills. Several species of fungi, bacteria, and plants are major organisms that have been identified and reported to be involved in bioremediation. There are specific conditions that enhance bioremediation. The conditions must be provided in order for bioremediation process to proceed as planned and expected. According to (Kenny et al. 2008; Ron and Eugene 2014), these favorable conditions include the following:

1. The organism shall be able to live and demonstrate its bioactivity under conditions of pollution
2. A consortium of microorganism that can successfully utilize the pollutant as a substrate must be present
3. Contaminant and the enzymatic system must come in close contact somewhere in or out of the cell
4. The organisms will have the effective enzymes that are important in bioremediation
5. Appropriate favorable environmental conditions must exist or be provided to enhance multiplication of the potential organism to be used for bioremediation

(Boopathy 2000) summarized the key conditions that affect bioremediation as microbial and environmental substrate, aerobic and anaerobic process, growth substrate and co-metabolism physico-chemical bioavailability of pollutants, and mass transfer limitations.

Bioremediation of Polyethylene Terephthalate (PET)

The discovery of the bacterium *Ideonellasakaiensis* 206-F6^T signified another scientific development in bioremediation of PET. The discovery presented *I. sakaiensis* as one of the many microorganisms whose potentials can be harnessed to remediate environmental pollution from post-consumer PET bottles that are disposed indiscriminately. The fungus *Pseudozymajejuensis* isolated from leaves of *Citrus unshiu* in South Korea earlier before the isolation of *I. sakaiensis*, has also been demonstrated to possess remarkable plastic-degrading potential as reported by (Tanasupawat et al. 2016). The fungus possesses the enzyme cutinase which has the ability to degrade some plastics according to (Tanasupawat et al. 2016). Despite the plastic-degrading potential of *P. jejuensis,* the organisms were not reported to degrade PET. This development clearly indicates the need to isolate specific microorganisms that are suitable to degrade each of the large groups of plastics that constitute environmental pollution. This necessitated the need for more scientific researches to isolate microorganisms that posses the ability to utilize PET as their source of carbon. The bacterium, *I. sakaiensis,* is important in bioremediation of post-consumer PET bottles that constitute environmental pollution (Yoshida et al. 2016). According to the report of (Tokiwa et al. 2009; Yoshida et al. 2016), the bacterium showed high PET-degrading potential when compared with previously isolated microorganisms. The authors highlighted factors that favor the bioremediation process in order to achieve optimum result (Fig. 2).

Reports of (Webb et al. 2013; Yoshida et al. 2016) explained that *I. sakaiensis* 206-F6^T possesses critical enzymes that are needed in the degradation of PET. The enzymes include PETase and MHETase. *I. sakaiensis* 206-F6^T uses the two

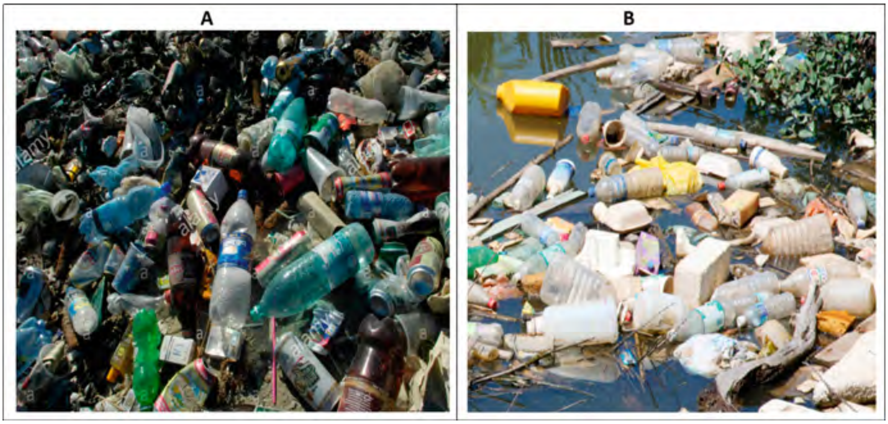

Fig. 2 Images of plastic pollution on both terrestrial and aquatic environment. (**a**) Dump site showing plastic pollution. Fig. 3 Schematic degradation of PET bottle by *I.sakaiensis*strain 206-F6^T. (Source: (Chan 2016))

enzymes to metabolize PET as its major carbon source (Fig. 3). PETase is a type of esterase and it initiates breaking of the long ester bonds in PET through hydrolytic activity. Esterase is an enzyme that has the ability to break ester bond in a compound. The hydrolytic activity PETase produces an intermediate called mono(2-hydroxyethyl) terephthalic acid (MHET) as presented in Fig. 3 below. The intermediate that results from the hydrolytic breakdown is taken back by the cell of *I. sakaiensis* 206-F6^T and is further hydrolyzed by the second enzyme MHETase. The responsibility of MHETase in the degradation process is to break the intermediate into the monomers of PET (Caruso 2015; Tokiwa et al. 2009; Yoshida et al. 2016). The two monomers are named Terephthalic acid (TPA) and ethylene glycol (EG). The report of (Chan 2016) showed that *I. sakaiensis* 206-F6^T damaged PET film extensively and almost completely degraded the film after 6 weeks at temperature of 30 °C.

In natural environments, PET bottles, like other plastics, are exposed to UV radiation. The radiation causes cleavage of the C—C bond of the polymer, thereby leading to the formation of low molecular weight fragments. This process increases the susceptibility of the polymer to microbial attack (Arutchelvi et al. 2008). This may be one of the reasons why (Yoshida et al. 2016) used low-crystalline (1.9%) PET film in their study as free-flying plastic bottles in nature may be of a higher crystalline percentage than the ones used by the authors in their research.

Conclusion

The above discourse shows that there are several options to reducing environmental pollution from post-consumer plastics in general and PET bottles in specific. However, bioremediation still stands tall as an important evolving option for sustainable remediation of post-consumer plastics. Other approaches such as discouraging unsustainable consumption of plastics and formulation and implementation of research-informed policies also need to be encouraged as a mean to reducing environmental pollution from plastics.

Microorganisms have the natural potential to use petroleum products including plastics as their sources of carbon and energy, thereby helping to reduce the menace of plastic pollution within the environment and subsequently mitigating climate change. The natural potential of microorganisms can be engineered and optimized through biotechnology as the sustainable way to "clean up" plastic pollution that threatens life on land, water, and air.

It is recommended that in order to further contribute to knowledge on harnessing the potential of microorganisms isolated from PET bottle recycling sites to degrade PET bottles, there is the need to test such microbial isolates with PET film of high crystalline value and be sure that the microorganisms can sufficiently hydrolyze the film. This is to ensure wider global acceptability of the technology because the PET bottles that are used to package food, drinks, and pharmaceutical products are made from high crystalline PET.

Abstract

A top-bottom approach where local problems are treated in isolation has proven ineffective in achieving sustainable development. The need for inclusive approaches to managing the demand for arable lands, forest resources, and the problems of resource exploitation and climate change calls for local understanding of these elements' interrelationship. Understanding the interrelationships among climate change, agriculture, and the ecosystems in different agroecological zones in Nigeria was the purpose of this chapter. Deforestation and forest degradation analysis approach was utilized. One state and two forest communities from each of the rainforest, savannah, and mangrove agroecological zones were purposively focused in this chapter based on forest distribution and cover. Focus group discussions involving 252 male and female farmers using 30 years as reference were used to garner relevant information. Climate variation caused a slight modification in cropping schedules of farmers due to prolonged dry season, mainly in the savannah region. Farmers engaged in mixed farming and also cultivate more hardy crops like cassava in response to climate uncertainties. Especially in the mangrove and savannah, ecosystem components such as agriculture and population showed increasing trends over the years as forest cover reduces. Downward trend in charcoal production was limited to mangrove and rainforest zones as fishing and hunting becomes vulnerable livelihoods across the zones. The degree and progression of climate change effects on the ecosystem in Nigeria agroecological zones is largely comparable and have both desirable and adverse livelihood outcomes. Affordable insurance policy, credit, agri-inputs, favorable forest regulatory framework, and youth empowerment supports would enhance sustainable adjustment to climate change.

Introduction

Nigeria is seriously threatened by climate change with a significant proportion of its terrestrial ecosystem on dry land mass which is frequently affected by desertification, sheet erosion, and droughts. The coastal and mangrove agroecological zones in the south are also prone to incessant flooding because of their proximity to the Atlantic Ocean, riverine nature of the setting, the very low altitude, and all-year-round and high volume of rainfall. In recent times, variations in climatic conditions have resulted in undesirable effects on food production and nutritional security. Unfortunately, the country has very weak adaptive strategies and capacity to mitigate the effects of a changing climate. Presently, the impacts of rising temperatures and rainfall variability on farming are being felt across major agroecological zones in Nigeria (Ayanlade et al. 2018).

Agricultural systems are dependent on ecosystem services such as nutrient cycling, pollination, soil fertility, hydrological balances, and biological pest control which ensure a balance in the ecosystem (Power 2010). However, agricultural intensification in the last century has distorted the ecosystem equilibrium and led to loss of ecological integrity, land degradation, and loss of environmental services provided by the ecosystems. These conditions are further worsened due to increasing effects of climate instability (Pretty et al. 2011). For instance, environmental problems such as groundwater depletion, variability in the onset and amounts of rainfall, increase in concentration of greenhouse gases, soil degradation, depletion of pollinators' habitat, which all have negative consequences on sustainable agriculture, are climate change-induced.

Forest communities, which are highly vulnerable to these adverse effects, are occupied by low-income earners who depend on the ecosystem for their income, food, nutritional security, and livelihoods. Hence, these rural populations will be seriously affected by climate change, with little or no resources to adapt or mitigate its effects. It has been reported that the livelihoods of these communities are made vulnerable by land use variation such as continuous grazing and monoculture plantation. For example, in coastal and mangrove regions, there is a shortage of food resources obtained from streams coupled and agricultural instability due to increased flooding (Ward et al. 2016). Similarly, savannah and rainforest agroecosystems are recording a decline in agricultural production outputs (Ayanlade et al. 2018).

Natural resource utilization forms the base of most livelihoods in developing countries including Nigeria. However, forest resources are gradually being depleted due to the pressures of degradation and deforestation, poverty, urbanization, and poor management (Azeez et al. 2010; Saka et al. 2013). In Nigeria and most parts of Africa, shifting cultivation among small-holder farmers results in large-scale habitat destruction (Cooper et al. 2008). For instance, over 75% of the Nigerian population still lives in rural areas with vast areas of forest vegetation and depend on extensive rain-fed farming as well as short fallows for their sustenance. However, this dependence is limited by loss of forest biodiversity, climate change, and exposure of fragile soils (Azeez et al. 2010).

Frequent changes in climate parameters affect the livelihoods of rural populations and poses challenges to food security, survival, and economic development (Tompkins and Adger 2004). For instance, savannah and tropical forest zones have experienced a dramatic decrease in annual rainfall and an increase in the length of dry season and rainfall variability (Malhi and Wright 2004; Veenendaal and Swaine 1998). It is therefore pertinent to investigate the forest-dependent communities' responses to the hazards posed by climate uncertainties on their environment and livelihoods (Lindner and Pretzsch 2013), as this will have important implications for sustainable development in the near future.

The capability of farming communities and agricultural stakeholders to manage the challenges and prospects of present climatic patterns must primarily be improved in order to enhance their adaptive capacity and reduce their exposure to the undesired effects of changing climatic conditions (Cooper et al. 2008; Tompkins and Adger 2004). The challenges are complex and call for integrative learning-oriented approaches that emerge from the bottom-up that will enable successful mitigation and adaptation. These approaches offer pathways for vulnerable communities to engage in developing response policies and ensure that there is room for change in those policies (Lindner and Pretzsch 2013).

Adaptive management is a cyclic, multiple stakeholder learning-oriented approach to the management of complex environmental problems such as climate change. The introduction of such approaches would encourage multi-stakeholder participation and the integration of all sectors in decision-making, policy formulation, and implementation (Stringer et al. 2006). Unfortunately, most policy implementers adopt a top-bottom approach where local problems are treated in isolation, and this method has proven to be ineffective in yielding or sustaining solutions. Therefore, the need for all-encompassing approaches to manage the demand for arable lands, forest resources, and the problems arising from resource exploitation and climate change (Lindner and Pretzsch 2013; Tompkins and Adger 2004). A step towards achieving this is to understand that the poor and vulnerable themselves are key actors in identifying important areas of their own livelihoods and solutions to their challenges.

For instance, rural communities have in times past developed indigenous technologies which have assisted in mitigating the risks associated with climate variability. These technologies are represented in local customs, traditions, and heritages, constituting a testimony of how societies have thrived well in various environments (Azeez et al. 2010; Vidaurre de la Riva et al. 2013). Therefore, research needs to integrate climate change impacts with sustainable agriculture in a stressed ecosystem. Such information will bridge the knowledge gap and assist planning for adapting and mitigating climate change. Therefore, this chapter explains how agriculture, climate change, and the ecosystems interrelate among themselves in the main agroecological zones of Nigeria. Specifically, this chapter discussed the effects of the changing climate on farming calendar and local adaptation measures employed, the trend in primary drivers of social vulnerability to climate variability, the drivers of vulnerability to climate variation as perceived by farmers, health and environmental effects of climate instability on forest communities in Nigeria, and forest inhabitants needs in services and or facilities for an effective adjustment to climate change.

Forest Livelihoods and the Challenge of Changing Climate

Forests are mainly situated in rural areas and/or frequently isolated areas (Aruwajoye and Ajibefun 2013). Apparently, such areas are in close harmony with nature with little development in terms of infrastructure (roads, potable water supply, markets, health facilities, and schools), government services, and jobs. Thus, it is not surprising that communities living in the fringe of these forests have limited livelihood opportunities and options (Wunder 2005). As a corollary to this, Bassey and Obong (2008) and Nayak et al. (2012) assert that communities around forest fringe are low-income earners who sought to build their economic capacity by engaging in the livelihood options provided by the forest.

In Nigeria, more than 90% of the rural populace depend on forests for their livelihood (Ayuk et al. 2011; Fadairo et al. 2017). These livelihood activities offered by forests include hunting of animals, forest-based farming, timber logging, gathering of building materials, collection of fuel wood for cooking or charcoal production, materials for local craft, fodder (grasses and leaves for livestock and grazing of livestock), medicinal plants, and non-timber forest products which include honey, leaves, and fruits. Suffice it to say that these forest products derived from the various livelihood activities are not solely for household consumption but also for commercial purposes.

Studies have documented the benefits accruing from forest resources in the livelihood activities of those inhabiting the fringes of forests as substantial (Levang et al. 2005; Sunderlin et al. 2005). These benefits according to Warner (2000) are increased income, improved food security, reduced vulnerability by providing safety nets, and increased well-being. Furthermore, some of these livelihood activities have social, religious, and cultural dimensions. For instance, hunting may serve as a cultural event for initiation into manhood while fishing maybe a social or cultural event. In addition to this, Shackleton (2004) opine that forests provide sites for spiritual healing and religious practices. Hence, it is not uncommon to find sacred places, herbalists, and native doctors in forest communities.

Agriculture as an important livelihood activity in most forest communities is affected by climate change in several ways, namely, changes in rainfall, standard temperatures, and climate extremes (heat weaves). Climate change influences planting and cropping conditions which in turn affects the supply of food. It necessitates changes in farming methods, increases soil pressure, reduces water supply to the root system, and increases farmers reliance on agrochemicals for farming. In addition, crops stressed as a result of climate changes become more susceptible to damage from diseases and pests. Animal husbandry industry is also indirectly affected following climate-induced changes in the availability of grains, pasture, and forages and its accustomed price increase. Animals health are usually affected negatively by extreme heat (Enete 2014). Furthermore, peasant and small-holder farmers who produce the bulk of food consumed in most developing countries are usually vulnerable to climate uncertainties due to their small size of farms, poor technology, and little working capital (Morton 2007). In addition, the seasonal calendar which provides information on planting, sowing, and harvestings periods of locally adopted crops in specific agroecological zones (Fadairo et al. 2019) is distorted by climate variability, predisposing farmers to risks arising from weather uncertainties.

Agriculture, Climate Change, and Food Security

The occurrence of climate change is interlinked with the performance of agriculture and attainment of food security. Agricultural production in most parts of Africa including Nigeria has been seriously affected by environmental degradation caused by climate change, making a case for serious intervention (Osuafor and Nnorom 2014). The current global climatic condition has both natural and man-made causes. The reliance on rain-fed agriculture by most African countries both as a source of income and consumption has resulted in their high vulnerability to climate change. Some of the devastating effects includes: erosion, flooding, drought, pests and diseases, desertification, gas emissions, fluctuation in rainfall patterns, and a host of others. These factors in turn impact on agriculture and consequently threaten food security. As a result, food security is at risk with a daily world population increase. In order to forestall the danger ahead, the United Nations has clearly set the targets of attaining food surplus, food security, and improved nutrition, and advancing sustainable agriculture as number two among its 17 Sustainable Development Goals (SDGs) for the year 2030.

According to Food and Agriculture Organization (2002) as cited by Coates (2013), food security exists when all individuals, at every time, have socioeconomic and physical access to adequate, nutritious, and safe food that meets their dietary requirements and food preferences for a healthy and productive life. Therefore, food security goes beyond having adequate supply of food but also include issues relating to the food safety and hygiene. For instance, use of chemicals such as fertilizer in planting or produce preservation as a response to climate fluctuation predisposes the population to poor health. This assertion is in line with Kinsey (2005) who opined that a nation is not regarded as food-secure just because food is available in the right quantity needed by its populace, but also when the food consumption does not predispose the people to any health hazard. In order to reduce the impacts of climate change on agriculture, various coping strategies have been put in place. Osuafor and Nnorom (2014) highlighted the strategies as including controlling greenhouse gases emission; preventing deforestation; planting climate-smart, disease-tolerant, and high yield crops; and adjustment of planting calendars by farmers.

Climate Change and Drivers of Social Vulnerability in Nigeria

In recent times, the variation in climate such as rise in temperature, increase in rainfall causing flood, delayed and inconsistent rainfall causing drought, strong wind, and landslides have threatened both the natural systems and the human society, specifically causing internal displacement of persons, destruction of lives, properties, and livelihood, food insecurity, disease outbreak, violence arising from struggle over resources, and increased suffering and penury. Yet, the impact caused by these climate extremes is not uniformly distributed among and within groups of people in the same country, state, and/or community (Petkova et al. 2015). Thus, it is unlikely for the impact of climate extremes to felt in the same way. Some groups or individual are likely to be more vulnerable than others. This underscores the need for researches to continually explore comparative analysis of climate change impacts across environmental, social, economic, and political factors in order to engender sustainable solutions.

In the views of Petkova et al. (2015), climate change effects will vary among age groups, sex, socioeconomic status, health condition, geographical location, and nature of livelihoods of the people. A measure of the extent of exposure of groups or individuals to stress as a result of the impacts of climate change extremes is known as social vulnerability. In this chapter, livelihood of the forest-edge communities in Nigeria is singled out among others for discussing the effects of vulnerability to climate change. Hence, stress in this perspective refers to the interference of the livelihood activities of groups or individuals in the face of climate extremes.

Evidence abounds that the people who are likely to be more susceptible to the adverse effects of climate extremes are people in the rural areas. Rural Nigeria is mainly agrarian with many of them living below the poverty line. Research reveals that rural communities are inexplicably vulnerable to climate extremes because their livelihoods are dependent on climate-sensitive activities (agriculture, forestry, fishing, recreation) in their rural environment (Fisher et al. 2013). Therefore, the effect of climate extremes poses a huge threat especially to the agrarian rural people many of whom already live below the poverty line.

Theoretical Framework

The Sustainable Livelihood Framework, as presented below, was considered relevant for underpinning the assumptions and approach utilized in this chapter.

Sustainable Livelihood Framework

Sustainable livelihood (SL) framework presents a tool for development workers to understand, analyze, and explain the real factors that affecting poor people's livelihood (Petersen and Pedersen 2010). According to Carloni and Crowley (2005), a livelihood comprises the assets (including both social and material endowments), capabilities, and activities necessary to earn a living. Ability to manage and recover from shocks and stresses, retain or enhance its assets and capabilities, while not depleting the natural resource base is what makes a livelihood sustainable. SL framework addresses the creation of guaranteed livelihoods for the poor by development workers. The basic principle of SL is that development work ought to focus on the people, with considerations of, what matters for the poor, cultural diversity, and its effects on livelihood processes. Secondly, poor people themselves are major actors in bringing about the change they desire. This is because they have a better knowledge of issues affecting them much more than any external person (Petersen and Pedersen 2010). The foregoing reechos the central argument in this chapter that adequate understanding of the perspectives of the local people whose livelihoods are

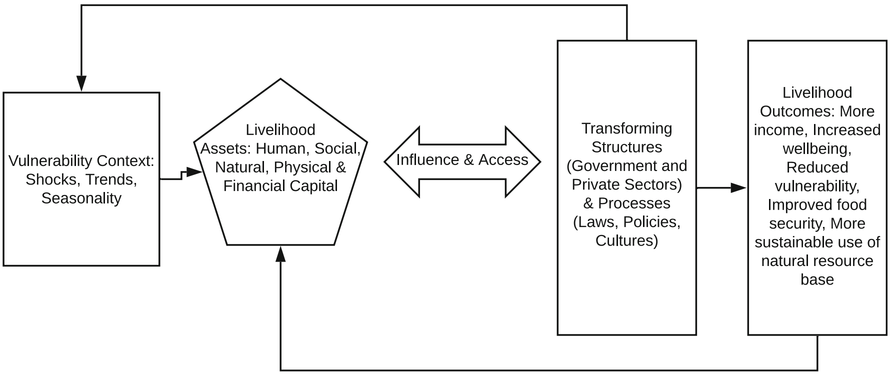

Fig. 1 Sustainable Livelihood Framework. (Source: DFID (2000), cited in Petersen and Pedersen (2010))

intertwined with and affected by climate variability is important for a more sustainable adaptation and mitigation measures for climate change. Hence, primary information used for discussion in this chapter were derived from engagement with those who are most affected in order to acquire their perspectives of their problems and what things to change to improve their condition. The key components of the SL framework are indicated in Fig. 1, and they include vulnerability context, livelihood assets, structure and process for transformation, livelihood strategies, and livelihood outcome.

Vulnerability context: This refers to people's external environment. It includes occurrences for which people have restricted or no control. Examples of such occurrences are critical trends of economic inflation, natural disasters, shocks, and seasonality, among others. The issue of vulnerability thus emerges when individuals are exposed to harmful threats they are not well equipped to confront (Petersen and Pedersen 2010).

Livelihood assets: Since the framework by nature focuses on the people, it thus seeks to have a better consideration of the people's power (capitals or assets). Since the approach relies on the belief that achieving livelihood outcomes requires a combination of assets, understanding how the conversion of the people's power to favorable livelihood outcomes becomes paramount. For this reason, the framework identifies five forms of capitals which support livelihoods. These are social, human, natural, financial, and physical capitals (Petersen and Pedersen 2010).

Structure and process for transformation: This refers to the establishments and regulations found from the household to the international levels that defines the livelihoods of the poor. These establishments and regulations stimulate how people access the various types of assets. Ownership rights and laws to secure individual rights are examples of processes, whereas structures are things like existence of ministries, banks with credit facilities for support groups and farmers (Petersen and Pedersen 2010).

Livelihood strategies: This refer to the way in which people organize towards achieving their anticipated livelihood and access to diverse types of resources determine the approaches to be employed. Furthermore, societal opportunities or constraints can be dictated by its structures and processes.

Finally, **livelihood outcome** refers to the resultant effect of livelihood strategies assumed by the people. These effects could be better income, enhanced wellness, decreased susceptibility, and food security, among others (Petersen and Pedersen 2010).

Chapter Approach

This chapter utilized synthesis of literature and collection of primary data to reach its conclusions. The field activities for primary information garnering were carried out in Nigeria. Nigeria's ecological environment consists of seven agroecological zones such as saltwater swamp, freshwater swamp, Sudan savannah, guinea savannah, Sahel savannah, tropical rainforest, and the montane zones. However, discussions in this chapter are mainly focused on its three broadly classified agroecological zones namely savannah, mangrove/swamp, and rainforest. Each of these agroecological zones has their own peculiarities and supports a wide range of plant and animal species. Nevertheless, the tropical rainforest has been adjudged the richest. All adult residents in forest communities who are engaged in farming and or other forest-based livelihood activities were engaged in discussions. Adults who were 45 years and above at the time of the field work were specifically targeted due to the 30 years reference period used in this chapter. A two-stage sampling procedure was used. First, from each of the three major agroecological zones, one state was purposively sampled based on distribution and extent of forest cover. Second, two forest communities in each sampled state were selected purposively based on intensification of climate variability in the past 15 years. Thus, six forest communities namely Iyamitet, Ikom Agoi (Cross River State), Wawa-Gbere, Emi-Hakimi Mokwa (Niger State), Osoku, and Fowowa (Ogun State) were sampled for primary information garnering (Fig. 2). In each of the sampled locations, a short survey was carried out to generate a pool of potential participants for focus group discussions as follows:

> Would you be willing to participate in a focus group discussion regarding climate change, rural livelihoods and other related issues? The discussion would take about 2-3 hours on .... (date) and you would be incentivised for participation. The discussion will be audiotaped for the purposes of review by the researchers.
>
> Yes [ ] No [ ]. Name................ Phone no. ....
>
> Age......................

Given the size of potential participants generated, four focus group discussions comprising 10–12 members per group were held in each forest community. Thus, qualitative data were collected from 24 focus group discussions held with 252 male and female farmers in selected sites. Deforestation and Forest Degradation Analysis adapted

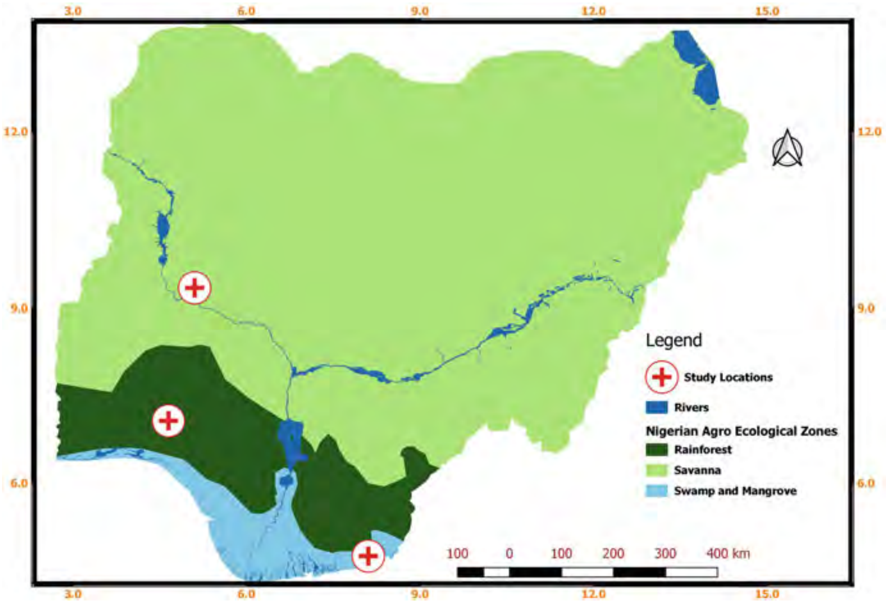

Fig. 2 Map showing the focus group discussion locations within the agroecological zones of Nigeria

from Tiani et al. (2015) was used in this chapter. Using a discussion guide and 30 years as reference, primary information was sought on effects of climate change on farming calendar, trends in primary drivers of social vulnerability to climate change, causes and consequences of environmental degradation in forest communities, and communities needs in services and/or facilities for an effective adaptation.

A visual representation showing seasonal activities among community members on a flip chart was used to facilitate conversation on how climate change affects farming calendar. Discussants indicated their cropping pattern in a calendar year, the associated activities, and why the activities are conducted in order to provide information on farmers' local climate change adaptation measures. Also, participants during the discussions used pebbles (stones) to proportionately represent areas covered by each ecosystem components (population, agriculture, forest cover, hunting, and charcoal production) as perceived over the past 30-year period (Figs. 3, 4, 5, and 6). The outcome of this exercise was represented in a single table to indicate the trend as perceived by the discussants. Influence of climate change on local livelihood activities were captured by asking participants to award scores to represent magnitude and impact of each climate parameter on available livelihood activities. Problem tree analysis and paired needs ranking participatory tools were used to investigate health and environmental impacts of unstable climate on forest communities and communities needs in services and or facilities for an effective adaptation to climate change, respectively.

During the discussions, audiotape recording, flip chart, and handwritten notes were taken by researchers and were later transcribed. Primary information collected

Fig. 3 Male participants during focus group discussion at Mokwa, Niger State on March 9, 2018

were coded and analyzed based on thematic patterns in the participants responses to issues raised in the focus group discussions. In doing this, particular attention was paid to important quotes from some of the respondents. Some of these quotes are used as evidences to support discussions in this chapter.

Limitations however exist in the approach used in this chapter due to language barrier experienced in some of the field locations as we observed that some respondents could not communicate well in the English language. Therefore, the researchers relied on translators to interpret the questions to the respondents and participants' responses back to the researchers. Some content and meaning may have been lost in this process. Also, due to the problems of insurgency, farmer-herdsmen conflict, and other security issues, most states within the savanna agroecological zone were deliberately excluded from the focus group discussions.

Effects of Climate Variability on Cropping Calendar in Mangrove, Rainforest, and Savannah Agroecological Zones of Nigeria

Farm households' ability to grow enough food to feed themselves and their animals is determined to a large extent by the weather since agricultural production depends on climate variables, such as temperature, precipitation, and light. Therefore,

Fig. 4 Male participants during focus group discussions at Iyamitet, Cross River on 14 February, 2018

Fig. 6 Female participants at FGD on April 11, 2018 at Osoku

shifts in temperature and precipitation are important parameters for farming communities in the timely operations of farm operations. Table 1 shows the activities done in relation to the major crops produced by each of the ecological zones. Yam, cocoa, and maize were focal crops in the mangrove, rainforest, and savannah zones, respectively. Within the mangrove ecological zone, the major activity between January and May was land preparation, with dry and wet seasons being observed in March 30 years ago. Currently, there is a little shift, as dry and wet seasons are now being observed in April. It was clear that there is a relatively longer dry season now compared to what it was 30 years ago as wet season was fully experienced from April to September, lasting a period of 6 months. In the recent times, however, the wet season now occur in May to August, lasting only 4 months. This trend is similar to what is observed in the rainforest and savannah zones with extended dry season compared with the referenced 30 years ago. This shows a drop in the duration of rainfall across the three agroecological zones. This change in climatic trend is in line with the position of Appiah et al. (2018) that there is a decrease in the intensity of rain in most forest reserves communities of most sub-Saharan African countries where there is still heavy reliance on agriculture as primary means of livelihood. This change has implications for agriculture in Nigeria which is known to be mainly rain-fed.

Further, two of the participants at focus group discussions gave explicit distinctions of the season and farming activities between 30 years ago and now as thus:

Table 1 Seasonal and cropping calendar for major crops in mangrove, rainforest, and savanna ecological zones of Nigeria

D =Dry, W = Wet, D/W =Dry & Wet

> Thirty years ago, we experienced little rainfall in the month of March and then the rains become fully established in April and then fade away in September. Presently, we experience little rainfall in the month of February which become fully established in April and then fades out in October.
>
> Land clearing of farmland in our area has shifted from January/February to March. This happens because onset of rain has shifted to April, currently any rain we see in February/March is tagged accidental rain.
>
> Another discussant also said:
>
> 'Compared to thirty years ago, there is reduced intensity and duration of rainfall' (A 50-year-old man, Muslim, farmer, savannah zone).

Access to food through both production and exchange will continue to depend not only on the productivity and profitability of agriculture, but also on how well the political climate enables people to respond creatively to their environment and prospects. As a means of adapting to the extended dry spell, farmers have adopted the cultivation more hardy crops such as cassava to reduce economic losses associated with climate change. Diversification into trading and processing of agricultural produce also take place during the off seasons to bridge income gap that is now experienced. This corroborates the assertion of Appiah et al. (2018) which argues that farmers in forest communities are often engaged in other economic activities to supplement their agriculture-based incomes. One of the discussants said thus:

> Presently, when there is no planting activity, we engage in other businesses like buying and selling so as not to be idle and to earn money.

Perceived Trend in Agriculture, Forest Area, and Population as Primary Drivers of Social Vulnerability

The relationship between climate change and ecosystem is intertwined. Climate change can affect the distribution and behavior of some ecosystem components. Conversely, the intensification of some ecosystem components such as forest cover also have implications for carbon sequestration capacity, and hence extent of climate change impact on the environment. In this chapter, element of the ecosystem such as agriculture, forest cover, population, and alternative income-generating activities in the sampled sites such as fishing, hunting, and charcoal production were focused for understanding the interrelationship among these elements and climate change. Across the three agroecological zones of rainforest, mangrove, and savanna, more people are presently involved in agricultural activities compared with 30 years ago. This, according to discussants, is due to lack of employment for graduates and irregularities in payment of salaries/wages to government workers. Therefore, the need for alternative sources of income or employment (for the unemployed) has caused the recent surge in the farming population in the areas. A 48-year-old woman farmer in one of the rainforest communities explained thus:

> Very few people were involved in agriculture thirty years ago in our community, then, youth only engaged in land clearing, planting and weeding of their parents' farms. However, as our population increases many people got involved in agriculture and young people now cultivate their own farmlands.

Population as a component of the ecosystem also witnessed increasing trend in the last 30 years in all the agroecological zones. Population is a key factor that differentiate Africa from other regions of the world. African population is projected to grow rapidly throughout the twenty-first century and this growth will have direct effect on the demands for agricultural commodities. Discussants explained that increase in population is caused mainly by two factors. First, migration of people into various communities within the area for livelihood, especially in agriculture. Rural areas are known to be rich in an important factor of production which is land. Second factor was increase in child-bearing and survival of children due to improved health awareness. However, while there was increase in population and intensity of agriculture across the agroecological zones, decrease in forest spread and abundance of non-timber forest products such as snails and mushrooms was observed across the zones in the last 30 years. This is caused by deforestation and bush burning, occasioned by increase in population. Increasing population exerts more pressure on resources leading to upsurge in the rate of felling of trees for cooking and charcoal production. Increasing involvement of people in agriculture and declining soil nutrient also led to agricultural "extensification" and the consequent expansion of land for agricultural activities. The implication is that more forest cover is removed in order to increase size of land cultivated for farming. A 52-year-old man in one of the savannah communities remarked during the focus group discussions as follows:

> The forest cover has drastically reduced against how it was. In those days we usually have 10-2 stumps of tree together, but due to deforestation by saw millers, increase in land acquisition for farming activities and construction of houses, almost all the trees are gone.

Further, hunting and fishing activities have assumed a downward trend in the savanna, mangrove, and rainforest zones in the last 30 years. This can be attributed to a decline in their distribution in their natural habitat and hence, reduced motivation on the part of the hunters and fishermen to continue in the business due to low rewards. In addition, reduced trend in fishing activities in the locations is plausibly due to water pollution, overfishing, and reduction in water volume caused by prolonged drought and a decline in intensity and duration of rainfall. Idowu et al. (2011) confirmed a decline in Catch Per Unit Effort (CPUE) in coastal areas of Nigeria due to pressure of climate change. However, charcoal production is among the gradually becoming prominent livelihood activities in savannah and mangrove zones. This is perhaps as a replacement for fishing and hunting livelihood activities that are already becoming faded in the areas. Charcoal production serves as an alternative income source for farmers in rural communities while ignoring its long-term implications for a sustainable environment. This is consistent with Mwampamba (2007) who had projected that by 2028, public forest resources would be depleted in some parts of Africa and there would be a total collapse of charcoal chain if no measures are put in place to stop the trend. Mwampamba's position suggests that there is an arbitrary involvement in charcoal production and that the rate of growth in the sector is largely unsustainable. Massive charcoal production in the areas have implications for availability of None Timber Forest Products (NTFPs) in the area. During the focus group discussion, one of the discussants explained (Table 2):

> Duration of time used for collecting products in the forest has reduced because of scarcity of these products in the forest. Harvest from NTFPs was much thirty years ago (A 45-year-old woman, Christian, farmer, rainforest zone)

Table 2 Trend in ecosystem components as primary drivers of social vulnerability to climate change

		Index of intensification in last 30 years (%)			
Agroecological zones	Ecosystem components	1987	1997	2007	2017

Perceived Effects of Drivers of Climate Change on Household Livelihood

Weather patterns are becoming unpredictable due to increasing variability in climate parameters. Rising temperature and increased frequency of extremely dry and wet years are expected to slow progress in crop productivity, livestock system, and improved food security. This section explains the effects of drought, flood, pest and diseases, increase in temperature, and strong wind as observable drivers of vulnerability to climate change in the Nigeria agroecological zones. The effect of each was captured in both direction (negative or positive) and magnitude (which measures the extent of such effects) on subsistent crop, cash crop, charcoal production, and animal production. In the agroecological zones, the negative effects of drought were most felt on subsistence crops. Cash crops such as cocoa were not spared as the effect was high, especially on the field. An opinion leader among the farmers in Iyamitet community (mangrove zone) explained thus:

> In recent times, there is incessant invasion of pests and diseases on our crops which we cannot effectively control. Most times, it takes a lot of time before we understand the nature and causes of such infestation and able to adjust to it. The result is a serious reduction in the quality of our crops and huge losses for us. Ugly experience from the last year harvest has even discouraged some few cocoa farmers from business.

Discussions further revealed that charcoal production was the most resistant or the least affected by drought in the ecological regions. The reverse was the case with respect to flooding, as charcoal production was reportedly highly affected in terms of quality of charcoal, quantity of wood (log), and duration of activities of charcoal production. The level of vulnerability was also high for subsistent crops, cash crops, and availability of NTFPs. Discussants during the focus group sessions justified their position that flood has a high negative effect on charcoal production explaining that when flood occurs, it washes away the charcoal heaps and woods, thereby terminating the charcoal production process. The implication is that while flooding is not an everyday occurrence, the few times it occurs, it has considerable negative effect on the quantity, quality, and hence profitability of charcoal production among producers.

Furthermore, livestock production was the least threatened livelihood by increased temperature, with little or no observable implications for livestock/milk production. However, almost all the livelihood activities were threatened by increased temperature with negative implication for future and present income generation among the people. The effects of pests and diseases, which were also directly associated with climate change as reported earlier, is also evident on subsistent crop, NTFPs, and cocoa production. This rating agrees with the position of majority during discussions as they were unanimous that pests and diseases had grown in both frequency of occurrence and severity of effects in the past few years with observable negative effects on crops and other means of income generation. On the other hand, the effects were less felt on charcoal and livestock production.

The last driver considered was strong wind. This chapter reveals that strong wind had the least effect on respondent's various livelihood activities, with the most visible effects on NTFPs and the least on livestock production. The effect was rated moderate on charcoal production. This rating was backed by some explanations during discussion as follows:

> Strong wind often has negative effect on quantity of charcoal produced. This is often due to strong wind and availability of opening on the charcoal heap. This causes air to enter the charcoal heaps. This occurrence often reduces production efficiency, leading to high ash to charcoal ratio, thereby reducing quantity and profitability of our charcoal production enterprise.

Causes and Consequences of Environmental Degradation in the Nigeria Agroecological Zones

The problem tree analysis in Fig. 7 illustrates the composite results of the effects of environmental degradation in the three ecological zones. It gives the causes and effects of the common problem identified as environmental degradation. The causes of environmental degradation identified in this section are consistent with earlier discussions and include drought, deforestation, strong wind, delayed rainfall, bush burning, use of agrochemicals, and air pollution. This corroborates the report of Somorin (2010) that impact of climate change could be felt by increased temperature, deforestation, and drought. Discussants also reported that the effects of

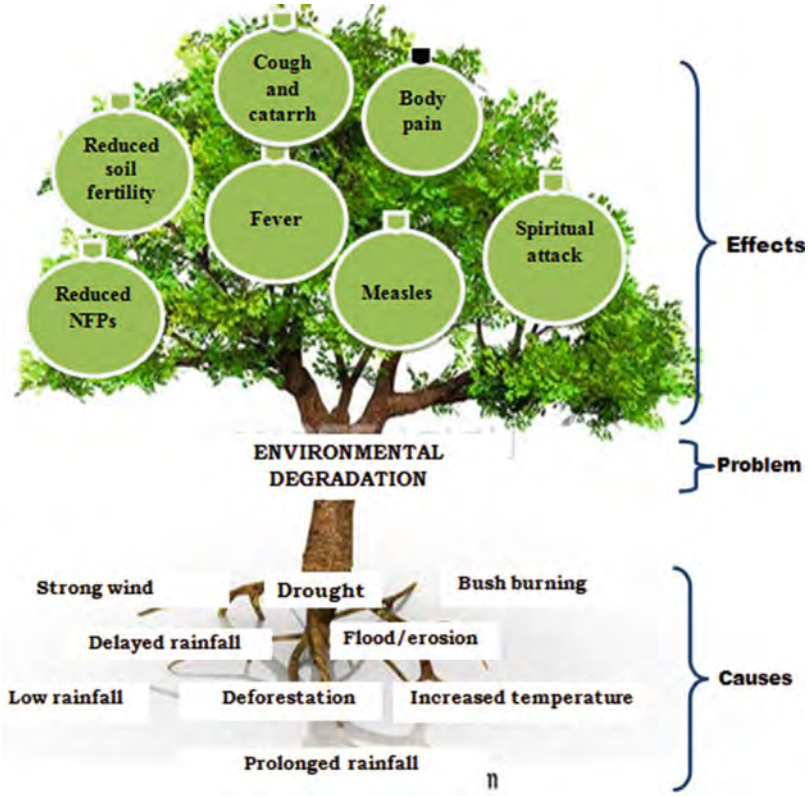

Fig. 7 Problem tree analysis of causes and consequences of environmental degradation in Nigeria

environmental degradation produced both adverse health and environmental consequences such as mental disorder, measles, meningitis, water scarcity, erosion, cough/catarrh, body pain, reduced NTFPs activities, erosion, poverty, low income and poor harvest, soil infertility, increased incidence of pest and diseases and fever.

Specifically, in savannah zone, respondents experienced strong wind which is carries particles of dust causing cough and catarrh. Idowu et al. (2011) established that respiratory diseases and infections like cough and catarrh are prominent in harsh climate due to presence of pollutants and dust. Also, increased temperature in the area causes meningitis and measles which is very common in children of less than 5 years. A 37-year-old woman from savannah zone and 30-year-old lady from mangrove zone are quoted, respectively, as follows while commenting on the consequences of some of climate change parameters on their health and livelihoods:

> During hot weather, as we now frequently experience here, there is usually the prevalence of meningitis, measles and chicken pox especially among our children. Also, wind is accompanied with dust, and this brings about occurrence of cough and catarrh is common. Increased temperature also affects our animals and crops as pests and diseases grow more

> when the weather is hot which slow down crop production (A 37-year-old woman, Muslim, farmer, savannah zone).

> The impact of wind is low and it could be beneficial when drying crops after harvesting them. But when it is too strong, it could destroy the crops' (A 30-year-old woman, Christian, processor, mangrove zone)

An interesting link between deforestation and pervasiveness of mental disorder among the people was alluded to in Wawa community (savannah zone) where the participants argued that deforestation releases certain spirits which are believed reside in trees to inflict young ladies with insanity. One of the male discussants said the following:

> Due to deforestation, spirits that abode in the trees are made homeless and therefore come to town and enter into our young ladies making them go insane. We are able to establish this because during deliverance session for some of the victims, the spirits confessed that their natural habitats have been disrupted and that's the reason for the attacks.

Farming Communities' Needs for an Enduring Adaptation to Climate Change in Nigeria

Farming communities' adaptation is key in translating climatic challenges and agricultural responses into changes in production, prices, food supply, and welfare. The potential for positive change for farming communities will increase if farmers are helped to adapt to climate variability. Table 3 therefore show the priority ranking of what communities in the agroecological areas adjudged as their needs to effectively adjust to climate changes impact. Across the ecological zones, respondents highlighted some needs that were important due to various problems and setbacks they encountered arising from climate change. Availability of credit facilities ranked first, suggesting lack of sufficient capital for various livelihood activities and effective climate change adaptation. Building of health center

Table 3 Needs matrix as identified by communities in forest-edge communities in Nigeria

Needs	Ranks
Credit facilities	1
Heath center	2
Farm inputs – improved seed variety, fertilizer, herbicides	3
Good road network	4
Pipe borne water	5
Power supply	6
Irrigation	7
Communication network	8

ranked second as most of the communities' lacked access to well-equipped health centers that can provide health care services. Farmers also require farm inputs in the form of herbicides, improved seed varieties, and fertilizer as the third ranked need. Perhaps, the need to easily connect outside communities for timely marketing of agricultural produce necessitated farmer's choice of good access-linking road. Discussions revealed that farmers find it difficult to sell their produce to right buyers due to poor state of farm-to-market road. Instead, commodities were often sold to middle men at farm gate prices and hence, low profitability for the farmers. Other infrastructure such as pipe borne water, power supply, communication network was also mentioned as some of their pressing needs across communities in the agroecological zones. The huge infrastructural deficit in the sampled locations is indicative of the state of physical development in most of the forest-edge communities in Nigeria. This corroborates the earlier assertion by one of the discussants:

> 'We strongly desire credit facilities and good road network to enable us perform better in our farming activities and also for outsiders to come into our community and trade with us' (A 52-years-old man, Christian, farmer, rainforest zone)

Conclusion and Recommendation

This chapter concludes that the scale and direction of climate change impact on agriculture as the primary rural livelihood and other ecosystem components in Nigeria's agroecological zones is largely comparable and have both positive and negative consequences on rural sustenance. While climate change impact combined with some other economic factors such as unemployment have encouraged urban-rural migration, agricultural intensification, and livelihood diversification on the one hand, it has increased vulnerability tendencies of rural households in forest-edge communities in all the agroecological zones of Nigeria on the other hand. Among several others, increased forest encroachment, lack of a well-coordinated policy framework which allows for alternative livelihood without accompanying forest regulatory framework were major vulnerability exacerbating factors for the rural poor. Although the rural populace need help for better adjustment to climate change, they also do have demonstrated ability to respond to changes occasioned by climate variability and are exploring these abilities to the best of their knowledge. Support in the form of affordable insurance policy, credit, agri-inputs, favorable forest regulatory framework, and youth empowerment would enhance sustainable adjustment to climate change among the rural people.

Abstract

Climate adaptation planning requires new ways of thinking and approaching the analysis of risks. Such thinking needs to be systemic in nature and practice/action-oriented while respecting the complexity of the physical and social sciences. Through this chapter on climate tipping points in Botswana, it is proposed

P. Urich (✉) · Y. Li · S. Masike

that a generic and practice-oriented analysis framework be applied with a mathematical foundation including modeling methods based on complex science. The objective is to promote a framework that privileges a worldview to avoid biased and partial explanations of risks. An Institutional-Socio-Earth-Economical-Technical systems (ISEET) approach is based on a systems science philosophy for risk governance analysis, with particular emphasis on tipping points and emergence which are some of the key elements that can support sound adaptation planning. Through the lens of the biodiversity sector in Botswana, the complex interrelationships of ISEET principles are explained. They provide a new, efficient, and practical framework for moving rapidly from theory to action for planning and implementing climate change adaption projects.

Tipping points · System dynamics · Climate change · Risk assessment · Biodiversity · Action research

Introduction

Humanity has modified the earth systems in significant ways and has initiated unprecedented Anthropocene risks (Keys et al. 2019; Baer and Singer 2018). Changes include fundamental aspects of the earth system such as all layers of the atmosphere, hydrosphere, and cryosphere through changes in weather patterns, climate, land surfaces, ocean chemistry, and geological structures. Anthropocene risks such as global connectivity either have reached or are approaching tipping points of various earth systems at different temporal and spatial scales (Steffen et al. 2018). Meanwhile, the emergence of new knowledge, technologies, and institutions has led to new approaches for problem-solving. An example of collective action is the Paris Agreement ratified by the United Nations Framework Convention on Climate Change (UNFCCC). However, progress in mitigating climate risk has not been satisfying. Responses are uneven and uncoordinated, and CO_2 emissions continue to increase globally, even with green energy and other technological advancements. New approaches to the analysis of risks need to be articulated systemically and be practice-oriented while respecting the complexity of the physical and social sciences (Sterner et al. 2019; Lucas et al. 2018).

The existing initiatives and frameworks are limited, such as the Sendai Framework for Disaster Risk Reduction, the Paris Agreement, and international programs such as IRGP-IDHP (Integrated Risk Governance Project-International Human Dimension Programme). These limitations transcend the research frameworks as well, such as SES (socio-ecological system), STS (science technology and sustainability, and IAD (institutional analysis and development). The weaknesses of these existing frameworks as analysis and practice tools are being more widely debated and are modified as society seeks a better understanding of systemic risks posed by climate change and large-scale socio-physical disasters (Cole et al. 2014; McCord et al. 2017).

A more generic and practice-oriented analysis framework is explored from a mathematical foundation, including modeling methods based on complex science. A structure of systems thinking applicable in the Anthropocene is proposed whereby analysis privileges a worldview and earth-view that attempt to avoid biased and partial explanations of risks.

Tipping Points and Emergence

There are standard features of systemic risks in different domains. These include the character of agents and emergence phenomena, tipping parameters indicating instability, and more noncommittal empirical observations. Instead, these features can be related as Lucas et al. (2018) describe on fundamental theory for relatively well-understood and straightforward systems in physics and chemistry. A crucial mechanism is the breakdown of macroscopic patterns of whole systems due to feedback reinforcing actions of agents on the microlevel, whereby the role of complexity science forms the basis for unifying the phenomena of systemic risks in widely different domains.

Tipping points sometimes also refer to shifting points. For example, the shift from an unsustainable to a sustainable society requires a radical historical change in the form of a profound transition which could involve a series of connected transitions in many socio-technical systems (e.g., energy, mobility, and food) toward sustainability. People who work from an SES point of view, studying the profound transition and radical change issues, use different expressions (Schot and Kanger 2018; van der Vleuten 2019).

According to Lenton et al. (2008: 1786), the term tipping point refers to a “critical threshold at which a tiny perturbation can qualitatively alter the state or development of a system.” The following attributes are identified as tipping points in the Anthropocene:

- Tipping points could impact the whole planetary scale, everything living on Earth.
- Tipping points could impact the transition or the change of regime.
- Interaction crosses boundaries, including administration and nature systems and ISEETS boundaries.
- Both collective and individual social actions operate in multiple sociocultural, technological, governance, biophysical, and knowledge systems which interact with many other systems at the same time and many levels.
- Tàbara et al. (2018) focused on the complexity of attribution and a reductionist approach about systems thinking and the historical drive to an oversimplified explanation of solutions, drivers of tipping points that could improve the likelihood of limiting global warming to either the 1.5 °C or 2 °C target.
- When social and natural scientists collaborate and integrate their studies, new patterns and previously unforeseen relationships that can accentuate understanding have been achieved. Such studies often reveal intricate causes and effects as such works are based on well-defined spatial, temporal, and organizational units,

be they culturally, physically, or politically determined. Another finding in such studies is their non-stationary and as Liu et al. (2009) feedback loops lag in effects from a range of identified causes and their relationship with resilience and thresholds can reveal new insights. It is also recognized that past interrelationships can have spillover effects that can continue to impact on not only a present state of a system but also its future.

- Tipping points are likely to be breached in the future; however, the underlying conditions are challenging to predict, and the accuracy in defining the time and place makes policy and decision-making currently inadequate for either mitigating or possibly avoiding transgressions.
- Thresholds are not constant. Instead, the position of a threshold along a determining variable can change. The consequences of crossing a threshold are context-dependent. The threshold is sometimes known, and the decision-making depends on the effects of crossing it.
- Tipping points or regime shifts are intricately related to the concept of system resilience.

Emergence and Innovation

Emergence plays a central role in theories related to integrative levels and complex systems. Emergence and emergent phenomena are essential concepts in complexity studies (Goldstein 2018). Emergence can be described as either the development or the presence of the existence or formation of common behaviors, whereby the collective actions within a system would not lead to a similar outcome if applied as individual, constituent parts with no recognized interaction. Emergence is also used to describe the properties of a system – what the system does under its relationship with the environment that it would not otherwise complete itself and is coupled to the scope and system boundaries (Ryan 2007). Emergence also refers to the ability of individual components of a system to collaborate, thus leading to rapid and diverse behavioral changes and new features. For the ISEET, more linkages and communication between subsystems, or the building of more relationships among the ISEET subsystems, could lead to new features emerging. These would then reflect the application of the more complex system and possibly more innovative systems thinking. Emergence is typically not reducible to, nor readily predictable from, the properties of individual system components. Therefore, it may appear surprising or unexpected (Halley and Winkler 2008). Emergent phenomena exist in all subsystems, which could provide solutions or options to the existing challenges in all subsystems if the emergence is managed properly (Ceccarelli et al. 2019; Lichtenstein 2014; Roundy et al. 2018).

Emergence could be applied in a conceptual framework. This framework could improve the understanding of scientific and technological progress (Alexander et al. 2012), innovation, and economic growth (Du and O’Connor 2019). Such a holistic innovation system could improve productivity through the diverse knowledge of business resources available. Emergence also could be scored to identify the topics and drivers of innovation (Porter et al. 2019).

The technology innovation process is central to effective adaption to climate change and development challenges. However, models from business and management tend to dominate innovation theory, which sits outside the adaption-development paradigm (Hope et al. 2018). The goal is, however, to support the development of sectoral and technologically detailed and policy-relevant country-driven strategies consistent with the UNFCCC Paris Agreement.

An ISEETS framework can be used to engage stakeholder input and buy-in; design implementation policy packages; reveal necessary technological, financial, and institutional enabling conditions; and support global stock-taking and ratcheting of ambition (Waisman et al. 2019).

Macro-level agreements, such as the UNFCCC Paris Agreement, should be designed to encourage debate on how to tackle climate change through the notion of innovation, applying both technological innovation and marketing issues. Innovation of a technical nature is part of the equation, but it is not the only requirement. It has been suggested by Asayehegn et al. (2017) that an enabling sectoral system of innovation (SSI) be prioritized where some technological innovations contribute to adaptation actions for climate change. Technological impact analysis could be included based on the following approaches: historical sectoral application and improvement on the systems, such as agriculture technology, livestock breeding and feeding technology, ICT technology, carbon sequestration technology, and others where appropriate.

With the emergence of adaptation technology, it can be defined as "the application of technology to reduce the vulnerability or enhance the resilience, of a natural or human system to the risks of climate change" (UNFCCC 2005: 5). Technologies are defined as either "hard" that includes equipment and infrastructure or "soft" such as institutions and management systems (Christiansen et al. 2011). However, some technologies, such as new crop varieties, are not so easy to categorize. Many technologies can be used to address current vulnerabilities to climate and other environmental, economic, and societal concerns and to reduce future exposure to climate change impacts. Some can also be used to address several types of climate change impact in different sectors.

ISEET modeling seems too big to be handled by either a single model or an existing framework. However, when considering specific modeling for a risk governance issue, the data, variables, and parameters could be selected and refined according to their importance and their functionalities. The modeling approaches from different disciplines could be either simplified or reorganized to fit specific purposes. For the subsystem in this chapter, the modeling approaches have been developed for specific contexts, which can be either absorbed or integrated into the ISEET modeling processes.

Modeling systemic or structural change in socio-environmental systems is not new. Tipping point modeling has been carried out by scientists from SES, climate systems, social systems, network analysis, and agent-based modeling disciplines. Based on the ISEET system analysis framework, Fig. 1 depicts an overview of an

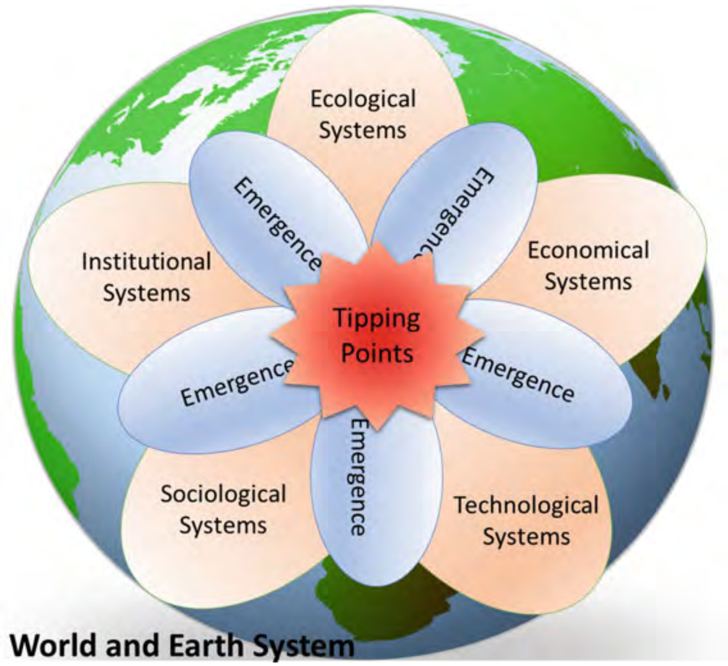

Fig. 1 The framework of Institutional-Socio-Economic-Ecological-Technological Systems (ISEETS) for a climate change tipping point study. (Source: authors)

ISEET structure for tipping points and the emergence of, and linkages between, five subsystems.

Tipping points and regime shifts are being studied within various disciplines applying a range of modeling approaches and analysis frameworks. One of the first obstacles in any study of systemic change is the terminology. Environmental and social science disciplines have engaged in relevant ideas of regime shift, structural change, non-marginal change, and transition theory, and each claims ownership (Polhill et al. 2016).

ISEET Analysis Framework

Institutional-Socio-Earth-Economical-Technical (ISEET) systems

ISEET describes five intrinsically interlinked systems formed around the Anthropocene. The method has at its foundation systems science concepts and mathematical methodologies for risk governance analysis, with emphasis on tipping points and emergence, which are the key characteristics that need to be analyzed for risk governance.

ISEET represents a dynamic system. Their elements, functions, and relationships change with time and across spatial scales. Historical evidence and future prediction are essential for risk governance. Human beings do not always passively react to risks. With new and different technologies and the extension of knowledge, the risk may become more manageable. Opportunities could be created through the emergence mechanism in ISEET.

ISEET systems can be characterized as the coupling of natural laws with world rules. The goals are to support mutual well-being of the earth (physical) and world (social) systems. To describe risk governance issues in the Anthropocene, ISEET framework subsystems are indispensable. ISEET risk governance is either realized or implemented by institutions. They require the full engagement of societies and apply certain economically viable technologies that should encompass sustainable ecosystem service support from the earth environment and its resources.

From the subsystem point of view, the interrelationship could be described as:

- An institution that must have close collaboration with its relational society, using environmentally and ethically sound and economically viable technologies.
- Societies that could live with the environment, given effective and efficient institutions, and be economically healthy, with controllable risks on the earth system.
- Societies that need to work together to advance and apply technologies with economic endeavors, to live sustainably with the earth system.
- The sustainable development of economic systems that could be achieved by a well-designed and well-operated institution, which include social capital and earth resources.
- Technology that may need to be advanced and applied and that does not harm the environment and is ethically healthy. In this way, societies are more likely to promote institutions, with the input from their constituent economic systems.

The Working Definition of a Subsystem

- An institution in ISEET implies a body that operates within regulations, laws, policies, and conventions. Such institutions can represent cross-sectoral entities established when either developing or implementing a related risk governance framework. For example, emergency management laws and emergency management ministries are all part of a larger institutional system.
- Social systems in ISEET refer to all the elements, functions, and relationships in societies, including the population and its age and gender composition, culture, religion, educational level, and connectivity. Complexity theory offers the toolkit needed for this paradigm shift in social theory (Walby 2007).
- Earth system refers to the biophysical existence of the Earth planet, including the living support environment, from top air to deep earth.
- An economic system, as defined by Gregory and Stuart (2013: 30), “is a system of production, resource allocation and distribution of goods and services within

a society or a given geographic area. It includes the combination of the various institutions, agencies, entities, decision-making processes and patterns of consumption that comprise the economic structure of a given community."

- Technological systems are sets of interconnected components that transform, store, transport, or control materials, energy, and information for specific purposes. Machines, software, and the hardware they run on are considered part of a technological system. Similarly, how humanity organizes itself to apply such technology are broader arrangements based on the organization's structures to exploit technology and techniques developed to optimize their application.

Case Study: Botswana's Biodiversity Sector

Time is of the essence for engaging in the intersection between climate change and the biodiversity extinction crisis. The Global Deal for Nature (GDN) is one opportunity as it is science-driven with the goal of saving the diversity and current relative abundance of life on the planet. The linkage of the GDN with the Paris Climate Agreement might help humanity avoid catastrophic climate change while conserving species and their increasingly recognized values, including ecosystem services.

Compelling recent findings add additional urgency to the issue as less than half of the globe's terrestrial realm is intact. The application of global climate points toward a tipping point. Habit conversions continuing as they were historically while greenhouse gas emissions maintaining its current trajectories may exceed humanity's chances of limiting global warming to the 1.5 °C target. Over the next 10 years, currently expanding conversion and poaching rates need to be slowed down considerably to avoid "points of no return" for some floral and faunal species (Fig. 2).

If global mean temperatures are permitted to rise above 1.5 °C, it is widely believed that fundamental aspects of ecosystems, both large and small, could unravel. Continued unsustainable use of the natural environment threatens our global health as witnessed by the rising risk of global pandemics, while mass migration owing to the lack of access to resources such as clean water and productive and uncontaminated land become more widespread. Global climate change and its increase in extreme events could accelerate the degradation of land and societies. For example, climate change-induced sea level rise and extreme still high-water events, which inundate coastal zones and droughts, may displace at least 100 million people by 2050. Most of those people currently live in the southern hemisphere (Dinerstein et al. 2019).

Botswana, as part of Southern Africa, is home to an appreciable portion of global biodiversity, and many of its ecosystems retain relatively intact species assemblages across all trophic levels. The region possesses an established network of protected areas that contribute both to conservation targets and to nature-based tourism. Pressure on biodiversity can result from regional and highly localized developments concerning extractive resource use. Anthropogenic climate changes are more widely accepted as a profound driver of such impacts for Africa's biodiversity, including

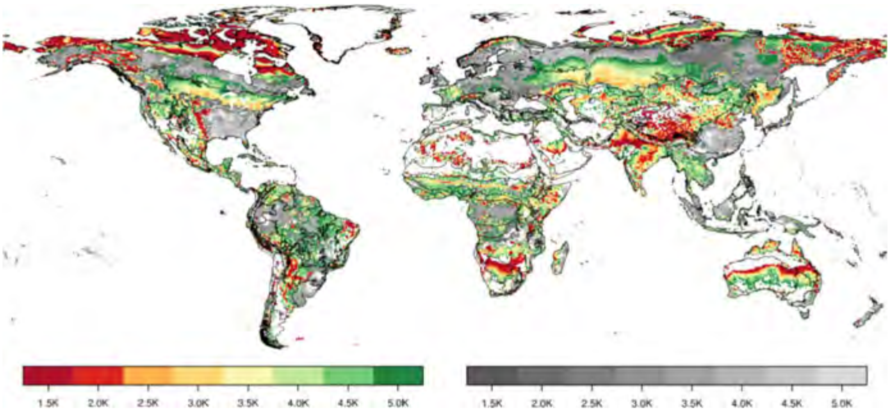

Fig. 2 Thresholds of temperature anomaly that could lead to significant local changes in land-based ecosystems. Colored areas (left legend) represent regions with severe transformation; gray areas (right legend) are likely to experience moderate transformation. Dark red transformation at 1.5 °C and light red at 2.0 °C. (Courtesy of Gerten et al. 2013)

Botswana, and it is increasingly likely to be harmful from both ecological and economic perspectives.

Worldwide, the United Nations is committed to mainstreaming biodiversity planning in a wide range of policies and programs and with the inclusion of climate change. In a country such as Botswana, mainstreaming biodiversity and/or wildlife management at the local, regional, and country level is critical to its economy and its place as a critical biodiversity REDD hotspot for several primary faunal species.

Botswana, in terms of biodiversity, is a country of contrasts. The diversity ranges from the wetlands of the north, dependent on water arriving season from neighboring Angola, to the broad and arid Kalahari Desert in the center and southwest. Each area is part of a systematic protected area system with the Okavango Delta representing the world's largest inland delta which is also a Ramsar site. At the same time, Chobe National Park has many varieties and populations of game and a considerable density of elephants. The country has innovated the first formally declared trans-boundary park in Africa, the Kgalagadi Transfrontier Park. There is also the Central Kalahari Game Reserve and the distinctive prehistoric lake that now consists of salt pans called the Makgadikgadi and Nxai Pans National Park system. This area has important habitats for migratory birds.

Botswana is developing a National Climate Change Policy, Strategy and Action Plan (NCCPSAP) with the framework for such being only recently devised. The policy will be implemented through the Ministry of Environment, Wildlife and Tourism in cooperation with the United Nations Development Programme. Among other objectives, the NCCPSAP aims to develop and implement appropriate adaptation strategies and actions that will lower the vulnerability of Botswana and various sectors of the economy to the impacts of climate change.

Biodiversity and Tipping Points

Biodiversity in the context of tipping points is a complex area for investigation. Alternate stable states are associated with abrupt shifts in ecosystems, tipping points, and hysteresis, all of which challenge traditional approaches to ecosystem management (Oliver et al. 2015). Ecosystems often maintain their stability through internal feedback mechanisms. Environmental perturbations (natural and enhanced by climate change) can change the frequency and magnitude of regime shifts leading to fundamental changes in the assemblages of species providing functions.

Systems can be more susceptible to environmental randomness/irregularity and perturbations/fluctuation close to these critical tipping points and can lead to sudden changes and foster a new equilibrium. Such evolved alternative stable states might be unsupportive in terms of ecosystem functions with a return to a previous state only possible through substantial and costly management interventions (hysteresis). Therefore, the recovery capacity of ecosystem function can be compromised. Alternative conditions have been documented in a wide variety of ecosystems from local to global scales. However, how stable and persistent these will be in the future, under rapid changes in climate, remain uncertain.

It is exceedingly difficult to understand how complex ecosystems, for example, the Okavango Delta, will behave as they either approach or surpass tipping points (Fig. 3). Exceedingly small changes in one or more conditions can lead to a cascade of other changes resulting in a large shift in the state of the system. Sometimes this process can be played out very slowly and therefore less perceptibly by society, and at other times, extreme events lead to radical shifts that exceed the capability of systems to slowly recover, and hence it is forced to find a new stasis; this is a natural process with volcanic eruptions, earthquakes, and flood events often leading to abrupt changes. However, climate change and its speed of onset, which varies from location to location, and the uncertainty in future projections can lead to management paralysis. The slowing down of a potentially catastrophic collapse of individual and highly relevant parts of a system is therefore preferred to prolong the sustainability of the large system.

Ecosystem management depends on monitoring and maintaining resilience because the loss of resilience renders ecosystems more vulnerable to undesirable shifts. Several works summarized by Dai et al. (2012) suggest that a set of generic indicators may aid in the sustainable management of fragile ecosystems. Signals of critical slowing down based on time series demand observations over a long span. Compiling such data is often tricky; therefore, if other indicators based on the spatial structure can be identified, they could be complementary to the early warning signals.

Tipping points are often driven by either complex feedback mechanisms or interactions between multiple drivers. Some of these triggers or drivers are found to be new and thus are not well represented in models currently in use (Leadley et al. 2010). An example is a relationship between dying back in Amazon forests and deforestation and climate change processes that resulted in an underestimation of impacts in earlier global biodiversity assessments. This situation may pertain in the

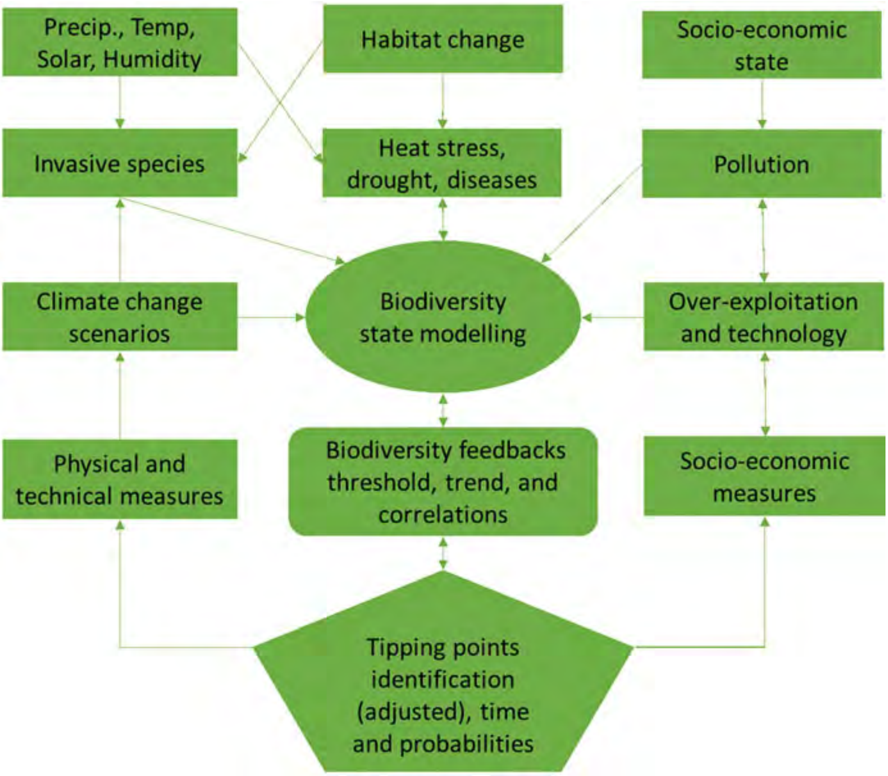

Fig. 3 Tipping point analysis framework for biodiversity in Botswana. (Source: authors)

case of the Okavango Delta where the sustained integrity of the Miombo woodlands on neighboring country of Angola leaves the well-established ecotourism focal areas such as the Okavango swamps in Botswana critically dependent on the sustained flow of sediment- and nutrient-free water from those upland parts of the wider river basin (Leadley et al. 2010).

Ecosystem service degradation can be linked with species extinctions, eroding species abundance, or as shown in this chapter potential shifts in biomes and associated species distributions. However, conservation of biodiversity and provision of some types of ecosystem services can conflict. The following tables list the already identified changes (from 2008 to 2019) in red category lists for plants and animals in Botswana in a limited African context (Tables 1, 2, and 3).

Midgley and Thuiller (2011) suggest significant impacts from unrestrained climate change for the southern part of the African region. However, overestimates of the speed of change and extent of those impacts may be the case owing to underlying assumptions of bioclimatic modeling. The analysis of a diverse range of studies does, however, support the rationale for a high level of concern as there is a signal across the available research that unmitigated changes in climate threaten a

Table 1 Red List Category summary country totals (plants) by the number of extinct, threatened, and other species of plants in each Red List Category in each country (IUCN 2008, 2019)

IUCN Red List Categories: *EX* extinct, *EW* extinct in the wild, *CR* critically endangered, *EN* endangered, *VU* vulnerable, *LR/cd* lower risk/conservation-dependent, *NT* near threatened (includes *LR/nt* lower risk/near threatened), *DD* data-deficient, *LC* least concern (includes *LR/lc* lower risk/least concern) considerable portion of southern African biodiversity. It is the underlying shifts in ecosystem structures, for example, increases and decreases in woody plant cover, that have a secondary impact on faunal diversity that is likely to alter the dominant savanna vegetation type of the region. Midgley and Thuiller (2011) pointed to the winter rainfall areas of the broader region that could suffer the most significant biodiversity loss. The trends identified in Botswana are echoed in other biomes. It is increasingly recognized that rates of disturbance vary with time and can depend on long-term climate trends, the influence of anthropogenic land-use practices (e.g., fire), wildlife population cycles, and other factors such as presence or introduction of invasive species (Wilson et al. 2019). As noted by Wilson et al. (2019), assessment of regional patterns and trends is needed, hence our approach that placed Botswana in the context of Southern Africa. Specifically, some crucial areas are mostly outside Botswana, but they have relevant spillover effects, especially for the Okavango Delta.

Specifically, when mammals in the region are differentiated by size and dietary requirements, some more telling climate risks emerge. Correlations are significant for annual temperature but only for large mammals, where 60–67% of the variability in species richness of large mammals is impacted versus <20% for small mammals (Andrews and O'Brien 2000). Small mammals are, however, strongly correlated with other either climatic or vegetation parameters. Plant richness, thermal seasonality, and frugivorous and insectivorous mammal richness are found to be correlated with thermal seasonality and minimum monthly PET (potential evapotranspiration). It is also found that arboreal and aerial species richness is associated with plant richness, thermal seasonality, and minimum monthly PET.

It is clear from Andrews and O'Brien's work (2000) that different classes of mammals respond to climatic and environmental factors in important ways. Earlier studies they contend did not identify these discrepancies, as the distinction between various sizes and guilds of mammal was not a common factor of analysis. With climate change, there will be issues across the diversity of mammalian species that should impact on their conservation in the future. This also points to the complexity of communities and the understanding of the potential importance of indicator species, whereby either a mammal's or other organisms' presence, absence, or abundance reflect on the environmental condition of either the ecosystem or biome. Such species can serve as critical indicators of tipping points in either an ecosystem or biome and act as a proxy for the health of that environment in the face of a changing climate.

Baseline Biodiversity in Botswana

Wide-ranging large carnivores are common in Botswana. They often range beyond the boundaries of protected areas into human-dominated areas. The mapping out on a country-wide scale and identifying areas with potentially high levels of threats to extensive carnivore survival is required when formulating national conservation action plans whether considering climate change or not. For this chapter, NPP (net primary production) in a historical context (and later in the context of climate change) has been linked with species biodiversity and richness.

This was done as the notion of NPP was linked with the country's large carnivore guild as part of a recent mapping project. In that project, Winterbach et al. (2014) identified and mapped areas consisting of leopard (*Panthera pardus*), lion (*Panthera leo*), cheetah (*Acinonyx jubatus*), brown hyena (*Hyaena brunnea*), spotted hyena (*Crocuta crocuta*), and African wild dog (*Lycaon pictus*) (Fig. 6). They discovered through this mapping project that habitat suitability for large carnivores depended primarily on prey availability but with secondary relationships with interspecific competition, plus conflict with humans. Winterbach et al. (2014) found that prey availability was a critical natural determinant. Wild ungulate species were preyed upon by the six large carnivores, and this helped to identify different management zones for large carnivore populations. The relationship with large ungulates and NPP

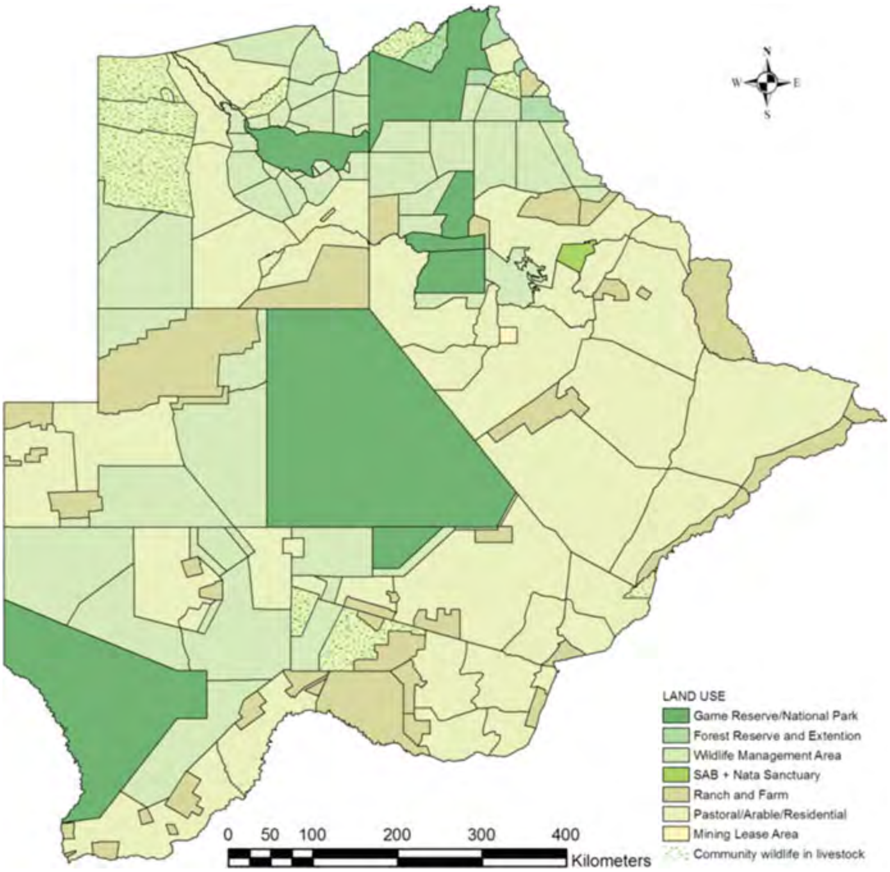

Fig. 4 Land-use zones in Botswana. (Courtesy of Winterbach et al. 2014)

in the country is strong. Therefore, small prey biomass was more evenly spread across large parts of the country, while high to medium biomass of large prey was primarily confined to conservation zones (Figs. 4 and 5).

As Botswana is central, both geographically and in terms of species biodiversity of the larger Southern African sub-Congo basin, its ecological system was deemed prudent to map changes in net primary production and species richness regionally. Changes historically and in the future in these factors will mean transboundary issues will ensue. It is evident in Fig. 6 that mammal species richness is linked with regional phenomena such as NPP, annual precipitation, and mean changes in temperature. The future will be different; hence, some biome shifts from areas currently outside the borders of Botswana could encroach into Botswana over time and as temperatures rise. Clearly, this could lead to critical transboundary implications for management of the subsequent changes in floral and faunal biodiversity.

Future changes in the three zones of species richness in Botswana (Fig. 7) across three key indicator groups, mammals, birds, and amphibians, show clear patterns from the southwest (low richness across all three groups nationally) to moderate richness in the east and high richness in the north. Importantly, these three zones are not national boundary bound but extend to neighboring countries as shown in Fig. 7.

Fig. 5 Entrance to Moremi Reserve. (Source: authors)

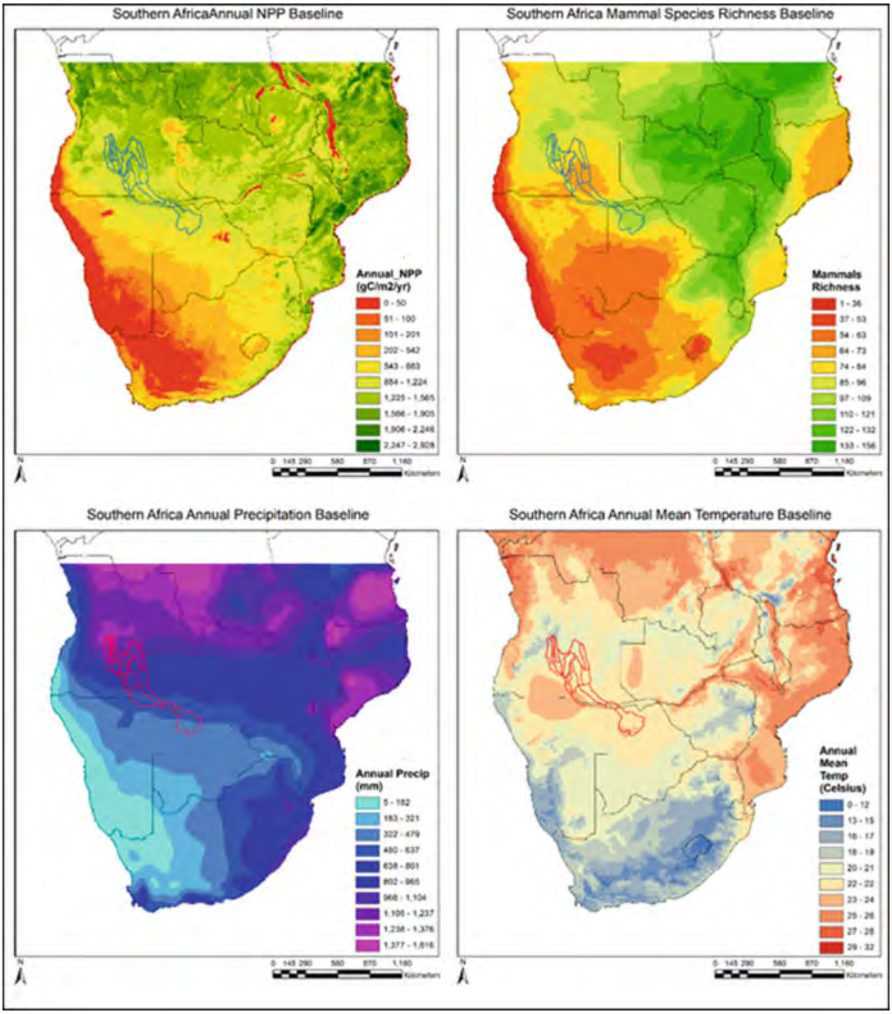

Fig. 6 Baseline NPP and the relationship between high values and mammal-specific richness, annual precipitation, and annual mean temperature. The Okavango River Basin that supports the Okavango Delta in Botswana is included as it is a key transboundary basin for Botswana species diversity and concomitant tourism and economic activities. (Source: authors)

Biodiversity, Ecosystem Services, and Tourism

Wildlife tourism in Botswana has provided strong economic incentives for conservation. With an abundance of wildlife and either the presence or absence of high-profile species, some zones are more suited to wildlife tourism. Winterbach et al. (2014) developed a set of parameters for assessing wildlife abundance and diversity.

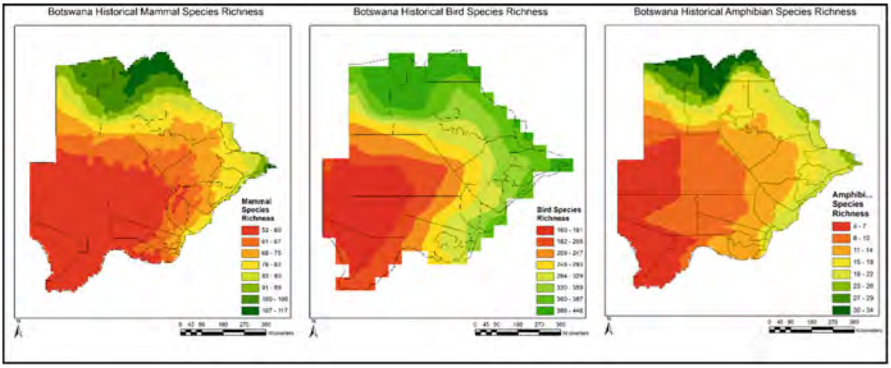

Fig. 7 Historical mammal. Bird and amphibian species richness highlight three key zones, the southwest (low), east (moderate), and north (high), and these three regions extend to neighboring countries. (Source: authors)

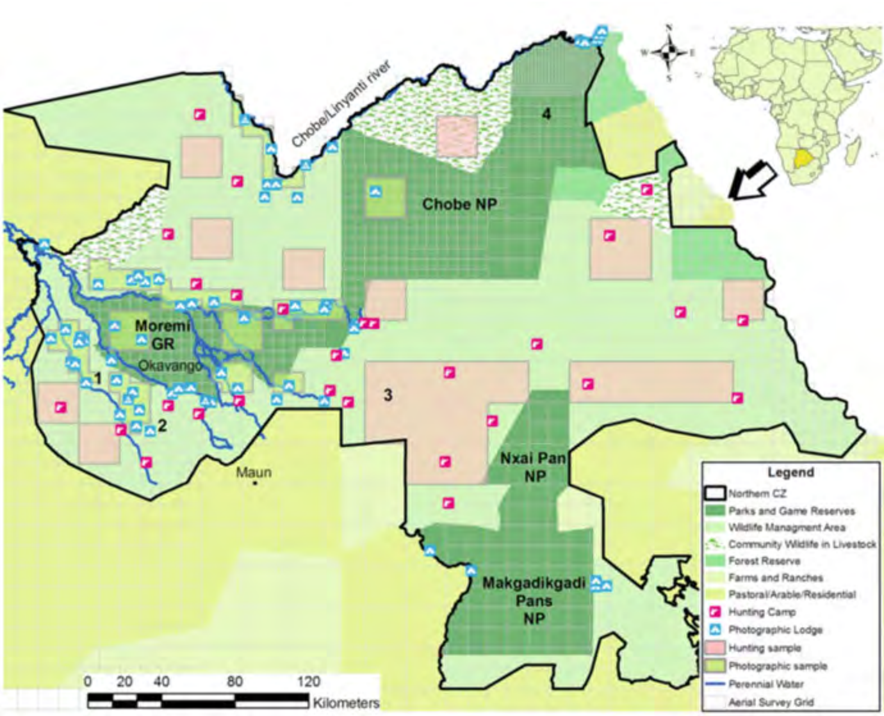

Fig. 8 Locations of photographic and hunting camps and land uses in northern Botswana in 2005. (Courtesy of Winterbach et al. 2015)

Their goal was to evaluate tourism potential in Botswana's Northern Conservation Zone. They also quantified and compared tourism experiences in areas with high and low tourism potential. Wildlife biomass is used as an indicator of NPP, and actual tourism experiences were included in their study to validate their mapping exercise.

Winterbach et al. (2014) found that areas used for high-paying/low-volume tourism had significantly higher mean wildlife biomass and diversity (Fig. 8). Only 22% of the Northern Conservation Zone against their framework had intermediate to high tourism potential. High tourism potential areas afforded tourists better wildlife sighting based on aerial survey data than low wildlife sights based on ground surveys. They also found that the economic viability of low-paying tourism may not even be met in zones with intermediate to high tourism potential. Much of the Northern Conservation Zone was found to have low tourism potential; however, this does not equate with a low conservation value.

Climate Change Impacts on the Biodiversity in Botswana

Africa is expected to be particularly severely impacted by climate change (IPBES 2018). Biggs et al. (2008) assessed the impacts on terrestrial biodiversity using the Biodiversity Intactness Index (BII). This index defines an average change in population size against a pre-modern state, across all terrestrial species of plants and vertebrates. In the next 100 years, they projected a decline in average population sizes of taxa that exceed by two to three times the decline that occurred since circa 1700. A reduction in this modeled declines of biodiversity loss in southern Africa posed considerable challenges. Better alignment is needed for integrated biodiversity conservation and development priorities in the region. Furthermore, what is thought to be required are context-sensitive conservation targets that account for the development of imperatives in different parts of the region.

The predominant climate signal from the climate models for southern African is for a hotter and drier future. This is having, and will likely continue to pose, serious consequences and challenges for policy development and management of environmental and related social change for the people of the region. Historical climate records, as indicated, fit reasonably well with future projections for the region, with the important caveat that temperature rises are trending faster than the global mean, especially in continental interiors such as Botswana. Rainfall, however, apparently has not changed significantly, as yet although the combination of higher temperatures and the potential for changes in the variability of rainfall (e.g., more intense) and also changes in seasonality has already shown changes in the trends in vegetation trajectories in the major biomes of southern Africa. Contrary to early projections for the Succulent Karoo biome, biomass and cover increased over time. This was mainly deemed in response to changes in land-use practices. MacPherson et al. (2019) also found that the fire-adapted fynbos biome either remained stable or increased over time with some expansion of forest species.

Meanwhile, and in the same study, it was found that the shrub-dominated Nama-Karoo biome increased in grass cover. Significantly, and in contrast with earlier model predictions, the grassland biome has expanded westward into former Nama-Karoo biome sites. Regionally, the predominant savanna biome has experienced a relatively rapid increase in woody plants at rates initially unexpected by climate/vegetation models (MacPherson et al. 2019). The availability of new model parameters for biomes and net primary production also provide a useful context for evaluating future changes and for considering tipping points.

Climate change and adaptation have also become a significant issue in contemporary tourism development and policy discussions. This is particularly the case in Botswana and the broader geography of Southern Africa where wildlife in its natural environment dominate the sector. A study on perceptions of climate change (Saarinen et al. 2012) and adaptation strategies of tourism operators in Kgalagadi South District, of southwest Botswana, which also looked at their adaptation strategies, found a general awareness, but the research was conducted nearly 10 years ago. At that time, most operators did envisage challenges to future business growth and Botswana's tourism competitiveness. The perception is that climate change did not at that time have any impacts and that few adaptation strategies were in place. Anecdotal evidence from the consultant's time spent in the Okavango Delta (2019) with a tourism operator of considerable experience pointed to heightened concern regarding climate change. However, problems with earthquake impacts and climate change were signaled as underlying factors in reduced water flow into various parts of the Delta.

One Example: The Okavango Delta

The Government of Botswana has adopted a policy of economic diversification, which is reflected in the National Development Plan 8. There is a strong emphasis on the sustainable use of renewable resources such as veld products and wildlife. Tourism has been identified as a potential "engine for growth" (Jones 2017) and that tourism is based on wildlife and nature experiences. There is an increasing emphasis on the conservation and sustainable use of these resources with a strong geographic focus on the Okavango Delta.

There are significant variations in the size of the actual wetland seasonally as well as from year to year, depending on rainfall intensities in the watershed and other factors (McCarthy 2003). About half of the wetland is permanently inundated, whereas the other half is only seasonally flooded (Anderson et al. 2003); the two areas are referred to as the permanent swamp and the seasonal swamps, respectively.

The Okavango Delta is important ecologically as well as economically. The remoteness, spectacular landscape, and richness in wildlife make the Okavango Delta a magnet for tourists, and tourism has become the second most important sector of the Botswana economy.

Climate change and development-induced land-use change are explicit threats to sustaining biodiversity (Newbold 2018). Modeling and data limitations have hampered a better understanding of the underlying systemic risks. Also problematic are the quite different scales at which land-use and climate processes operate. Newbold

Fig. 9 Differentiation in water distribution within the Delta. (Source: authors)

(2018) predicted that climate change effects will become a significant pressure on biodiversity and could exceed the effects of land-use change by 2070. Both pressures were predicted to lead to an average cumulative loss of 37.9% of species from vertebrate communities under a "business as usual" scenario with an uncertainty range from 15.7% to 54.2%. The biomes to face the most significant pressures were tropical grasslands and savannahs (Fig. 9).

Tipping Points for Climate Change for the Biodiversity Sector

Results and Recommendations

Climate change is already well advanced in Botswana and has already created new challenges for biodiversity conservation. Evidence shows that two key elements that are driven by changes in climate are in a national-scale tipping point analysis: shifting biomes and changes in species composition that relates to net primary production of specific environments. Owing to the complexity of biodiversity and variability of species richness across the country, it was only possible to define broad relationships in terms of potential tipping points.

As mentioned, the dominant relationship between net primary production and biome shifts with the potential to support stable biodiversity mixes is complicated. Natural succession of species must be disentangled from a complex web of confounding factors including a plethora of human factors as well as a relatively rapid change in climate regimes. There appears to be emerging a maturing of the science related to shifts on biomes with changes in climate and signals are thus becoming more transparent that climate has a more dominant role to play in the transition of landscapes and hence biodiversity.

The mapping of mammalian, bird, and amphibian species in Botswana (Fig. 7) with modeled climate-induced changes in net primary production provides insights into possible future changes as temperatures continue to rise regionally. Of note, the temperature profiles of 1.5 °C, 2.0 °C, and 3.0 °C are presented in the introduction and are expected to be reached under current business as usual scenario (84th percentile) (RCP 8.5) in roughly 2028, about 2036, and around 2050, respectively. There will, of course, be lag times in the response regarding average net primary production in the regions and subsequent potential shifts in biodiversity, barring any management interventions and other human dimensions of change that could ensue over the next 30 years.

The trend in net primary production, which is a driving factor in species richness, is for expansion from southwest to northeast of the lower productivity zone. Concurrently, across all three future temperature profiles, the higher NPP areas of the east and north also become progressively less productive. The same trends are then seen in Fig. 7 where the mammalian species richness diminishes nationwide, i.e., there are no parts of the country that with a temperature change should expect to see an expansion in species richness under natural conditions and changes in the net primary production. Again, these projections are made barring human dimensions of change and its management interventions. The same situation pertains to bird and amphibian species richness with a general overall reduction nationwide but with a general trend of a decline in net primary production from the southwest to northeast.

The change in NPP and species richness while following these trends also presents the opportunity to look contemporarily at areas with current NPP and species richness and consider how economic development strategies may intersect when the conditions found in one area expand into others and transition other biomes and communities. Therefore, there are current activities in the zones that will develop that may present insights for the future as these zones shift into new geographies. Given the relative homogeneity of the Botswanan topography, such transitions could expect to vary relatively little from current forms as they expand. Importantly, there is a change in NPP at the 3.0 °C tipping point that is different. In all the species richness projections (Fig. 7) at this degree of warming, a new low-end species richness category could exist in Botswana that is currently not represented. This is presented in the species richness maps as the 42–48 category for mammalian and bird species richness and the 2–4 range for amphibian species richness. Areas with these ranges of species richness could be found to the west and southwest of Botswana currently, but analysis would need to be done to see if these are, in fact, presently located in the broader region or this new low-end category is currently unknown in the area (Figs. 10, 11, 12, and 13).

Related to the shifts in NPP and species richness described above, the ranges and ecological dynamics of the country are changing, and current reserves will possibly struggle to support all species they were designated to sustain. Climate is, however, just one of the myriads of ISEET issues that impinge on the sustainability of Botswana's biodiversity. Action to mitigate the deterioration in biodiversity varies by spatial scale and the actors required. It is generally viewed that adaptation will require more and better regional institutional coordination, which broadens spatial and temporal perspectives with climate chance scenarios being considered as integral to the planning of actions. Local communities are critical to attaining conservation goals, as there are multiple threats to success. Regional planning, site-scale management, and the continued assessment and modification of conservation plans

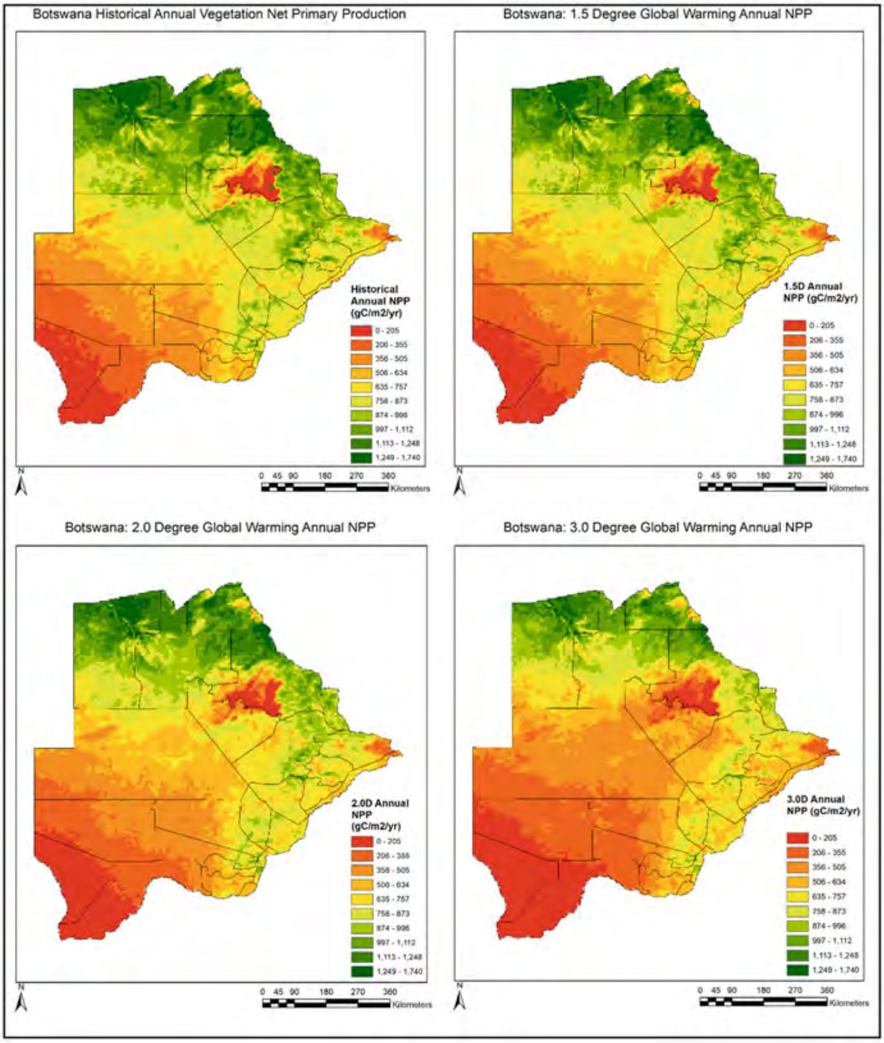

Fig. 10 Changes projected for net primary production (NPP) under the three tipping point scenarios of 1.5 °C, 2 °C, and 3 °C, from baseline (average of 2000–2016). (Source: authors)

will be required as the pace of climate-induced changes mirror those of society. The following needs have been identified:

(1) more specific, operational examples of adaptation principles that are consistent with unavoidable uncertainty about the future;
(2) a practical adaptation planning process to guide the selection and integration of recommendations into existing policies and programs; and,
(3) greater integration of social science into an endeavor that, although dominated by ecology, increasingly recommends extension beyond reserves and into human-occupied landscapes. (Heller and Zavaleta 2009: 14)

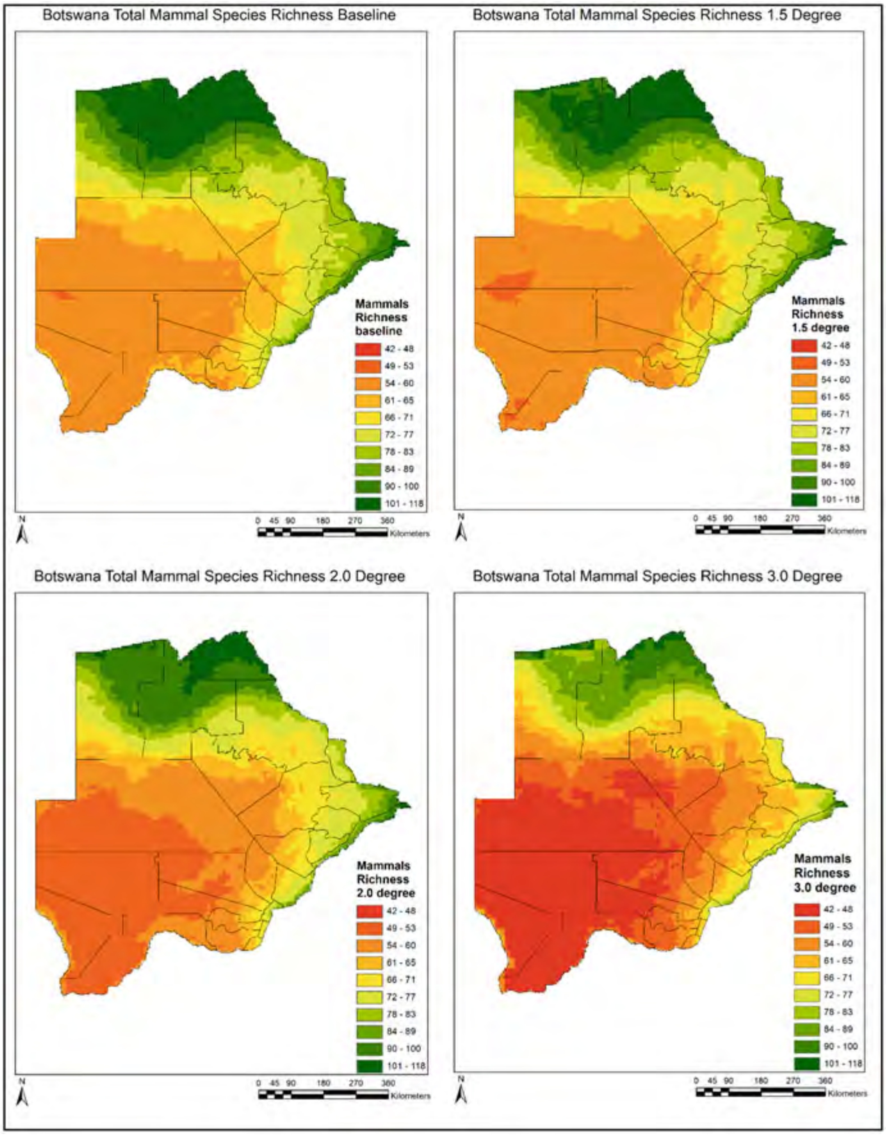

Fig. 11 Changes projected for mammalian species richness under the three tipping point scenarios of 1.5 °C, 2 °C, and 3 °C, from baseline. (Source: authors)

The Paris Agreement is deemed to be beneficial to the cause of species biodiversity conservation as it represents a template for a GDN by setting global targets, an evolving model for financial support, and recognizes the values obtained from bottom-up efforts. Nearly all nations have signed the agreement. Climate scientists have arrived at a single numerical target for maintaining Earth's atmosphere at safe

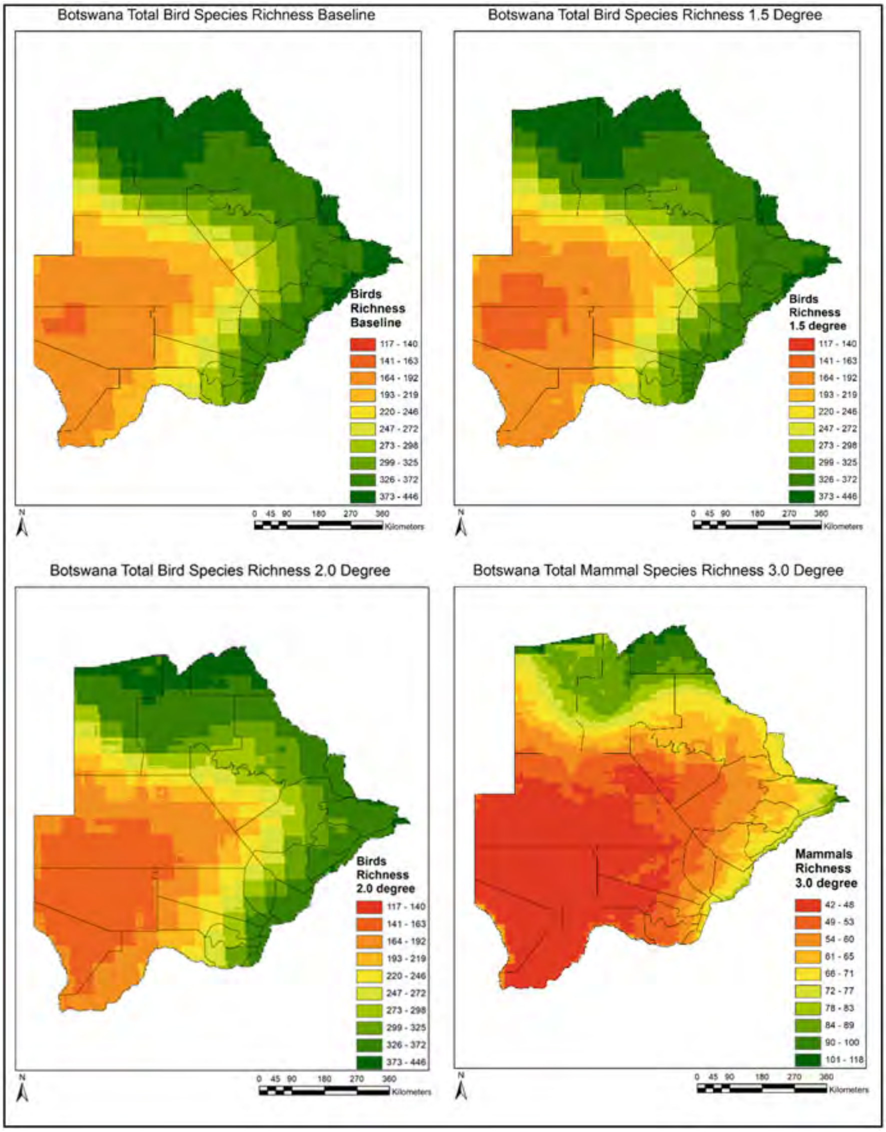

Fig. 12 Changes projected for bird species richness under the three tipping point scenarios of 1.5 °C, 2 °C, and 3 °C, from baseline (note: data source available is at a different resolution than mammalian and amphibian sources, hence the different map smoothness). (Source: authors)

limits (1.5 °C); however, biodiversity scientists work with multiple targets to conserve the rest of life on the planet given the diversity of life and ecosystems and range of resilience. The challenge clearly shown in the case of biodiversity in Botswana is the interconnectedness of the nation with the southern African region

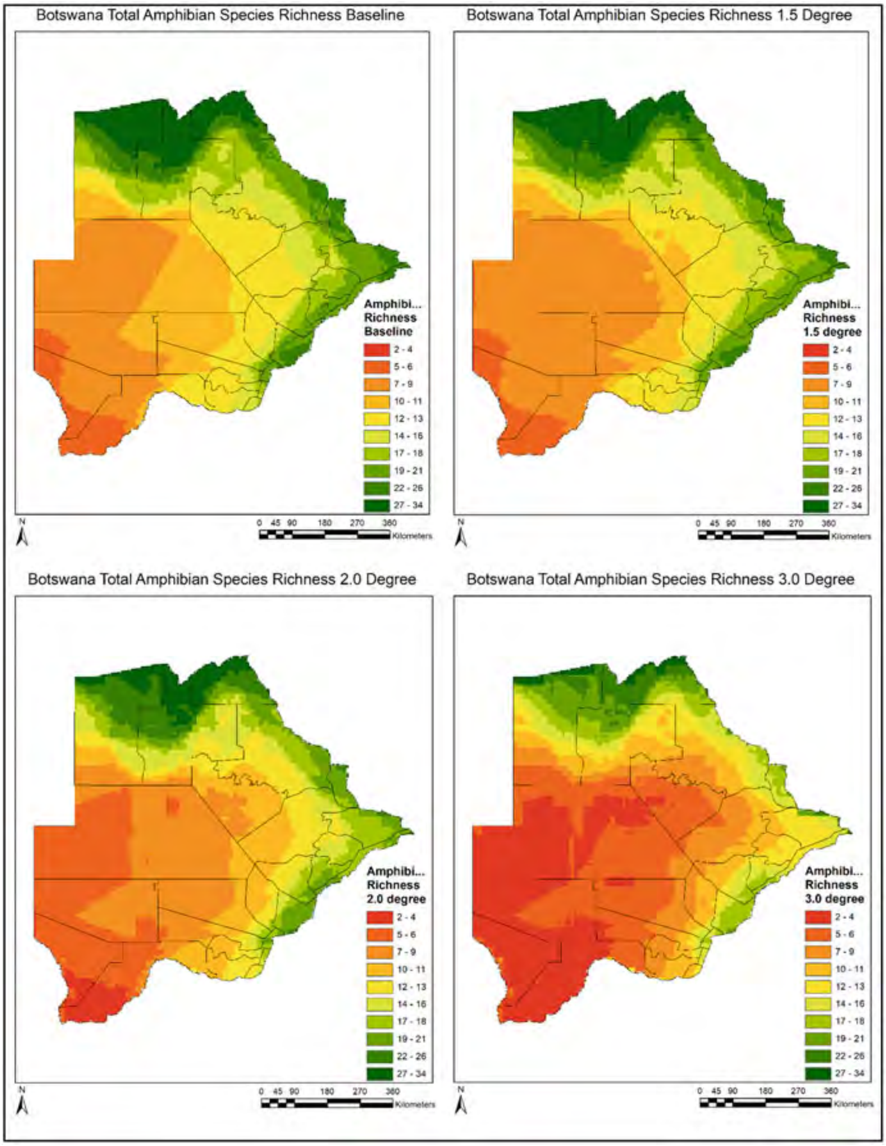

Fig. 13 Changes projected for amphibian species richness under the three tipping point scenarios of 1.5 °C, 2 °C, and 3 °C, from baseline. (Source: authors)

and the faster than global average rise in temperatures. The international climate science goal of limiting global temperatures to 1.5 °C by 2100 is not relevant for places such as Botswana that could reach that average rise in temperature as early as 2028. The GDN has expressed its own target like the Paris Agreement: protect at least half of Earth's biodiversity by 2050 and ensure that these areas are connected

Table 4 Biodiversity sector tipping point analysis summary table

Impact factors	Slow processes	Variabilities	Extremes	Potential tipping points
Earth systems (climate change): Threshold risks	Biodiversity decrease vegetation primary production, land degradation, access to water, heat stress, diseases, tourism and agriculture land pressure, conflict	International variability increase, death rate increase, diseases, poaching	Extreme drought and diseases (foot and mouth) events Low water flows in Okavango Delta Wildlife movements/ encroachments to cropping areas	Continuous drought years could cause the wildlife high death rate and migration
Earth systems (climate change): Potential adaptation options	Recover and reserve natural habitats for natural earth systems	Provide alternative areas/substantial buffer zones for ecosystem change and succession	System integrity enhancement to support biodiversity resilience at times of climatic stress	Species migration pattern shifts Species decline and extinction Increased human/ biodiversity conflict
Social systems: Threshold risks	Tourism sector dependency, livestock number increase, rural labor force, and food relationship	Tourism natural conservation and human conflicts	Wildlife decrease during an extreme drought event	Dramatic changes in tourist sector behavior Loss of economic tourism opportunity without changes in location and interaction with species
Social systems: Potential adaptation options	Tourists and local people education and behavior regulation	Natural and human relationship education and behavior regulation	Reduce human impacts, support system natural recovery where is possible	Biodiversity and tourism sector in collaboration with other ISEET for systematic analysis and uplift social system support

(continued)

Table 4 (continued)

Impact factors	Slow processes	Variabilities	Extremes	Potential tipping points
Institutional system: Threshold risks	Deficiency and out of date in biodiversity protection legislation and policy, land-use and planning legislation and policy	Government policy and institutional implementation capacity	Institutional dramatic changes	Policy failure
Institutional system: Potential adaptation options	Balanced policy and regulation and implementation capacity for biodiversity protection and tourism development	Policy and regulations support the resiliency of the biodiversity conservation that allows natural system recovery	Reinforce and stabilize institutional system, prepared for emergencies	Work together with closely linked ISEET systems, to build the robust institutions for biodiversity conservation and tourism
Economic systems: Threshold risks	Tourism sector over development Irrational land-use and agriculture development	International tourism market variations. Changed habitats and protected area systems too rigid for continuous protection of biodiversity as biomes shift	Market collapse, financial crisis	International financial crisis Tourist air travel depressed by GHG accounting and social pressure to reduce flying
Economic systems: Potential adaptation options	Financial regulation for overdevelopment and land development	Economic measures for sustainable tourism and biodiversity protection subsidies and compensation incentives	Tourism sector support and alternative work development	Overarching economic and financial arrangement for biodiversity and tourism, in coordination with ISEET systems

(continued)

Table 4 (continued)

Impact factors	Slow processes	Variabilities	Extremes	Potential tipping points
Technological systems: Threshold risks	Wildlife and biodiversity conservation technology improvement Human intervention at a large scale to enhance biodiversity management regimes	Technology insufficiency Maladaptation in the management of biodiversity and conservation	Technology failure Species collapse from linked with wider environmental collapse from extreme heat and drop in net primary production	Huge biodiversity loss by technological system failure Disease outbreak and biome changes lead to mass extinction events and loss of keystone species
Technological systems: Potential adaptation options	Sustainable knowledge and technology applications development and introduction for biodiversity and tourism	Development and introduction of the knowledge and technologies for resilient biodiversity and tourism sectors	Technology improvement and backup mechanisms	Technology innovation and knowledge gaining for ISEET system stabilization

(Dinerstein et al. 2019). Over time the role of intact, diverse systems has been repeatedly demonstrated, and they are integral to carbon storage and hence the link to the Paris Agreement. For Botswana, intactness and linkages regionally will become increasingly relevant and urgent given the accelerating pace of temperature and other changes facing the country, which are well ahead of the global trends (Table 4).

Summary and Conclusion

The implications of climate change are a growing concern for biodiversity managers in Botswana. Even simple extrapolation of current trends in temperature makes clear that a warming climate can have negative impacts on many facets of Botswana's society and ecosystems. The sum of these troubling effects, although highly uncertain, motivates efforts to assess and manage potential climate change impacts.

Climate change may trigger major social transformations. As seen around the globe, both slow-onset climate change and extreme weather events can, for example, induce food and water insecurity. Subsequent riots, mass movements of people, and pressure on governance systems to respond to limit social anxiety and loss of national cohesion are being increasingly researched.

However, it is not a simple, one-to-one relationship. The relationship between climate and biodiversity and social change is not easy to identify. The scale of climate change that can induce significant and consequential change and related calls to action, including social transformations, may be minor or major. Often it is built-in resiliency of Institutional-Socio-Economic-Ecological-Technological Systems (ISEETS) that determines if a drought, flood, fire, epidemic disease, or another extreme event will trigger a societal response.

Climate change experts such as Tim Lenton pioneered the use of the term tipping points to refer to "abrupt and irreversible changes in the climate system." The concept has been taken further than climate knowledge to further our understanding of the consequences of climate change. What are often overlooked in climate change research are the social determinants of changes, for example, inequities in determining the social impacts of climate change. Also ignored are perceptions and (mis) representations of change in whatever form that might be, as well as governance systems and institutions, solidarity networks, and cultural values, and underlying technological condition and opportunities in their evaluation of the future social impacts of climate change.

The experience of those interested in biodiversity in Botswana forms a recent historical example of how ecological tipping points are identified and sometimes managed historically ineffectively but with increased local and specific cultural and environmental awareness, more effectively. What are, therefore, more challenging to determine are the social tipping points that would potentially lead to more accurate assessments of the future impacts of climate change. This then expands the thinking about climate change to more fully grasp the biological effects of a changing climate and our technological capacity to forecast them and respond more effectively.

News has emerged on the recognition of the cross-sectoral importance of a more resilient Okavango ecological system which is encouraging. The signing in 2019 of the three-country pact to work, titled "Transboundary cooperation for protecting the Cubango-Okavango River Basin and improving the integrity of the Okavango Delta World Heritage," properly championing an integrated approach to the entire river basin management is an important step forward (Kari and Kaboza 2019). The actors and agents involved and their perspectives represent an ISEET-like approach. The follow-up activities of implementation of defining activities and their monitoring and evaluation will be critical. Time is running out as climate change and its impacts accelerate across Southern Africa.

Contents

Abstract

Malaria is a persistent health risk for most rural communities in tropical wetlands of developing countries, particularly in the advent of climate change. This chapter assesses household access to water resources, livelihood assets, and vulnerability to malaria in the Okavango Delta of north-western Botswana. Data were obtained from a cross-sectional survey of 355 households, key informant interviews, PRA-

based focus group discussions (FDGs), interviews with experts in various related fields, PRA workshop participant interviews, and literature review. There was high access to natural capital, and most households engaged in nature-based livelihood activities. Access to resources determined type of livelihood activities that households engaged in. However, there was no association between household exposure and/or susceptibility, and type of livelihood activities pursued by households. Household vulnerability to malaria was higher in remote and rural locations than in urban neighborhoods. Malaria prevention and vulnerability aversion programs need to be coupled with improvements in housing and well-being in the Okavango Delta and similar wetlands.

Livelihoods · Malaria · Vulnerability · Wetlands

Introduction

In developing countries, access to natural resources largely determines human livelihoods and general well-being of households in many rural communities (Rebelo et al. 2010). Due to lack of access to various forms of capital including financial, physical, human, and social capital, and because of general poverty the dependence on natural resources has been increasing in wetland communities around the world. This is because wetlands act as sources of various forms of ecosystem services that support livelihoods. At the same time, wetlands provide suitable habitats for disease-carrying organisms and therefore remain vector- and water-borne diseases endemic areas. Some vector-borne diseases such as malaria account for millions of human morbidity and deaths annually. For instance, the World Health Organization (WHO) reported that in 2018 malaria accounted for 228 million morbidity cases and 405,000 deaths globally, 94% of which were in Africa (WHO 2019). Due to climate variability and change, the prevalence and virulence of vector-borne diseases (VBDs), including malaria, may increase (IPCC 2007). The challenges associated with malaria outbreaks include deaths of breadwinners in mostly poor households, which largely depend on the labor of their able-bodied members. Given that such mortalities often result in increased suffering of mostly women, children (WHO 2019), and other vulnerable groups, the fight against malaria requires concerted efforts on the part of governments, NGOs, communities, and other stakeholders to enhance access to prevention and treatment. Prevalence of malaria in tropical and subtropical regions including Africa, continues to overwhelm existing measures for prevention and treatment. This leads scientists and policymakers to assess existing forms of prevention and treatment with a view to developing effective means for combating malaria.

Various approaches have been adopted particularly in the prevention and treatment of malaria including (a) distribution of free insecticide-treated mosquito nets (ITNs) in rural communities, (b) use of preventive antimalarial medicines,

(c) interior and exterior spraying, (d) awareness creation, and (e) educational campaigns. Most of these efforts have been supported by governments, NGOs, and global organizations including the World Health Organization. As a result, there is a general decline in the prevalence of malaria in developing countries. In some countries, where malaria prevalence had been recorded and often led to deaths, malaria has been successfully eradicated.

Botswana is one of the 21 countries which were identified by the WHO for malaria elimination by 2020 (WHO 2019). Botswana is also among eight southern African countries which formed the Elimination-8 partnership aimed at eradicating cross-border malaria transmission by 2030 through collaborations and synchronization of policies and initiatives. At the national level, a rapid notification and response strategy was developed to eliminate malaria in hotspot areas, including the Ngamiland District in the Okavango Delta in Botswana (Chihanga et al. 2016).

Despite all these efforts, malaria remains pervasive in wetlands of developing countries, including Botswana, particularly among poor households. This calls for additional efforts to determine the general vulnerability of communities to malaria to improve general knowledge on factors that contribute to its persistence. This chapter is aimed at improving knowledge on household vulnerability to malaria in the Okavango Delta and similar areas around the world. Specifically, the chapter assesses (a) household access to water resources and (b) household vulnerability to malaria in Shakawe and Ngarange villages and the surrounding areas. The chapter is arranged as follows: the next section discusses the conceptual framework used, followed by environmental and socioeconomic context, research approach and data collection, the results on access to capital and household vulnerability, and finally, the section on discussion, conclusion, and implications for malaria policies in the Okavango Delta and other wetlands in similar socioeconomic and environmental conditions.

Conceptual Framework

This research was informed by the sustainable livelihood framework supplemented by the socio-ecological framework. These frameworks were selected for their wide use in microeconomic analyses on access to resources, rural livelihoods, and household vulnerability to shocks in developing countries. The frameworks differ in their approach to the household vulnerability context; the former views livelihood shocks as exogenous factors that are beyond household control, whereas the latter posits that shocks and household livelihoods are interlinked within the broad human–environment interactions (Berkes and Folke 1998; Ellis 2000). Both frameworks were influenced by the changing view on vulnerability as not just the biophysical nature of the shock but the state of the affected social unit as well (Wisner et al. 2004).

The sustainable livelihood framework provides an understanding of the broad concept of a livelihood, particularly the vulnerability context within a livelihood is constructed. In the sustainable livelihood framework, a livelihood can be defined as

"...comprising of assets (natural, physical, human, financial, and social capital), the activities, and the access to these (mediated by institutions and social relations) that together determine the living gained by the individual or household" Ellis (2000, p. 30). The sustainable livelihood framework has some limitations because it does not cater for changes over time (Ellis 2000). It is nonhistoric because it takes current household access to resources as given, without looking at the origins and possible causes of current access conditions (Small 2007). Furthermore, it neither provides for tracing historical factors leading to current institutional structure, nor for understanding the nature of interactions between actors brought together by various interests and complying to set rules, norms, and practices (O'Laughlin 2002). For instance, it does not clearly show the role of the private sector as part of the organizations that mediate access to forms of capital. Furthermore, it does not provide adequate guidance on the analysis of institutions and the behavior of actors involved.

Another observation is that the vulnerability context in the sustainable livelihood framework does not consider the full context of shocks, trends, and seasonality, partly because it does not clearly show the position of the household itself. Although it considers both the negative and positive aspects of these processes, it does not clearly show how negative livelihood outcomes can exacerbate the impacts of shocks in the vulnerability context. This may be because it construes shocks as exogenous factors and therefore beyond household control (Ellis 2000). The sustainable livelihood framework is an integrating analytical tool which was never intended to be used in isolation (Farrington et al. 1999). The sustainable livelihood framework was supplemented with the socio-ecological framework to overcome some of its limitations. The socio-ecological framework was useful in locating the household construction of a livelihood within the broad human–environment interactions in which it occurs. In other words, it helped clarify the broad livelihood vulnerability context in the Okavango Delta. The socio-ecological complex or framework emanated from classical human ecology in the 1930s (Berkes and Folke 1998). It was influenced by the concept of resilience which has now become important for understanding complex relationships between human and other ecological systems (Folke 2001). The socio-ecological framework has been modified and used for analyzing human-environment interactions in developing countries and providing the basis for some contemporary vulnerability frameworks (Arntzen 1989; Adger 2006). This framework analyses rural development in terms of clusters of elements and interactions among clusters, which finally lead to a sustainable society or community (Arntzen 1989; Berkes and Folke 1998). It distinguishes four elements that characterize the socio-ecological linkages and interactions. These are population, organization, the environment, and technology at the micro-scale, with influencing factors at the macro-scales (regional, national, and global) (Arntzen 1989; Berkes and Folke 1998).

Understood in the context of this framework, the household as a human construct (illustrated in Fig. 1 below), and the livelihood as a subset of the household system, fall within the broad human–environment system.

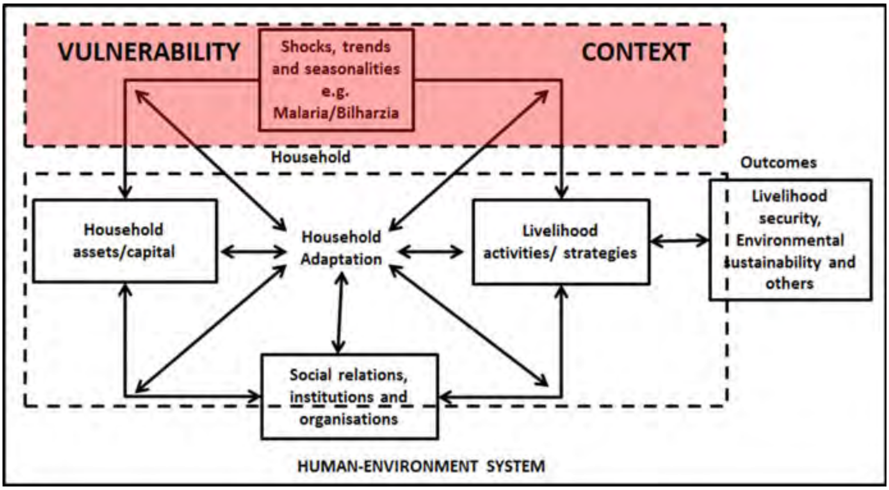

Fig. 1 Sustainable livelihood framework. (Source: Adapted from Ellis (2000, p. 30) with insights from Berkes and Folke (1998, p. 15))

Therefore, the impacts of a shock such as malaria, on a household livelihood and the household responses are part of the interface between the human and environment subsystems. In other words, it is acknowledged that livelihood shocks such as malaria are exogenous to a household because they fall beyond household control as posited by Ellis (2000). However, the effect of their impacts falls within household control depending on household exposure, susceptibility, and capacity to adapt. Therefore, such effects are part of the household vulnerability complex made up of the social (human) and biophysical (or ecological) aspects (Marshall et al. 2009). In the case of malaria endemicity in the Okavango Delta, household adaptation which is the inverse of vulnerability can therefore be viewed as the process and actions within a livelihood system occurring or being undertaken to positively influence or be influenced by livelihood security and environmental sustainability. This position is informed by the view that a livelihood is sustainable if it can adapt, be resilient, and therefore less vulnerable to shocks while not degrading the natural resource base (Scoones 1998).

Household adaptation to a livelihood shock such as malaria may occur at various dynamic levels influencing or being influenced by livelihood security and or environmental sustainability. It may also reduce the impacts of a shock on both livelihood assets and household livelihood activities, as well as the impacts of the institutions, social relations, and organizations, which modify or mediate access to household assets. Household actions to reduce vulnerability to malaria may also affect the setting up of livelihood activities with influence on the type of activity and location within which they may be undertaken. Of course, in case of maladaptation which has a positive effect in increasing vulnerability, the influence will be negative, leading to livelihood insecurity and environmental degradation. Of interest in this chapter is the household access to assets in the process of constructing livelihood activities and how such access exposes and makes households susceptible to malaria as a health risk. The chapter focuses on the vulnerability context as illustrated in Fig. 1 above.

Okavango Delta: Environmental and Socioeconomic Context

The Okavango Delta is an alluvial fan and a vast wetland well-renowned for its biodiversity, species richness, and prominence as a Ramsar Site, and 1000th UNESCO World Heritage Site in north-western Botswana. Due to its richness in flora and fauna, the Okavango Delta enhances dynamic livelihood systems within a semiarid environment of the southern African Kalahari plains. The Okavango Delta and related floodplains, at an altitude of 900 m above sea-level, within a low-physiographic zone given the generally flat terrain, and daily temperatures ranging from 12 °C to 40 °C provide a suitable habitat for the anopheles mosquito (*Anopheles arabiensis*). Rural communities found in many settlements around the Delta fringes as they depend on the natural resources in the form of flora such as papyrus, riverine reeds, grasses, and others, as well as faunal species including fish, birds, and small game.

The specific research sites were the villages of Shakawe and Ngarange in the Okavango sub-District of Ngamiland District. Ngamiland West, a Ministry of Health designated area which largely covers the Okavango sub-District, is among the poorest regions in the country with 47.3% of people below the poverty datum line compared to the national figure of 20.7% (Statistics Botswana 2011). Ngamiland West is a malaria-endemic area due to the high persistence of this disease in many of its villages. HIV/AIDS prevalence in the Ngamiland District is also high (18%), compared to the national average of 17.6% (Central Statistics Office 2009) (Fig. 2).

Shakawe and Ngarange villages are in an area commonly referred to as the panhandle, which is made up of the Okavango River as it enters Botswana from the Kavango Region of Namibia. Shakawe village has a population of 6693 people and Ngarange has 998 people. The population structures of these two villages (Fig. 3) depict a wide base in the young age groups compared to advanced age groups; the patterns that are typical of population structures found in developing countries.

However, there appears to be an anomaly in that the population pyramids in these villages have a narrowed base particularly in the infant cohorts and under-five age group, which is indicative of low fertility and possibly high mortality in these age groups. This is a logical observation in that due to high prevalence of HIV/AIDS, women may tend to postpone their engagement in sexual activity, or totally abstain from sex to avoid repeat infections and/or opt for effective birth prevention methods (Lewis et al. 2004). Due to illness and the impacts of opportunistic diseases, HIV/

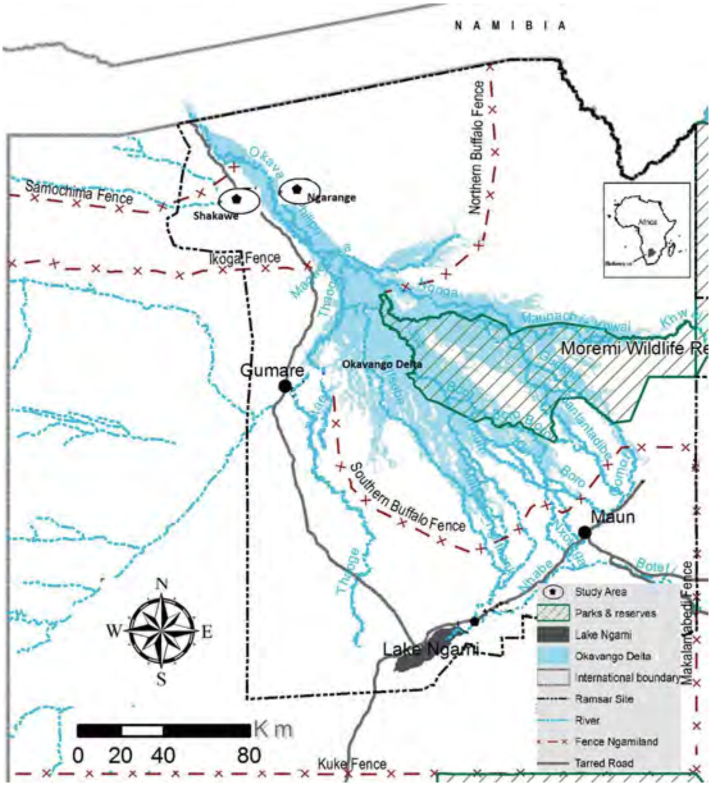

Fig. 2 Map showing the Okavango Delta and the study villages. (Source: ORI GIS Lab)

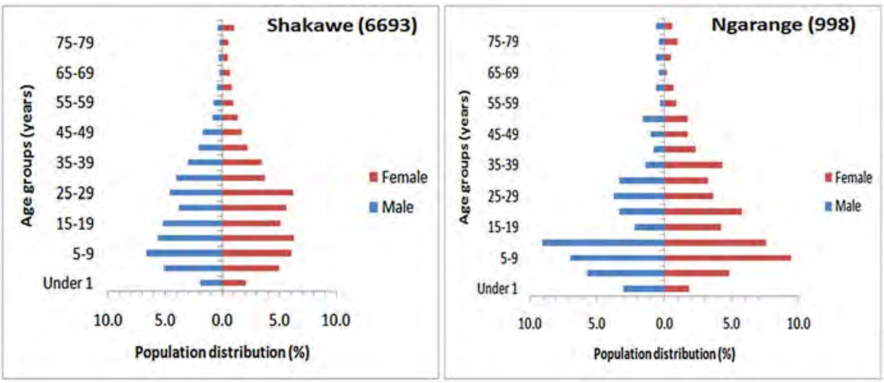

Fig. 3 Population structure in Shakawe and Ngarange villages

AIDS also has adverse effects on fertility (Ross et al. 1999). Infant and under-five mortality is generally higher in communities with high HIV/AIDS prevalence than in those with low prevalence and this may have been contributed to the narrow pyramid base in these two villages. From the foregoing, households in Shakawe and surrounding villages including Ngarange may be vulnerable to other diseases including malaria.

Shakawe has been identified as a malaria hotspot in Botswana mainly due to the high number of confirmed cases in this village. Ngarange has been observed to have low confirmed cases compared to other settlements in the same area. These two villages were selected to understand this apparent contrast and general dynamics surrounding household vulnerability to malaria in the Okavango Panhandle and the Okavango Delta in general.

Research Approach and Data Collection

A convergent parallel mixed-method approach was adopted; it involved the concurrent use of qualitative and quantitative methods of data collection and analysis. This approach made it possible to exhaustively obtain information from the various methods used and substantively confirm outcomes through triangulation. It was also noninterventional given that no further action was taken in treating those infected with malaria; affected individuals received treatment from local health clinics in the respective villages.

Secondary data were obtained through desktop searches in the World Wide Web and from the review of published and unpublished sources including journal articles, global and regional health (and other) organizations' reports, and the national health policy and strategy documents. Primary data were obtained, (a) through a participatory rural appraisal (PRA) methodology which included key informant interviews and PRA-based focus group discussions, (b) through a household survey and informal discussions with community members, and (c) from interviews with various stakeholders including officers in local health clinics, the district office in Maun, the sub-District main office in Gumare, and from the Ministry of Health head office in Gaborone.

Participatory Rural Appraisal (PRA) Workshop

A PRA workshop was held on June 25–27, 2014 in Shakawe with the aim to create project awareness, stakeholders' involvement, and participation in the project, and to collect baseline data on key areas that required further scientific enquiry. In the latter aim, the researchers were able to document community knowledge on livelihoods, the social, environmental, and climate change factors that influence household vulnerability to vector-borne diseases including malaria. Stakeholders including traditional leaders, traditional health practitioners, representatives of various village committees, modern medical practitioners, government health officers, and non-governmental organizations' (NGOs) representatives were invited to the workshop.

The criteria for selecting other members of the community included (a) being adult women and men above the age of 18 years, (b) having lived in the locality for 10 years or more, and (c) being knowledgeable on vector-borne diseases. A total of 40 people, 25 (63%) from Shakawe, and 15 (38%) from Ngarange were invited; the total consisted of 13 (32%) female and 27 (68%) male. Given the diversity of stakeholders and level of representation, the PRA workshop provided opportunities for interviews with the attendants individually, as key informants, discussants in focus group discussions, and as participants in a plenary.

Household Survey

The household survey was undertaken following a stratified sampling of households. Information on malaria occurrence was first obtained from the local clinics in the villages of Shakawe and Ngarange. Using such information, village wards were identified and differentiated according to high, medium, and low number of malaria cases. Village wards were then randomly selected from the broad categories of high, medium, and low malaria cases. In Shakawe, a total of seven out of fourteen wards were selected. Although the same stratification criteria of high, medium, and low malaria cases were used in Ngarange, given the small size of the village, all wards were selected. After the selection of wards in both villages, all households in the selected wards were listed. From a list of households in all the selected wards, households were selected proportionate to size of ward. In Shakawe, a total of 877 households were listed in the seven wards, whereas in Ngarange 300 households were listed in the four wards, therefore some overall total of 1177 households were listed in these two villages. The sample size in the two villages was calculated at 95% confidence interval with margin of error of plus/minus five (+/−5). An overall sample of 355 households (266 in Shakawe and 89 in Ngarange) was selected in the two villages (Table 1).

Table 1 Number of households listed and sampled in various wards of Shakawe and Ngarange villages

Village	Ward	Listed households ($N = 1177$)	Sampled households ($n = 355$)
Shakawe ($n = 266$)	Mabudutsa	29	9
	Matomo	55	17
	Ukusi	83	25
	Ndumbakatadi	163	49
	Saoshoko	178	54
	Diseta	140	42
	Gauxa	229	70
Ngarange ($n = 89$)	Modubana	103	30
	Newtown	48	14
	Mukumbe	107	33
	Sekandeko	42	12

A questionnaire comprising structured and semistructured questions were developed. It had sections on (a) household demographic and socioeconomic characteristics, (b) types of livelihood activities, (c) access to and ownership of assets or capital, (d) malaria prevention and coping strategies and other sociocultural variables. Data on household characteristics, livelihood types, and malaria prevention and coping strategies were captured through open- and close-ended questions. Data on access to capital were obtained through several proxy indicators. For example, access to financial capital was measured using questions on whether (or not) a household had access to cash, credit, and insurance, and access to physical capital was measured through questions on ownership of assets such the plowing equipment, vehicles, telecommunication equipment, and so on.

Various forms of capital were measured using different units; therefore, composite unitless indices similar to the UNDP's human development index were developed to consolidate the various measurement units. Data on household adaptive capacity, susceptibility, and exposure were also captured and transformed into unitless indices. Vulnerability was then calculated using a composite index, being a function of exposure less adaptive capacity, multiplied by susceptibility. Details of the techniques used are described in detail in Hahn et al. (2009), Motsholapheko et al. (2011), and UNDP (1990), so they will not be repeated in this chapter. The questionnaire was administered through face-to-face interviews with household heads, their spouses, and adult representatives. The survey data collection was undertaken in the period October 27 to November 6, 2015, in the two villages of Shakawe and Ngarange.

Access to Water Resources in Shakawe and Ngarange

Results from the survey (Fig. 4) reflected generally similar patterns of access to capital in the two villages. Access to natural capital was higher than that of other capital types in both Ngarange and Shakawe. However, specific differences can be identified; households in Ngarange had slightly higher access to natural capital than those in Shakawe; the index values were 0.67 and 0.61, respectively. Worth noting is that access index values are all above 0.5 and edge toward the value of one which is the maximum. This result is not surprising given that Ngarange has a small population and the village is remotely located on the eastern side of the river which has vast floodplains than in the western escarpment where Shakawe is located. The proportions of households who stated that they had unimpeded access to land, water, forest, and aquatic resources were higher in Ngarange, ranging from 63% to 75%, compared to Shakawe where these proportions ranged from 56% to 72%. In wetlands, such as the Okavango Delta, rural communities depend on natural resources to make a living.

Ngarange households had slightly higher access to financial capital than their counterparts in Shakawe with index values of 0.5 and 0.36, respectively. This was a counter-intuitive result given that Shakawe, as the main commercial center in the area, is more urbanized than Ngarange. A further assessment of household characteristics and livelihood activities revealed that most households in Shakawe were

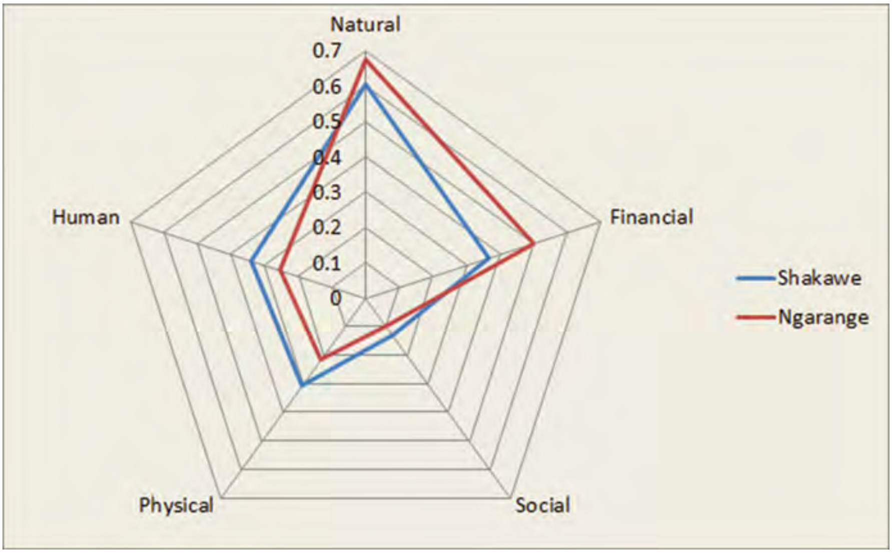

Fig. 4 Household access to resources in Shakawe and Ngarange villages

de jure female-headed (57%) whereas male-headed households accounted for 33% and the rest were de facto female-headed at 10% (De jure female-headed households are those that are directly headed by females, whereas de facto female are those headed by females in the absence of the substantive male head (Motsholapheko et al. 2011).). Conversely, most households in Ngarange were male-headed (44%), the remaining being *de jure* (25%) and de facto (31%) female-headed. Interviews with experts on livelihoods and social development in the area revealed that although Shakawe is more urbanized than most settlements around it, the village could have experienced retarded development related to ownership of land. Large portions of undeveloped land in the village belong to a few individuals whose capacity to develop may either be limited or depends on self-interest and monopolistic tendencies. A further scrutiny of the above indices for Ngarange (0.5) and Shakawe (0.36) indicates a generally low access to financial capital in both villages, given that households have access values of up to half or less than the maximum value of one.

Access to physical, human, and social capital was higher in Shakawe than in Ngarange. Index values were 0.31 and 0.21 for physical capital, 0.34 and 0.25 for human capital, and 0.13 against 0.1 for social capital in Shakawe and Ngarange, respectively. A key observation here is that although Shakawe village households have a slight edge over those in Ngarange, all the above values are very low ranging from 0.26 to 0.36 which reveals very low access compared to a maximum value of one. In terms of ranking, access to natural capital would be the highest followed by financial, human, physical, and social capital in that order. Social capital was least accessed by households in both villages. Key informant interviews have revealed that access to social capital in these villages was adversely affected by loss of culture, breakdown in family ties, individualism, and general lack of cooperation within the village community.

Household Vulnerability to Malaria in Shakawe and Ngarange

Results from PRA-based key informant interviews (Table 2) revealed a general awareness among interviewees that malaria exposure was dominant among some social groups than others within their communities.

Most key informant interviewees (78%) stated that under-five children were the most exposed to malaria whereas safari operators were the least exposed, being stated by 35% of the interviewees. According to key informants, the top five most affected social groups were under-five children, primary school, commercial fishers, pregnant women, hook and line fishers, and river reed/grass harvesters. Commercial fishers and pregnant women were stated by an equal proportion of key informants at 52%. The various social groups stated above are linked to the types of livelihood activities they engage in, as well as their levels of possible susceptibility to malaria given their physical condition. For example, under-five children and pregnant women are known to be more susceptible to most diseases due to their physical condition (Bates et al. 2004).

Key informant interviewees also perceived that some livelihood activities such as commercial fishing and river grass harvesting were high-risk activities for malaria exposure; they were stated by 62.5% and 50% of the interviewees, respectively (Table 3). The top five livelihood activities stated by interviewees as likely to expose households and community members to malaria were commercial fishing, grass harvesting, reed harvesting, livestock herding, hook and line fishing, and arable farming.

Table 2 Key informants' perceptions on social groups and vulnerability to malaria

Social group	Proportion of key informants % ($n = 40$)	Top five social groups
Children <5 years	78	1. Children <5
Primary school children	58	2. Primary school children
Pregnant women	52	3. Commercial fishers and pregnant women
Commercial fishers	52	4. Hook and line fishers
Hook and line fishers	50	5. Reed/grass harvesters
Reed/grass harvesters	48	
Polers	40	
Cattle herders	38	
Safari operators	35	

Table 3 Proportions of key informants and their perceptions on level of risk of malaria infection and related livelihood activities

Livelihood activities	Proportion of key informants (%) by perception of level of risk ($n = 40$)			
	High	Medium	Low	Don't know
Commercial fishing	62.5	22.5	10	5
Grass harvesting	50	20	15	15
Reed harvesting	47.5	17.5	25	10
Livestock herding	45	7.5	32.5	15
Hook and line	42.5	17.5	32.5	7.5
Arable farming	42.5	22.5	25	10
Tourist poling	40	15	22.5	22.5
Basket Fishing	37.5	22.5	27.5	12.5
Tswii harvesting	37.5	12.5	32.5	17.5
Tour guiding	35	15	15	35
Molapo farming	30	12.5	10	47.5
Basket weaving	20	12.5	50	17.5

*B*asket weaving was perceived by 50% of interviewees as less likely to expose households and community members to malaria. Furthermore, *molapo* farming was one of the activities viewed as less likely to expose households and community members to malaria being stated by 30% interviewees. However, most interviewees (47.5) indicated that they did not know the likely level of exposure to malaria for *molapo* farming households and community members. This could be due to insufficient knowledge on *molapo* farming among Shakawe and Ngarange communities. Studies have indicated that *molapo* farming is not widely practiced in these communities compared to their counterparts in the mid- and lower parts of the Okavango Delta.

Results from the socioeconomic survey (Fig. 5 below) indicated that the top five livelihood activities undertaken by households in Shakawe were river grass harvesting in which 60% of households were involved, reed harvesting (58%), dryland/rain-fed arable farming (49%), livestock farming (35%), and *tswii* (waterlily or Nymphaea tuber) harvesting (30%).

These results corroborated key informant interview results on four of the five livelihood activities. Although hook-and-line fishing and commercial fishing were indicated as possible high-risk activities, the socioeconomic survey indicated that these livelihood activities were undertaken by a low proportion of households at 15% and 4.8%, respectively.

Household Exposure, Susceptibility, and Adaptive Capacity

Survey results (Fig. 6) revealed that households in Ngarange village had higher exposure to malaria (0.5) than their counterparts in Shakawe (0.34). These results are quite realistic in that Ngarange village is located near a vast floodplain where water flow is limited compared to Shakawe, which is located along an escarpment.

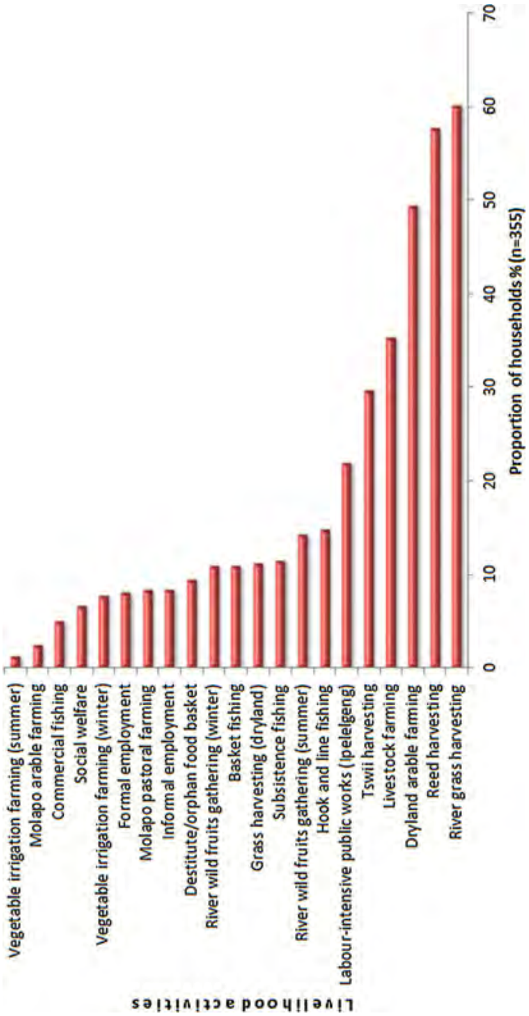

Fig. 5 Proportion of households and livelihood activities in Shakawe and Ngarange. Note: Other livelihood activities accounted for 0.3–0.6% of households

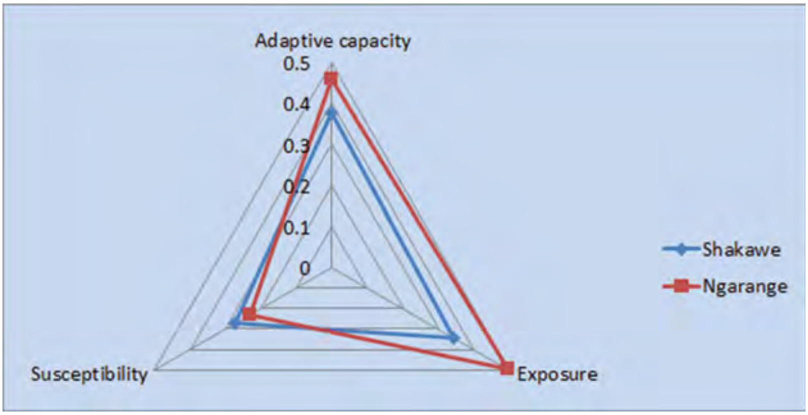

Fig. 6 Village-level susceptibility, adaptive capacity and exposure to malaria

Ngarange households also had higher adaptive capacity (0.46) than those in Shakawe (0.38). Worth noting is that household exposure (0.5) to malaria in Ngarange was higher than adaptive capacity (0.46) meaning that within the village, households could not adequately prevent malaria transmission. In Shakawe, households had higher adaptive capacity (0.38) than exposure (0.34) meaning that they could prevent malaria transmission.

In both villages, the overall household susceptibility to malaria was lower than both adaptive capacity and exposure. Ngarange had a slightly lower susceptibility value (0.23) than Shakawe (0.27), which indicates that households in both villages had almost the same level of susceptibility to malaria. A further assessment of household exposure, adaptive capacity, and susceptibility within these two villages indicates that households in five out of seven wards in Shakawe had higher adaptive capacity than exposure to malaria. The five wards of Diseta, Matomo, Ndumbakatadi, Mabudutsa II, and Saoshoko had adaptive capacity that exceeded exposure values, whereas in the two wards of Gauxa and Ukusi, the exposure values of 0.39 and 0.44 were higher than the respective adaptive capacity values of 0.35 and 0.28 (Fig. 7).

This indicates that households in Gauxa and Ukusi wards of Shakawe were not adequately adaptable to malaria than their counterparts in the other five wards. Household susceptibility in to malaria in four of the seven wards of Shakawe was higher than both exposure and adaptive capacity. The susceptibility values in these wards were 0.65 or higher compared to both exposure and adaptive capacity values that ranged from 0.27 to 0.44.

In Ngarange, household exposure was higher than both adaptive capacity and susceptibility to malaria in all wards except in Mukumbe Ward, which had a susceptibility value of 0.63 that was higher than both adaptive capacity and exposure. These results indicate that households in all the wards in Ngarange are not adaptable and as such vulnerable to malaria, particularly Mukumbe Ward which had higher susceptibility than the other wards.

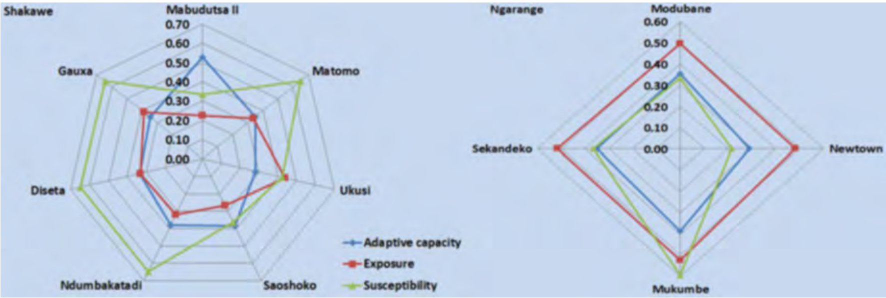

Fig. 7 Household adaptive capacity, susceptibility and exposure to malaria in Shakawe and Ngarange

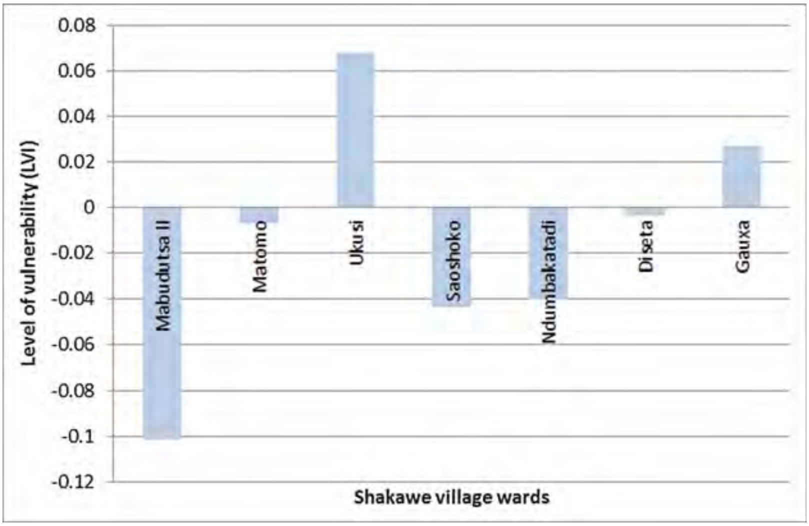

Fig. 8 Level of household vulnerability (LVI) by ward in Shakawe

The overall livelihood vulnerability indices for these villages were −0.0092 for Shakawe and 0.0088 for Ngarange, which confirms the above suggestion that households in Ngarange were not adequately adaptable and therefore vulnerable to malaria whereas their counterparts in Shakawe were not vulnerable. A further analysis indicates that households in Mabudutsa II ward of Shakawe had the lowest vulnerability score of −0.101 (Fig. 8), which indicates that they could withstand the impacts of malaria much better than their counterparts in other wards.

The other four wards of Saoshoko (−0.043), Ndumbakatadi (−0.04), Matomo (−0.007), and Diseta (−0.003) also had low vulnerability scores. The two wards of Ukusi (0.068) and Gauxa (0.027) were vulnerable to malaria given that they had positive values. The vulnerability scores for the two wards of Matomo and Diseta

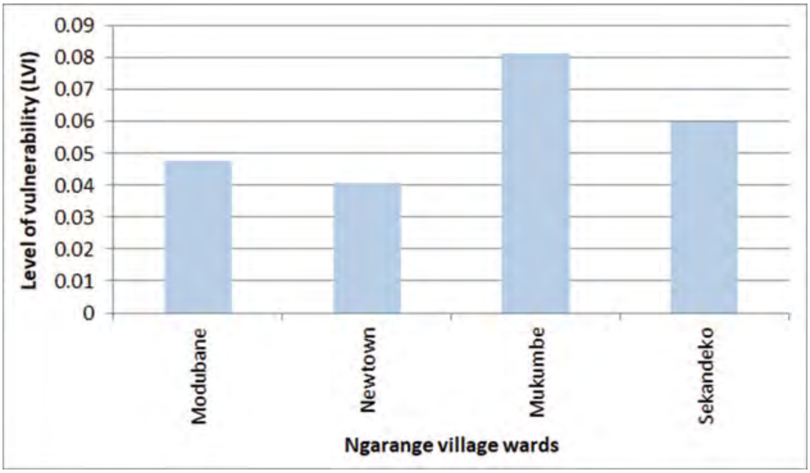

Fig. 9 Level of household vulnerability (LVI) by ward in Shakawe

were close to the value of zero, which indicates that even though these two wards were not vulnerable, any slight decline in adaptive capacity or increase in exposure to malaria may render households in these two wards vulnerable to malaria.

In Ngarange, all wards were vulnerable to malaria, Mukumbe Ward having the highest vulnerability value of 0.08 whereas Newtown Ward had the lowest vulnerability at 0.04 (Fig. 9).

A further analysis indicated that households in the two most vulnerable wards of Mukumbe and Sekandeko in Ngarange were the most susceptible and least adaptable to malaria.

Discussion and Conclusion

This chapter assessed household access to water resources as well as vulnerability to malaria in the Okavango Delta. The results indicate that household access to natural capital was much higher than that of other types of capital. Households mostly engaged in nature-based livelihood activities such as rain-fed arable agriculture, livestock, and the harvesting of aquatic reed, river grass, and *tswii* (nymphaea). Most Ngarange households engaged in nature-based livelihoods than their counterparts in Shakawe village, which was relatively more urbanized than Ngarange. Social capital was the least accessed of all the five forms of capital. It has also been demonstrated that households in Ngarange were more vulnerable to malaria than their counterparts in Shakawe and that this vulnerability emanated from high-household exposure mainly due to low capacity to adapt to malaria than their counterparts in Shakawe.

Due to high access to natural capital compared to other capital forms, households engaged in nature-based livelihood activities. This is typical of most rural communities in developing countries, particularly those residing in wetlands of sub-Saharan

Africa (Babulo et al. 2008; Rebelo et al. 2010; Angelsen et al. 2014). As earlier indicated in the conceptual framework, households' choice of livelihood activity depends on access to capital such that the most accessed type of capital may determine the main livelihood activity in any livelihood portfolio (Ellis 2000; Berkes and Folke 1998).

Access to social capital was lower than that of other capital forms contrary to expectation that this form of capital is higher in rural communities than in urban settings. Key informants attributed this low access to social capital to loss of culture, breakdown in family ties, a rise in individualism and general lack of cooperation within the village community. Low access to social capital may have adverse impacts on the well-being of households given that cultural diversity, social cohesion, and network are critical components of social sustainability (Munasinghe 2000).

Households in Ngarange were found to be more vulnerable to malaria than their counterparts in Shakawe. This vulnerability could be attributed to high exposure to malaria partly due to type of housing, and household practices relating to malaria prevention. Some studies have posited that malaria transmission is related to type of housing, and with increased urbanization and change of housing structure malaria transmission is likely to decrease in sub-Saharan Africa (Saugeon et al. 2009; Parnell and Walawege 2011). Household livelihood activities (such as agriculture) and practices have also been found to be confounding factors for malaria transmission, in Africa and Southeast Asia even in urban communities (Klinkenberg et al. 2008). Effectively, malaria transmission directly relates to type of housing, preventive measures, and practices relating to mosquito bites avoidance (Tusting et al. 2016).

Vulnerable groups such as pregnant women, under-five children, and the elderly require targeted programs with emphasis on availing the means to prevent malaria transmission. There is a need for long-term, sustained prevention, and control to reduce and/or eliminate malaria in the Okavango Delta and Botswana, in general.

Abstract

Phone-based applications, Internet connectivity, and big data are enabling climate change adaptations. From ICT for development and agriculture perspectives, great interest exists in how digital platforms support climate information provision for smallholder farmers in Africa. The vast majority of these platforms both private and public are for delivering climate information services and for data collection. The sheer number of digital platforms in the climate information sector has created a complex information landscape for potential information users, with platforms differing in information type, technology, geographic coverage, and financing structures and infrastructure. This chapter mapped the existing climate information services and examined their impact on policy and practices in smallholder farming development in Africa, with a focus on Ghana. Specifically, the chapter provides highlights of digital platforms available to smallholder farmers and agricultural extension agents, analyzes the public and/or private governance arrangements that underpin the implementation of digital climate information delivery, and assesses the potential of these platforms in scaling up the use of climate information. The chapter contributes to understanding the dynamics of climate information delivery with digital tools in Africa, and suggests a future research agenda.

Keywords

Climate information services · Digital platforms · Smallholder farming · Ghana · Africa

Introduction

Climate change and variability are complex problems affecting different geographical regions, people, and socio-ecological systems. Africa is likely to be the most adversely affected due to its overdependence on climate-sensitive sectors for development. For instance, studies have shown that Ghana is highly prone to drought; temperatures are projected to increase at the rates of 3.8% (1.02 °C), 5.6% (1.5 °C), and 6.9% (1.8 °C) for the near future (2040), mid-future (2060), and far future (2080), respectively, and rainfall is expected to become more erratic (Dumenu and Obeng 2016). The changing climate conditions and the projections of increased temperature and precipitations have implications for smallholder farming and household food security.

The Intergovernmental Panel on Climate Change (IPCC), in recognition of the heightened climate impacts, vulnerabilities, and need for adaptation, encourages the adoption of a cross-sectoral and integrated approach to the development and adoption of long-term and sustainable adaptation and mitigation strategies (IPCC 2014). Adaptation, along with mitigation efforts, is a complementary approach for reducing and managing the risks associated with climate change and sustainable development particularly in developing countries (Federspiel 2013; IPCC 2014). Countries are therefore expected to develop mechanisms (plans, programs, and policies) that enhance resilience and provide support for local practices for climate change adaptation (Dougill et al. 2017).

To support farmers to better adapt to climate change and variability, context-relevant, accurate, and timely climate information services (CIS) have become a relevant strategy (World Meteorological Organisation 2015). CIS range from climate data delivery, transformation of climate-related data together with context information into customized products such as projections, forecasts, trends, economic analyses, analysis on best practices, development and evaluation of solutions, user interactions, and capacity development (Vaughan and Dessai 2014; Vogel et al. 2019). Through the provision of CIS, farmers can make crucial decisions regarding when to plough, sow seed, apply fertilizer, and harvest, thus, reducing exposure to risks (Tall et al. 2014). It also provides actors such as agricultural extension agents, researchers, and policy-makers with the requisite knowledge to support farmers to adapt to climate change. Despite the relevance of CIS, smallholder farmers are unable to access it due to high illiteracy rates, technical information, financial constraints, sociocultural barriers, and infrastructural challenges (Singh et al. 2016, 2018). In this regard, the Global Framework for Climate Services (GFCS) has become a prominent mechanism to address these challenges (World Meteorological Organisation 2015). The framework recognizes the role of digital tools for the provision of tailored CIS to meet the needs of users including smallholder farmers (Singh et al. 2016). Digital tools include new ICTs such as smartphones and old ICTs such as radio and television (Asenso and Mekonnen 2012). The growing innovations associated with ICTs create new opportunities for information-sharing, alternative forms of connectivity, financing models, and governance arrangements (Bennett and Segerberg 2012; Karpouzoglou et al. 2016; Soma et al. 2016).

Despite the opportunities associated with the application of ICTs for the delivery of CIS in Africa, opinions abound regarding the extent to which smallholder farmers use ICT-delivered CIS.

Some of these opinions include:

- Old technologies such as radio, television, and farmers' networks remain the most relevant and cost-efficient ICT platforms for the delivery of CIS.
- ICTs remain underused despite the hype due to the lack of relevant content information, lack of or poor infrastructure, low affordability, low literacy, lack of access to ICTs, and absence of conducive social norms, such as trust.
- ICTs are social transformational tools which are enabling farmers to become co-producers of CIS rather than consumers.
- The delivery of ICT-based CIS results in changes in institutional logics in farming communities in the form of new interactions and information exchange and other forms of innovation intermediation.

The differences in the opinions on the application of ICTs for the delivery of CIS for smallholder farmers may be attributed to the relatively underdeveloped CIS sector in Africa (Graham et al. 2015; Hansen et al. 2019). This can also be attributed to the fact that studies on CIS use among smallholder farmers in Africa are often framed under themes, such as gender, accessibility, local content development, and local knowledge, while ICTs are mostly treated as sub-themes. Based on this gap, this chapter examines the application of digital tools for the delivery of CIS for smallholder farmers with a focus on Ghana. This chapter is guided by the following questions:

- Who are the actors of ICT-based CIS delivery?
- What digital tools are used for the delivery of CIS for smallholder farming in Ghana?
- Which category of farmers applies CIS?
- What financing modes and governance arrangements are used for the delivery of CIS?

The chapter contributes to the literature on climate change adaptation in two ways: First, it provides an overview of the landscape of digital tools that are being used to provide CIS to smallholder farmers in Ghana. Second, it provides insights and directions for further research on the delivery of CIS with digital tools in Ghana in support of adaptation. The chapter consists of an "Introduction", "Methodology", "Results", and "Conclusion" sections.

Methodology

To generate data for the chapter, a systematic literature review was carried out with three databases: Scopus, Google Scholar, and CAB Abstracts. Keyword searches of terms "Climate services" AND "Ghana," "Climate information services" AND "Ghana," "Weather information" AND "Ghana," and "Weather information services" AND "Ghana" were entered as queries. "Weather and climate information services" AND "Ghana," "Climate and weather enterprise" AND "Ghana," and "Agrometeorological services AND Ghana" were conducted. Other queries include "Hydroclimatic information," "Weather information services," "Agroclimatic information," "Services," and "Information." Articles that had the abovementioned key terms in their title or abstract were selected through a process of "abstract sifting" to help align with the language, concepts, and subject matter. Since CIS is still in its infancy and now gaining attention in the literature in Africa, limited literature was generated for the period 2000 to 2020. Hence, the snowball strategy was used to expand the scope of the literature by identifying additional literature from the selected peer-reviewed journals. Other literature which had combined themes on CIS and agricultural extension or had a regional scope on Africa with case studies on Ghana were also selected.

Additionally, desktop search was conducted by reviewing the websites of public, nongovernmental organizations (NGOs) and business organization that provide CIS in Ghana including ESOKO; MFarm; Farmerline; e-agricultural platform; Climate Change, Agriculture and Food Security (CCAFS); African Cashew Initiative, Ignitia, Technical Centre for Agricultural and Rural Cooperation ACP-EU (CTA); US Agency for International Development (USAID); and Agricultural Cooperative Development International and Volunteers in Overseas Cooperative Assistance (ACDI/VOCA). Relevant policy documents, thesis, and gray literature were also reviewed to provide information for the analysis. The limitation of the method used for the selection of literature for the chapter is the application of only three databases. Also, new publications could have been made after the literature search was conducted. The intertwining nature of CIS, ICTs, and other broad themes could have resulted in the omission of certain literature that might have relevant information on the application of ICTs for smallholder farming in Ghana.

The content analysis of the selected literature was guided by the research question and core themes: ICTs, digital tools, CIS, smallholder farming, and Ghana. Additionally, the content of the literature was analyzed based on the geographical settings, governance arrangements, geographic scope, type of digital tools or products, content of the digital messages, stages in their development, targets in the farming sector, and organizations providing CIS with ICTs. Here, the content analysis helped categorize and structure the sub-themes in order to select new themes emerging from the literature.

Results

Actors Involved in the Provision of CIS with ICTs

The actors providing CIS with ICTs to smallholder farmers were grouped broadly since a more comprehensive analysis indicating all actors is beyond the scope and objective of this chapter.

Actors who collected weather data with ICTs include the Ghana Meteorological Agency (GMet). At the international level, international weather organizations (National Oceanic and Atmospheric Administration (NOAA) and European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT)), the European Centre for Medium-Range Weather Forecasts (ECMWF), the National Aeronautics and Space Administration (NASA), UKMet, and the World Meteorological Organization also provide weather data (Mills et al. 2016; Usher et al. 2018). Farmers also constitute CIS data providers as they also generate information on local weather indicators in their communities for co-creating weather information with formal scientific models (see Kadi et al. 2011; Nyadzi 2020).

Intermediary CIS providers add value to the weather data. They include business weather data providers, like aWhere, Satelligence, and Weather Impact, mobile telecommunication network providers, and ICT platform providers (e.g., Prepeez) (Singh et al. 2018), while some knowledge institutions also play this role. Some actors double as intermediary CIS providers and also deliver the information directly to farmers with their ICT platforms, e.g., Farm Radio International, MFarm, Esoko, Farmerline, and VOTO Mobile among others.

The delivery of CIS information for farmers is carried out by a variety of actors from the government agencies, e.g., GMet, GTV, National Disaster Management Organization, and regional public radio channels (Adjin-Tettey 2013). International development partners in collaboration with ICT companies also provide CIS to farmers (Mohammed 2018). Businesses, commercial radio channels, and agri-input companies are also involved in the delivery of CIS to farmers. Other actors include processors, input suppliers, aggregators, exporters, agricultural service providers, and NGOs. They focus on providing complex interventions (e.g., demonstrations, visual aids, agronomic inputs, logistics, and resources) to ensure farmers' access to information (Slavova and Karanasios 2018).

Digital Platforms for the Delivery of CIS to Smallholder Farmers

This section is divided into three subsections.

Data Collection and Production of CIS

Few studies provide information on the application of ICTs for collecting data and producing CIS for the smallholder farming sector. Even so, some studies which captured data collection at the farming community level were identified. These include ground-level measurements and nowcasts that are derived from ICT-enabled platforms such as algorithms, automatic weather stations, weather models and historical observational weather data, automatic rain gauge, sensors, data logger, and ground-level radio with the aid of mobile telecommunication network radar (Gotamey et al. 2018; Usher et al. 2018; Nyadzi 2020). Global Positioning Systems (GPS) are also used to pick the location of communities, and some of the abovementioned technologies are triangulated to provide location-specific data. The mobile phone or smart technologies are also used to transmit data from weather stations in different locations to weather information producers, although carried out on a trial basis (Akudbillah 2017; Usher et al. 2018). In the case of the actual provision of weather data, the technologies are mostly based outside Ghana, and so the role of the Internet becomes relevant for data transmission (Chudaska 2018). For example, supercomputers and cell tower-mounted or co-located automatic weather stations capitalize on the increasing availability of secure, powered, connected telecommunication infrastructure in Ghana. Smartphones are used to collect personal data, type of crops cultivated, and location with Geographic Information Systems (GISs), and the data is stored to a server. Also, some organizations have researched the production of CIS with ICTs, such as chip sensors, in the northern part of the country for monitoring temperature and other weather indicators in local communities (Mills et al. 2016; Usher et al. 2018). The collection of local weather indicators with a smartphone for co-producing location-specific CIS has also been carried out on a trial basis (Nyadzi 2020; Sarku et al. forthcoming).

Data Management and Analysis

CIS information providers usually have supercomputers, data processing, analytical models, sophisticated algorithm proprietary data sets, or multilayer ICT architecture with a system of modular components (functionalities and interfaces) that communicates with a central cloud application, which includes a central database (see Fig. 1) to interpret and convert raw data into accurate forecasts. For example, Ignitia uses supercomputers to provide real-time weather forecasts to farmers. The geospatial data collected from many locations over time are collated in a central database and then interpreted by experts (Chudaska 2018). Application Programming Interfaces (APIs) are used to deliver real-time CIS data to systems and businesses (e.g., aWhere and Farmerline). Cloud computing is used to limit the impact of unstable power and air conditioning systems in computer rooms (e.g., aWhere and Ignitia). CIS bundling is one of the key marketing strategies of market-led ICT platform information providers. It involves the collection of GPS coordinates and profiles on farmers' socioeconomic characteristics to provide value-added services such as agronomic advisory (Etwire et al. 2017; Partey et al. 2020). Some pilot projects indicate the use of different ICTs to integrate the weather data with soil and crop advice and make suggestions for minimizing losses and optimizing inputs (Eitzingera et al. 2019). Decision-support systems such as RainCast application have data source that uses OpenWeatherMap with the aid of an API to extract weather data (Omoine et al. 2013). From the API, the app retrieves temperature or weather conditions for the day and the time the condition is expected to occur for as much as 5 days ahead (Dinku et al. 2018; Gotamey et al. 2018). Mobile telecommunication networks also help to locate users in a variety of ways through network-based call detail records (CDRs), triangulation via LBS, and user registration, which enable the creation and delivery of highly localized, farm-level forecasts based on user location.

Information Delivery

To enable the delivery of CIS to farmers, the focus is mostly on the medium of information delivery due to its influence on the usability of the information for decision-making in farming (Dilling and Lemos 2011; Lemos et al. 2012). Often a distinction is made in the literature between existing and emerging technologies as "old" and "new" ICTs, respectively, based on different factors. From the social perspective, ICTs are classified as new, due to the ability to mostly complement or spur real-life interactions, and two-way communication (Materia et al. 2015; Sulaiman et al. 2012; Slavova and Karanasios 2018). They also enable alternative forms of connectivity and virtual communities for different actors (Bennett and Segerberg 2012; Cieslik et al. 2018). Another factor that is used to distinguish ICTs as either old or new is based on the capacity of the technology to collect data, process, and deliver information within a short period across space and time (Asenso-Okyere and Mekonnen 2012; Munthali et al. 2018). Also, ICTs are classified as new based on the innovations attached to the technologies such as the ability to provide mobile push-and-pull services (e.g., social media) (Bell 2015; Barber et

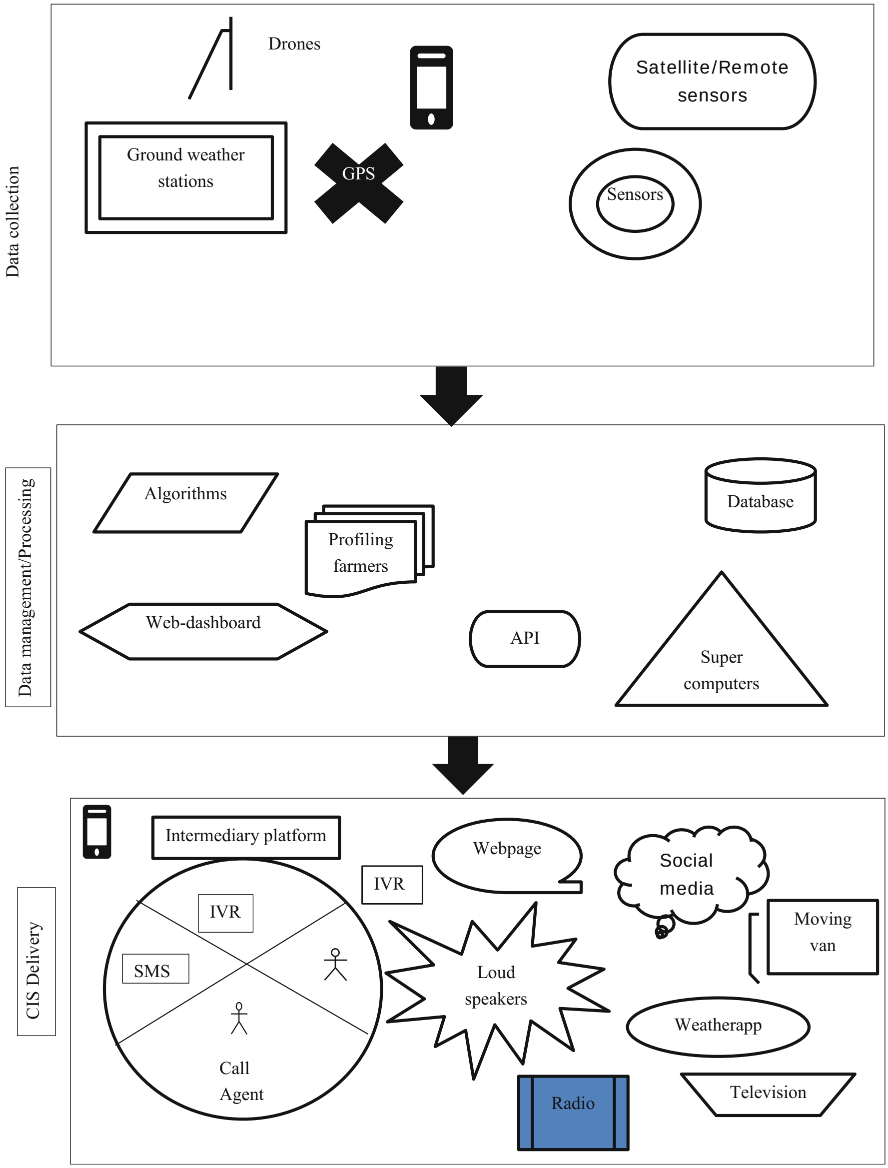

Fig. 1 Flow chart indicating how digital platforms are used for the delivery of climate information services

al. 2016; Suchiradipta and Saravanan 2016). In some instances, new technologies are identified to support environmental monitoring through the involvement of citizens in data collection (Buytaert et al. 2014; Karpouzoglou et al. 2016; Nyadzi 2020). With regard to the governance or institutional perspective, old ICTs have remained large under the control of state organizations, while new ICTs seem uncontrollable and have transformative powers due to the numerous actors who use it to provide information across space and time (Mol 2008; Soma et al. 2016). In reference to these factors, a plethora of new ICTs is identified for the delivery of CIS for farming (Akudugu et al. 2012; Munthali et al. 2018).

New ICT

Mobile phones for CIS delivery are increasing in Ghana due to its different functionalities. As tools for oral interpersonal communication, mobile phones have a high level of ownership among farmers (Anuga et al. 2019). Farmers stressed the importance of mobile phones as tools for accessing formal and informal networks. For instance, they are used to contact agricultural extension agents (e.g., dealing with pests) or reach out to fellow farmers for assistance (Alhassan et al. 2013). The are several advantages associated with the use of a mobile phone for the delivery of CIS (see Table 1). The functions of mobile phones used by RainCast for the delivery of CIS include a selection of options for language, location, type of forecast required, and other information related to farming (Omoine et al. 2013).

Interactive voice response (IVR) is a voice-based channel of communication; others include call centers and voicemail (Zougmoré et al. 2018). The e-extension platform for the Ministry of Food and Agriculture (MoFA) has a mobile application called Farmer Direct which allows farmers to call in and receive pre-recorded information (Modernizing Extension and Advisory Services (MEAS) 2012; Munthali et al. 2018).

The voice/audio and video messages are in the form of pre-recorded information in the local languages to meet the needs of different categories of farmers. The voice forum is a feature that allows farmers to ask questions by calling a toll-free helpline with a short code. Agricultural extension agents can answer questions via a web interface, and answers are sent to farmers as voice SMS (Slavova and Karanasios 2018).

Short message services (SMS) are short written text with description on weather conditions and other agricultural information on how to tackle pests or diseases, agricultural techniques, optimum planting times, available subsidies, and weather forecasts, local fairs, and crop prices (Aker 2011). For example, Ignitia Ghana partners with ACDI/VOCA to deliver weather forecast through SMS to farmers who are part of the Agricultural Development and Value Chain Enhancement (ADVANCE) II project. Automated SMS alerts are also used for the delivery of CIS (Mohammed 2018).

Weather apps such as AccuWeather, Rainsat, and others are installed on smartphones to provide a daily forecast. Some of these apps provide a forecast for 48 h or the entire week. Some weather apps are available to specific network subscribers (Caine et al. 2015). The smartphone has also enabled user-specific weather apps with an interface designed for several functionalities and applications for farmers (Gotamey et al. 2018).

Mobile-based-only platforms include MTN and Vodafone telecommunication network scribe to access CIS with SMS and IVR. Vodafone farmer clubs have

Table 1 Overview of ICT platforms for information delivery to farmers

Categories	Type of ICT platform	Application during the farming seasons	Advantages	Challenges
Voice-based	Mobile phone	All-year usage	• Social identities through personalized ringtones • More durable and portable • Can be used in numerous ways due to the multiplicity of functions for illiterate farmers • Missed calls can be traced • Cheap technology • Allows for two-way interaction with other farmers or agricultural extension agents • Two-way flow of information provides opportunities for information providers to generate feedback	• Access to messages not free • Illiterate farmers cannot access messages delivered in the English language • Novice users cannot trace or navigate through the phone to trace missed calls • Most existing phone-based services are not free, and this raises the issue of information asymmetry where farmers who can pay access to information • Loss of phone results in loss of messages and cost implications
	IVR (interactive voice response)	Used only during the farming season	• Available on feature phones • Interaction with information provider is possible • Accessible for illiterate users • Has the potential to reach more people • Richer content • Cost-effective alternative to access information	• More expensive than a text message • Require training to use
	Television	All-year usage	• Free access • Uses images and symbols • Oral presentation	• No interaction with viewers • Access affected by the unavailability of electricity • Weak network signals and poor reception • Communication of CIS is in English • TV ownership not common among farming households • Unfamiliarity with symbols depicting weather conditions such as rainfall or sunshine

	Interactive community and commercial radio	Mainly at the onset of the farming season	• Can be powered by batteries or solar panels • Free access to information • Exist in portable forms and movable • Multiplicity of radio channels in a specific area with wide frequency coverage • Presentation of information in (multiple) local languages • Timely broadcast of CIS programs • Satisfies the needs of all listeners including illiterates • Engages different panelists with different knowledge levels • Formation of listenership groups in communities • Integrated with phone-in activity to enable listeners share experience, challenges, and questions • Discussions bridge gap in communication of uncertainties in the forecast • Uses voice prompts, vox pops, beep calls, Beep4Weather system, and pre-recorded information • Values farmers' local knowledge, cultural beliefs, and attitudes • Local contents embedded in discussions build trust in CIS • Level of dialogue is synonymous to face-to-face methods • Integrates a variety of ICTs into the programs, e.g., phone-in	• Provides less opportunity for in-depth discussion and interaction with panelists • Phone-in sessions during the in-studio discussion are limited • Schedule programs and limited time allotted for CIS programs throughout the week, e.g., 1 h per week • Program formulation can be top-down • CIS programs run mostly at the onset of the season • Possible altering of information in the process of translating from English to the local languages • Broadcasts are fleeting; one either hears them when they are broadcast, or they are missed • Limited ways of accessing missed programs unless they are recorded and played back • Affordability of batteries or solar-powered radio sets • Limited in facilitating learning-by-seeing or visual presentations

(continued)

Table 1 (continued)

Categories	Type of ICT platform	Application during the farming seasons	Advantages	Challenges
	Video (YouTube)	All-year usage	• Facilitate better comprehension of complex ideas, specifically for illiterate farmers • Access to mobile internet opens significant new possibilities for knowledge-sharing and exchange with social networks • Allows for visual display of data and discussions	• Not easily applicable in all devices • Poor Internet connectivity affects its use
Text-based messaging	SMS (short message service)	All-year usage	• Available on all mobile phones • Low-cost message • Low technical setup • Can be stored for later viewing or forwarded • Information is straightforward • Easily accessible on any mobile phone • It is readily available	• Deductions debited from call credit • SMS nuisance due to numerous messages from telecommunication networks • Requires two-sim phones to subscribe if farmers are subscribers of other networks • Information delivered in English • Inability to read information deters some farmers from accessing information • No graphic communication • Messages are sometimes too short to allow adequate comprehension of information • Limited communication of uncertainty • Scheduled delivery of SMS at fixed times • No provision of outlook forecast for the day • Lack of interactions
	Mobile network based on platform	Used only during the farming season	• Service providers enable free calls between subscribers • Access to an expert helpline (Vodafone 2015) • Simple and comprehensive messages • Voice SMS in 13 local languages • Provision of a variety of temporal CIS	• Disadvantages same as SMS

	Mobile weather apps for smartphones	Irregular use during the farming season	• Almost unlimited • Informative and intuitive • Visualizations are possible • Symbols exist to illustrate CIS • Visualization capabilities in mobile apps help to overcome the challenge of limited literacy rate in rural communities	• Low level of smartphone ownership • Mobile data expensive • Unavailability of the Internet • Inability to use a smartphone • Complexity attached to navigating apps • Inaccessibility to the Internet to enable the use of online mobile apps • Many farmers are smartphone phobia due to language and literacy barrier
	Smartphones	Irregular use during the farming season	• Smartphone application is simple and optimized for fieldwork usage • Variety of functions, e.g., social media, registration of farmers, pick GPS points, apps • Can be used for offline data collection, and data can be uploaded upon the availability of the Internet	• Difficulty in swiping sensitive screen, switching data, and renewal of Internet data and other more sophisticated functions • High cost of Internet data • Inaccessible Internet in most locations • Technology not coded in local language • Keyboard does not have alphabets for local languages
	Website	Irregular use during the farming season	• Website that provides weather fore for 24 h • Focused on all regions in Ghana	• Offer limited opportunity for interactions • Limited Internet access affects its use in many rural communities • Farmers will find it difficult to read and interpret information by themselves because of limited literacy
	Newspaper and bulletins	Mostly used at the onset of the farming season or for outlook forecast	• Written text suitable for literate farmers	• Constrained by low literacy rates • Scheduled publication deliveries • Available at certain periods of the year • Accessibility to a few farmers and in urban areas

(continued)

Table 1 (continued)

Categories	Type of ICT platform	Application during the farming seasons	Advantages	Challenges
Intermediary platforms	Platform intermediaries	Used only during the farming season	• Play intermediation roles • Engages farmers to identify their tacit knowledge and integration with scientific CIS • Foster continuous information flows and trust building • Collection of databases for information on farmers • Aids in scaling up access to CIS through the combination of SMS, call-in services, rural radio, agricultural extension or field agents, farmer organizations, and social networks • Offers learning opportunities in broader networks	• Inadequate experts to play the intermediation roles • Logistical constraints in staff deployment
	Call center	Used only during the farming season	• Provision of expert advice • Voice-based calls • Access the helpline by dialing a short code at a regular call rate • Provides tailored and interactive solutions • Offers timely responses to all category of farmers • Provides a mechanism to receive feedback on the service • Offers services in a variety of languages • Builds trusts in CIS • Helps in contextualizing the information and discuss risks	• Unavailable 24/7 • Cost of call credit for farmers

	Informal: van, loudspeakers, community information center	Mostly used at the onset of the farming season	• Facilitates intensive face-to-face interaction • Can target a wide audience • Information presented in the local language • Relatively low cost	• Information not frequent • CIS available at a specific period of the season • Other social issues prioritized above CIS
	Social media/ weather app	Irregular use during the farming season	• Combines text, images, animations, symbols, and videos • Provides timely delivery of climate information • Low-cost information delivery • Enables information to travel easily • Attractive forms of communication • Can provide outlook forecast during the day	• Requires advance ICTs such as apps and smartphones • Not accessible to all farmers • Unavailability of the Internet and other infrastructures can be challenging • Inability or difficulty in using ICTs, e.g., mobile phone, smartphone • Farmers' inability to navigate several ICTs and read messages • Schedule delivery • Little local content and guide on the application of information

Source: Authors' construct based on literature review been created as part of the setup enabling the provision of information on nutrition, weather information, and market prices for eight regions in Ghana: Eastern, Western, Ashanti, Central, Northern, Volta, Brong-Ahafo, and Greater Accra (Aker et al. 2018). Vodafone has partnered with ESOKO whereby subscribers to the Vodafone network are connected to input suppliers, aggregators, extension services, and other value chain actors (Nyarko et al. 2013; Duncombe 2016).

Social media platforms such as YouTube, WhatsApp, and Facebook play a role in the delivery of CIS by GMet. YouTube video showcases a 2-minute video on nationwide weather forecasts. On GMet's Facebook page, there are flyers of impending weather conditions for the day or the bulletins to provide an outlook for changes in weather conditions on specific days. The role of WhatsApp is to provide a real-time forecast on an impending storm spotted on satellite images. At the onset of the rainy season, GMet also disseminates its seasonal forecast through YouTube or Twitter.

The website is another channel for the delivery of CIS but mostly it is not tailored for farming. Websites provide general CIS to the public on how to prepare for the dry season or impending floods (Anuga et al. 2019). For instance, during the minor season in 2019, GMet used its website to provide an overview of the weather conditions for the seasons.

Concerning print media such as the newspaper and seasonal forecast bulletins, information on the weather forecasts is communicated via state-owned electronic media and published bulletins from Ghana Media Association (GMA), Ghana News Agency, and the *Daily Graphic*. Some of the outlooks for the rainy season are also published in newspapers (e.g., daily graphic), and it is usually at the onset of the main season.

Intermediary platform is also used for the provision of CIS for farming. Intermediary platform consist of farmer audio library, IVR where a farmer can call a specific toll-free line and is taken through the procedures for the desired CIS in their local languages, and agricultural extension agents or field agents who are also equipped with smartphones or tablets to provide a two-way information. It also consists of a call center equipped with agents and a special telephone number (MEAS 2012, Agyekumhene et al. 2018; Munthali et al. 2018; Slavova and Karanasios 2018). With intermediary platforms, field agents or agricultural extension agents serve as mediators between the ICT platforms and farmers. These intermediaries ("infomediaries") may reside within the farming communities, access information on behalf of farmers, and discuss it with them. In some of the case studies, intermediaries are lead farmers and community knowledge brokers. Examples of intermediary platforms include ESOKO, e-agricultural platform, Smartex, and GeoFarmer (Munthali et al. 2018; Quaye et al. 2017).

Old ICTs

Despite being conventional, old ICTs are also applied in innovative ways to suit the needs of rural farming communities, especially where the use of old ICTs dominates and is intertwined with the social networks and institutional logic of farmers. This contributes significantly to enhancing the spread of information in the farming communities (Duncombe 2016). The chapter captured the nuanced interplay of innovation with old ICTs.

Radio is one of the conventional digital means of communication that is still relevant in the delivery of CIS to farmers in Ghana (Sam and Dzandu 2016; Nyantakyi-Frimpong 2019b). The use of radio is popular in CIS delivery for several reasons (see Table 1). Community radios, such as Simli Radio at Dalung and Radio Ada at Big Ada, create interactive programs which feature community discussions, interviews, live panel discussions, and call-in shows in local languages. CIS is broadcasted on community radios at specific days in the week when farmers are available, and special signature tunes to draw the attention of listeners (Asenso-Okyere and Mekonnen 2012; Chapman et al. 2003; Nyamekye 2020). Programs are designed and periodically updated throughout the year in response to the types of CIS and agricultural information that are needed (Perkins et al. 2015). Sometimes, farmers are consulted directly during radio programs for relevant data on local indicators for the onset of the season, and comparisons are made with a scientific forecast in a panel discussion to further interpret information (Sam and Dzandu 2016). At a point in the programs, listeners are permitted to call in to interact with panelists, ask questions, and share problems and experiences. At times drama and pre-recorded programs are aired when a panel discussion is not carried out. Commercial radios also provide CIS (Chudaska 2018; Slavova and Karanasios 2018; Nyamekye 2020).

Government- and private-based television channels are other means through which farmers receive CIS, for example, GTV and TV3 (Adjin-Tettey 2013; Anuga et al. 2019). A study also indicated that some farmers also obtain weather forecasts from international television stations such as Aljazeera, CNN, and BBC (Chudaska 2018).

Informal CIS delivery channels have been shown to be preferred by farmers due to oral communication and personal conversation that are mostly practiced in farming communities (Drafor and Atta-Agyepong 2005; Drafor 2016). Farmers still prefer CIS to be delivered by agricultural extension agents, workshops, village knowledge centers, and mobile vans and pamphlets produced by NGOs (Nyantakyi-Frimpong 2019b). Traditional information mediums like drums, loudspeakers, public address systems, gong-gong beaters, town criers, churches, and the loudspeakers of mosques are still relevant (Padgham et al. 2013; Drafor 2016). Others include CIS delivery through Ghana Information Services Department's mobile vans (Anuga and Gordon 2016; Slavova and Karanasios 2018). The information received by farmers is then communicated to others in the farming community. In some communities, CIS is displayed on notice boards, while farmer-to-farmer or farmer cooperatives are also used to facilitate information delivery (Anuga et al. 2019).

Category of Farmers' Use of CIS Delivered Through ICTs

CIS is delivered to farmers with different socioeconomic backgrounds: gender, marital status, and level of education. Mostly, men are able to access CIS with a variety of ICTs than women due to their ability to easily access mobile phones which are the most common new ICTs in rural communities in Ghana (Partey et al. 2019). Women's access to digital tools is limited to radio and mobile phones which are often owned by their husbands. In some cases, women who had no formal education rely on local knowledge (Chaudhury et al. 2012; Partey et al. 2019). Despite women's use of the radio as the main ICT channel to receive CIS, they are unable to access regular information due to their engagement in numerous household activities. Apart from the ownership of the ICTs, men have a higher capacity to use and operate ICTs especially the mobile phone than women without relying on others for assistance (McOmber et al. 2013). This is attributed to the level of education between men and women (Nyantakyi-Frimpong 2019b). The usage of mobile phones is limited to simple handsets with the exception of a few educated and young farmers. Young people (20–29 years) use new ICTs such as smartphones, apps, and social media. Hence, they are able to access CIS with all forms of ICTs. Within the category of men, young male farmers mostly received SMS and IVR (Partey et al. 2020).

Mostly, the beneficiaries of the CIS-funded projects select a household member or recognized owner of household land to access the information with the assumption that they would share the information with other members of their household (Mohammed 2018). With the application of such criteria, women do not access the information directly (Anaglo et al. 2014; Nyantakyi-Frimpong 2019a). Most women are unable to access CIS with ICTs because of the domination of patriarchal norms which promotes access and control of productive resources as well as decision-making authority by men (Nyantakyi-Frimpong 2019a). Even if women are selected to receive CIS with digital tools, the application of the criteria "one member per household" results in the selection of an adult woman. This implies that within polygamous households where seniority is a norm, it is the elderly women who gain access to CIS.

The frequency of receipt of CIS delivered through ICTs range from daily, 48 h, 5 days, weekly, and monthly forecast. However, there are instances when lots of pending or unopened messages are seen on farmers' phones, and they wait until their literate relatives are around (Mohammed 2018). The reason for this is attributed to low levels of literacy or inability to manipulate the phone (Alemna and Sam 2006). The reliance on relatives who own ICTs to access CIS remains a challenge since their absence could mean the inability to receive information.

Farmers have different types of information needs during each stage of the farming season, and ICTs are used to meet these needs. Seasonal forecasts are CIS provided to farmers at the onset of the farming season with interactive platforms, such as radio and call center. They come with advice on how much rain to expect, the length of the season, and the onset dates (Gbetibouo et al. 2017; Nyantakyi-Frimpong 2019a). Additionally, SMS, IVR, bulletins, social media, websites, and print media are also used to provide seasonal forecasts to support farmers' decision-making on the selection of a variety of (specific) crops.

During the farming seasons, the provisions of local content- and location-specific forecast with the IVR and SMS are mostly used. Also, the weather influences crop pest and disease conditions during the farming seasons; therefore, intermediary platforms such as call centers are used by farmers to generate information on the application of agrochemicals (Munthali et al. 2018). Some CIS have a short-term lifespan in terms of relevance to decision-making and therefore must be delivered within an appropriate timescale to farmers (daily up to 7 days) with different forms of ICTs (Zougmoré et al. 2018). In this regard, the intensity of the rains and the number of rainy days require the provision of daily forecasts with SMS, IVR, and radio to enable decision-making on when to weed and conduct other fieldwork (Partey et al. 2020). When floods or dry spell conditions are expected to occur, radio, SMS, social media, and intermediary platforms are used as the main channels to deliver outlook for the day or week (Stigter et al. 2013). Besides, ICTs help to contextualize CIS and integrate it into farmers' own schemes of experiences (Leeuwis 2004). Some of these CIS include information on the availability of transport and tractor services, credit options, input and market prices, and crop insurance during the farming season (Adiku et al. 2017; Anuga et al. 2019). For instance, the Vodaphone farmer club SMS provides a holistic CIS such as weather information, market prices, costs and availability of inputs (seed and fertilizer), and pest recommendations (Usher et al. 2018; ESOKO 2020). At the end of the farming season, SMS, IVR, and other informal channels are prominent means of delivering CIS such as a 10-day forecast for optimum harvesting period and processing of farm produce.

Type of Information Needed by Different Categories of Farmers

Farmers' information needs are associated with major decision-making for the farming season. The decision-making includes the type of crop and the variety of seed to select, land size and the number of farmland to cultivate, when to plough, when to sow seeds, when to transplant seedlings, when to do irrigation, when to apply fertilizer and(or) agrochemicals, and when to start harvesting, marketing, and processing (Sarku et al. 2020).

The scant literature on CIS indicates that gender plays a role in the information needs of different categories of farmers. Men have more CIS informational needs to mitigate climate risk compared to women. This is due to differences in preferences and vulnerabilities to climate-related risks, access to farm resources, land ownership, access to labor, access to information, and financial resources (McOmber et al. 2013). Jost et al. (2016) also indicated that limited access to finance, extension services, and farm resources affected women CIS needs. Furthermore, access to a mobile phone, access to irrigation, type of crop produce, and land ownership were influential in determining whether or not someone will use CIS (Partey et al. 2020). Table 2 shows an overview of the information needs for categories of farmers.

The first key decision for the farming season in relation to the application of CIS is the type of crop and the related variables that need to be cultivated. In most households, this decision is the responsibility of household heads who are mostly men. In some contexts, the household head and spouse (or spouses if polygamous) discuss privately and communicate with the rest of the family (Nyamekye 2020).

Table 2 Information needs of categories of farmers

Type of forecasts	Information needs	Categories of farmers: Young men	Young women	Elderly men	Elderly women
Seasonal forecast	Type of crop and the variety of seed to select			✓	✓
	Land size and number of farmland to cultivate			✓	✓
	When to plough	✓	✓		
Daily-weekly forecast	Sowing of seeds or transplanting of seedlings	✓		✓	
	When to apply fertilizer and other agrochemicals	✓		✓	
	When to weed	✓	✓	✓	✓
	When to start harvesting	✓	✓	✓	✓
	Marketing and processing				✓
Legend	✓	Applicable to specific category of farmers			

Source: Authors' construct based on literature review

This implies that young men's and women's information need concerning CIS is mostly dependent on the household heads (Nyantakyi-Frimpong 2019b).

Once farmers decide on the type and variety of crop(s) to cultivate, the next information needs is a forecast on the onset of the rainfall. This information is required to decide on when to prepare the land. Since land is usually prepared when soil moisture is assumed to be high, arrangement for land preparation with a tractor or manual labor becomes the responsibility of the male in the farming household (Chudaska 2018; Partey et al. 2020).

Sowing of seeds or transplanting of seedlings is carried by all categories of farmers after a rainfall. With this practice, CIS is needed by all categories of farmers. Additionally, men usually carry out the application of agrochemicals (e.g., application of fertilizer, weedicides, pesticides, and insecticides). Considering the cost of farm inputs and the availability of labor, CIS is needed by all categories of farmers to decide on when to apply agrochemicals (Sarku et al. 2020). The provision of a forecast on the amount or frequency of rainfall for the farming season is also required by all categories of farmers since it enables them to make arrangements for labor to augment household effort (Nyamekye 2020).

The study deduced that women's information needs to follow the same pattern as men yet it is tied to their relationship with men due to the unavailability of resources at their disposal. In instances where women are in charge of a household and need to take decisions concerning when to start farming, they often consult the men in the household or experienced male farmers in the communities (Nyantakyi-Frimpong 2019a, b). In some cases, women more often than not expect their husbands to provide them with information or determine the various aspect of the decisions for the farming season even when they operate different farms due to their husband's control over the household (Etwire et al. 2017; Partey et al. 2020). This finding adds evidence to support the growing call for the provision of CIS with ICTs which suit the needs of different categories of farmers.

Financing and Governance Arrangement for the Delivery of CIS with Digital Tools

CIS is a public good that can be accessible to all farmers to enable them to adapt to changing weather and climatic conditions. Yet the application of digital tools for the delivery of CIS has several costs associated with data collections, weather models, Internet data, and telecommunication networks. Therefore, CIS delivery in Ghana comes in the form of quasi-public good with some excludability as users pay for CIS to enable the recovery of cost (Naab et al. 2019). The cost of CIS delivery with ICTs brings to the fore discussions on farmers' willingness to pay for CIS delivered through ICTs (Quaye et al. 2017).

In this regard, two patterns can be identified: First, the majority of smallholder farmers recognize that the provision of CIS is a public good with the responsibility of the government to provide such services. Farmers who rely on free CIS delivered through the radio or television do not have access to tailored information, or they rely on their local knowledge in predicting the weather for farming (Nyantakyi-Frimpong 2013; Naab et al. 2019). Second, some farmers are willing to pay for CIS delivered through ICTs but within a minimum range (Acquah and Onumah 2011; Nantui et al. 2014). These categories of farmers have some socioeconomic characteristics such as age, sex, farm size, on-farm income, membership of a farmer-based organization, literacy level, productivity of crops in a particular season, and perception of climate change experience. Ownership and ability to use ICTs also influence farmers' decision to pay for seasonal CIS. Some studies have, however, indicated that male household heads are more willing to pay for CIS delivered through ICTs. Hence, farmers' willingness to pay for CIS delivered through ICTs is mixed and inconsistent (Adjabui 2018; Ibrahim et al. 2019). The financing mechanisms for the delivery of CIS by an organization involve several options as indicated in Table 3.

Linked to the financing model is the governance model which backs the provision of CIS with ICTs to farmers in Ghana. Although the governance model is not codified due to the absence of a CIS policy in Ghana (Naab et al. 2019), different governance modes are used for CIS delivery to farmers.

Donor or NGO Governance Approach

International donor agencies or organizations establish agricultural projects within specific agroecological zones for farmers. Some projects may be specific toward the provision of CIS, while others have different objectives (Asuru 2017). Numerous donor agencies or NGOs are operating with this governance model, and the provision of an exhaustive list is beyond the scope of this chapter. Few notable ones include ACDI/VOCA, TechnoServe, World Vision, FAO (Food and Agricultural Organization), USAID, Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ), International Fund for Agricultural Development (IFAD), CARE

Table 3 Financing of CIS with ICTs to farmers in Ghana

Category of CIS financiers	Funding mechanism
Government financing	Free provision by GMet and GTV through tax and sometimes product levies
Financing by agri-input companies, e.g., Wienco Ghana Limited	Provides embedded services by including the cost of CIS as part of the cost of the product
Commercial output buyers	Makes CIS freely available but incorporates the cost as part of the contract farming
Farmer-based associations, e.g., Cocoalink	Membership fees, donor subsidies, government subsidies, and contracts
Direct payment	Direct fees paid through farmers' call credit or airtime, e.g., Esoko
Funded projects	Donor contracts information providers to deliver CIS freely to target groups of farmers
Contract sale	Farmers' subscription is paid by insurance companies or agribusinesses
Business advertisement on CIS platforms	Advertisement of agricultural products linked to the provision of CIS
Minimum payment under public-private partnership	Subsidized payment is made by farmers under a project compared to those who are not part of any project

Source: Based on authors' literature review

International, OXFAM, and the Department for International Development (DfID) (McNamara et al. 2014). These NGOs partner mostly with market-led ICT platform information providers such as ESOKO, MFarm, Ignitia, Farmerline, and others to provide CIS to farmers. Examples include ADVANCE II, Smartex, African Cashew Initiative, and Farm Radio International's African Farm Radio Research Initiative. These projects mainly focused on specific areas such as the Guinea and Sudan savanna agroecological zone of Ghana due to the presence of donor activities in these areas (Naab et al. 2019).

Public-Private Partnership

The use of digital tools for the provision of CIS results in an interconnected network of activities between smallholder farmers and actors providing and mediating the process leading to the formation of public-private partnerships (PPP). The PPP governance mode of providing CIS for farmers involves NGOs, public sectors, mobile network telecommunication providers, market-led ICT platform information providers, and climate/weather model or satellite providers together with farming communities (Partey et al. 2019). With these arrangements, each actor provides certain resources for CIS delivery. Examples of PPP in the provision of CIS with ICTs include the CGIAR Research Programme on Climate Change, Agriculture and Food Security (CCAFS); businesses such as ESOKO, Vodafone, and Toto agric and aWhere; and public organizations that collaborate with GMet, the Council for Scientific and Industrial Research (CSIR), and MoFA to provide CIS to some farmers in the Upper West region under the Planting for Food and Jobs programs (Etwire et al. 2017; Partey et al. 2019, 2020).

Participatory or Co-production Approaches

ICTs enable cross production of knowledge from different sectors of society (Karpouzoglou et al. 2016; Vogel et al. 2019). In Ghana, ICTs are enabling this process through co-production of CIS with farmers' local knowledge and that of scientists. In some cases, farmers collect data on their local weather indicators, or they contribute their knowledge in several ways (Nyadzi 2020; Sarku et al., forthcoming). For example, Participatory Integrated Climate Services for Agriculture (PICSA) is an approach that has involved over 5000 farmers in Northern Ghana by using both historical climate information and forecasts to support farmers' decision-making with participatory decision-making tools that suit their contexts (Etwire et al. 2017; Clarksona et al. 2019).

Farmer Organization Provision

Another governance approach is the provision of CIS by producer cooperatives/ associations. These organizations deliver CIS to farmers in the group. Payment for the CIS is drawn from the coffers of the association or through donor support. Examples of such governance models are used by Kuapa Kokoo cooperatives, the Africa Cashew Initiative, and Cocoalink (MEAS 2012).

Business Model

Business companies use a wide variety of business models to deliver CIS, and no single model is dominant. Six different business models were identified:

- Business-to-business-to farmer model, e.g., Esoko.
- Business-to-business-to-consumer model is used between market-led ICT platform information providers (Ignitia), mobile telecommunication networks (MTN Ghana), and farmers (Chudaska 2018). Another example is farmers on the ADVANCE II project who are connected to MTN Ghana which runs the promotion sale of simple mobile phones to enable farmers to receive CIS (Mohammed 2018).
- Direct services to farmers, e.g., Vodafone farmer club where farmers pay US$ 0.20 per month as a direct debit from their call credits to receive CIS. Subscribers also receive free airtime to call members of the group (Partey et al. 2019, 2020).
- Business to nucleus farmer and outgrower schemes is an approach that is becoming common where CIS is provided as an embedded service model. In this approach, agri-input companies, in particular, provide information about farm inputs, and CIS is added as a package. The cost of the CIS is embedded as an unidentified component of the sales price. An example of this governance approach is used by the USAID-funded ADVANCE project to promote the use of input supplies, improved seeds, and CIS (MEAS 2012; Mohammed 2018). Wienco Ghana also provides CIS with this model in the areas of cash and food

crops for both small- and large-scale farmers in the agricultural value chain (Naab et al. 2019).

Informal governance approach for the provision of CIS includes traditional institutional arrangement used by farming communities. These are in the form of rules or norms that the farming community adheres to (Slavova and Karanasios 2018).

Discussion of Emerging Issues

First, informal channels of information delivery still hold prominence among smallholder farmers as a means for interaction. For instance, the provision of CIS by agricultural extension agents, workshops, participatory approaches, and the use of social networks are still prominent (Nyantakyi-Frimpong 2019a). Furthermore, information sources in farming communities are often embodied in knowledgeable people and shared through interactions occurring at the market, religious meetings, bus stops, community centers, and other places of meetings. Most often, the CIS is received by one person in the community, and it is shared with other members of the farming community (Kirbyshire and Wilkinson 2018). This has implications on credibility, trust, and sustainability of financial models of actors who provide CIS through ICTs. Due to the need for interactions among smallholder farmers, preferences for ICTs for the delivery of CIS still hinge on interactive technologies which provide an opportunity for farmers to ask questions and share their experiences. This suggests the need to support innovations on the use of interactive ICTs for the delivery of CIS.

Despite the limited use of new ICTs among farmers, mobile phones, in particular, have helped farmers to communicate CIS to other farmers, thereby enhancing interactions and reinforcing interpersonal relationships and norms of openness among farmers. First, mobile phones strengthened bonds in the rural community by enabling information exchanges between family, farmers, and intermediaries. Second, mobile phones complement informal ways of communicating among farmers. Therefore, norms of openness, inclusiveness, and information-sharing are strengthened rather than challenged. The findings suggest that the informal and formal channels of CIS delivery support smallholder farming institutional logic than ICTs destroying informal institutions.

Additionally, intermediaries who provide CIS with ICTs are able to exploit complementarities among digital tools and informal channels of communication. They are able to fuse characteristics and logics of informal communication channels with ICTs such as call center, IVR, and radios which relate to established patterns of interaction among smallholder farmers. The use of mobile phones, SMS alert, or peep call during radio programs is also an example. The combination of informal and ICTs helps to increase farmers' access to CIS.

Despite the evolution of sophisticated ICTs, the provision of CIS with ICTs is limited to simple ones like mobile phones, radio, and television. Thus, farmers rarely use social media, weather apps, and websites to receive useful CIS. Some farmers are unable to operate the phone without the assistance of relatives. This leaves the potentials of ICTs untapped for the delivery of CIS, or it results in the use of platform intermediaries. These challenges are attributed to increased sophistication of ICTs without being tailored for local farmers with literate and visual challenges and limited training on the use of ICTs (Alemna and Sam 2006; Sarku et al. forthcoming). The unavailability of local content ICTs also affects its usage as technologies are originally coded in English. In addition, many languages in Ghana use characters that are not found on the keyboards of most ICTs. Furthermore, the provision of CIS for the target group requires specific local content which affects the scalability of CIS to other agroecological locations in Ghana. There are issues regarding the affordability of ICTs such as smartphones, expensive call charges, and data (Partey et al. 2020; Etwire et al. 2017). All these challenges have implications on information asymmetry as some farmers can use ICT and access tailored CIS, while others still rely on their local knowledge for forecasting.

Findings in this chapter show that the delivery of CIS with ICT platforms are mostly piloted or funded by donors. At the end of the project, farmers are expected to subscribe to continue to receive information at a fee. However, their willingness to pay for the information raises questions about the continuity of CIS delivery. Many of the projects are designed with a top-down approach, without collaborations from farmers at the implementation stage. This raises questions on upscaling from pilot projects to larger farming communities. A limitation of relying on donors to fund the delivery of CIS with ICTs is that specific agroecological zones are targeted for a short period (McNamara et al. 2014). This affects the number of farmers who are reached within the specified period. Since climate change and variability impacts are experienced differently in specific agroecological zones in Ghana, it will be important to have nationwide CIS tailored for all farmers.

Conclusion

This chapter examined the delivery of CIS with digital tools to smallholder farmers by reviewing existing literature on the sector. Overall, our rapid scoping assessment found very positive results on the use of various digital tools for the collection, processing, and delivery of CIS to farmers. The delivery of CIS with ICTs was used mostly by men and during the farming season; a variety of ICTs are used to deliver CIS due to the level of demand for information. Old technologies, like radio, remain the most relevant and cost-efficient ICT platforms for the delivery of CIS. Some ICTs remain underused by farmers calling for the role of ICT platform intermediaries like agricultural extension agents and field agents. The delivery of CIS with ICTs results in changes in institutional logics in farming communities in the form of new interactions, information exchange, and other forms of innovation intermediation. Overall, informal information delivery channels coexist with ICT modes and are sometimes blended in various ways to provide CIS. The analysis in this chapter provides a coherent overview on the application of digital tools for the delivery of

CIS for smallholder farming in Ghana. The emerging issues identified in the literature have contributed to the identification of areas for future research. These include (1) exploration of appropriate financial models for the sustainability and scalability of CIS delivery with ICTs; (2) application of ICTs for the delivery of CIS for other value chain actors such as processors, transporters, and aggregators; (3) increase research on how ICTs are used for data collection and production at the community level; and (4) assessment of the quality of CIS provided to smallholders.

Clean Energy Technology for the Mitigation of Climate Change: African Traditional Myth

62

Abel Ehimen Airoboman, Patience Ose Airoboman, and Felix Ayemere Airoboman

Contents

Abstract

The global Anticipated Energy Transition Period (AETP) is one that all stakeholders must embrace with respect to curbing energy poverty, thereby addressing issues related to climate change especially in the sub-Saharan region of Africa. The region is endowed with abundant richer, cleaner, and affordable energy sources, majority of which has remained untapped due to many reasons, one of which is tied to the socio-cultural traditional beliefs and value systems of the

citizens. This has forced majority of the inhabitants to continue to rely on the use of non-biodegradable materials for the purpose of cooking and many other activities. This value system, therefore, contributes to have had an adverse effect on the climate and also on the health of the citizens most of whom are women and children residing in rural areas. The outlook on the AETP, their effect on climate change, the use of Clean Energy Technology (CET) domestically, the various strata expected to come with the AETP, the socio-cultural dynamics in terms of acceptability by all (rural, peri-urban, and urban areas) is addressed in this chapter. The chapter concluded by designing a CET model that could assist in planning for the AETP and mitigating climate change.

Introduction

Energy plays a vital role in socioeconomic affairs of people, but it must be available in a desired quality and quantity to be able to meet their needs. Only 290 million people out of the 915 million people in sub-Saharan Africa has access to electricity (IEA 2014; Aboua and Toure 2018). It is equally expected that in the years to come, the population in Africa will grow rapidly, and this may cause a major challenge to the international community due to the slow energy penetration it has received over the years. One of the goals of the appropriate authorities in years to come would be to phase out the use of coal and oil in the market due to their harmful effects on the environment, livestock, and people and then replace them with clean energy for residential, commercial, and industrial uses. According to IRENA (2019), the price of solar PV, solar battery, and solar wind has reduced by 70%, 40%, and 25%, respectively, since 2010, and this is an indication that the Clean Energy Technology (CET) is gradually penetrating the market due to reduction in prices and an improvement in the technology. Generally, energy consumption has direct effects on the role of individuals and communities, whether local, urban, or peri-urban. The idea is that energy contributes to the technological, sociocultural, agricultural, educational, as well as psychological standards in a given settlement; thus, it should be accessible, reliable, affordable, and available when needed. One of the technological penetrations as a result of Anticipated Energy Penetration (AEP) would be the use of Clean Energy Stove (CES) for cooking. Energy comes in different forms from either biomass or biogas. Biomass, as an energy source, has been appreciated by people over the years because it is readily available and appears to be cheap. However, it is anticipated by the United Nations that by the year 2040, electricity should be appreciated by people all over the globe as their first choice of energy. This chapter, therefore, looks at the CET during the pre-AET and post-AET period, their effects, and how they would contribute to the sociocultural dynamics of settlements in sub-Saharan Africa and the sustainability of their environment.

Clean Cooking Energy and Their Challenges

According to WEO (2017), 2.8 billion people across the globe is presently denied access to CET. Majority of them presently reside in Asia and Africa. Similarly, the World Health Organization (WHO) recorded that 7.7% of death rate worldwide is the result of indoor pollution and incomplete combustion; and mostly, women and children are the most vulnerable. One of the contributing factors among others is the inefficient manner in which the solid biomass fuel is used. Furthermore WEO (2017) also affirmed that four out of every five persons in sub-Saharan Africa are yet to appreciate the CET; rather, they prefer the use of solid biomass as fuel, and the effect of this is deforestation, desertization, pollution, erosion, loss of species, global warming, impaired human development, and scarcity of raw materials for other technological purposes. During the AET period, it is expected that solid biomass fuel such as firewood, agricultural residue, coal, animal dung, and generic organic waste would be phased out gradually and replaced with electricity. It is also envisaged that during this period, the choices for other forms of energy other than electricity available across the globe should be reduced drastically because the more the choices are available, the greater the burden in transiting to Clean Cooking Energy (CCE). The advent of the AETP is expected to gradually integrate the CET into the market and this technology will be geared to address inefficiency in cooking methods while speeding up the rate of clean energy penetration and otherwise. However, for a smooth transition to be recorded, reviews are needed due to availability, adequacy, stagnant growth as well as political reasons. A novel method to CCE should therefore take cognizance of various dimensions and complex nature owing to the stringent measure in eliminating localized ways of cooking. For the locals, this is already a way of life, a doctrine, a culture and a belief system.

Before this transformation, there is the need for moral requirement to properly educate and enlighten the indigenous people to ensure they are able to make informed consent and autonomous decision without any imposition, coercion, manipulation, or persuasion and the people's autonomy is respected (Faden and Beauchamp 1986; Beauchamp and Childress 1994). Besides, these technologies should be friendlier to the people and their natural environment; they should not make the environment hazardous and uncongenial to the people. They should conform to ethical duty (Desjardins 2006: Rachels 2007) and the utilitarian end (Rachels 2007) of the people and their environment, both at present and in the future. They should not be adopted on the sole aim of profit making and on the motive of instrumentalization of the people and their environment. Relying on the Divine Command Theory of Morality (DCTM), one is prompted to ask whether God would require, permit, or prohibit people being deceived, cajoled, or forced to jettison a way of life that they have been accustomed to and lived by or force them to accept a view and way of life that they may consider inimical to their well-being (Desjardins 2006). Unless these fears are allayed, there is no guarantee, for example, that when the Clean Cooking Stove (CCS) and other new technologies are provided to the locals during the AET period, they would not be stacked. Depending on the temperament of the people, there is the tendency to reject or put up resistance when new ideas and ways of life are introduced to people who already feel secured in their comfort zones, unless adequate care is taken. There is the tendency on trado-cultural ground on the part of traditional rulers or chiefs and traditional doctors to have their meals cooked in special dishes and specified manners or methods and styles, if they are to retain their authorities, powers, efficacies, and sanctities, which may not be amenable to newly introduced alternative technologies. There may also be difficulty of embracing and adapting to new ways of life. Adjustments may cause lots of inconveniences and discomfort to the extent that the people may want to revert to their accustomed and secured styles of living. These may cause some friction in accepting newly introduced technologies.

Another issue of concern is that it pleases the locals to walk some kilometers to gather firewood at no cost rather than trekking some meters to expend their money in buying energy at a high price. Infact, some may not have money to expend in purchasing alternative energy due to their degree of poverty. It would be morally wrong to sway people away and "coerce" them into accepting a way of living they are unaccustomed to without adequate enlightment programme and also without providing them with an affordable, safe, and simple alternative especially, if their previous methods and modes of living are innocuous, that is, it constitutes no harm or danger. In this way, the enforcing government, agency, or any other body fails in their moral duty.

For instance, in Nigeria, cooking in urban and rural areas is actualized by 50% and 99.8% of nonbiodegradable fuels, respectively. The high margin recorded in the rural areas is because they are unable to pay for a neater and cleaner substitute, lack awareness, and lack value systems in addition to the lack of accessibility to such fuels. Another challenge faced by the rural areas is stacking of any technology on the ground that they are scared of operating any electrical gadgets. Although their present technology might look cheap in the interim, other cooking options would be cheaper in the long run (National Energy Policy 2013). If remedial actions are not taken effectively, then the nation's 15 million hectares of forest according to National Energy Policy (2015) could be depleted within the next 50 years, and the goal of AETP might not be met from the Nigerian perspective.

Also, the nonbiodegradable fuel source in Nigeria contributes about 37% of the total energy demand at a consumption rate of $43.4 * 10^9$ kg of fuelwood annually, making an average of 0.5–1 kg of fuelwood per person on a daily basis. This practice, has therefore encouraged the cutting down of trees, thereby making it a lucrative business owing to the huge and increasing demand of fuelwood, thus making Nigeria one of the largest fuelwood markets in the world (EIA 2014).

The cooking energy demand can therefore be represented mathematically in (1) as presented in NECAL (2015):

$$CED = \frac{CD}{H_H} \times \sum_{i=1}^{n} H_{H_i} \tag{1}$$

CED = cooking energy demand, CD = cooking demand, H_H = household.

According to (ECN 2015), 71.9 million hectares of land in Nigeria is fertile, therefore making it a good potential for biofuel production other than fossil fuel. However, with the level of hunger and poverty, low gross domestic product (GDP), etc., it might be difficult to sacrifice the primary sources of biofuels which are actually foodstuff like cassava, sugarcane, soya bean, oil palm, etc. for the purpose of generating clean energy for domestic purposes. Although (Kela et al. 2015) have shown the introduction of CCS which includes clay-based improved stove, energy-saving stove, various solar cookers, double-pot improved stove, etc., their use is still at the experimental stage and therefore requires financial support to increase the level of awareness as well as mass production.

As a way forward, Olaniyan et al. (2018) proposed the use of nonfood crops for the production of bioenergy in some West African countries. However, based on the arable hectares of land in Nigeria and other African countries, another way forward is the genetic modification of certain biofuel plants for the purpose of producing fuel directly for domestic use and for the purpose of cooking. Plants with high calories can also be modified to produce more sugar than expected which can be used for fuel production. From these, excess sugar can actually be picked from the plant for the purpose of fuel production, and domestic use while the other part of the plants continues to remain edible for consumption thereby guaranteeing food security. Other than this, with respect to the AET, the full dependence on electricity for domestic use is also anticipated. In Fig. 1, the stages of AET and CET period are described. In Figs. 2 and 3, the level of merchandising of fuelwood and the use of solid biomass in cooking at restaurants in urban area are presented. From Fig. 3, it is shown that any deviation from this mode of cooking implies that the traditional smoky flavor is absent, hence reducing customers' patronage in the restaurant.

Role of Government During the AET Period

There is a call across the globe for nations to move from "oil-driven economy" to "clean energy economy." Various changes are expected to be noticeable worldwide during this period with respect to regulations, policies, financing, consumption pattern, and so on. Now, what will be the fate of the individual citizens of those countries whose economy is strongly dependent on oil if the issues that directly affect them, and if what their daily living depend upon, are left at the hands of their decision-makers and the international community? Hence moral rectitude is required in convincing indigenous people. Again, given the abundant resources in their country, would they also transition during the AET period? If yes, at what pace? If no, why? The world is fully aware of the abundant primary sources of energy in Africa which are yet to be harnessed, and there is a call for a carbon-free environment in the nearest future, yet Africa continues to be the largest market for generator dealers across the world due to the high level of unreliability in the electric power sector. Part of the effects of generator use is that it constitutes health hazards to humans and the natural environment. It contributes to acid precipitation, depletion of ozone layers, carbon poisoning, and so on (Airoboman and Tyo 2018).

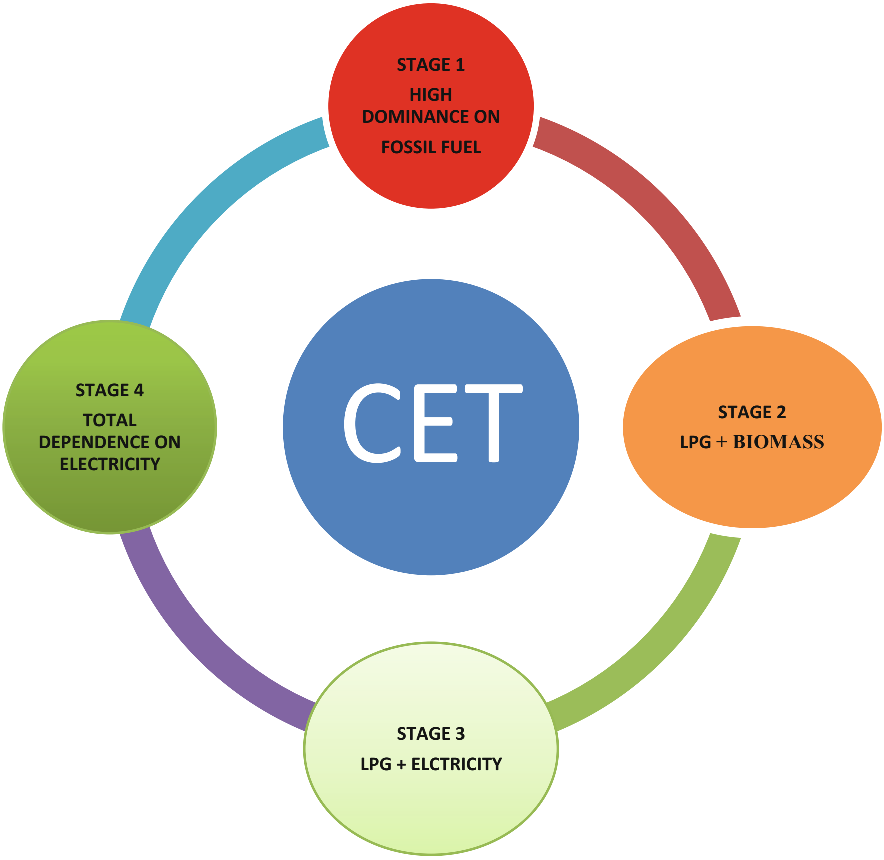

Fig. 1 Anticipated CCS stages

Fig. 2 Merchandising on fossil fuel in North-West Nigeria

Fig. 3 Commercial cooking with solid biomass

There is therefore the need for stakeholders across the globe to deliberate on this issue to see how this energy can be managed in the most efficient way so that it can continue to be a means of wealth creation for the nations involved rather than asking or "forcing" them to give up their natural resources and go green. Also, if sustainability is to be recorded, then the number of portable generator sets penetrating the African market must be reduced and replaced with a more eco-friendly one. The role of each respective authority during the period would encompass awareness programs through the use of various advertisements, signs, agencies, and jingles, among others, to inform their citizens on the need to transiting from the use of solid biomass fuels to CET. The appropriate authority is also expected to enlighten its citizens on the cancerous effects that these fuels would cause in the long run and would continue to cause if their use is not abolished or optimized. The distance traveled by women and children to gather firewood contributes to the impairment of human development. Besides, the time wasted in all these processes which could have been valuably geared toward other meaningful engagements is also a call for the appropriate authority to answer. Climate change and depletion of the ozone layer is another strong point that the government is expected to use in convincing its citizens. How well this will sink into the hearts of the people is another cause of worry for the government. Therefore, integration of stakeholders and nongovernmental organizations (NGOs) whose job would be to interact and connect with the people one on one; study their beliefs, cultures, and ways of life; and then finally come out with the best and sustainable CET for a given community. It is also expected that electricity tariff should be made very simple and affordable. There should be guarantee by the concerned authority to its citizens that electricity, which is now their first choice of energy, will always be reliable and available when needed. Furthermore, the prices of the CCS should be subsidized and made at various sizes so that even the poorest person in a rural, peri-urban, and urban area can afford them.

The Psychological Myth of Locals

Universal access to energy especially in the local community continues to be a worldwide priority by the year 2030, there is a need to look at how the lack of access to energy has contributed to development impairment and most especially how the CET would be appreciated by locals and the entire citizens of a given country especially in Africa. A key factor to be considered here is that the traditional fire does not only serve as a cooking stove, but it also plays other significant roles such as providing warmth during cold, drying of clay object, preservation of some agricultural product till the next planting season, prevention of weevils from some harvested crops, chasing out of wild animals from a vicinity, heating of the environment during a particular time of the year, a source of light during moonlight stories, waste disposal, drying of clothes, security purposes, and a sign of faith as practiced by some orthodox churches during a certain time of the year. If CET could penetrate the African continent, then it is expected that it should be able to address all these "ways of life" in the simplest manner and with simple technology. Besides, the CET should be cost-effective. The idea behind the use of CCS is simplicity in size and cost. If this is not achieved, various options to fuel available could make the CET objective a herculean task. Furthermore, there are some unique cultural preferences that might be difficult for locals to give up, and one of such examples is the traditional smoky flavor on meals prepared. The locals believed strongly that such flavors and taste could only be gotten through the use of fuelwoods and coal, and as such, the use of CCS could change the taste of their food. Even the rich often times visits small canteens where the source of energy used is firewood in order to get that traditional smoky flavor which makes their food sweet rather than visiting big restaurants whose source of energy is mostly microwaves because of the fear of radiation that causes cancer. The irony that the locals prefer to prepare their food using the traditional firewood because of its "simplicity" rather than using any other sources such as modern energy stoves because of their "complex nature" is also a call for concern and worry.

Simplicity for them is a priority and it comes before availability. Another issue of concern is that it pleases the locals to walk some kilometers to gather firewood free of charge rather than trekking some meters to expend their money in buying energy at a high price. In addition, some may not have this money to expend at all to purchase alternative energy due to their degree of poverty. Despite this "way of life" (which we may call archaic and uncivilized in the modern times), it is on record that people in villages live longer than people in the city. Hence, selling a technology from the city to the villages requires stringent measures. It would be immoral to impose, coerce, or deceive the locals to accept a method or an alternative way of life without informed consent, free choice, or adequate enlightenment, including relevant and adequate knowledge about the benefits and harms of the technology to be introduced. Concerning what makes an issue moral, Barcalow (1994) argued among others that the choices people make about such issues affect their well-being and the well-being of others; and such well-being may be physical or psychological. Such actions should also be capable of causing benefit or harm. It would also be a moral dilemma for those knowledgeable or well informed about the actual and potential hazards of the habits and practices of a people to allow them to continue in those habits whether or not it directly affects them, when they are unwilling to change.

A Look at Environmental Ethics

The heavy burden imposed on nature in recent times because of various activities by humans, it is now impossible for nature to regenerate itself the way it used to. Environmental ethics could therefore be put forward as one of the ways of tackling environmental issues and simultaneously meeting human needs. According to Omonzejele et al. (2017), every culture possesses certain notion of what is good and bad and what "ought" and "ought not" to be done. Therefore, the bad aspects of using fossil fuel plants for the purpose of heating, cooking, drying, security, etc. by rural areas may be left hanging as it is already a value system and a way of life; hence, all they see is the "good" aspect of using fossil fuel as the word "bad" may sound offensive because of what it projects and represents. The rural dwellers are of the opinion that the human life has value. Then, if prevented to sufficiently interact with its environment, it may be tantamount to saying the value of the non-human life is superior to the human life, and this could negate their traditional and cultural doctrines of Anthropocentrism. Therefore, a point of alignment between the non-human life and the human life needs to be defined to address these stringent issues with respect to educating the rural dwellers especially on the doctrine of Sentientism which opined that an element of consideration should be afforded to the non-human life. Also, the doctrine of Biocentrism strongly stated that all life is sacred! In this sense, the human life must refrain from cutting branches from trees for any purpose. The doctrine of Ecocentrism also asserts that nature is the center for the existence of human life upon which this life is parasitic. In Airoboman (2017), one of the reasons for environmental concern is to curb issues and proffer solutions on issues relating to climate change. The author stressed that development is a function of the level of interaction with the environment. However, with the present climate change challenges, one may ask if the gain as a result of development is worth the trouble posed by the climate? If yes, should the underdeveloped nation aspire to develop or remain static developmentally because of possible fear of climate-related issues? These questions are begging for answers. Therefore, environmental ethics should be included in high school and colleges curricula in order for all parties involved to be guided accordingly.

In Fig. 4, the occupant of the apartment uses LPG for cooking. However, the color of the ceiling shows otherwise, and this may be a result of the inefficient way the LPG was used, thereby constituting environmental challenges as well health challenges especially to the occupant of the apartment. CET should not just be about the use of clean energy but also of the way(s) it is used with respect to each environment. As a means of addressing the myth behind cooking using the CET, the authority concerned would have to convince the masses that:

Fig. 4 A polluted kitchen

1. The technology behind CCS would be very simple such that it would be easy to operate.
2. It is not time consuming because the energy required would always be available rather than traveling longer distances to fetch firewood.
3. Maintenance of the CCS would also be made very simple and available.
4. The locals would be involved directly in the maintenance, thereby creating jobs for them.
5. It is the presence of carbon black that affects visibility. Hence, there should be a paradigm shift.
6. There are negative impacts on the method they have been accustomed to have on the natural environment.
7. There are actual and potential hazards, which impact the human beings, future generations, and general ecosystem.

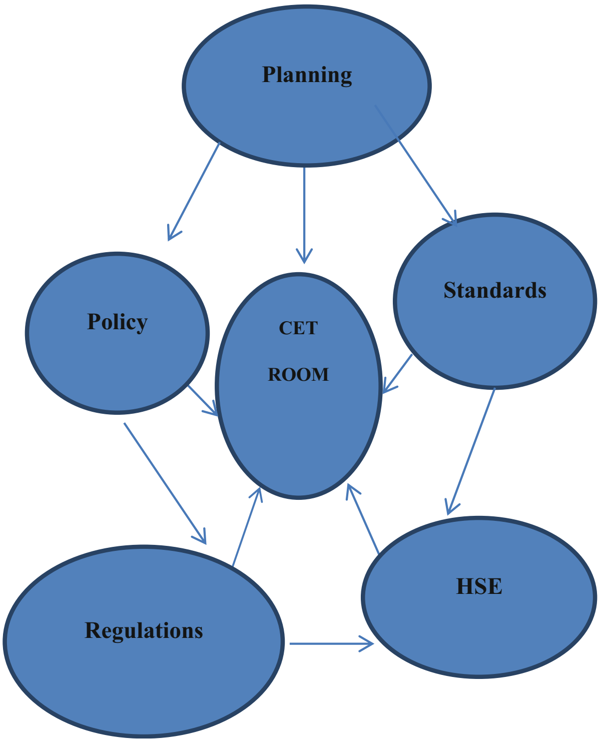
In addition to the above, there is also a need by the authority concerned to introduce CCS designed to give that traditional smoky flavor in food, as well as addressing the fear in operating CCS because of its "complexity" and fire hazards.

The Way Forward

As the world continues to strive in meeting its objectives regarding universal access to energy and CET, there is a need to deplore methods to be followed in order for these objectives to be met. In Fig. 5, a model which incorporates planning, policy making, regulations, health, and safety and standards is proposed. In this scenario, analysis is done at various levels to get a master plan for CET in the near future.

1. The planning level involves various coordinated policies and strategies to be adopted for a smooth AET.
2. The policy level should incorporate the drafting and implementations of policies.
3. At the regulation phase, it is expected that suitable regulation standards both technical and economical are taken into cognizance. The direct involvement of government is expected here because it has to protect the consumers' right and ensure that any tariff adopted must be simple and cost-effective.
4. Health and environment protection agency regulates the impact of the technology on the health and safety of the environment as well as the personnel.
5. At the standard phase, regulations such as conformity to WHO standards should be enforced. It should be noted that it is not only laboratory test that is required here; other regulations that will ensure sustainability through availability of spare parts and maintenance must be taken into cognizance.
6. The CET room investigates the report from various agencies, regulators, and policy makers to see the potentiality of the CET penetration in a given area, and when satisfied, they move to the next phase as shown in Fig. 6.

Fig. 5 CET policies and regulatory phase



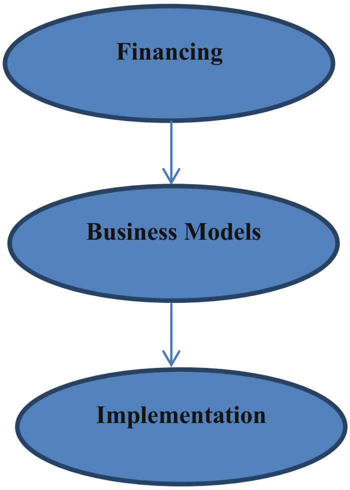


Fig. 6 CET implementation stage

The second stage of the model comprises the financing, the business models to be adopted and finally the implementation.

1. At the financing phase, it is expected that there is enough fund to support investors, willing to go into the CET business. There should also be a body under the CET that manages and gives out funds to potential investors. There could also be a Public Private Partnership that allows these investors to build, operate and transfer the technology at the required time.
2. Furthermore, it is expected that stakeholders in the sector will have to meet and develop business models that favor a given region with respect to the natural resources available in that region.
3. Since the goal of every business is to get return on investment, it is expected that this phase should be time consuming owing to various scenarios analysis and feasibility study needed to ensure a very simple but affordable tariff expected by potentials customers. When all this is put in place, the implementation stage comes to fore. This involves the coordination and supervisory roles needed during installation of CET within a given area. Such supervisory role should be handled by an expert in the field who will ensure that all equipment deploy to the field conform to appropriate standard, pass the LAB tests and also meets the WHO requirements.

Conclusion

In this chapter the injustices that lack of energy access has caused globally and especially in sub-Saharan Africa is highlighted. Energy poverty has slowed down technological infrastructure and has led to a slow economic growth rate. As the world is expected to transition to renewables and CET in the nearest future, it is expected that there would be a swift shift from the use of solid biomass fuel to electricity. Therefore, there is a need for Africans and especially sub-Saharan African to start preparation for the AET in earnest in order not to be caught in the web of uncertainty. With proper preparation, good policies, regulations, proper planning, nice business models can be put in place in the African continent because Africa has been designed to rule the world in the nearest future. Hence we must get our technology right; and in doing this, there must be a universal access to energy especially to women and children. The study also concurrently looks at some socio-cultural and economic impediments that may have impeded this goal, as well as some moral issues involved and attempt to address them.

Green Technology Approaches to Solid Waste Management in the Developing Economies

63

T. B. Hammed and M. K. C. Sridhar

Contents

Abstract

The severity of extreme weather and climate change impacts around the world has been a public health concern in the last few decades. Apart from greenhouse gas generation, poor waste management exacerbates consequences of global warming such as flooding, lower crop yields, and the epidemic of diseases which can escalate into disastrous situations. The general public in developing economies sees wastes as valueless materials and disposes them through open burning, stream dumping, or as conveniently as possible. Also, the cutting of trees for firewood leads to deforestation and desertification that increase people's vulnerability to climate change impact. Against this backdrop, there is a need for a paradigm shift toward developing indigenous technologies that convert solid waste to cheap and clean energy. Various innovations use the "green technology approach" in putting trash back into the value chain. Furthermore, the green technology approach has a great potential to enhance adaptation and resilience

among climate change-displaced populations where they can set up microenterprise on useful end products. In this chapter, unique features of these technologies at the Renewable Resources Centre of the University of Ibadan, practice-oriented researches, and a case study at Kube-Atenda community Ibadan, Nigeria, are presented. This chapter is therefore set out to showcase examples of waste management initiatives and strategies that have been successfully implemented elsewhere by the authors. It also focuses on how some countries in the continent, with developing economies, may foster their resilience and their capacity to adapt to climate change.

Introduction

Africa continent is at the forefront of vulnerability to global climate change within the world. The overall public in this continent sees wastes as valueless materials and disposes them through open burning, stream dumping, or as conveniently as possible (Hammed et al. 2018). Healthcare wastes are burnt in low-temperature incinerators with gaseous emissions. Also, the cutting of trees for firewood ends up in deforestation and desertification that increase people's vulnerability to temperature change impact. As an example, many households in Nigeria (up to 70%), including households in rural areas (86%), and households in urban areas (42%), depend on solid fuel as their primary source of energy (Sridhar et al. 2016). The majority of the families that use solid fuel for cooking (94%) operate open fire or stoves that have no chimneys or hood (Gwatkin et al. 2000). Other than climate change, the utilization of firewood as fuel for cooking exposes people, and most children and women, to smoke which poses a health risk to them and might cause respiratory illnesses (Salvi and Barnes 2010; Oluwole et al. 2012). Consistent with some researchers (Smith et al. 2001; Dehoust et al. 2005), the waste management sector makes a relatively minor contribution to greenhouse gas (GHG) emissions at a global scale, estimated at approximately 3–5% of total anthropogenic emissions in 2005. Also, the average annual per capita waste generation in developing nations is estimated at 10–20% of that of developed countries, which is rising in response to economic growth. The waste sector is, however, in an exceedingly unique position to maneuver from being a secondary source of world emissions to becoming a major saver of emissions. It is on this premise that the Chief Director of the United Nations Environment Programme (UNEP) has been developing a technique for cobenefits of waste management within the context of global climate change. Integrated Solid Waste Management (ISWM) based on the 4Rs (reduce, recycle, reuse, and recovery) approach, with a special focus on sustainable consumption and production, E-waste management, conversion of agricultural biomass and waste plastics into energy and material resources, and management of hazardous waste, is being considered by the UNEP (UNEP 2010).

A recent report by Oyelaran-Oyeyinka of the UN Human Settlements Programme (UN-Habitat) (The Guardian, 27 April 2015) indicated that “African cities are the engines of wealth creation and therefore the centers of manufacturing, production, and innovation.” This fact has not yet been justified and, as such, many cities have changed to slums that are characterized with incessant poverty, homelessness, the prevalence of preventable diseases, environmental pollution, maternal and child mortality, and other problems. These problems are further aggravated by social, economic, and environmental issues posed by climate change. There is, therefore, a need to strategize how African nations may foster their resilience and adaptation to the implication of climate change. Moreover, UNEP has identified two categories of solid waste management techniques that can reduce GHG emissions or contribute a net benefit to the development (UNEP 2010). The first set of technologies in view is technologically simple, locally available, and relatively cheap. The other set involves sophisticated, expensive technology and typically requires over 5 years to implement due to some factors, including financing, planning, and regulatory processes. The first process is seen to be very useful to strengthen resilience and adaptive capacities to counteract climate-related hazards within the developing economies. This chapter showcases samples of successful waste management initiatives and strategies that have been successfully implemented at the grassroots to build the capacity of the rural and urban dwellers, and foster their resilience to the menace of climate change.

Green Technology Approach to Waste Management and Climate Change Mitigation and Resilience in the Developing Economies

The significant problems of solid waste management in low-economic settings include lack of interaction and collaboration between stakeholders (community members, researchers, industrialists, and policymakers) in the policies that deal with waste. Also, there is a lack of political will for a waste-recycling program, no provision for research funds, unavailability of sustainable technologies and over-dependence on imported technology, and lack of transparency and marketplace for recycled products. There is usually no sense of belonging in utilizing any project in which the end-users are not involved and motivated (McDonald and Ball 1998; Tucker et al. 1998; Paula and Elizabeth 2008; Fauzul and Viradin 2011; Hammed et al. 2012). Consequently, waste disposal systems do not conform to best practices, and in most cases, there is no sound or acceptable disposal method for solid waste in place. These wastes are usually heaped in piles within residential areas and oftentimes burnt once they overflow, or the stench from them becomes unbearable, creating air pollution-associated issues. The disposal and treatment of wastes lead to GHG emissions with severe global climate change impacts. Methane is the most significant GHG gas emanated from solid waste in the landfills, which is released during the breakdown of deposited organic matter (IPCC 2006).

The gross of socioeconomic, environmental, and health difficulties the climate change phenomenon brings to the human being is depletion of natural resources, atmospheric pollution, outbreaks of vector-borne diseases, and flooding as well as crop failures that lead to malnutrition. Ironically, these impacts are mostly strongly seen and felt in developing countries, whose contributions to GHG emissions are far lower than their counterparts in the industrialized world. The aforementioned has called for effective initiatives and strategies such as those that supply renewable power from waste, mitigate climate change, create job opportunities, and promote growth in Gross Domestic Product (GDP) through wealth generation mechanisms. Generally, the benefits of green technology approach in the form of 5Rs (reduce, reuse, recycle, recover, and repair) to waste management include:

- Conservation of natural resources
- Environmental sanitation and protection from soil erosion, gully problems, deforestation, and desertification as trees are not cut
- Prevention of biodiversity loss
- Reduction of demand for landfilling of wastes
- Job creation and poverty eradication in the state; create wealth among peasant farmers
- Food security in the country through organic fertilizer production
- Promotion of local technology for sustainable development
- Reduce the amount of CO_2 and methane gas being released into the atmosphere
- Saves foreign exchange for the nation

Considering the hierarchy of sustainable waste management, waste prevention is generally far better than any other waste management practice. That is, waste prevention eliminates greenhouse emissions and other environmental problems that are resulted from waste disposal and also ensures fewer resource extractions and manufacturing (the United States Environmental Protection Agency 2006). Following waste prevention, in terms of benefit, is waste recycling which may be a closed-loop or open-loop process. The open-loop recycling process occurs when recycled material is employed to form a completely new item. During this case, there is a loss of fabric quality which is brought up as "down-cycling." Another strategy being employed in line with waste recycling is industrial symbiosis. Here, industries exchange useful by-products among themselves (Ashton et al. 2009). Sometimes, the industries involved in this arrangement may form "recycling clusters" to facilitate the sharing of resources (Chertow and Lombardi 2005; Harris 1999). A good example is the United kingdom's National Industrial Symbiosis Programme that has successfully saved more than five million metric tons of wastes that could have ended in landfills and eliminated more than five million metric tons of GHG emissions since 2005 (Chertow 2009). The above state of affairs illustrates the necessity for identification of processes, methods, and tools which may help African nations from international best practices. This approach calls for global thinking and local action.

Field-Oriented Activities at Renewable Resource Centre, University of Ibadan

The Renewable Resource Centre (RRC), located in the poultry unit of the Teaching and Research Farm, University of Ibadan, Nigeria (Fig. 1), was established in the year 2013. The center started with a few viable technologies developed in the Department of Environmental Health Sciences of the University which were scaled up in the field at several locations nationwide. The techniques are now proven to be viable to exploit commercially. The RRC has several sections, which are shown in Fig. 2:

(i) A building with training facilities to train up to 30 trainees, a storeroom, a research exhibition area (TECH park) to display environmental health research outputs, a caretaker's restroom, two toilets for visitors, a well-equipped mushroom spawn production area, and a small lounge where a visitor can sit and relax.
(ii) Biogas digesters to generate biogas from poultry piggery and cattle wastes for lighting and compression into cylinders.
(iii) A mushroom cultivation hut with thatched roof and bamboos, and accessories to produce on a large scale.

Fig. 1 The RRC main building in the university

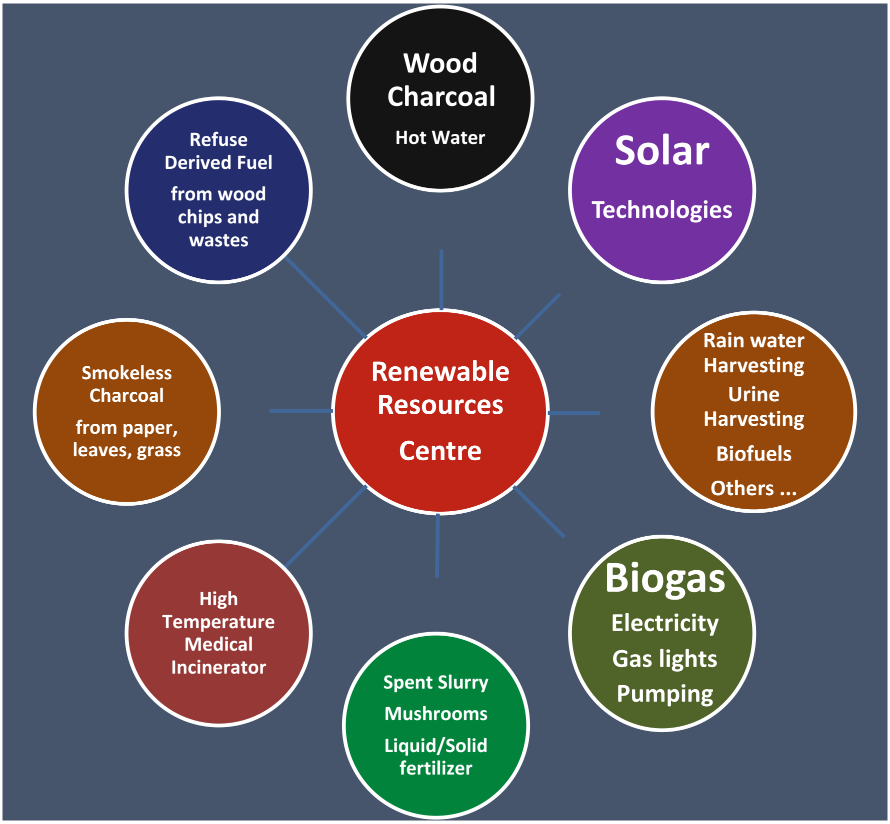

Fig. 2 Various sections at Renewable Resources Centre

(iv) Liquid fertilizer production from biogas-spent slurry.
(v) Permanent kiln for smokeless charcoal/biochar production.
(vi) Charcoal Kiln (a design adopted from Kenyan/Ethiopian technology) to produce charcoal within 24 h from fallen and cut trees.
(vii) Home composter for low-scale production of compost at house and farm unit.
(viii) Portable refuse-derived fuel unit.
(ix) A demonstration plot land set aside opposite the biogas section for demonstrating some of the products for agricultural production. Here, various field-based experiments are carried out.
(x) Rainwater harvesting for ensuring the availability of water all year round with elementary and useful technology.

It is expected that the RRC will become a center of attraction for people to get trained on “Waste to Wealth” and “Waste to Energy” technologies. The center will benefit Nigerian communities as well as other developing economies through “Town and Gown” meet.

Activities and Climate Change Adaptive Technologies at Various Sections of the Center

Training Hall: About 30 people can comfortably sit and receive training. The room is equipped with two air conditioners, a PowerPoint projection, and a cupboard to display some standard books for the trainees to use. The target training participants include interested individuals, small and big scale farmers, members of cooperative society, students, and retirees (Fig. 3a).

Biogas Generation and Compression

There are two types of biogas digesters: One is 8 m^3 capacity, flexible, and a product of PVC which can expand as the gas is generated (Fig. 4a). This kind of digester is suitable for larger families or establishments that need more gas for consumption. The other is a unique floating dome variety; the capacity can vary from 1 to 10 m^3 or more, built from readily available water storage tanks from the local markets. They are affordable for households and have the potential for promotion at community levels to individual families. The biogas plants are designed to use dairy waste, poultry waste, piggery waste, or food waste from

Fig. 3 Training activities at the center (**a**, **b**, **c**, **d**)

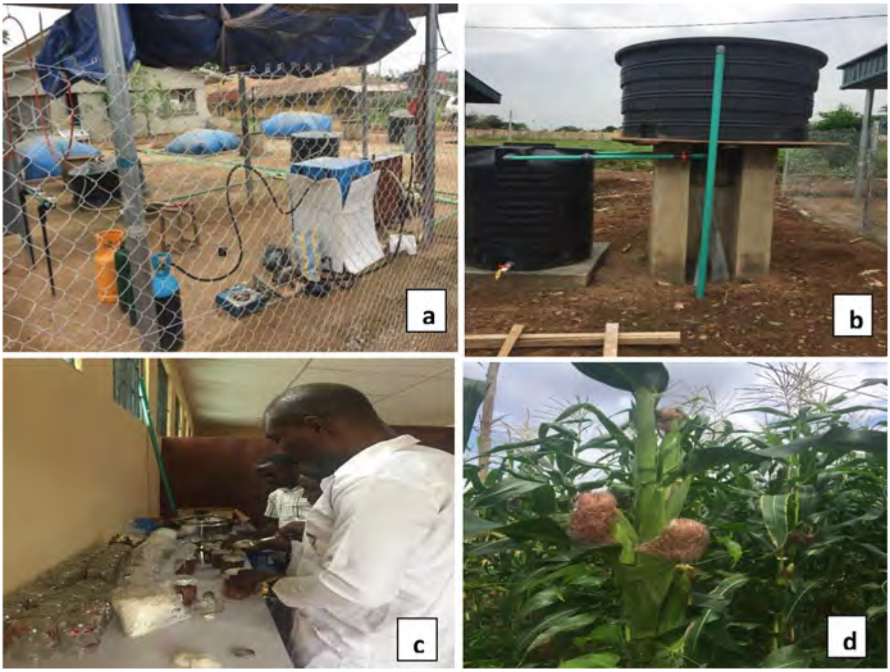

Fig. 4 Various components at RRC: (**a**) biogas compression unit; (**b**) effluent treatment filtration tank; (**c**) mushroom spun production room and (**d**) con-planted on treated effluent with many fruits on a stem

kitchens. Available end products from this section are biogas lamp, biogas compressor, biogas- multipurpose electricity generator, space heater, cooking stoves, and liquid and solid fertilizers produced from an effluent treatment filtration tank (Fig. 4b). The lamp is suitable for lighting an area without greenhouse gas emissions while the biogas cleaning unit is used to increase the percentage of methane. There is a kit that can be fixed to a household petrol-driven generator so that it can be adjusted to use petrol, natural gas, or biogas. The biosolids obtained after proper filtration are made into a very rich organic fertilizer that is used for mushroom cultivation (Fig. 4c) and raising crops at the demonstration plot (Fig. 4d). Besides, the space heater is used for warming young chickens in the poultry pens. At the same time, biogas fuel conversion kits and the portable cylinder are being tested to run vehicles, including cars, motorcycles, and tricycle, on biogas production from organic waste.

Mushroom Cultivation

A mushroom hut was built using materials ideal to maintain the required low temperature and humidity. In this hut, mushrooms will be grown from waste materials such as spent slurry, sawdust, etc. Also, bottles of spun (mushroom seedlings) of various tasty varieties are produced for household cultivation.

Wood Charcoal Kiln

A lot of trees fall due to heavy breeze and storms, and they are moved out by needy people for cooking purposes in an environmentally unfriendly manner that exacerbates climate change effects. A modern kiln available at the center can convert wood and cutoff trees to quality charcoal good commercial value (Fig. 5f). The furnace

Fig. 5 Other climate change adaptive technologies at RRC: (**a**) RDF plant; (**b**) smoke-free incinerator; (**c**) household composter; (**d**) smokeless charcoal kiln; (**e**) smokeless charcoal pellets; (**f**) wood charcoal

eliminates the traditional rural practice of digging holes all around and burning the wood openly, thus releasing greenhouse gases. In a 48-h cycle, 15–25 bags of charcoal are produced. Apart from a brick-made kiln for wood charcoal, there is another metal type (Fig. 5d) that converts light putrescible wastes to smokeless charcoal that is very popular in most of the western countries. By definition, when the charcoal is burned, no smoke is generated in the kitchen. This technology converts agroforestry residues: grass clippings, fallen leaves, maize stalks, lawn mowing, paper, sawdust, and other wastes from farms to biochar useful for farm input, wastewater treatment domestic cooking (Chang et al. 2011), warming house during cold weather, septic tank treatment, and others. The end product is in the form of charcoal powder (biochar) which is pelletized using a hand-operated extruder after some binder is added. Rejects and dust in the wood charcoal kiln are charged with treated effluent from the biogas digesters to produce nutrient-rich biochar that is sold to farmers as cheap fertilizer. The center also provides biocide-embedded smokeless charcoal for malarial control and energy for domestic cooking, at the same time (Fig. 5e). In the charcoal production process, a lot of heat is lost to the environment. The technology incorporated piped water into the furnace, whereby the temperature can be used to produce hot water. The poultry on the farm uses a lot of hot water, and it is a benefit.

According to Ana et al. (2013), global warming and its consequences on climate are among the problems posed by overdependence on fossil oil reserves. These drawbacks require exploring alternative energy sources such as biofuels that are environmentally friendly and renewable. Meanwhile, Bouros and Samiou (2001), Da Costa et al. (2004), and (Karve 2006) have earlier linked gaseous emissions from wood charcoal fires especially in an indoor environment to the incidence of many respiratory illnesses. The use of smokeless charcoal can reduce indoor air pollution, diseases, and gross environmental problems, arising from solid waste mis-management while creating access to business opportunities for women and disadvantaged groups.

High-Temperature Incinerator

For managing healthcare wastes, a recommended method is incineration operated at 1200 °C (Fig. 5b). However, none of the incinerators utilized in developing countries meets that requirement as they generally produce temperatures below 600 °C. World Bank tried to promote an incubator designed in the UK (De Montfort). Even this model is not able to maintain such an extreme temperature. Through locally developed and improved technology, the center designed an incinerator that uses heat generated from syngas. The heat is injected back into the incineration chamber to increase its temperature to around 800–1000 °C. The unit can also be used to handle pyrolysis of scrap tires and some types of e-waste which is an emerging global environmental health importance, as these wastes have become one of the fastest-growing waste types in the world (Sharma et al. 2012). The available end products in this section are carbon black and black oil that are generated from the smoke that might contribute to global warming as well as metal scrap salvaged from scrap tires. The distinctiveness of the plant is that: the unit is entirely covered to reduce the emission of GHGs, heat produced during the operation, in form of syngas, is used to replenish the furnace temperature, and the smoke generated is converted to diesel after some treatment. The unit can be operated safely at any convenient place since there is no pollution of the environment. Additionally, materials used in constructing the unit are locally available while the unit powers itself to treat hazardous wastes, hospital waste, and agricultural wastes.

Refuse Derived Fuel (RDF) Plant

This compartment uses small wood chips (paper or any dry waste) and charcoal which on heating produce a black oil and, on further heating, produce a gas (syngas). This gas can be stored in a bag or cylinder and may be used to run a household generator to produce electricity, similar to biogas. The gas can also be used directly such as biogas for cooking at the household or institutional level. In this section, the end products are syngas and charcoal that emit very little smoke. This new innovative technology (Fig. 5a) has been developed to generate syngas from all types of combustible solid wastes and use the gas to run generators for electricity. In addition to health safety and environmental protection, this technology will be of great benefit to the rural and peri-urban populations who may want to develop small or medium scale entrepreneurship with low investment and very little skills. It does not need electricity or any sophisticated mechanical devices.

Gasification- and pyrolysis-related processes are usually confused with one another. Zhou et al. (2008) identified the major difference between the two methods as the gasification occurs in the presence of oxygen. On the other hand, pyrolysis does not require oxygen or air during its process. However, gases and liquids produced in the pyrolysis and gasification processes have high contents of carbon monoxide (CO) and hydrogen gas (H_2) that can be a good source of syngas. The syngas is used for the production of methanol and ethanol or H_2 used in fuel cells (Baumlin et al. 2006). For example, gases with the main benefit of pyrolysis is that it offers clean heat, which is needed to develop cooking technology with lower indoor pollution by smoke than is typically generated during the burning of biomass (Bailis et al. 2005). Also, the by-product is smokeless briquette charcoal, because, during carbonization, its smoke disappears.

Home Composter

This unit was designed for low-scale production of compost at houses and farm units (Fig. 5c).

The RRC is intended to be operated on a sustainable basis through various sources of revenue generation, including the following:

(a) Consultancies and turnkey projects for public and government bodies on the technologies developed at the center (fertilizer, biogas, charcoal, smokeless charcoal, etc.)
(b) Sale of products such as charcoal, biogas kits, mushrooms, maggots, liquid and solid organic fertilizers, black oil, carbon black, and organically grown produce from the demonstration plot

(c) "Science Tourism" and education visits of schools, and the public
(d) Assisting researchers through the use of locally fabricated equipment
(e) Training programs (short-term) and hands-on training
(f) Donors and philanthropists
(g) University support for innovative researches and grants
(h) Hospital waste management services
(i) Compression of gas into cylinders for domestic uses

From Climate Change to Community Change: Lesson from Kube-Atenda, Nigeria

This scheme is community-led waste management for reducing greenhouse gas emission and mitigating climate change effects at Kube Atenda, Ibadan, Nigeria. The project was carried out under the Climate Impacts Research Capacity and Leadership Enhancement in Sub-Saharan Africa (CIRCLE) program and executed by the UK's Department for International Development (DFID), in collaboration with the Association of Commonwealth (ACU) and African Academy of Sciences (AAS). Transformative adaptation and sustainable responses to climate change (Fig. 6a–d) that were adopted included: a large scale stakeholders' workshop that comprised community people (the users), local council representatives, private practitioners, and selected people from the general public; creation of a sorting center/recycling kiosks for recyclable buyback arrangement and entrepreneurship opportunities; Waste-to-Electricity through a newly invented pyrolytic chamber for converting accumulated waste to energy and useful by-products; developing market links for recyclables between the community's buyback center and resource recovery centers; developing effective communication among all the stakeholders and decision-makers; and instituting monitoring and evaluation for progress control through the involvement of Department of Community Development Inspectorate (CDI) at Ibadan Northeast LGA (local council). Specifically, this project focused on behavioral change of the community member toward solid waste management practices that will ensure wealth creation and development, using the 4R concept (Reduce, reuse, recycle, and recover).

Before this uptake activity, the community had been faced with a big challenge of solid waste management. There were heaps of waste around the community while people were disposing of their garbage on illegal dumps, in open spaces, and in water bodies, or burning them openly in an environmentally friendly manner. The training component of the research led to building people's capacity in waste to wealth as the community members were taught on how to sort their solid waste into paper, glass, plastics, and other recyclables for recycling, reuse, and sale at the community buyback center. They were also taught a way to produce organic fertilizer from organic waste and biochar (smokeless charcoal) from agroforestry residues to generate an inexpensive and clean source of energy for domestic cooking. There was a rise within the level of awareness of the consequences of poor solid waste

Fig. 6 Climate change mitigation and adaptation initiatives at Kube-Atenda: (**a**) recycling kiosks for recyclable buyback arrangement, (**b**) field demonstration on charcoal production, (**c**) pyrolytic chamber, and (**d**) phone-charging center

management, such as health hazards, esthetic damage, and other environmental problems in the community.

Moreover, the pyrolytic chamber generates gas that powers a generator for electricity supply and produces black oil from which diesel and kerosene can be distilled. The electricity supplied is used to power a phone-charging center (Fig. 6d) that financially empowers the youths who are managing the center.

The center is now a study area for young- and midcareer researchers and postgraduate students in universities across the country. This project is meeting the people's needs, including economic development, safe environment, poverty reduction, and healthful living. Also, policymakers in the state and across the country will find the uptake and research evidence very useful in their planning and activities.

Integrating Waste Picking at Dumpsites into a Value-Added Chain in Nigeria

Old dumpsites contain a high proportion of recyclables, including minerals and metallic components including e-waste, ferrous scrap, aluminum, and copper cable that could be salvaged and reprocessed. Also, the highly calorific waste components (wood, plastics or paper, textiles, and paper) could be used to generate energy (Bachmann and Cordes 2007). Recycling of these wastes has the potential to create jobs for waste pickers, by promoting entrepreneurs to establish waste recovery facilities at dumpsites. Adding waste into the value-added chain formally will reduce the quantity of wastes disposed to landfill sites and improve the practices that endanger the health and safety of waste pickers, at landfills/dumpsites.

In many developed countries such as those within the European Union, policies of reduction, reuse, and diversion of wastes from dumpsites/landfill are strongly promoted (European Environment Agency 2003). The situation is quite different in Nigeria as the main fractions of wastes generated are recyclables including organic materials, plastics/rubbers, cardboard, metals, and glass bottles (Ojolo 2004). These wastes are stored and transported directly to some designated dumpsites where they are burnt eventually. This practice has potential impacts on the health and hygiene of people in the neighborhood and the esthetic nature of the environment.

Zerbock (2003) noted that waste dumping is the well-liked method of putting off solid waste rather than sending wastes to landfills in most African countries. Wastes are solely dumped in low-lying areas without engineered measures to prevent environmental pollution. In open dumps, there is no consideration for leachate and gas management. Also, operational standards, such as registration of users, control of the number of tipping fronts, or compaction of waste, are few, if not absent. This method is neither hygienic nor safe as waste is tipped haphazardly. However, African countries have a minimal choice because of their low financial capacity and lopsided institutional arrangements. The responsibility of waste disposal is vested in local governments which are weak and cannot usually raise money to construct sanitary landfills. Some countries use semicontrolled landfills whereby wastes are dumped uncontrollably at designated dumpsites without covering with topsoil to prevent odor and rodent nuisance. In this kind of landfill, various wastes such as municipal, industrial, or clinical/hospital wastes are dumped, not following internationally approved best practices.

Waste-Picking Activities at the Dumpsites: A Case Study of Ibadan, Nigeria

Through Focus Group Discussion (FGD) sessions and observation checklist, the authors assess the dynamic of waste picking at the four designated dumpsites in Ibadan, Nigeria. The dumpsites included in the survey were: Ajaganka, Awotan, Lapite, and Afonfura. For the FGD, questions were structured to cover the following major activities: population and category of workers, business activities, method of business apprentice, factors that affect the operation, including technical, environmental, social, and economic factors, and perception of scavengers on business optimization and improvement.

Category of Workers and Prices of Items

When asked about the number of scavengers at each dumpsite, the following responses were gathered: Ajaganka – 20 (17 males and 3 females); Awotan – 20 (15 males and 5 females); Lapite – 5 (4 males and 1 female); and Afonfura – 28 (18 females and 10 males). There were more males than females except at Afofunra where 18 females were found as against 10 males. As per the year of experience, the age ranged between 3 and 20 years. According to the discussants, there was a competitive demand for recyclables. They sold the recyclables to the manufacturers who came to buy them directly from the sites. Each recyclable had a fixed price and the unit of measurement was either in kg, ton, or dozen, depending on the types of recyclables. The prices of the recyclables were given thus: tin (including milk can) – 20/kg; pet bottles – 30/kg; glass bottles – 20/dozens (depends on sizes and color); plastic scrap – 30/kg; nylon – 12/kg; aluminum (including some beverage cans) – 50/kg; copper (wire) – 800/kg; brass – 400/kg; steel – 30/kg; zinc – 50/kg; stainless metal – 80/kg; electronics (including computer panel) – 800/kg; sacs – 60/dozen; carpet – 20/kg; and Rug – 10/kg. The prices of the recyclables depend on demand from industrialists who use recyclables as potential materials for manufacturing. Economic aspects of salvaging recyclables from dumpsites have been widely reviewed (Rettenberger 1995; Van der Zee et al. 2004). In these studies, possible costs and benefits that may be obtained from using dumpsite as material recovery centers were outlined on a large scale. Some of the benefits listed were revenue from recycled materials and saving land space at dumpsites to increase their life spans. Contrary to this observation, the economic feasibility of landfill mining could not be meticulously addressed by previous studies (Savage et al. 1998; Cossu et al. 1996), and in some studies, such initiatives have been considered nonbeneficial (Cobb and Ruckstuhl 1988; Bryden 2000).

At all the dumpsites, more males were found than females because more physical strength required for the job was attributed to males and that females were usually discouraged by the stigmatization attached to the work by the people. The discussants were satisfied with their job because of their achievements and sustainable daily income from the sale of recyclables.

Method of Business Apprenticeship

The waste pickers could not identify any method of apprenticeship during the discussion. The majority of them joined the business haphazardly; they associated their enrolment into the job with severe financial problems and bankruptcy. Their main plan was to leave the job as soon as they recovered from insolvency. Contrarily, having tasted the good returns from the job, they found it difficult to go, even after they had overcome their financial burdens. The waste pickers said further that the business required little or no capital to start with and the principal instrument required was a picker. They did not register with any government agency or ministry. As such, there was no monitoring from the government or any nongovernment organization.

Factors That Affect the Operation of Waste Pickers

Among other things, almost all of the discussants listed the following as significant constraints they faced in the job: lack of proper and controlled tipping that sometimes leads to site congestion and open burning, disturbances from environmental health officers who usually extort money from them, odor and flies from abattoir waste, transportation, lack of business regulation, and fire outbreak. Other constraints cited were sickness (mostly from fever, body pains, whitlow, and laceration) as well as smoke, and flies and odor problems. When asked about steps taken for their preventive measures, many of them used self-medication. Besides, almost all of the discussants did not use Personal Protective Equipment (PPE), claiming that the use of PPE was not convenient to them and that they lacked financial capability to do so. This practice may have a profound effect on their health and well-being. Most of the waste composition studies address environmental and safety issues at dumpsites (Hogland et al. 1995; Cossu et al. 1995; Zhao et al. 2007; Prechthai et al. 2008) and show that the practices at municipal dumpsites are not effective. Many of the dumpsites have no fence, allowing unregulated access to the site and dumping of restricted materials, such as toxic wastes. Additionally, owing to the poor control of activities at dumpsites, medical and hazardous wastes end up at those dumpsites even though there are no particular dumping areas for such wastes in the city.

Perception of the Waste Pickers on Business Optimization and Improvement

Suggestions on how the job can be improved were sought from the waste pickers. Very few of them that responded said the government should absorb them into the civil service, give them proper training, especially on waste recycling, and support them with necessary facilities. Also, the discussants thought that the marketing of the recyclables could be improved significantly if the government could purchase the recyclables from them and act as a wholesaler. According to Mocker et al. (2009), due to the increasing scarcity and costs of different raw materials, the recovery of recyclables from dumpsites as a source for raw materials is rising steadily.

Quantity of Waste Picking Per Month at the Four Dumpsites

The output, in terms of quantities of recyclables salvaged per month for the four sites, is represented in Fig. 7. The most purchased component was plastics, followed by paper and organic waste. Rugs and electronics were found at the lowest proportions. The thin film and organic waste were not sorted, though they equally had high recycling potentials. According to the participants, "*Organic waste was messy and very difficult to deal with*"; *it could not be stored without much problem, especially those related to odor and flies nuisance*. Besides, thin film such as pure water sachets remained very common; it could be found anywhere and everywhere without stress, leading to its low offered price. Waste components such as disused mattresses and packaging plastic foams had very little or no secondhand values; they could instead be reused than recycled. Also, an individual waste picker was assigned with a specific type of recyclable, and the number of waste pickers working at each site reflected the quantities of recyclables obtainable at such site.

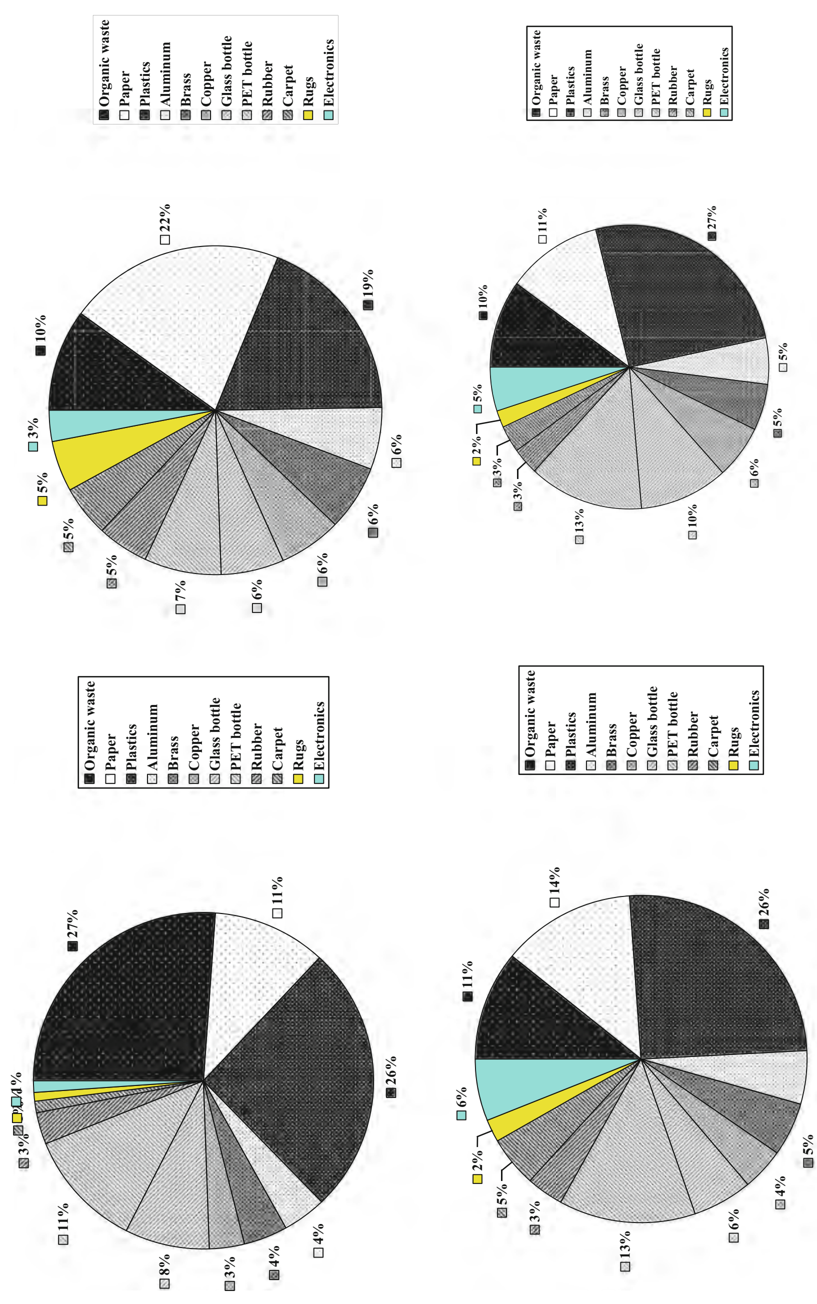

Fig. 7 Quantity of recyclables at the four dumpsites per month. Left top (Lapite); Left bottom (Afonfura); Right top (Awotan); Right bottom (Ajakanga)

Conclusion

The rate at which climate change affects developing economies has called for urgent measures to cope with unexpected climate phenomena. Climate change effects threaten to exacerbate existing vulnerabilities and pose unprecedented challenges and opportunities for people in this part of the world. Based on these premises, this chapter describes grassroots projects and the diversity of approaches to climate change management. Apart from the results of research and field projects, this section also showcases practice-oriented procedures, case studies, innovative local adaptation practices as well as barriers and limits to climate change management. The contents are expected to foster resilience and capacity building among communities in developing countries.

Pyrolysis Bio-oil and Bio-char Production from Firewood Tree Species for Energy and Carbon Storage in Rural Wooden Houses of Southern Ethiopia

64

Miftah F. Kedir

Contents

Abstract

The need for emission reduction for climate management had triggered the application of pyrolysis technology on firewood that yield bio-oil, bio-char, and syngas. The purpose of present study was to select the best bio-oil and bio-char producing plants from 17 firewood tree species and to quantify the amount of carbon storage. A dried and 1 mm sieved sample of 150 g biomass of each species

was pyrolyzed in assembled setup of tubular furnace using standard laboratory techniques. The bio-oil and bio-char yields were 21.1–42.87% (w/w) and 23.23–36.40% (w/w), respectively. The bio-oil yield of *Acacia seyal*, *Dodonea angustifolia*, *Euclea schimperi*, *Eucalyptus globulus*, *Casuarina equisetifolia*, and *Grevillea robusta* were over 36% (w/w), which make the total yield of bio-oil and bio-char over 62% (w/w) of the biomass samples instead of the 12% conversion efficiency in traditional carbonization. The calorific value of firewood was 16.31–19.66 MJ kg^{-1} and bio-oil was 23.3–33.37 MJ kg^{-1}. The use of bio-oil for household energy and bio-char for carbon storage reduced end use emission by 71.48–118.06%, which could increase adaptation to climate change in comparison to open stove firewood by using clean fuel and reducing indoor pollution.

Introduction

The adaptation and mitigation of climate change and energy security requires alternative energy sources that reduce emission of greenhouse gasses (GHG) in the place of fossil fuel dominant economy of the world (Krajnc et al. 2014). Liquid biofuel production from biomass pyrolysis is new form of the old technology that reduces waste and improves the low bulk density, high moisture content, hydrophilic nature, and low calorific value of firewood (Arias et al. 2008). Pyrolysis is a thermochemical process of converting biomass in to solid bio-char, liquid bio-oil (also called pyrolysis oil), and syngas in the absence of oxygen at 300–1000 °C, heating rate 0.1–1000 °C s^{-1}, and vapor residence time 0.5–1800 s (Granada et al. 2013). Pyrolysis of dry biomass ($C_6H_{10}O_5$) produces combustible gases (H_2, CH_4, CO) and noncombustible gases (CO_2 and H_2O) resulting in condensable gases forming bio-oil (C_6H_8O with H_2O) (Cordeiro 2011). High heating rates above 500 °C and short vapor residence time gives more pyrolysis oil; and low temperature below 400 °C produces more bio-char (Xiu and Shahbazi 2012).

Feedstocks for pyrolysis can be a variety of woody and non-woody biomasses, forest products, solid organic wastes, forest/agricultural residues, paper and cardboard except toxic biomasses that have heavy metals, polyaromatic hydrocarbons, and dioxins (Garcia-Perez 2008).

The calorific value of bio-oil can be chemically upgraded to 44 MJ kg^{-1} (Elliot 2012). Firewood combustion pollutes indoor air and affects health but bio-oil has no significant health, environment, or safety risks and its GHG emission is lower than petro diesel and gasoline (Shimelis 2011).

Bio-char and charcoal are similar products of pyrolysis technology that are used for different purpose. Bio-char is charcoal like, fine porous structured, positively charged, high carbon and low moisture containing co-product of bio-oil but charcoal is coarse structure as a sole product. Bio-char could be used for energy supply, soil carbon storage, and fertility amendment but charcoal is usually used for energy.

The pyrolysis of organic matter alters the chemical structure of carbon to aromatic carbon rings called recalcitrant carbon that resist microbial decomposition. Wood bio-char stores 25–50% of its carbon for millennia, 100–1000 years but organic residue compost stores 10–20% of its carbon from weeks to 5–10 years (Kannan et al. 2013).

Capturing the volatiles during pyrolysis to get bio-oil, in addition to bio-char and syngas instead of mere charcoal, is an increment of conversion efficiency of carbonization in traditional charcoal making (Brown 2009). Charcoal making emits primary GHG of the energy system, carbon monoxide, ethane, pyroacids, tars, heavy oils, and water (Bird et al. 2011). Firewood and charcoal have CO_2 emission factors of 112,000 kg TJ^{-1} on net calorific value basis (IPCC 2006). About 1788±337 g CO_2 and 32±5 g CH_4 per kilogram of charcoal are produced, which varies with different vegetation parts and burning conditions (Chidumayo and Gumbo 2013). In charcoal making the three steps include wood sourcing, carbonization, and end use, and the emission is 29–61%, 28–61%, and 9–18%, respectively (FAO 2017).

Climate change adaptation to energy is the adjustment in natural or human systems in response to actual or expected energy deficit of climatic stimuli or their effects, which moderates harm or exploits beneficial energy production opportunities. Ethiopia in particular and Africa in general have low adaptation capability to climate change (IPCC 2006). The conversion of firewood and charcoal in to multiple products of bio-char, bio-oil, and syngas reduces consumption of biomass that reduces deforestation and increases income sources in order to adapt to climate change. In Ethiopia and elsewhere in Africa, adapting technology for alternative sources of bioenergy is one of the strategies of climate change adaptation (FAO 2017). Environmental sustainability could be achieved by local management of firewood saving and macro policy adjustment in order to promote the sustainability of land resources and climate change adaptation (Eze et al. 2020). Therefore, developing biomass saving technologies like pyrolysis is important for climate change adaptation and mitigation.

Pyrolysis oil during biomass carbonization can be produced over a wider range of temperature above 300 °C by screening a large number of biomass yielding trees (Xiu and Shahbazi 2012). According to Okoroigwe et al. (2015) tropical woody biomass produces up to 66% (w/w) bio-oil for energy and it contains industrially useful chemicals. Bio-oil production is an attractive venture with significant commercial application and value, and dry feed can produce up to 80% (w/w) bio-oil. However, there is dearth of information on condensing the volatile matters to bio-oil, especially at 600 °C and residence time of 2 s in Ethiopia for firewood species, except *Catha edulis* (Yishak 2014). In fact, it is studied that biomass residues at 600 °C has high recalcitrant character and low volatile nature (Jindo et al. 2014). One of the most important characteristics of biomass fuel is heating value which can be determined experimentally by adiabatic bomb calorimeter (Sheng and Azevedo 2005), which was not available for many of the firewood tree species in Ethiopia. The purpose of the present study was to inform tree selection in plantation development by the bio-oil and bio-char yield, and by their carbon storage potential in selected firewood utilizing rural households of Southern Ethiopia.

Material and Methods

Description of the Study Area

Biomass samples of fire wood species were collected in Southern Ethiopia, three agro-ecologies of Enemorina Ener district (county). From each agro-ecology a representative peasant association (PA) or Kebele (lowest administrative unit) was sampled. In lowland agro-ecology, 500–1600 m altitude above sea level (asl), Ener Kola PA; in midaltitude agro-ecology, 1600–2400 m altitude asl, Daemir PA; and in highland agro-ecology, 2400–3200 m asl, Awed PA were selected (Fig. 1). The local

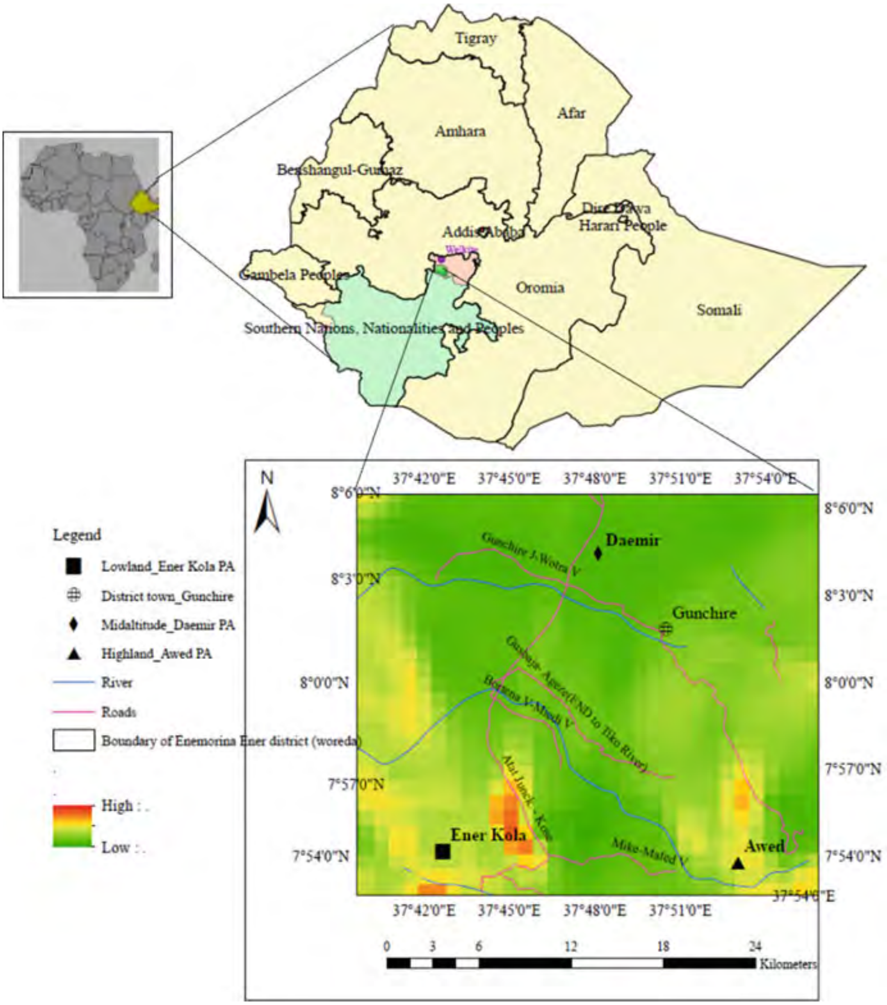

Fig. 1 Location map of most samples collected areas. (The legend and scale refers only to the three studied peasant associations or Kebeles and nearby features)

people had been practicing mixed farming, trading, and pottery work. The main fuel for cooking was firewood with or without kerosene light.

Methods of Data Collection and Analyses

Field Sample Collection

Woody biomass samples were collected from the selected PAs after interviewing 5–10 key informants, and district energy offices about the preferred firewood tree species that ranked 1–5. The most preferred tree species were selected for pyrolysis test in each agro-ecology; seven species in lowland and midaltitude each and one species in highland. Additional samples from two species (*Catha edulis* and *Prosopis juliflora*) were obtained from other places (Table 1) because of their abundance and common firewood value for comparison purposes, making a total of 17 species. That is *C. edulis* is abundant throughout Ethiopia and *P. juliflora* is an invasive species used for charcoal making in North Eastern Ethiopia. The family, diameter at breast height (DBH), and total mean height (*H*) of the selected species are given in Table 1.

From the 15 tree species in the forest, three standing trees were randomly selected and cut from each. Then the wood without debarking was chipped in to 1–5 cm long pieces by excluding branches (≤5 cm diameter) and leaves. In *C. edulis*, leafy residues and in *C. megalocarpus,* fruit pod were collected. Then the 17 tree species biomass samples were air dried, separated from any impurities, ground, and sieved by 1 mm sieve size.

Experimental Analyses

Pure, composite, ground, dry biomass samples of 150 g were pyrolyzed in assembled setup of tubular furnace in three replications. The pyrolysis was done at 600 °C temperature, at a heating rate of 100 °C min^{-1} and 2 s vapor residence, using 1.5 atmosphere inert nitrogen gas with 20–25 mL min^{-1} flow rate. The setup consisted of feeder, reactor, glass liquid collecting condenser, and chiller (Fig. 2). Only bio-oil and bio-char were collected. The weight of bio-char and bio-oil was measured with balance (Adam Lab.equipment Leicester LE67FT-England, 0.001 g) and volume by graduated cylinder. The yield of bio-char and bio-oil was determined from the proportion of dried biomass feedstock pyrolyzed (Eq. 1) and loss by deduction (Eq. 2). The percentage throughout this chapter is given as (%) for percent weight to weight (%, w/w) or % (w/w) or %, unless otherwise specified as percent volume to volume as (%, v/v) or % (v/v).

The bio-oil and parent firewood Gross Calorific Value (GCV) was determined by adiabatic oxygen bomb calorimeter (Parr® model no.1241EF adiabatic calorimeter S.no. 5172, 115 v, 50 Hz, 2.0 Amps, Parr Instrument Company). About 1 g sample and oxygen filled bomb at 30 atmospheres were used. GCV was converted to net calorific value (NCV) by multiplying with 0.95 and 0.80 for oil and dry woody biomass, respectively (Forest Products Laboratory 2004). Ash content of firewood and bio-oil was determined by burning 5 g sample in furnace at 600 °C for 4 h.

Bio-char samples were characterized using proximate analysis (ASTM 1989) to obtain fixed carbon, moisture content (D3173), ash content (D3174), and volatile matter (D3175). Moisture content of bio-char was determined by drying 1 g initial sample in oven at 105 °C to constant weight for 3 h (Eq. 3); volatile matter by heating 1 g moisture free sample at 950 °C for 6 min (Eq. 4); ash content by heating 1 g sample at 750 °C for 3 h (Eq. 5) and fixed carbon by deduction (Eq. 6).

$$\mathbf{Vm}\left(\%, \frac{\mathbf{w}}{\mathbf{w}}\right) = \left(\frac{\boldsymbol{W}\ \mathbf{of\ sample\ at\ 105^{\circ}C}\ (\boldsymbol{g}) - \boldsymbol{W}\ \mathbf{of\ sample\ at\ 950^{\circ}C}(\boldsymbol{g})}{\boldsymbol{W}\ \mathbf{of\ initial\ sample}\ (\boldsymbol{g})}\right) \times \mathbf{100} \tag{4}$$

$$\mathbf{Ash}\ (\boldsymbol{A})\left(\%, \frac{\mathbf{w}}{\mathbf{w}}\right) = \left(\frac{\boldsymbol{W}\ \mathbf{of\ sample\ at\ 750^{\circ}C}\ (\boldsymbol{g})}{\boldsymbol{W}\ \mathbf{of\ initial\ sample}\ (\boldsymbol{g})}\right) \times \mathbf{100} \tag{5}$$

$$\mathbf{Fixed\ carbon\ of\ biochar}\left(\%, \frac{\mathbf{w}}{\mathbf{w}}\right) = (\mathbf{100} - (\mathbf{MC}, \% + \mathbf{Vm}, \% + \boldsymbol{A}, \%)) \tag{6}$$

where MC is moisture content; W is weight; Vm is volatile matter; A is ash content

The common GHG (CO_2, CH_4, and N_2O) emissions in rural wooden houses were determined based upon NCV (IPCC 2006) of bio-oil and firewood with or without kerosene. Although emission exists throughout the life cycles of these fuels, from

Table 2 Emission factors and global warming potential of common GHGs from different fuels

Type of GHG	Residential source of Gas Emission Factors on a net calorific basis (Stationary Combustion) (IPCC 2006) (kg TJ^{-1})				GWP (100-year time horizon)
	Firewood in conventional stove	Bio-oil (other liquid biofuels)	Charcoal	Other kerosene	
CO_2	112000	79600	112000	71900	1
CH_4	210	10	330.5	10	23
N_2O	4	0.6	1.6	0.6	296

planting, woody biomass harvesting to consumption, the present study's concern of indoor pollution reduction dealt the emission only at the end use or consumption. The IPCC default emission factors were applied (Eqs. 7 and 8). The GHGs were converted to carbon dioxide equivalent ($CO_2{}^{-e}$) using the global warming potential (GWP) of each gas (Table 2).

The average end use emission of firewood and bio-oil combustion and bio-char soil carbon accumulation was determined. For comparison purpose, the daily consumption of firewood and kerosene at household level in each agro-ecology was obtained from Miftah et al. (2017). It was assumed that a household consumes the same amount of energy in using firewood alone, firewood with kerosene or bio-oil.

The carbon storage of bio-char was determined by its fixed carbon content (Eq. 9). Stable carbon fraction to be stored for over a century used 80% factor (Roberts et al. 2010). In the presence of modern pyrolysis reactor 75% bio-oil and 12% bio-char yield was assumed to be produced from woody biomass (Granada et al. 2013). The total energy of the fuels was determined by the dried weight of the fuel and their calorific value (ASTM 1989).

The emission from firewood combustion in conventional wood stove using IPCC (2006) was calculated as Eq. 7.

$$\mathbf{Wd\ em} = \sum_{i}^{k} \mathbf{Wd\ cons}_{(ijk)} \times \mathbf{EF}_{(ijk)} \quad \times \mathbf{GWP}_{(ijk)} \tag{7}$$

where Wd em is emission of GHG ($kgCO_2{}^{e-}$) from firewood combustion; Wd cons is firewood consumption in net calorific value ($TJkg^{-1}$); EF is emission factor of firewood on net calorific value basis ($kgTJ^{-1}$); and GWP is global warming potential of a given gas on 100 years; i is CO_2; j is CH_4, and k is N_2O.

The emission from bio-oil combustion in stove using IPCC (2006) was calculated as Eq. 8.

$$\mathbf{Bo\ em.} = \sum_{i}^{k} \mathbf{Bo\ cons}_{(ijk)} \times \mathbf{EF}_{(ijk)} \quad \times \mathbf{GWP}_{(ijk)} \tag{8}$$

where Bo em is emission of GHG ($kgCO_2{}^{e-}$) from bio-oil combustion; Bo cons is bio-oil consumption in net calorific value ($TJkg^{-1}$); EF is emission factor of bio-oil on net calorific value basis ($kgTJ^{-1}$); and GWP is global warming potential of a given gas on 100 years basis; *i* is CO_2; *j* is CH_4 and *k* is N_2O.

Carbon storage in bio-char of organic wastes was calculated as Eq. 9.

$$\textbf{Csb}\ (\boldsymbol{g}) = (\textbf{dry biomass}\ (\boldsymbol{g})) \times (\textbf{biochar yield}\ (\%)) \times (\textbf{fixed}\ \boldsymbol{C}\ (\%)) \qquad (9)$$

where Csb is carbon storage in bio-char.

Results

Bio-oil and Bio-char Yield of Different Woody Biomasses Species

The bio-oil (Fig. 3) yield of woody biomass samples ranged from 23.03 (%, w/w) in *A. schimperi* to 42.9 (%, w/w) in *E. globulus* which was statistically different at $p<0.05$ (Table 3). The bio-oil yield of fruit pod of *C. megalocarpus* was about 21.1 (%, w/w), lower than the other woody biomasses; and the leaf of *C. edulis* was intermediate about 25.83 (%, w/w). Tree species like *E. globulus, A. seyal, D. angustifolia, E. schimperi*, and *G. robusta* produced greater amount of bio-oil (Table 3) and highly preferred for firewood (Table 3).

The bio-char (Fig. 4) yield of the biomass samples ranged from 23.2% (w/w) in *E. camaldulensis* to 36.4% (w/w) in *C. edulis* which was statistically different at $p< 0.05$ (Table 3). The mass losses of pyrolysis product ranged from 31.23% (w/w) in *E. schimperi* to 46.37% (w/w) in *A. schimperi* (Table 3), which could be attributed to the specific characteristics of the species.

Calorific Value and Moisture Content of Bio-oil and Bio-char in Comparison with the Parent Firewood

The calorific value of firewood used for the pyrolysis process ranged from 16.31 $MJkg^{-1}$ (in *E. schimperi*) to 19.66 $MJkg^{-1}$ (in *P. julifolra*) at moisture content

Fig. 3 Bio-oil from pyrolysis of woody biomass

of 7.92–10.22 (%, w/w) (Fig. 5). Firewood from *D. angustifolia, E. camaldulensis, G. robusta, A. decurrens*, and *E. globulus* had calorific value above 18 MJ kg^{-1}. *C. edulis* leafy residues had comparable calorific value with the other firewood species (Fig. 5), but not used as firewood (Table 3) because of its smoke. The calorific value of bio-oil ranged from 21.43 $MJkg^{-1}$ (in *A. albida*) to 33.37 $MJkg^{-1}$ (in *E. globulus*) (Fig. 5).

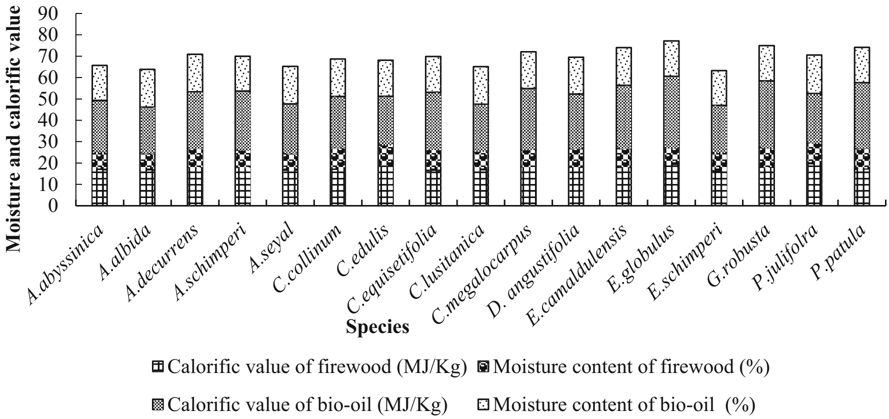

Fig. 5 The mean calorific value of parent firewood, bio-char, and bio-oil of a given plant species

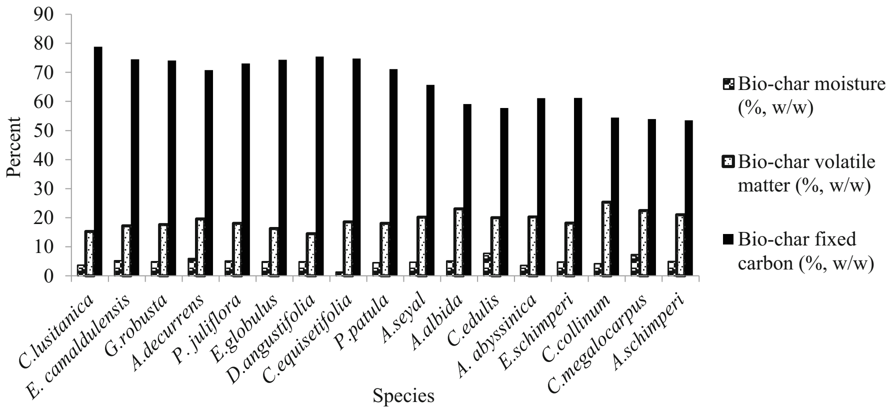

Fig. 6 Mean fixed carbon, volatile, and moisture content of bio-char

Fixed Carbon, Volatile Matter, and Moisture Content of Different Tree Species Bio-chars

The fixed carbon content of bio-chars of the different tree species ranged from 53.48 (%, w/w) (in *A. schimperi*) to 78.85 (%, w/w) (in *C. lusitanica*); and volatile matter from 14.52 (%, w/w) (in *D. angustifolia*) to 25.31 (%, w/w) (C. *collinum*) (Fig. 6).

Ash Content of Firewood Feedstock, and Bio-oil and Bio-char

The percentage of the ash content of the different tree species firewood and bio-oil was not consistently increasing or decreasing (Table 4). The ash in bio-char ranged from 2.27(%, w/w) in *C. lusitanica* to 20.65 (%, w/w) in *A. schimperi.* In firewood the ash content ranged from 0.434 (%, w/w) in *E. camaldulensis* to 8.418 (%, w/w) in *E. schimperi*. The lowest proportion of ash was obtained in bio-oil, ranging from

0.135% in *G. robusta* to 0.892% in *C. equisetifolia*. As the ash content of the firewood increases the ash content of the bio-char also increased (Table 4).

The Potential of Pyrolysis Oil and Bio-char in Reducing Firewood End Use Emission

Rural households were using firewood and kerosene as energy sources. In the presence of kerosene, the amount of firewood biomass used was reduced, but both biomass and kerosene together during consumption emitted annually about 2.323–4.509 t CO_2^e in each household. The end use emission from fire wood combustion was 2.335–4.527 t CO_2^e year^{-1} (Fig. 7), which could be reduced to 1.88–3.645 t CO_2^e year^{-1} in bio-oil heating in each household of the studied PAs. Moreover, bio-oil production has corresponding bio-char that can store carbon 1.214–4.363 t CO_2^e year^{-1} (Fig. 7) that makes the net emission of 0.67 to net storage of 0.72 t CO_2^e year^{-1}. The pyrolysis in the present study that produced bio-oil yield of 21–42.87(%, w/w) as alternative energy for a household cooking and bio-char for carbon storage reduced end use emission by 71.48–118.06% in each household of the PAs when compared with the emission by firewood (Fig. 7). In using bio-char that produced 23.23–36.4%, w/w (Table 3) from a household firewood for soil amelioration can store 0.27–0.95 t C year^{-1} for over a century (Fig. 8).

Discussion

The use of pyrolysis technology to reduce the wastage of biomass and diversify products like biochar, bio-oil, and syngas increases adaptation and mitigation to climate change (Shackley et al. 2012). Greater bio-oil yield was obtained from locally preferred firewood species that also had less bio-char and less parent material ash (Tables 3 and 4). *E. globulus* was the highest bio-oil yielder (43%, w/w) and locally preferred for firewood (Table 3). This was confirmed by other studies, as the amount of bio-oil yield of pyrolysis of *E. globulus* and pine wood was 75 (%, w/w) at 500 °C, at a rate of 1000 °C s^{-1} and 1 s vapor residence time (Granada et al. 2013). Maximum bio-oil yield of about 70–80% on dry basis of woody biomass pyrolysis was obtained at 480–530 °C from previous other studies. The temperature limit of 600 °C used in the present study was in line with other studies for lignocellulosic biomass (Amutio et al. 2012). The overall yield of bio-oil was similar with other studies of different species; however, different tree species could require different levels of temperature, rate of heat, and vapor residence time (Okoroigwe et al. 2015), which require further study for each species.

Bio-oil and bio-char production of woody biomass depends on the structural components, cellulose, hemicellulose, and lignin. According to Akhtar and Amin (2011), higher content of cellulose and hemicelluloses favors formation of bio-oil; and higher lignin content favors formation of bio-char. *E. globulus* that produced the highest bio-oil (Table 3) contained 50% (w/w) cellulose (Dmitry and Neto 2007), than *G. robusta,* 46.38% (w/w) (Madan and Roymoulik 1990). However, the cellulose content of *C. edulis* in Yishak (2014) was 59% but had low bio-oil amount (25.83%, w/w) in the present study and requires further study. The ash content of bio-oil of the woody biomasses was lower than other studies (Table 4), which could be because of the lower ash content of the parent firewood (Table 4). The highest bio-char obtained from leaf residue of *C. edulis* (Table 3) could be attributed to the highest extractive and lignin content, about 31.5% (Yishak 2014). *G. robusta* was a recently introduced species when compared with a century old *E. globulus* and *E. camaldulensis* in the study area. Most of the fuel characteristics of *G. robusta* bio-oil were comparable to *E. globulus*, and therefore, it can be used as firewood plantation tree species in the area.

The calorific value of the bio-oil in the present study was relatively higher than other studies (Oduor and Githiomi 2013) (Fig. 5), which might be because of centrifuging the bio-oil with distilled water and subsequent dehydration. Better calorific value was obtained from the bio-oil than the parent firewood. Depending on the level of technology, the same wood from a tree species can be used in three different forms of biomass fuels including firewood, bio-oil (bio-char), or charcoal. The processing from firewood to bio-oil diversifies income source. The production processes of bio-char and charcoal have similar pyrolysis technique with similar calorific value, about 28–30 MJ kg^{-1} (Namaalwa et al. 2007). Therefore, in order to reduce the deforestation rate, conversion to bio-oil and bio-char increases the efficiency of biomass use and improves the adaptation to climate change.

In the bio-char, the amount of fixed carbon and volatile matter at moisture content 1.3–7.74 (%, w/w) (Fig. 6) were comparable to other studies. Volatile matter of less than 20% and bio-char fixed carbon content over 50% from all of the 17 species (Fig. 6) obtained in the present study indicated the absence of labile carbon and their potential of long time carbon storage (Awad et al. 2012).

Since GHG emissions from bio-oil and firewood are taken up by the re-growing trees, there is no net emission except end use emission as indoor pollutant smoke. The end use emission as indoor pollution of bio-oil is lower than the firewood combustion because in bio-oil non-condensable gases are removed in manufacturing areas. Therefore, the use of bio-oil is safer than the direct use of firewood because of the reduction of smoke (Demirbas 2004).

The carbon storage in bio-char is a synergy to afforestation and to reduce climate change (Lehmann et al. 2006). The bio-oil and bio-char production technology could also use cheap sources of feedstock like organic wastes to reduce pressure on forests, to dispose waste and retard emission. Moreover, the reduction in forest biomass utilization improves water resources availability, secures clean air to breathe, and generates income by selling the forest products so that climate change adaptation could be improved.

Conclusion and Recommendation

The pyrolysis of woody biomasses of different tree species produced different quantity and quality of bio-oil and bio-char yield. Since the bio-oil and bio-char yield of *A. seyal, D. angustifolia, E. schimperi, E. globulus, C. equisetifolia*, and *G. robusta* was over 62% (w/w) of the parent firewood biomass used in pyrolysis, these can be selected for plantation development and climate change adaptation. Centrifuging pyrolysis oil with distilled water and subsequent dehydration resulted in increased calorific value to 33 MJ kg^{-1} in *E. globulus*. The production and simultaneous use of bio-oil yield (21.1–42.87%, w/w) and bio-char yield (23.233–36.40%, w/w) for household cooking energy and for carbon storage, respectively, instead of firewood reduced end use emission by 71.48–118.06% in each household of lowland to highland PA of the studied area, which could increase adaptation to climate change by reducing the cost of indoor pollution. Therefore, pyrolysis of biomass generally reduces wood wastage, creates jobs, and provides organic carbon as adaptation to climate change. In order to reduce transport cost of low density and high volume biomass, and to reduce the number of transportation vehicles, it is important to establish small-scale biomass pyrolysis firm in electrified parts of Ethiopia that produce bio-oil and bio-char from woody and non-woody organic wastes to diversify income and to increase the adaptive capacity of the rural people to climate change. Moreover, carbon storage potential of bio-char can be used to improve soil fertility in rural areas as a means of climate change adaptation and mitigation. The tree/shrub species used for making charcoal in Ethiopia are mainly slow growing indigenous species existing in natural forest, and there should be a guiding policy to plant tree species like *A. seyal, D. angustifolia, E. schimperi, E. globulus, C. equisetifolia*, and *G. robusta* for charcoal making and to strengthen climate change adaptation.

Contents

Abstract

The vicious cycle of food insecurity in Kenya and Africa at large is partly attributed to the high reliance on rainfed agriculture, which makes production systems vulnerable to the adverse impacts of climate change and variability. Conservation agriculture (CA) has been disseminated as a climate-smart practice that operates on three main principles to realize the multiple benefits of making

crop production systems more resilient to climate change impacts, enhancing food security, and providing environmental services, such as carbon sequestration. As a major source of livelihood in the Taita Hills, agriculture is constrained by climate change owing to its rainfed nature. The yield and environmental and economic benefits of CA make it a suitable alternative approach to sustainable agricultural intensification, which is fundamentally different from conventional approaches based on intensive tillage and often disrupts ecosystem functions. This chapter provides the rationale for enhancing the adoption of CA in the Taita Hills by evaluating the current challenges affecting crop production, the role of CA in addressing the challenges and its potential benefits, and the barriers that must be overcome in order to promote its wide-scale adoption. A number of constraints appear to hinder the wide-scale adoption of CA in the Taita Hills, including lack of awareness, tenure-related issues, and weak policy and institutional support. Addressing these constraints will help catalyze investments for upscaling CA in the Taita Hills, with potential for replication in other parts of the country.

Keywords

Food insecurity · climate change and variability · vulnerability · tillage · conservation agriculture

Introduction

Despite being the backbone of many sub-Saharan Africa (SSA) economies, agriculture remains predominantly (95%) rainfed and therefore vulnerable to the impacts of climate change and variability (Adhikari et al. 2015). The Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) presented strong evidence that surface temperatures across Africa have increased by 0.5–2 °C over the past 100 years. The report further indicates that from 1950 onward, climate change has altered the magnitude and frequency of extreme weather events. The frequency of cold days, cold nights, and frost has decreased, whereas the frequency of hot days, hot nights, and heat waves has increased (IPCC 2014). In addition, the recently released IPCC Special Report on global warming of 1.5 °C emphasizes that there are significant negative impacts at 1.5 °C temperature increase above pre-industrial levels and highlights that the observed warming in 2017 already reached 1 °C above pre-industrial levels (IPCC 2018). Since global warming of 1.5 °C is associated with extreme weather events, it poses a high risk to unique and vulnerable systems in Africa, especially agriculture, which is highly sensitive to weather and climate variables, including temperature, precipitation, and extreme weather events, such as droughts, floods, and severe storms.

The high spatial and temporal variability of rainfall, high temperatures, extreme weather events such as droughts and floods, and degradation of the sector's natural resource base (land, water, etc.) affect the agricultural production and thus food security. Even during seasons with favorable weather conditions, poor agronomic practices have been indicated to limit crop production. According to the Montpellier Report (2015), projections show an approximately 20% increase in hunger and malnutrition levels in SSA due to climate change-related impacts. Therefore, the biggest challenge for SSA remains, i.e., meeting the required food needs through sustainable intensification practices, considering the continued reliance on rainfed agriculture.

In Kenya, the key staple crops include maize, beans, and cruciferous vegetables. As an example, maize is consumed by over 90% of the total population as a staple crop (Ochieng' et al. 2017). However, crop production is primarily done by smallholder farmers who have limited resources for investing in sustainable production practices. Kiboi et al. (2019) noted that the maize productivity in Kenya is currently very low (1.0 ton ha^{-1}) relative to the attainable potential of 6–8 ton ha^{-1}. The huge gap in maize yield is primarily attributed to low soil fertility across the country's cropland resulting from poor management and nutrient mining without proper replenishment. Erratic patterns of rainfall and high frequency of droughts interacting with lack of investment in practices that conserve soil and water also contribute to low crop yields (Ochieng' et al. 2017). As the population continues to grow and climate change impacts aggravate, the situation in Kenya is likely to worsen over the coming years. The scaling up and out of practices that can support crop production even in periods of sporadic rainfall through soil water retention and increased organic matter can help break the vicious cycle.

Conservation agriculture (CA) has been disseminated as a climate-smart practice for intensifying crop production and increasing farmers' resilience to climate change (Sommer et al. 2018). The Special Report on Climate Change by the IPCC (2019) indicates that conservation agricultural practices have the potential to restore degraded land and enhance food security. However, the statistics provided by the Food and Agriculture Organization (FAO) show that the uptake of conservation agriculture in Kenya is still very low and far from the recommended 10% adoption rate, which is considered as the threshold level that can spur widespread adoption of the climate-smart agricultural technique in the country. Statistics further show that of the 5.8 million ha of arable land in Kenya, only 40,000 ha is under CA, 70% of which is by large-scale farmers (Mutuku et al. 2020).

The agriculture in Kenya is a major driver of the economy and the entire food systems. It is a major source of livelihood for the majority of Kenyan people in terms of food security, economic growth, employment creation, and foreign exchange earnings. As a major source of livelihood and well-being in the Taita Hills, agriculture remains highly sensitive and exposed to the impacts of climate change. This emphasizes the need to create an enabling environment to increase investments in sustainable agricultural practices that enhance farmers' buffer capacity while increasing productivity in the long term. The CA practice in particular has the potential to offset these impacts and make agricultural systems more resilient to a changing climate.

This chapter therefore provides the rationale for enhancing the adoption of CA in the Taita Hills by evaluating the current challenges affecting crop production, the role of CA, and its potential benefits as well as the challenges and barriers that must be overcome in order to promote its wide-scale adoption The findings of this chapter will enable policy makers to prioritize investments for scaling up the adoption of CA practice in the Taita Hills, with potential for replication in other parts of the country.

Status of Sustainable Agriculture in Kenya

A number of practices have been promoted as sustainable practices to enhance the resilience of farming systems in Kenya. These include agroforestry, soil and water conservation techniques such as terracing and irrigation, integrated soil fertility management, crop diversification, and conservation agriculture, inter alia (Kurgat et al. 2018). Despite the potential that these farming practices present for smallholder farming households and the environment, their adoption remains generally low in Kenya. The low adoption of sustainable agricultural practices is mainly attributed to barriers, such as low awareness, inadequate technical know-how, limited access to extension services, small farm sizes, and lack of capital.

Considering the smallholder nature of farming systems in Kenya, high population growth, and fragmented land holdings, the adoption of sustainable intensification farming practices is the most viable option to increase agricultural productivity (i.e., crop yield per unit area) to meet the constantly increasing food needs (FAO 2011a). It is also important to make production systems more resilient to biotic and abiotic stresses, especially those triggered by climate change, by maintaining soils in a carbon-rich state. In addition, avoiding further degradation of agricultural land and ecosystem services and rehabilitating the already-degraded agricultural land are urgent.

To achieve this, a shift is required from the current conventional tillage (CT)-based production systems of agricultural intensification as they have negative impacts on crucial natural resources, such as soil and water (Dumansky et al. 2014). The degradation of land resources is often accompanied by a decline in crop yields, hence the need for an alternative approach to agricultural production that is both ecologically sustainable and profitable (Jat et al. 2014). Another challenge for agriculture today lies in its environmental footprint and contribution to climate change. According to the IPCC (2014), agriculture contributes approximately 30% of the total greenhouse gas (GHGs) emissions comprising CO_2, N_2O, and CH_4 and is also affected by the impacts of climate change.

The sustainable intensification of the agricultural production paradigm proposed by the FAO (2011a) emphasizes the need for agricultural practices that are productive and remunerative, which enhance both the resilience of the natural resource base and environment and provide environmental services, such as carbon sequestration. This implies that the sustainable intensification of crop production should not only reduce climate change impacts on crop production but also address the causes of climate change through GHG emission reduction. Moreover, sustainable intensification practices should enhance above- and belowground biodiversity within the crop production systems to achieve better productivity. According to Jat et al. (2014), CA delivers on all of the aforementioned goals. The CA practice promotes the soil's biological activity, thus stabilizing the yields in the long term and increasing the soil's sequestration capacity.

The Concept of CA

Conservation agriculture is described as an approach to managing agro-ecosystems for improved and sustained productivity, increased profits, and food security while preserving and enhancing the natural resource base and the environment (FAO 2014a). CA is founded on three main principles, namely:

- Minimum or no tillage: This entails the minimum soil disturbance during planting, weeding, or harvesting. In special cases, seeding may be done in strips or bands, taking care to disturb less than 25% of the soil surface (FAO 2014b).
- Maintaining permanent organic mulch on the soil comprising of crop residues or cover crops.
- Diversifying the species of crops grown through sequences, rotations, or where perennial crops are involved using a balanced mix of leguminous and non-leguminous crops.

Through the three overarching principles, CA aims to conserve, improve, and make more efficient use of natural resources through integrated management of available soil, water, and biological resources (Vanlauwe et al. 2014a). This enhances environmental conservation and sustained agricultural production. CA has also been shown to reduce crop vulnerability to extreme weather events. For instance, in drought conditions, it reduces crop water requirements by up to 30%, makes better use of soil water, and facilitates deeper rooting of crops. In extremely wet conditions, CA facilitates rainwater infiltration, reducing the risk of soil erosion and downstream flooding.

The minimum soil disturbance principle of CA emphasizes the need for direct seeding, and once the soil condition has been well developed, tillage should be eliminated altogether. Soil disturbance from cultural practices such as weeding should be as minimal as possible, and a permanent or semi-permanent organic soil cover should be maintained all year round. This can be in the form of intercrops, cover crops, or mulch acquired from the residues of the previous crop. In addition, the diversification of crop rotations, association, and sequences adapted to the local environmental conditions should be practiced regularly (Njeru 2016). These help in maintaining above- and belowground biodiversity, fixing nutrients such as nitrogen into the soil, building soil organic matter, and suppressing the buildup of pests. The crop rotation principle also enhances soil fertility when legumes are included. The sequencing of crops according to seasons in the crop rotation cycle further minimizes the buildup of insect pests and diseases while optimizing nutrient use between the different types of crops.

The Benefits of CA

Impacts on Soil Quality

Soil is considered to be of good quality when it can sustain biological productivity, maintain environmental quality, and promote plant and animal health. The positive impact of CA with respect to soil quality improvement is often exhibited by an increase in soil organic carbon, good infiltration rates, high water-holding capacity, and good soil structure (Naab et al. 2017; Bamutaze et al. 2019; Mgolozeli et al. 2020). For instance, in their study, Mgolozeli et al. (2020) demonstrated the effect of CA in improving soil organic carbon particularly in the top 10-cm soil depth, promoting higher soil aggregate stability and improving the overall condition of the soil. Comparative studies of the infiltration capacity of soils under no-tillage (NT) and CT systems showed that soils in the NT system had higher total infiltration, and in the final steady state, the NT plots had an infiltration rate that was four times that of the CT plots (Fig. 1).

A conversion to conservation tillage from the conventional practices, in line with the CA principles, therefore helps improve soil structure and soil organic carbon, reduce the soil erosion risk, conserve soil moisture, reduce soil temperature fluctuations, improve soil quality, and the regulatory role it plays in the environment (Dube et al. 2012; Kakaire et al. 2015).

Impacts on Soil Carbon

Conventional tillage practices, such as the disk and chisel plough, are often associated with the significant loss of soil carbon (Fig. 2). The intensive cultivation of agricultural land has been shown to result in low amounts of soil carbon, limiting not

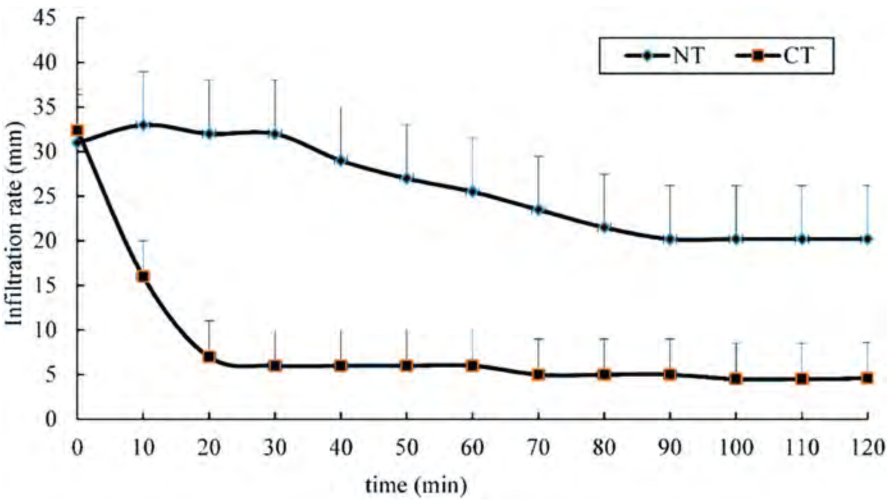

Fig. 1 Changes in the soil infiltration rate within 120 min under no-tillage (NT) and conventional tillage (CT) treatments. (Source: Mgolozeli et al. 2020)

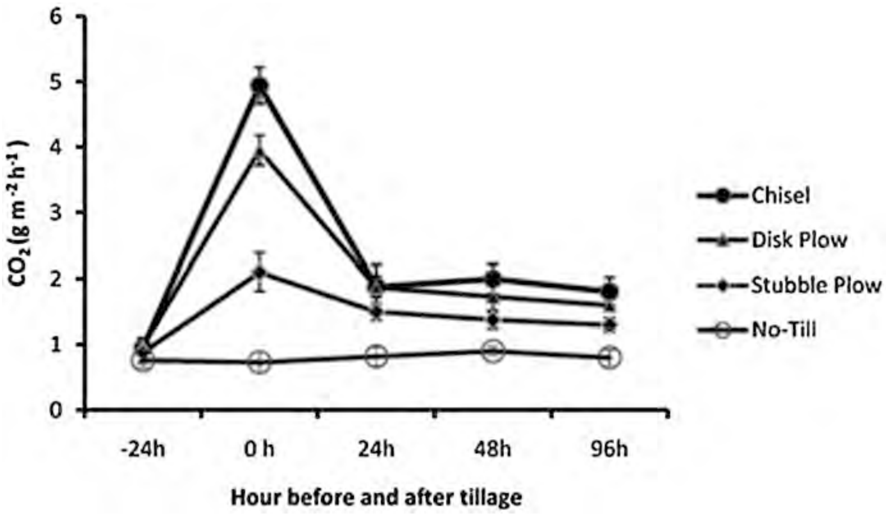

Fig. 2 CO_2 fluxes from soils associated with full tillage and NT systems. (Source: Mgolozeli et al. 2020)

just the soils' carbon sequestration capacity but also productive capacity (Dube et al. 2012). Under a changing climate, organic mulch has the potential to enhance soil productivity through the moderation of soil temperatures. For instance, combining mulching and NT can help combat climate change by enhancing carbon sequestration processes while minimizing CO_2 emissions into the atmosphere (Haddaway et al. 2016). Thus, aside from the increased productivity and soil and land restoration, CA realizes additional benefits of environmental sustainability.

Economic Benefits

In addition to the potential of CA in sustaining crop production, the practice has also been established to realize economic benefits for farmers. The findings from a study by Micheni et al. (2015) showed that although the initial costs for CA establishments, especially with weeding, were high in the first two seasons, the net income from NT systems was significantly higher compared with that of CT practices in the long term. For instance, in the fourth season, the CA costs significantly decreased to USD 24/ha compared with the constant costs of conventional systems of USD 88/ha. High cost saving was realized from the elimination of land preparation and weeding, which are common agronomic practices in CT systems. These findings are comparable with those of Guto et al. (2012) and Naab et al. (2017) who indicated that the net income from CA was higher than that of conventional systems. The low labor requirements in the CA system imply that there will be more time available to engage in off-farm income-generating activities. Additional studies from Morocco show that for many smallholder farmers, the economic gain attained from a practice supersedes the gains made in soil conservation when it comes to the adoption of labor-saving technologies (Mrabet et al. 2012). The benefits accruing from NT practices are therefore not just ecological/environmental but also reduced production costs and higher incomes to improve the well-being of farm families.

Overview of Climate Change Risks and Vulnerability in the Taita Hills

The Taita Hills are located in the Taita–Taveta County within the coastal region that lies in South Eastern Kenya. The hills form the northernmost part of the 850-km^2 stretch of the Eastern Arc Mountains in Kenya and lie within the Tsavo ecosystem which is mainly semiarid. The hills extend through different altitudinal zones depicting different agro-ecological zones within the area (Fig. 3).

Climatic and non-climatic factors interact to make the Taita Hills vulnerable to the impacts of climate change. According to Waithaka et al. (2013), some of the visible changes associated with climate change and variability in the area include the degradation of soils from moisture stress and high temperatures, limited rainfall as observed in the reduction of the volume of water in rivers, and increased frequency of extreme weather events such as floods and droughts, among others. According to the GoK (2017), the Taita Hills experience two major rainfall seasons: the long-rains season experienced between March and May (MAM) and the short-rains season experienced between October and December (OND), which in turn give rise to two planting seasons. Farmers rely on both seasons for the cultivation of their staple crops. However, the short-rains season has been noted to be more reliable than the long-rains season (GoK 2017). This is because the long-rains season is characterized

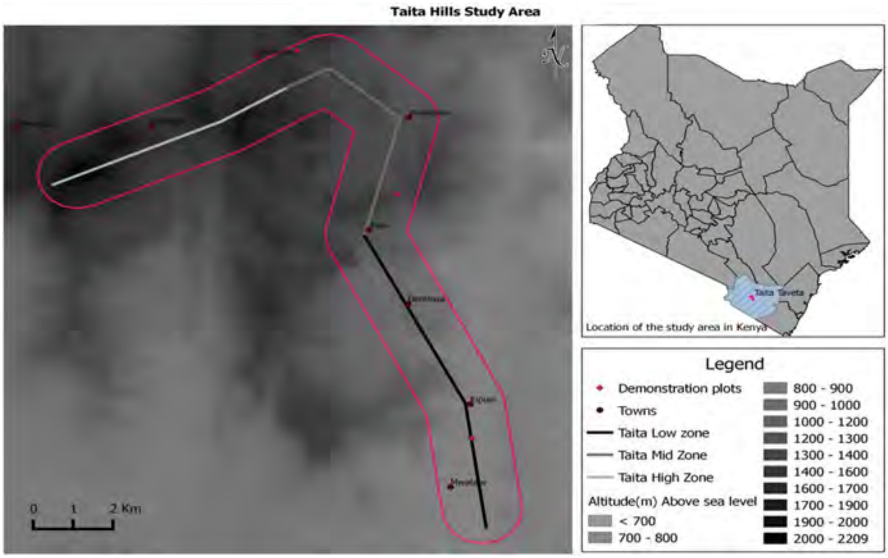

Fig. 3 Geographical location of the study area (Source: Motaroki 2016)

by, among other factors, unreliable rainfall patterns, whereby the onset of rain is delayed and cessation occurs very early in the season.

Non-climatic factors, such as high population growth, high poverty levels, poor farming methods, deforestation, and low use of technology, also have negative impacts on the status of agricultural resources, such as land and water. Due to the high rates of population growth, the area is currently characterized by small fragmented land holdings that are cultivated frequently with minimal conservation efforts, thus resulting in highly degraded soils with low fertility (Maeda 2012). A study by Muya et al. (2019) in the Taita Hills showed that in the maize-based and horticultural systems that are intensely cultivated, the amount of soil C was very low (1.6%) compared with soils under forests where the amount of C was about 7.6%. The land use intensity (LUI) in horticulture and maize-based systems was found to be over 30% compared with the LUI in forest systems (less than 2%). A similar trend was observed in the productivity index (PI), with the highest (40–50%) being recorded in natural forest and grassland and the lowest (15–20%) in horticultural and maize-based systems. The study concluded that the low soil quality and low productivity in horticulture and maize-based systems were associated with the intensification of land use as a result of inadequate knowledge on the appropriate management practices to apply. High poverty levels and lack of information cause people to engage in unsustainable practices, such as deforestation and poor farming methods, which result in land degradation. In the areas that have undergone deforestation, soil erosion has been indicated to be a major problem, with most of the terrain characterized by deep gullies.

Climatic Variability in the Taita Hills

Analysis of rainfall data for the County showed an overall declining trend in the amount of rainfall received in the various agro-ecological zones since the 1960s. The time series plot for Wundanyi (mid-altitude agro-ecological zone) showed a decline in the amount of rainfall received, the average for the years between 1993 and 2006 being less than 600 mm. This is an area that initially received between 900 and 1200 mm of rainfall per season, thus indicating a large deficit in the mentioned years (Fig. 4).

The time series analysis of Maktau in the lower zone shows the highest amount of rainfall recorded to be 626.4 mm in 1967; otherwise, there is a general declining trend in the years following 1967, with most of them receiving less than 350 mm of rainfall. This is below the average precipitation range for the lowlands which lies between 350 and 400 mm. Furthermore, the optimum rainfall condition for productive agriculture in the lowland areas is 450 mm, considering the maize variety grown. However, the time series shows the amount of rainfall received to be less than 450 mm for the period when rainfall was recorded in the weather station at Maktau (Fig. 5).

The time series analysis for the short rainy season (OND) also shows a general declining trend of observed rainfall in all the three agro-ecological zones. In the high-altitude zone, the average annual rainfall received is below 700 mm for an area that received more than 1000 mm in the past years. Similar trends are observed in the

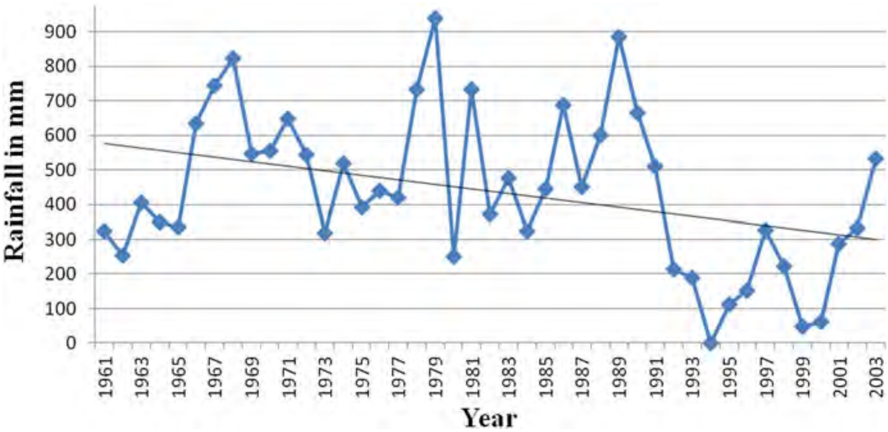

Fig. 4 Time series plot of MAM rainfall season for Wundanyi–1480 m.a.s.l (Source: Motaroki 2016)

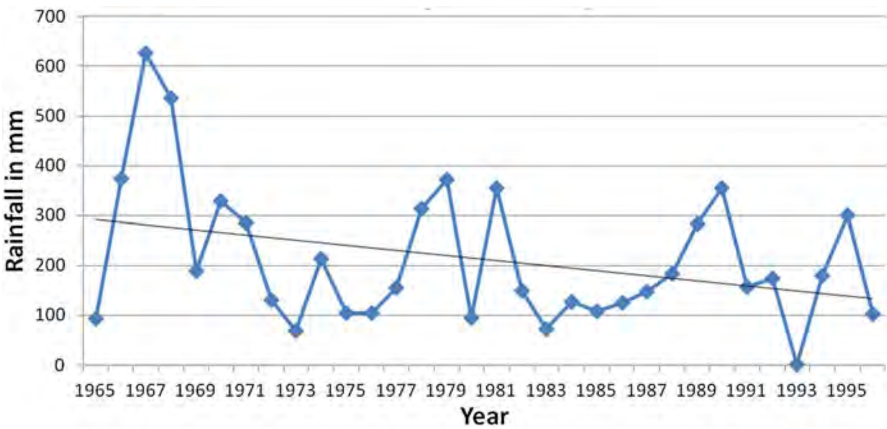

Fig. 5 Time series plot of MAM rainfall season for Maktau–700 m.a.s.l (Source: Motaroki 2016).

mid- and low-altitude agro-ecological zones where the average annual rainfall remains below 600 mm and 400 mm, respectively.

This is in agreement with the farmers' perception of variations in rainfall. The respondents from the focus group discussions (FGDs) conducted in each of the three agro-ecological zones noted that they were aware of the changes in rainfall that had taken place in the Taita Hills area over the past 20 years. The most obvious changes in rainfall reported by the respondents included drought and erratic rainfall patterns characterized by late onset and early cessation of seasonal rainfall. More specifically, drought was reported to be the most serious event, as it usually results in the loss of the entire crop, whereas erratic rainfall patterns resulted in a decline in crop yield and food shortages. Similarly, studies on the Taita Hills by Mwalusepo et al. (2015) established that the farmers were aware of the climate variability and change within their localities and the perceived changes in rainfall regimes and temperatures as well as the implications on their livelihoods.

Drought has already been indicated as a threat to food security in Kenya and is reported by the GoK (2012) as an important cause of crop losses in the Taita Hills. Observations from the IPCC (2014) show that rainfall in East Africa is likely to increase in the twenty-first century, which will be indicated by an increase in the number of extreme wet days to roughly 20%. However, even if the amount of rainfall recorded in the preceding years increased, it may not translate to improved agricultural production because the projected increases in temperature will lead to high evapotranspiration rates, thus causing water scarcity. Farmers also noted significant temperature variation with the cycles for crops like maize getting shorter and bean farming particularly in the high altitude areas that were initially very cold becoming more favorable. The high temperatures have also been accompanied by an increase in the incidence of pests and diseases that causes the decline in productivity in both crops and livestock. According to the Food and Agriculture Organization, FAO (2016), the production techniques that are part of conservation agriculture, for example, crop rotations and maintenance of a permanent soil cover, enhance soil and water conservation, thus enabling crops to withstand periods associated with rainfall variability and drought.

Crop Production Trends

The data from Osano *et al*. (2018) show that 80% of the total households in the Taita–Taveta County engage in maize production, 46% in bean crop production, and 31% in cowpea production. However, while the acreage under crop production has continuously increased, yields have continuously declined over the years due to climate change and other factors (Table 1). The overall productivity of major staple crops is very low, hence the need for better farming technologies and improved varieties. The maize crop in particular is highly sensitive to fluctuations in climate, with moisture and heat stress identified as the primary hazards for the crop.

Table 1 Short-rains crop production in the Taita–Taveta County in 2017

Crop	Acreage (ha) planted in the short-rains season	Long term average (LTA) acreage planted in the short-rains season	Actual production (90 kg bags) in the short-rains seasons	LTA production (90 kg bags) in the short-rains season
Maize	9172	9600	7849	60965
Cowpeas	805	810	4035	6830
Green grams	1079	1289	5186	5930

Source: Osano *et al*. (2018)

Table 2 Long-rains crop production in 2017

Crops	Acreage (ha) planted during the long-rains season	LTA (ha) (5 years) planted during the long-rains season	Actual long-rains production (90 kg bags)	Long-rains seasons LTA production (90 kg bags)
Maize	3681	7380	5522	22140
Beans	1069	1735	3207	10410
Green grams	1123	1566	4492	8613

Source: GoK (2017)

The land area under maize and cowpea cultivation during the 2017 short-rains season was near the long-term average (LTA), excluding the land area under green gram cultivation, which was 16% below the LTA (Osano et al. 2018). Despite the slight reduction in acreage under cultivation, the actual production of green grams was better than that of maize and beans. The 2017 short-rains seasons was also characterized by an 87% decline for maize production, 40% for bean production, and 13% for green gram production compared with the LTA (Table 1). The decline in maize production was attributed to late onset of the short rains, poor rainfall distribution both in time and in space, early cessation of rains, and crop damage caused by wildlife. Cowpea was affected by increased plucking of leaves by farmers for vegetable consumption, which negatively affected the yields and the crop's growth, hence reducing the production.

The County is mainly dependent on short rains for crop production, whereas the long rains that have increasingly become unreliable contribute 20% of the food requirements in the County. Table 2 shows the production of maize, beans, and green grams, which are the major crops grown during the long rains. The area under maize, bean, and green gram production declined by 50%, 38.4%, and 28.3%, respectively, due to prior weather forecasts, indicating the possibility of reduced rainfall during the long rains. Poor performance of the preceding short-rains seasons also contributed to the farmers' reluctance in cultivating large areas during the long-rains season (Muraguri and Nyamai 2017).

There was a significant decline in the production of all the three major crops: 75% for maize, 69.2% for beans, and 47.8% for green grams. Such a decline is mainly attributed to poor rainfall distribution in time and space as well as late onset and early cessation of rainfall. This is in agreement with the findings from a household survey targeting 600 households in the area where respondents noted that food shortages are currently on the rise, and farmers do not obtain enough yields as they did in the past. The main reasons reported for this were climatic events, including erratic rainfall patterns, above- and below-average rainfall, strong winds, floods, and frost. Other factors mentioned were high occurrence of pests, such as bean aphids, bean weevils, and cutworms, soil factors especially poor soil fertility, poor agronomic practices, and lack of inputs. The decline in crop production is a clear indication that farmers need to adopt CA which has shown potential to increase production through the integrated management of available soil, water, and biological resources

(FAO 2018). This reduces the vulnerability of crops to extreme weather events, such as droughts and floods, thus sustaining crop production.

Soil-Related Constraints

Soils are the foundation for agricultural production, hence the need for their sustainable use and management. The fertility status of soil determines the level of crop yields achieved. According to the GoK (2014), soil degradation is a major challenge to agricultural production in the Taita Hills, which leads to a decline in soil fertility. Based on the results from the household survey (Table 3), 63.3% of the respondents considered their soils to be moderately fertile, 15% noted that it was poor, 18.7% reported their soils to be very fertile, whereas 3% did not know the fertility status of their soils. When asked whether there had been a change in the fertility of their soils considering the quantity of yields obtained over the last 10 years, 55.9% indicated that it had declined, 25.2% reported it remained the same, whereas 15.2% reported that it had improved. The key factors responsible for the decline in soil fertility include continuous ploughing reported by 22.9% of the respondents, drought reported by 13.5%, use of inputs mentioned by 13.7%, floods reported by 9%, and lack of inputs reported by 2.2%. Those whose soil fertility had improved attributed such an improvement to enhanced land use practices. However, a larger percentage (29.7%) did not know the reason for the decline in the fertility of their soils.

Although the use of farm inputs, such as improved seeds, fertilizers, pesticides, and herbicides, is essential to achieve optimum crop production, assessments at the county level show that such use is generally low in the County. The low rates of input

Table 3 Soil fertility status in the Taita Hills

Soil Factors	High Zone	Mid Zone	Low Zone	Total
Soil Fertility N = 401				
Very Fertile	32	15	28	75
Moderate	89	76	89	254
Poor	20	24	16	60
Do not know	1	1	10	12
Change in Soil Fertility N = 401

Reasons for the Decline in Soil Fertility				
Continuous tillage	38	28	26	92
Droughts	30	10	14	54
Use of inputs	12	40	5	57
Floods	5	11	22	38
Lack of inputs	5	3	1	9
Improved land use practices	13	7	12	32
Do not know	31	40	48	119

use is attributed to a number of reasons, including high input prices, limited access due to the distance to markets, and failure to access inputs at the right time (GoK 2014). From the survey, the various inputs used in producing maize (staple crop) include commercial fertilizer reported by 24.2% of the respondents, improved seed variety reported by 35.9%, manure reported by 30.7%, and pesticides reported by 4.5%. However, the inputs used in common bean production were minimal, including commercial fertilizer reported by only 2% of the respondents, improved seed reported by 6.2%, manure reported by 4.7%, and pesticides reported by 0.2% of the respondents. Farmers attribute their constant low yields to the use of poor-quality seed, lack of fertilizer, and manure amendments during planting.

Coping and Adaptation Strategies Currently Employed by Farmers

Just like most households in SSA, households in the Taita Hills rely on a combination of informal risk-sharing arrangements to cope with the impacts of climate change and variability. These include, for example, taking cash loans from neighbors and relatives to buy food, relying on remittances, and sending children to live with relatives (Shuaibu et al. 2014). These coping mechanisms are not sufficient or sustainable to address the challenges, and they are even more limited for the poor, landless and unemployed individuals, women, children, and large-sized households who are more vulnerable (Shuaibu et al. 2014). The respondents reported various ways in which they are coping up with the climatic events impacting their households. In coping with drought events, most of the respondents (70.9%) reported that they bought food, 6.6% sought off-farm employment, 2.8% ate different types of food, 4.7% borrowed from friends and relatives, 2.8% relied on food aid from the government, and only 2.3% changed their farming practices. However, while coping strategies such as buying food may help them in the short term, it is important to find long-term sustainable solutions, such as a shift into sustainable farming practices or livelihood diversification to off-farm activities that generate income to buffer against climate shocks (Table 4).

Table 4 Actions taken to cope with drought

Action (N=213)	High Zone	Mid Zone	Low Zone	Total
Did nothing	4	1	8	**13**
Assistance from friends/relatives	3	3	4	**10**

Bought food	48	35	68	**151**
Sought off-farm employment	5	5	4	**14**
Ate different types of food	2	1	3	**6**

(Source: Motaroki 2016)

According to the MoALF (2016), the government of the Taita–Taveta County has supported and promoted adaptation strategies, such as drought-tolerant varieties of crops, rainwater-harvesting techniques, growing of trees, terracing, and other climate-smart agricultural practices. However, despite the critical role that CA plays in restoring degraded soils, stabilizing yields in the long term, and enhancing food security, few studies have attempted to assess its role in making smallholder farming systems more resilient to the impacts of climate change.

Conservation Agriculture to Enhance Adaptation in the Taita Hills

Projections show that in the period 2021–2065, the temperature in the Taita–Taveta County will increase by 0.4 °C, with greater changes expected in the long-rains season (MAM) (MoALF 2016). During the same period, projections show a 0.8% increase in precipitation in the long-rains season and a 6% increase in the short-rains season (OND). However, high evapotranspiration rates resulting from high temperatures will lead to prolonged moisture stress. The number of consecutive days experiencing moisture stress is expected to increase from 70 to around 85–90 in the long-rains season but is projected to decrease from 80 consecutive days to approximately 30 in the short-rains season.

Conservation agriculture in the Taita Hills has the potential to restore soil fertility and sustain agricultural production by stabilizing yields even during periods of sporadic rainfall and increased moisture stress, which are expected to increase in the future, while achieving other co-benefits, such as soil erosion control and reduced labor demands. However, making substantial gains from CA requires understanding when and where the practice is most effective. According to Mutuku et al. (2020), smallholder farming systems have large variations in terms of soil properties and rainfall conditions, which in turn affect the impact of CA-based practices on crop yields. There are also differences in the physical, biological, and chemical conditions of soils at the field scale as well as variations in weather patterns over time and scale.

Case Study of CA in the Taita Hills

Although few studies have tried to assess the potential of CA in the Taita Hills, the experimental assessments of CA in comparison with conventional farming practices undertaken by Motaroki (2016) established that the practice can help in increasing crop production, particularly in the semiarid lowlands.

Case Study 1

A participatory learning and action approach was used to set up demonstration plots in each of the three agro-ecological zones to compare yields from conventional tillage practices and CA for two consecutive seasons. There was no visible difference in the key yield indicators for the two seasons

(continued)

examined in both the high and mid-altitude agro-ecological zones. This could be explained by the fact that farmers in the high and mid-zones do not experience extreme conditions of drought as the lower zones. However, for the two seasons studied, there was a large visible difference in all the yield indicators for the CA treatment compared with the conventional tillage practices in the low-altitude agro-ecological zone. The zone lies in an arid and semiarid land area characterized by low rains for most parts of the year and poor soils. The effect of mulch in conserving soil moisture as well as the combined effect of organic and inorganic fertilizers could explain the immediate change in the observed yield for the area. As a matter of fact, in the second season, only the CA plot sustained crop growth, whereas the entire crop died when the conventional practices were used due to low and erratic rainfall.

Case study 1 emphasizes the importance of soil protection using mulch and the role that good agronomic practices play in minimizing the growth of weeds, promoting the growth of healthy plants, and consequently improving crop yields, especially in the drier lower zone. The conventionally grown farmers' practice plots are characterized by poor crop growth and exposure to surface runoff. Furthermore, the fact that only the CA treatment yielded results during the JJAS season further reinforces the importance of CA in arid and semiarid zones as well as the need to invest in drought-tolerant varieties of crops. Similarly, on-farm experimentation of CA by Micheni et al. (2015) showed that in drier environments, crop yield response to CA was immediate, whereas in the wetter (highland) zones, significant advantages in yield were observed from the third season onwards.

Barriers to Effective Uptake of CA

According to Njeru (2016), the issue of land tenure is a major factor influencing the adoption of CA in Kenya and many countries in Africa. There is a very low possibility of farmers investing in land with unsecured access in the long term. Particularly, considering the small sizes of land holdings in the Taita Hills, farmers have a tendency to rent in more land for their crop production. Farmers have reservations about adopting soil conservation practices such as CA because chances are high that the owners will claim their land back as soon as the fertility increases and they notice increased yields. Moreover, when farmers rent in land, they are more interested in maximizing profits from their tenancy; hence, investments in conservation practices such as CA that realizes benefits in the long term are not their priority.

In the initial years, CA increases weeds on the farm and requires additional inputs, without necessarily increasing yields. It may take up to 4 years before farmers can notice any differences in yields after adopting CA since the restoration of soil fertility takes time. In the field assessment of CA, Motaroki (2016) established that in the two seasons examined, minimal changes in yield were observed between the CA and CT plots, especially in the high and mid-altitude agro-ecological zones. As such, farmers renting a plot for less than 5 years are less likely to adopt CA as their primary concern is to increase production and profits in the short term rather than increase the quality of soils they will only use temporarily. This implies that in order to scale up and enhance widespread adoption of CA in the Taita Hills, assuring farmers of tenure security is critical.

Further, a transition from tillage-based systems to CA incurs significant costs, and for the resource-poor farmers in the Taita Hills, this may be a hindrance to their adoption of the practice. It is therefore important to provide financial support and enable the initial stages of CA adoption by giving farmers the necessary incentives in the form of subsidies. In their analysis, Kassam et al. (2014) noted that there have been cases in SSA where farmers reverted to their conventional farming practices once support for CA adoption was stopped. The above observations are in line with the results from the household surveys which showed that with regard to farmers' knowledge of the CA practice, 39.7% of the survey respondents stated that they were aware about the practice, having been introduced to it through seminar and by neighbors, agricultural extension officers, and the radio. However, only 3.7% of those who were aware about CA practiced it on their farms, stating several barriers, such as high risk and lack of economic returns (Table 5).

Cultural barriers have also been identified as one of the greatest challenges to CA adoption that has been reported in Kenya (Njeru 2016). For as long as they have been farmers, Kenyans and Africans at large have always tilled their lands such that the introduction of zero or minimum tillage faces resistance and skepticism. Another important challenge arises from the slash-and-burn system that is common in many parts of the country and Africa at large, which diminishes the availability of crop residues for mulching and incorporation into the soil (Kassam et al. 2014). Furthermore, studies show that many farmers are reluctant to use herbicides in their farms, making weed management a challenge and a hindrance to optimum crop production. Giving these farmers support in understanding new concepts and principles will create the desired change in the mindset and promote commitment to a long-term process of changing their production systems and testing and adapting new practices and technologies.

Table 5 Barriers to CA Uptake

Barrier s (N= 105)	High Zone	Mid Zone	Low Zone	Total
Small farm size	5	2	2	**9**
Expensive	1	3	4	**8**
Not profitable	29	5	10	**44**
Risk-prone	1	7	8	**16**
No specific reason	10	4	13	**27**

Studies by Pretty et al. (2011) have shown social capital to be an important prerequisite for a wide-scale adoption of sustainable practices. Farmers often have a tendency to trust their peers more than their formal advisors when evaluating potential innovations for their farms. This in effect emphasizes the importance and role of farmer organizations in embracing CA and drawing in more members within the locality to adopt the practice. Furthermore, scaling up CA to achieve impact at the local, sub-national, and national level will require a strong enabling policy and institutional environment characterized by training and enhanced access to knowledge, research, and the required inputs. If properly organized, the farmer groups or organizations can use their bargaining power to pressure local governments and institutions to create the required reforms to upscale CA (Kassam et al. 2014).

Lessons Learned, Limitations, and Recommendations for Future Research

Conservation agriculture has been shown to stabilize yields in the long term and increase the soil's ability to sequester carbon, thereby delivering on both adaptation and mitigation goals. However, a number of barriers still hinder its effective upscaling to promote widespread adoption in the Taita Hills. Overcoming these barriers will require implementing a number of measures, including incentivizing resource-poor farmers in terms of tenure security and subsidies, enhancing farmers' understanding on the benefits of CA activities such as minimum tillage, creating an enabling environment through institutional and policy support, and leveraging on social capital in target localities to promote the adoption of CA, inter alia. The case study that informed this chapter was only conducted for two seasons, which hindered the evaluation of the significant differences between the treatments used. As such, future research will need to explore the possibility of conducting field assessments over several seasons and where possible replicate the treatments in order to assess whether significant differences in the actual yield exist between CA and conventional farming methods.

Conclusion

Studies conducted in the Taita Hills have established that climate change and variability are occurring in the area as characterized by erratic rainfall patterns, high temperatures, and increased frequency of extreme weather events, such as droughts and floods. This poses a major threat to farming, which is the major source of livelihood in the area, considering that it is mostly rainfed and thus under the direct impacts of climate variability and change. Although CA has been established to maintain the soil in a carbon-rich condition and sustain production under a changing climate, its adoption remains slow due to existing barriers. To overcome these barriers and catalyze investments for upscaling and bringing about the desired reforms to advance the CA cause, strategies (policy, technological, and institutional) must be put in place for an effective adoption. These include assuring farmers of tenure security, providing financial and technical support through appropriate subsidies, capacity development, and gender-responsive policies, inter alia.

Do-It-Yourself Flood Risk Adaptation Strategies in the Neighborhoods of Kano City, Nigeria

66

Aliyu Barau and Aliyu Sani Wada

Contents

Abstract

The urban poor in developing countries is hit hardest by climate-related extreme events such as flooding. Also, informal settlements lacking municipal support and immediate public response to flooding incur losses and thus exacerbate their sufferings. Left out or left alone, the vulnerable people from some parts of the ancient city of Kano develop their own efforts to protect themselves against the recurrent flood events. Hence, this chapter examines the nature of community-driven do-it-yourself (DIY) adaptation The data was collected through field-based surveys, interviews, and questionnaires to enable in-depth analysis of the problem from socioecological point of view. The results identified flood drivers to include

the nature of surface topography, torrential rainfalls, lapses, and inadequacies in the availability of drainage infrastructure and human behavioral lapses in drainage management. On the other hand, the DIY adaptation manifests in the use of sandbags, de-siltation of drainage, construction of fences, and drainage diversions. It is important to highlight that DIY adaptation is a good strategy; however, municipal authorities must come to the aid of such communities and revisit the absence of urban planning by supporting them through capacity building to find more effective solutions to the challenges of the changing climate and environment.

Introduction

Climate-related disasters continue to spread and affect the poorer populations in both urban and rural areas. It has been suggested that flooding is the most widespread climate extreme event that accounts for more than 40% of disasters globally (Nkwunonwo et al. 2016). It is also considered as the third most damaging disaster after storms and earthquakes (Wilby and Keenan 2012). It was estimated that the average annual number of people affected by floods is likely to increase from one million in the 1990s to 25 million by 2050 (Salami et al. 2016). Nevertheless, the increased awareness and concerns over climate change have reinforced the need for adjustments on how human use land and other resources in order to limit risks and vulnerabilities that originate from global climate change (Verburg et al. 2012). Besides climate change, many studies have attributed the exacerbation of flooding to the nature of population density and standard of living especially in the lived environments of developing countries (Devkota et al. 2014). In other words, this implies that built environments in developing countries are most exposed to flooding and hence more response actions are needed from within and outside the lived environment. Efforts from within involve action by individuals and municipalities, and action from outside may involve states and federal actions to strengthen resilience to flooding and climate change. Importantly, it is critical to also put in place modalities for communicating climate knowledge to public in order to enable proper response to climate crisis (Barau and Tanko 2018).

Researchers from developing and developed countries consider flood adaptation from different approaches. For instance, Alfieri et al. (2016) focused on adaptation measures for flood risk reduction by putting emphasis on adaptive measures such as relocation, reduction of vulnerability, reduction of peak flows, and increased flood protection levels. On the other hand, Barau (2008) focused on adaptation measures oriented toward institutional perception but fails to assess public adaptation strategies deployed to prevent flooding. Some authors suggested that relief materials including healthcare services supplied to flood victims in Nigeria were inefficient and paid too little attention given to efforts to reduce the future flood menace (Soneye 2014; Olanrewaju et al. 2019). Contrastingly, since the 1990s, the United States introduced the Community Rating System (CRS), a community-driven program that incentivizes local actions for addressing flood risk (Noonan and Sadiq 2018). It is apparent that climate change adaptation is not an exclusive business of the state or formal planning processes, but it goes down to efforts of communities and businesses to protect themselves (Colenbrander and Barau 2019; Udelsmann Rodrigues 2019). By implication, climate adaptation has become a concern of every stakeholder given the weakening resilience of urban areas in developing countries. Nevertheless, designing neighborhood or community resilience to flooding will benefit from understanding the social and ecological attributes of societies which are not limited to biophysical changes, infrastructure, mitigation planning, and public perceptions of extreme events (Parsons 2019). The potentials of grassroots action to address flooding in African countries are said to be a promising and effective self-defense mechanism in poorly serviced areas (Udelsmann Rodrigues 2019).

Flooding in Nigeria is the most common and recurring disaster with unprecedented damages caused by heavy rainfall and surface runoff which in 2012 in particular contributed to submergence of settlements along the Kainji, Jebba, and Shiroro dams in Niger State, the Lagdo dam in Cameroun located along the River Benue, the Kiri Dam on the River Gongola, and numerous additional irrigation dams (PDNA 2013). Consequently, this triggered the displacement of thousands of people and loss of lives and properties. According to the National Emergency Management Agency (NEMA), 363 people were killed, 5,851 injured, 3,891,314 affected, and 3, 871, 53 displaced due to the resulting floods. Similarly, it is has been observed that flood disaster happens to be more frequent in Kano, Niger, Adamawa, Oyo, and Jigawa states possibly due to influence of river Benue, Niger and Ogun (Nkwunonwo et al. 2016).

Since the 1960s, the rainfall received in Kano region has exhibited notable fluctuations, however with increased flood incidents due to encroachment on environmentally sensitive areas such as floodplains along the ancient city walls which were traditionally reserved specifically for urban gardening (Barau et al. 2015). Studies revealed that between 2003 and 2007, Kano has experienced severe urban flood that claimed many lives and property – roughly 16, 730 households were affected, 14 people were reported dead – and many were displaced (Barau 2008). In addition, flood water contaminates and pollutes the environment with garbage; many factors are responsible for the recurrent flood events with prolong rainfall leading to large volume of water with tendency of overwhelming the infiltration capacity of the soil. This often yield to large surface runoff beyond the carrying capacity of the already narrowed drainages filled with garbage and simultaneously adjoined with poor maintenance which end up polluting the environment (Azua et al. 2019). It is apparent that damages to lives and property has become a cyclic phenomenon in Kano metropolis. It was also reported that 18, 397, 29, 151, and 177 people in 2003, 2004, 2005, 2006, and 2007, respectively, were affected in the Dala Local Government Area, due to impact of flood (Barau 2008). The aim of this chapter is to assess flood risk and adaptation measures in Dala Local Government Area in Kano city, Nigeria, and this is with a view to improving adaptation strategies in the area by identifying suitable and sustainable planning recommendations.

An Overview of Conceptualization of Flood Risk Adaptation

Floods can occur within a matter of minutes, and its effects can be local, impacting a neighborhood or a community; it can even go beyond a single community to affect the entire river basins and multiple areas (Wilby and Keenan 2012). Flood risk and flood-related losses may increase due to human activity or decrease through an appropriate flood management, planning, and adaptation strategies (Kubal et al. 2009). Human interventions in the natural processes such as increase in settlement areas, removal of biotic habitats, population growth, and economic assets over low-lying plains make them more prone to flooding especially when alterations of natural drainage and river basin patterns and deforestation are on the rise (Muo 2015). This situation is typical of what obtains from urban areas of developing countries including Nigeria which has the largest population in Africa. Hence, flooding and its impact on population is a socioecological challenge as it has links and feedbacks between human and natural systems. The socioecological system approach is said to be important in private flood hazard adaptation strategies (Fuchs et al. 2017).

Cirella and Iyalomhe (2019) categorized flooding on the basis of spatiality which includes coastal flooding and river flooding, while Dhiman et al. (2019) added urban and areal flooding to the list. In a situation whereby towns and cities are located on these types of landscapes and in the case where the most vulnerable populations are located on such marginal lands, the struggle with risks of sea-level rise becomes even more complicated. Another factor is the accumulation of rainwater in low-lying areas with a high water table, or inadequate storm drainage (Cirella and Iyalomhe 2019). In addition to this, the main causes of flooding as posited by same author are not limited to heavy rainfall, blockage of waterways, building on flood plains, and poor land use planning. According to Dhiman (2019), urbanization was the most important driver of flood risk in the cities where inadequate drainage system in combination with ineffective spatial planning increases the flood risk. Additional damages from the floods are also included in the framework where simulation using climate model and further downscaling indicate high potential sensitivity of flood risk to climate change.

Flooding with its numerous and varied impact causes mortalities, population displacement, and property damage which may also critically endanger sustainable development pathways (Vojtek and Vojteková 2016). The literature on flood health impact rarely quantifies or classifies the causes and circumstances of deaths which in many instances are also determined by the prevailing socioeconomic and health conditions of the affected communities (Jongman 2018). Flood impacts range from socioeconomic, psychological, cultural, to environmental impacts (Alfieri et al. 2016). The economic impacts include damage to public buildings, public utility works, housing and household assets, losses in industry, and business trade. Other losses are those affecting petty shopkeepers, low-income earners, loss of revenue, and interruption of road and railway transportation. Flooding also triggers the outbreak of infectious diseases, e.g., fever, pneumonic plagues, dysentery, and common cold among others.

On the other hand, Devkota et al. (2014) identified the following responses of adaptation strategies at community level undertaken before, during, and after flood event. Responses identified before flood event include management plans, keeping contact information, pre-estimating of flood risk, and producing human resources/ trained manpower. Response strategies undertaken during the flood event at community level include perfect communication at community level and selection of makeshift settlement. Proper assessment of flood risk in urban areas is still challenging simply because of its complexity as compared to situation in rural areas. Common flood risk analyses do not usually incorporate social and ecological impacts but exclusively assess economic damages, which can be measured in monetary terms (Haque et al. 2012). Comprehensive approaches which try to integrate economic, ecological, and social impacts are less available (Schanze 2006). Particularly, the latter are frequently omitted due to a lack of suitable data.

There are many studies with different conceptual frameworks for flood vulnerability, risk assessment, and adaptation. For instance, Oculi and Stephenson (2018) observed that one of the earliest "frameworks" of adaptation were based on three attributes: climatic-stimuli, the system that is adapting, and method of adaptation. They also recognized that adaptation strategies can be grouped by timeframe of interest, types of behavior, sector, scale, and level of governance. Adaptation to extreme events such as flood is vital in the present era due to the multifaceted nature of the causes and effects, which is exacerbated due to the increasing population and climate change. The ever-changing and cross-boundary nature of flood risk renders adaptation strategies as very crucial in this period of fluctuating social and environmental conditions (Jongman 2018). Flood adaptation strategies are often intended to minimize impacts on various sectors such as built environment, human health, water quality, and transport infrastructures (Wilby and Keenan 2012). The efficient and effective adaptation strategies should have the services and facilities to slow flood waters; use nature-based solutions, early warning systems, and financing schemes to tackle and reduce the economic loss; and practice risk-informed land planning (Jongman 2018).

Observing the Nature of Flood Risk Situation in Kano City

The sites observed in this chapter are located in Dala Local Government Area (LGA), which is the nucleus of the ancient Kano city in northern Nigeria. It is named after the Dala, a residual hill which is the original site from which the city emerged since prehistoric times. The area is located around between latitude 12° 00′ 00″ N to 12° 03′ 21″ N and Longitude 8° 27′ 30″ E to 8° 31′ 40″ E. (Fig. 1).

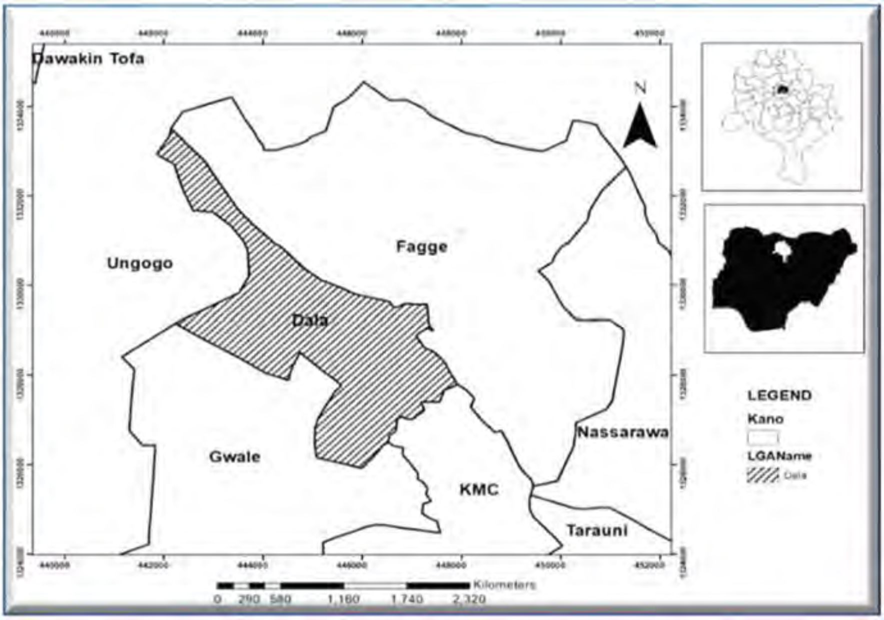

Fig. 1 Map of urban Kano showing the location of Dala Local Government Area

This LGA covers a total land area of about 19 km^2 and total population of 415,777 as of 2006 national population and housing census. There was significant increase in the natural population in the state and the study area. The natural increase was estimated to have risen from 2.51% in 1960s to 3.3% in 1980s and 4.5% till date, although the urban growth rate is about 5.5% annually (Mustapha et al. 2014). This implies that the area is a high density core urban settlement and given its nature of terrain is vulnerable to flooding. Previous studies suggested the importance of socioecological systems in understanding the urban environment in Kano (Barau et al. 2013).

Relief and Geology

Relief of the state is said to be 80% of composed basement which comprises of marbles, granites, and gneisses (Salami et al. 2016). Jakara River is underlain by crystalline Basement complex of pre-Cambrian origin which losses its identity by disappearing into the Chad Formation. Crystalline basement of pre-Cambrian forms the underline of River Jakara, made up of granites extending to Gabasawa toward East and Yadai toward North. This river serves as the natural drain in the study which collects runoff from different tributaries. This geological setting suggests that the study area is susceptible to flood based on its largely impervious surface.

Climate and Hydrology

The climate of the state is tropical wet and dry type according to Koppen's classification, although climatic changes are believed to have occurred in the past. The climate features in Kano as a whole are typical of West African savannah. Temperature in the region is generally high all year round, together with gradual increase every season. It can be said to be higher usually from January to April which may reach as high as 43 °C, respectively (Mustapha et al. 2014). According to Sanni and Okhimamhe (2009), the annual rainfall values are unpredictable from 1 year to another. For instance, 1999, 2004, 2010, and 2012 witnessed highest annual values in both temperature and rainfall, that is to say, above normal, compared to previous years.

Research Data

Primary data were collected using questionnaire, field observations, field surveys, and in-depth interview. The questionnaires were administered to household heads and/or adult respondents in each residence that were within the 100 m radius of flood-prone areas. This strategy enabled the researchers to identify factors that exacerbate flooding and types of response undertaken to lessen flood risk. Initially, the authors worked with communities to identify the flood hotspots in addition to observations made during previous flood events in the study area.

Global Positioning System (GPS) was used during field survey to take the coordinates of the flood-prone areas which was later imported into the Google Earth for spatial representation of the flood prone areas which was also used in generating the Digital Elevation Model (DEM) and contour map of the study area to analyze vividly the nature of terrain as well as contour of the study area. ArcGIS 10.4 was used to generate the location map and flood-prone areas respectively. Google Earth was used to produce the satellite imagery which was used for spatial representation, while interview was used to source institutional responses to flood risk in the study area, respectively. Interview was conducted in State Emergency Relief and Rehabilitation Agency (SERERA) and Kano State Urban Planning and Development Authority (KNUPDA) with key informant on flood risk and adaptation measures in the study area. This further aid in determining the extent to which these institutions respond to flooding.

Secondary data was sourced through searching the keywords with the aid of Google Scholar (i.e., flood, risk, flood risk, adaptation, and adaptation measures) from scholarly peer-reviewed journals, books, and government archive which provided proper understanding of the research problem at local and global level. The information sourced provided an insight to the researcher on flood risk, flood impacts, its causes, as well as factors that exacerbate flooding.

The questionnaire was administered to the seven (7) flood-prone clusters (462 houses) which include Kofar Ruwa, Kwanar Taya, Gwammaja, Babban Layi, behind Filin Dantata, Lunkwi, and adjacent Gidan Baban Gwari, respectively. Two hundred and seventeen (217) copies of questionnaires were randomly distributed to the residents within 100 meter radius of each flood-prone area (31 for each zone for equal and unbiased representation) using the simple random sampling techniques. However, only one hundred and ninety six (196) copies of the distributed questionnaires were retrieved due to loss and failure to fill by the residents. Questions asked were tailored toward identification of causes of flood, factors that exacerbate flooding, as well as resident adaptation measures to flood risk in the study area. In addition, data related to demography and socioeconomic characteristics were also captured. The sampling size adopted for this study was determined using Taro Yamane's formula (1967) with 95% confidence level. The formula is given as

$$\mathrm{n} = \frac{N}{1 + N(e)2}$$

where

n = Sample size required
N = Number of population in which the sample will be drawn (462 houses)
e = Margin of error, given as 0.05
1 = Constant.

$$\mathrm{n} = \frac{462}{1 + 462(0.05)^{2}}$$

$n = 214.3851508121/7 = 30.626450116$. (Akukwe 2014)

After calculating the sample size by substituting the number of dwelling units (462) into the Yamane formula, the number of sample was 214.3851508121 houses. Dividing this number by the number of flood-prone areas (7) yielded 30.626450116 houses respectively. Therefore, in order to obtain a reliable data, researcher rounded up the sample size to 31 dwellings per each flood-prone area (Fig. 2). Thus, a total of 217 sample size emerged out of 462 sample frame. For convenience and transparency, nine (9) variables were used which include heavy rainfall, poor drainage facilities, slope and topography of the area, dumping of refuse in drainages, blockage of drainage channels, impervious surface, absence of drainage channels, and unplanned development along floodplains. The targeted respondents on a normal circumstances were the household heads, but in a scenario where the household heads were not around, an adult respondent from each dwelling was selected to fill in the required questions based on 5-point Likert scale from Strongly Agree (SA = 5) to Strongly Disagree (SD = 1). This procedure was adopted from a study conducted by Devkota et al. (2014).

Institutional responses were obtained through an in-depth interview with key informants from Kano State Emergency Relief and Rehabilitation Agency (SERERA) and Kano State Urban Planning and Development Authority (KNUPDA). In SERERA, the interview was oriented toward past flood damages,

Fig. 2 Google image showing flood-prone areas and houses within the 100 m radius of each other. (Source: Authors' Field Survey 2019)

existing adaptive measures to respond to flood hazard for pre-, during, and post-flood events. This information was relevant to the study because it helped in determining the extent to which the stipulated hazard in the study area was responded to. In KNUPDA, issues raised were concerning planning regulations around the flood-prone areas. This information was relevant to the study because it further helped the researchers to bring out the level of compliance (public) to adapt to the problems of flood-prone area or otherwise. In all the cases, the interview was recorded (with permission of respondents) using phone audio recorder, which was subsequently transcribed to a verbatim record.

Five-point Likert scale and weighted average index (WAI) on the basis of "Highly Applicable" to "Very Less Applicable" were used for analysis of the questionnaire. The first part of the questionnaire was demographic and socioeconomic information of the respondents. These were analyzed using SPSS, and the results were represented in simple tables, charts, and graphs. ArcGIS 10.4 and Surfer software were used to draw and analyze the digital elevation model and contour map of the study area. While community responses were collected before, during, and after flooding by the public were analyzed using weighted average index (WAI) against a scale of 1 to 5. The adaptation strategies for each respondent were rank based on the weighted average index (WAI) which is given as

$$\mathrm{WAI} = \frac{\mathrm{F1} \times \mathrm{W1} + \mathrm{F2} \times \mathrm{W2} + \mathrm{F3} \times \mathrm{W3} + \mathrm{F4} \times \mathrm{W4} + \mathrm{F5} \times \mathrm{W5}}{\mathrm{F}_1 + \mathrm{F}_2 + \mathrm{F}_3 + \mathrm{F}_4 + \mathrm{F}_5}$$

$$\mathrm{WAI} = \frac{\sum fi \times \mathrm{W}i}{\sum \mathrm{fi}}$$

where

F = frequency of the respondents
W = weight of each scale
i = weight

Note (5 = highly applicable, 4 = applicable, 3 = moderately applicable, 2 = less applicable and 1 = very less applicable) (Devkota et al. 2014). This generated the measures and/or strategies that were mostly applicable and least applicable by the respondents in the study area.

Digital Elevation Model (DEM) of the Study Area

The digital elevation model (DEM) as illustrated in Fig. 3 revealed the elevation of the study area from which the blue shades represent the areas with the highest elevation 520–525 m above sea level (Dala hill), while the green represents the areas with the lowest elevation 470–475 in the study area respectively. These green shades on the DEM represent the locations of the flood-prone areas. It is apparent that after rainfall the stormwater radiates in a centrifugal direction reaching the lowest elevation (flood prone areas) as natural drains. However, as built-up areas, they easily become flooded.

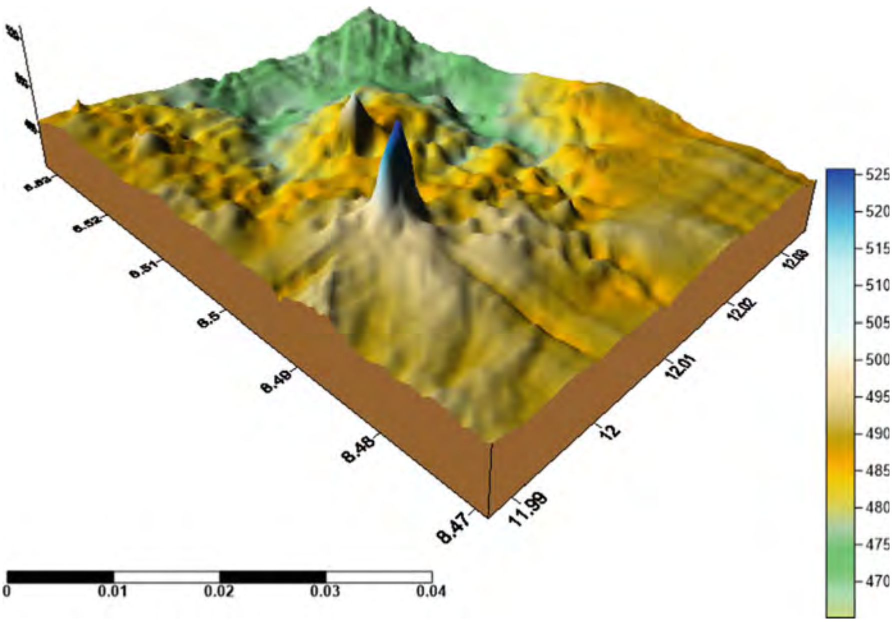

Fig. 3 Digital elevation model (DEM) of the study area showing variation of elevation

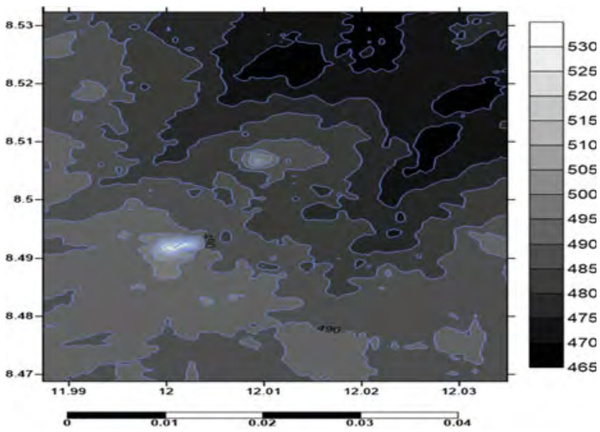

Fig. 4 Contour map of the study area. The lighter spots depict areas with highland, while the darker spots represent areas with low land

The green shades represent lowlands, while the blue shades represent highland areas (Dala hill) in the study area.

On the other hand, the contour map (Fig. 4) illustrates the variation of elevation of the study area. The white portion represents the point with the highest elevation (530 m), while the dark portion represents the points with lowest elevation (465–470 m). From these, it can be deduced that elevation still determines floodability of even highly urbanized areas.

Socioeconomic Characteristics of the Residents

The tendency of flood risk is not the same for all people although all may be situated in a flood-prone areas. It varies considerably with demographic and social characteristics. Although flood risk presents significant health burden worldwide, socioeconomic status is closely related to being flooded or otherwise (Aerts et al. 2018). This section explains the socioeconomic characteristics of the residents in the study area which cover residence, gender, age, marital status, educational level, occupation, average monthly income, housing condition, and construction material used.

Socioeconomic Characteristics of the Respondent in the Study Area

Table 4 revealed the respondent residential locations of the respondents out of which (28) 14.3% were from Kofar Ruwa, (26) 13.3% from Kwanar Taya, (30) 15.3% from Gwammaja, (27) 13.8% from Babban Layi, (29)14.8% from behind Filin Dantata, (30) 15.3% from Lunkwi, and (26) 13.3% from Gidan Baban Gwari which constitute the sum of 196 respondents. Gender is another important variable in any research of this nature. The gender distribution of respondents revealed dominance of male respondents. Male respondents featured more than female as they dominate household headship. Again their female counterparts were not freely available to interact with researchers due to cultural barriers in the study area. In general, there is an indication that majority of the respondents are still in their active and productive age. Age is an important attribute that helps in understanding people's perception about a given phenomenon. And with regard to flood risk and adaptation, it helps in improving the methods to be used in adapting to risk as well as mitigating its impact.

The perception and attitudes of an individual due to marital status may differ; findings presented in Table 4 showed the dominance of married respondents in the study area. In addition, marital status is relevant to the study because married people will be more willing to initiate coping strategies in trying to reduce potential losses than the unmarried population simply because they are more attached to the community, and it is assumed that each married person has apartment which is in the long run liable to flood risk. Household size is important to understand socioeconomic status and vulnerability of households. In this context, it is assumed that the larger the household size, the more is the risk of losing more lives and/or property and vice versa.

Knowledge influences reasoning, attitudes, and understanding of individuals from a given social phenomenon. The findings presented in Table 4 also outlined respondents' level of education where (71) 36.2% has tertiary education and (53) 27.0% with informal education, while (59) 30.1% and (13) 6.6% were having only secondary and primary level of education, respectively. This is an indication that majority of the respondents were literate and thus capable of providing adequate and relevant information with regard to flood risk and adaptation measures in the study area.

Occupation or livelihood is another important factor of consideration as it determines people's choice of residence. Thus, the social class of individuals determines their area of residence. It has been established that the more comfortable and secured areas of residence are occupied by the richer households while the less privileged are left with the marginal areas (Salami et al. 2016). In addition, income is an important determinant which is congruent with income and occupation. The situation in the study area in relation to income further highlights what is known with regard to the poor who occupy areas associated with unplanned urban growth and substandard informal settlements on floodplains among other things (Salami et al. 2016).

Age of building is another important determinants of consideration simply because building has a lifespan just like humans. Buildings deteriorate with time and thus become more exposed to destructive flood impacts. Findings revealed that with exclusion of some buildings among which are Government Girls College, Dala, and National Orthopaedic Hospital majority of the buildings in the area have undergone transformation. This implies that majority of the buildings were constructed not so long, thus a concrete evidence of recent encroachment on open spaces and changes in building materials. Building materials play important role in proofing water absorption. Such changes in urban morphology are said to have increased flood events in urban Kano which covers the study area (Barau 2015) (Table 1).

Table 1 Showing frequency and percentage response on the socioeconomic characteristics of the respondent

Gender	Frequency	Percent
Male	150	76.5
Female	46	23.5
Total	**196**	**100.0**
Age		
18–25 years	57	29.1
26–32 years	51	26.0

Public Perception and Current State of Flood Risk and Adaptation

Adaptation may include modifying susceptibility, increasing response capacity, and reducing exposure (Merz et al. 2010); thus, this section focused on community perception of flood risk, vulnerability profiles of the households regarding flood experience, as well as the residents' adaptation (coping) mechanisms against flood risk (i.e., actions taken by the public prior to, during, and after flood event) in the study area. Questionnaire survey was used to assess the level of flood severity and whether or not affected previously. The following parameters "severely affected," "affected but not severe," and/or "not affected at all" were used in generating this information which revealed that (68) 34.7% of the respondents were not affected at all, (91) 46.4% were affected but not severe, while (37) 18.9% of the respondents were severely affected by previous flood havoc in the study area. In order words, it can be deduced that 65.3% of the sampled population were affected by flood disaster in the study area (Fig. 5).

The factors that cause and exacerbate flooding in the study area based on the outcome of the current study include heavy rainfall, dumping of refuse on drainages, as well as blockage of drainage among others as shown in Table 2. These factors were ranked based on average mean score (X) of each factor and sum weighted value (SWV) of responses derived from questionnaires.

Findings as presented in Table 2 established that the indicator with the highest rating is rainfall with a weighted value of 4.77 and a positive deviation of 0.82 from the mean, while the least rated indicator was impervious surfaces with a weighted value of 3.08 and a negative deviation of −0.87 from the mean, respectively. This denotes that heavy rainfall is the major cause of flood in the study area. Thus, climate change appears to be a major factor and driver of flooding incidents in urban areas of developing countries. Therefore, it is imperative for urban areas to embrace priority action to tackle climate change both as local and global challenge (Bai et al. 2018). The study further revealed that out of the nine indicators used, five had a positive deviation which are the major causes of flooding in the study area, while four had a negative deviation from the mean. The indicators with positive deviation about the mean include heavy rainfall (with a weighted value of 4.77 and a positive mean of 0.82), dumping of refuse and/or waste on drainages (with a weighted value of 4.42 and a positive mean of

0.47), slope and topography of the area (with a weighted value of 4.09 and a positive mean of 0.14), blockage of drainage channels (with a weighted value of 4.05 and a positive mean of 0.1), and poor drainage facilities (with a weighted value of 4.05 and a positive mean of 0.1). On the other hand, the indicators with negative deviation about the mean were unplanned development along floodplains (with a weighted value of 3.80 and a negative mean of −0.15), absence of drainage channels (with a weighted value of 3.74 and a negative mean of −0.21), soil type (with a weighted value of 3.21 and a negative mean of −0.37), and impervious surface (with a weighted value of 3.08 and a negative mean of −0.87).

The results presented here highlight the importance of socioecological dimensions of flooding because of close and tangential relations between human and naturally induced drivers of climate change, landscape, ecology, and infrastructural development. It is equally important to recognize that the impact of human transformation of landscape and/or misuse of infrastructure galvanize negative effects of climate change in the society. For instance, as evident from Figs. 6, 7, and 8, people erect structure in areas where the morphology is not favorable, and hence flood waters cause destruction to buildings (Fig. 6). On the other hand, indiscriminate dumping of waste causes siltation and sedimentation of waterways which cause flooding in the study area (Figs. 7, 8, and 9). In other words, people need to be educated and informed about climate change as it is obvious that level of education does not sufficiently make people more informed. Hence, it is critical to follow multiple strategies of educating and communicating climate change to the public (Barau and Tanko 2018).

Public and Institutional Adaptation Response to Floods in the Study Area

Public and institutional response to flood risk is one of the objectives of the study. Here, public response to flood risk was collected through observation and questionnaire survey, while the institutional response was collected through an interview with key informants in the specified planning and environment agencies. Firstly, with

Fig. 9 Area submerged during the 2019 flood in Kwanar Taya. (Source authors' field work 2019)

regard to people's effort to prevent flood risks which some researchers called it do-it-yourself (DIY) adaptation (Udelsmann Rodrigues 2019), a field survey revealed that the residents of the study area also employed this strategy through the use of sand bags, raising of walls, and de-siltation among others to divert flood water away from their residential area (community), and this was specifically observed in Gwammaja besides Dala National Orthopedics Hospital and also at Kwanar Taya which is another section of the study site. All these efforts represent the community's local responses to reduce potential harm and adverse effects of flood incidents. However, due to uncertainty of rainfall and anthropogenic factors that induce the floods, the community members can hardly achieve complete defense of their locality as it is beyond their capacity to prevent floods. This situation remarkably improve our understanding of the DIY adaptation efforts and at the same time the indispensability of municipalities to support the efforts of vulnerable communities particularly those inhabiting marginal areas that are more exposed to climate change.

The study further revealed that most of these areas that were subjected to frequent flood hazard have developed different flood risk management approaches for pre-flood, during, and post-flood period. Table 3 outlines the residents' coping strategies undertaken before flood/rainy season. Clearing of waterways appeared to be the first with WAI of 4.45 and followed by de-siltation as the second most practiced strategy with WAI of 3.77; widening of drainage channels was ranked third with WAI of 3.51, and producing human resource/trained manpower was ranked fourth with WAI of 3.48. Likewise use of metal sheeting and/or sandbag was ranked fifth with WAI of 3.26, while sharing of contact information was ranked sixth with WAI of 2.86 as the least strategy practiced in the study area, respectively.

The current study has further revealed that community adaptation planning is undertaken at various scales reflecting, in particular, the seasonality of rainfall. For instance, among the 196 respondents, 128 (63.5%) stated that clearing of drainages in anticipation of rainy season was a highly considered strategy for improving the drainage capacity and its functionality. This strategy was regarded as the most relevant flood risk adaptation strategy in the study area which is followed by 115 (58.7%) of the respondent that mentioned de-siltation as the next most important adaptation strategy that is used in the community (see Table 3). Again, it is important to note that local governments have actually failed in delivering their responsibility of environmental upkeep which can be carried out through increased financing and enforcement environmental and sanitary provisions. In other words, while the DIY role played by the communities is commendable, the total neglect of vulnerable communities is deplorable. In the interest of environmental justice and social equality and inclusion, it becomes imperative on local governments in developing countries to consider integrated and larger adaptation strategy that will tackle community level vulnerabilities and strategic efforts such as DIY as a means of achieving an inclusive adaptation to flood risk. The need to focus on flooding is very important as it has been identified as universal issue in global climate change risk which affects more people than any other form of disaster (Nkwunonwo et al. 2016; Salami et al. 2016).

Flood Adaptation Strategies at Community Level

The above subsection dwelt on pre-flood DIY efforts, while Table 4 in this subsection shows the residents' coping strategies during flood/rainy season based on applicability of various adaptation strategies. According to the outcome of the survey, selection of safer place to stay was ranked first (most applicable) in the study area with 3.85 WAI. Whereas relocation to the nearest neighborhood until after rainfall was second with 3.82 WAI, the third most applicable strategy was taking care of the children, the aged, and people living with disability (PWDs) with 3.68 WAI. Here, the results point out the critical role of decision-making as to how to respond to rainy and floodable days in these urban communities. One of the limitations of this study is its inability to explore the nature of decision-making with respect to displacement of people.

Moreover, the study revealed that out of the total respondents, 86 (43.9%) respondents mentioned selecting safer location to stay, while 71 (36.2%) mentioned taking care of the children, the aged, and PWDs as the most applicable strategy practiced during flood in the community. Similarly, temporary relocation to nearest neighborhood until after flooding 112 (57.1%), perfect communication at community level for assistance 65 (33.2%), and taking care of the affected people 73 (37.2%) were enlisted among applicable (although not highly applicable) strategies in the community for adapting to flood risk during flood. The relocation sites are mostly homes of friends and relations that have raised buildings and more spaces to accommodate people. Even under this scenario, DIY adaptation strategy is very active and effective. For instance, digging of channels to divert waters 70 (35.7%) and praying for lesser rain 58 (29.6%) were mentioned among moderately applicable strategies to adapt during flood. The total loss of confidence in the government manifested clearly as 27.6% of the respondents mentioned the government intervention.

Post-flood Community Response on Adaptation Strategies

Flooding can have immediate-, short-, and long-term impacts on urban communities. As such, community adaptation responses may extend to beyond the rainy season. In the context of this study, communities in the study area lack the appropriate solutions but hang on the adaptation strategies that they have developed over time. Nevertheless, our questionnaire created a kind of public conversation among the respondents who revealed their thoughts on what seems to be their perceptions of best adaptation strategies. In this regard, Table 5 outlines the roles of clearing blocked drainages in the community which was ranked as the most applicable flood adaptation strategies with a WAI of 4.11. People themselves have acknowledged the role of education as a driver of community adaptation, and this knowledge will in a long way support and enhance their capacity for DIY adaptation. This further revealed that no relief materials were received by the public in these flood-prone areas. Again, as can be seen in Table 5, the respondents stressed the need for equality in distribution of relief

Fig. 10 Resident adaptation measures (coping strategy) to flood, to hold back and/or divert flood water away from their residence (Gwammaja)

materials from the public sector if and when at least they come to the victims of flooding. In other words, there is seemingly lack of trust on the government and its agencies for their failure to assist people. While it has been a culture for governments at all levels (local, state, federal) to allocate for disasters such as the recurrent floods, there is dissatisfaction from the side of the vulnerable communities. Again, as can be seen in Figs. 10 and 11, there is evidence of community DIY actions that aim at protecting neighborhoods and their households from recurrent flood incidents.

Institutional Flood Adaptation Response Strategies in the Study Area

Public institutions such as agencies have duty and responsibility to promote adaptation measures within their area of constitutional jurisdiction and governance system operational in a given urban area. Against this backdrop, this study sought for explanations from relevant agencies which in this case are two organizations, namely, Kano State Urban Planning and Development Authority (KNUPDA) and State Emergency Relief and Rehabilitation Agency (SERERA). In the case of KNUPDA, our questions were answered by the Zonal Coordinator who is in charge of development control in the study area. By virtue of his knowledge of the area, he affirmed that "the problem of flood in the local government is not a new phenomenon," adding that the study site is "among the ancient settlement in the state which existed for long prior to initiation of the Control Department (CD) or KNUPDA itself." This view impliedly suggests that probably the planning authority has been

Fig. 11 De-siltation of drainages to improve free flow of storm water, but not properly evacuated which have tendency of finding its way back into the drainage

overwhelmed with the flood incident in the study area and possibly lacks sustainable solutions for the challenge. Given the experience of the United States, it is important for authorities in developing countries to tap on community initiatives in dealing with flood hazards (Noonan and Sadiq 2018).

Furthermore, the officer argued that "increased population and urbanization make the community continue to become more congested." In addition, he mentioned that there were numerous buildings that were developed without planning approval and that majority of the area was not properly planned or designed. Accordingly, such haphazard developments are among the key drivers of perennial floods. The situation is also not unconnected with inadequate drainages and encroachment of open spaces by private buildings among others. However, the officer maintained that some areas were but still suffer from lack of proper implementation of design principles and enforcement of planning regulations. Hence, he argued that "adaptation strategy employed is insisting on people to seek proper approval and development permit before construction." In doing so, KNUPDA provides prospective developers with adequate standards in developing their properties. According to him, they also convey messages to the ward heads as a mean of ensuring control of development and stop any development that encroaches floodplain in the Local Government Area which eventually might pose a problem such as environmental hazard.

With regard to the implementation and enforcement of planning regulations, the key informant asserts that "some officials are always in constant inspection of the area and these officers are responsible for reporting (immediately) any suspicious development." Another notable problem noted by the officer is the lack of proper waste collection and disposal infrastructure in the ancient city of Kano. Although poor waste disposal is invariably connected to flooding, the officer noted that waste management is no longer the business of KNUPDA as it has been assigned to another authority. Nevertheless, he insisted that KNUPDA had severally issued stop work notice and in some instances demolished hazardous structures when they are deemed to constitute a threat to safety. Some areas within and around the study area hardly experience flood incident and attributed that to their interventions in the local government area.

In SERERA, an agency responsible for responding to all forms of disasters in the state, the key informant revealed that they "don't have pre-flood adaptation measures" because they only embark on emergency response with immediate effect when it is reported to them. This agency does provide parties affected with relief materials ranging from building materials like cement, blocks, nails, and planks, among others. They also embark on assessment reports, making recommendations for relief measures, occasional involvement in the distribution of relief materials, and evacuation of stranded persons in spots of emergency. The respondents added that their personnel were trained on how to rescue individuals from either fire or flood disaster which is sent on special assignment when the need arises.

When asked on whether they have any special plans for the identified flood-prone areas under study, they responded that that they just act in case of emergency and provide relief materials; things provided include mosquito nets, foodstuffs, drugs, mattresses, temporary camping of stranded people, as well as taking care of the aged and children. Their response is mainly on immediate report of accidents, and they work hand in hand with fire service department whose mandate include rescue services.

Based on information given by the key informants, it is obvious there is disconnect between the approaches and philosophies of communities and public institutions responsible for tackling climate disasters and, in particular, flooding. The recurrent floods cause loss and damage to communities, and this situation increases temporary loss of shelter or displacement from their houses. This is an indication of the situation in many developing countries where there is disconnect between planning policy and climate change mitigation and adaptation. It is obvious there is need for capacity building and reorientation of urban climate change governance architectures to enable creation of a broad-based consultations and policy formulations between communities and public agencies. This is necessary because at the moment actions by communities and the agencies do not complement each other. At the same time, there is fragmentation even between and within public organizations responsible for urban planning, waste management, and rescue operations.

Conclusion

This chapter is premised on the socioecological notions which enables to gain a better understanding of flood adaptation response in urban areas of developing countries. In other words, it is imperative to look into the connections of human and social dimension of environmental and climate change as we observe climate vulnerability in cities and towns. This chapter has established the critical role of the physical environmental features such as relief and topography and their interface with flood incidence in high-density urban areas. Thus, it is crucial to recognize the role of physical terrain when planning and designing human settlements in this age of changing climate. In relation to this, municipalities in developing countries should prioritize the importance of systematic environmental data in urban planning climate adaptation strategies. The recurrence of flooding in cities and towns cannot be disconnected with neglect of terrain factor in stormwater overflows and its redistribution within the built-up areas. Again, as urban surface is becoming more impervious and waterproofed, it is important to reconsider the place of nature in tackling climate change.

The neglect of nature in urban development is closely followed by neglect of people in the effective management of climate crisis and, in particular, perennial floods that ravage cities and towns. It appears that in developing countries public agencies operate in silos even when there is evidence of commitments to addressing climate challenges. Therefore, it is high time to address such gaps and disconnects which cause failures and loss of time and resources due to such unyielding interventions. Invariably, the persistence of fragmented efforts leaves public to suffer resounding devastation of infrastructure as well as people's dwelling places and sources of livelihoods.

More people inhabit urban areas more than ever before in human history, and this human dominance is being challenged by climate change and its impacts. The neglect of climate vulnerable groups inhabiting informal areas has continued in most developing countries. This situation violates the principles and goals of the United Nations' Sustainable Development Goals (SDGs) and, in particular, the SDG 11 – which focus on sustainable human cities and communities. In a situation like this, one of the best options left for the people left out in the schemes of policy and planning is DIY adaptation. This adaptation strategy is found to be effective and useful to many poor and neglected urban citizens in developing countries. Hence, it is imperative on local authorities to support such efforts by working with communities that use this kind of adaptation measures. What is most attractive about DIY adaptation is that it focuses on directly correcting or tackling flood causative and/or multiplier factors. Therefore, researchers and especially climate experts and scientists need to recognize DIY as part of the grassroots efforts and local knowledge and actions which are essential in building global climate adaptation.

carbon strategy based on renewables is a global strategy, while waste management of biodegradable materials through the use anaerobic technology to meet energy demand is a local action. Nigeria is among the vulnerable countries to global climate change impact; this is even more aggravated by its dependence on fossil fuel usage as well as poor waste management, which two, contribute significantly to greenhouse gas emissions. This chapter presents analysis of purified compressed biogas production, a waste conversion option, as a local action to meet rural household energy demand and contribute to global strategy of reducing climate change impact. It discusses both technical and business model approaches to upscale a laboratory experimental procedure for biogas production through anaerobic digestion using vegetal wastes. It shows that using anaerobic technology can achieve efficient waste management and at the same time generate energy that can be used to achieve avoided emissions for climate change impact reduction. The study also concludes that upscaling the project will be sustainable for rural energy augmentation as it produces clean and renewable energy, reduces the use of fossil fuels, provides jobs for skilled and unskilled labor, and generates new return streams.

Global strategy · Local action · Waste management · Anaerobic technology · Rural households · Avoided emissions · Business model

Introduction

Energy is a very crucial input for attaining sustainable development. This has become even more pronounced for growth-driven economies, as those in developing countries as Nigeria. Most energy inputs driving economic activities are currently derived from fossil origin, principally hydrocarbon and solid fuels as firewood. These are not socially, environmentally, and economically efficient and therefore not sustainable. Fossil fuels contribute significantly to greenhouse emissions (Bölük and Mert 2014), while solid fuels produce indoor air pollution (WHO 2015). On the other hand, waste is produced from unwanted and discarded materials of human society (Bharadwaj et al. 2015), which needs to be managed properly. Management of waste is a global phenomenon (Isiaka 2017), although the challenge is more pronounced in developing countries for three reasons. These are the increased generation of waste due to increased population, improved living standards, technical and human capacity limitations (Guerrero et al. 2013). African countries are now faced with huge amounts of municipal waste, which has a direct effect on human health, safety, and environment (Bello et al. 2016). Although there is a paucity of data on waste generated annually in Nigeria, however, Isiaka (2017) reports that about 3 two million tons of waste are generated annually, while Vanguard (2017) reports a value of 24 million tons. Of these, only about 20–30% is collected with vegetal wastes, making up 65% of those collected (Isiaka 2017; Ogwueleka 2009).

Vegetal matter refers to substances produced by plant or growing in the manner of plant that can be decomposed by microorganisms. Significant contribution to greenhouse gases and volatile organic compounds emissions comes from their high moisture, organic contents, and biodegradability (Sridevi and Ramanujam 2012). Nonetheless, converting this resource properly could contribute to sustainable energy provision, which Nigeria is in dire need of. Anaerobic digestion is a technology that is recognized to be useful for converting vegetal and animal wastes to generate renewable energy in the form of biogas and organic fertilizer (Arsova 2010). This could result in saving the environment from further degradation, supplementing the energy needs of the rural population (Ahmadu et al. 2009), and generate extra returns streams for farmers and investors (Twidell and Weir 2005; Aransiola et al. 2014; Budzianowski and Brodacka 2017). This contributes significantly to the circular economy in rural communities (Jun and Xiang 2011). Vegetal matters usually occur in large quantities, making it difficult to dispose of easily; over time, this tend to make them become a source of harmful and offensive substances in landfills due to their decomposing qualities (Misi and Forster 2002).

The deployment of a co-digested anaerobic process using cow rumen as inoculum as local action for climate change impact reduction is reported. Essentially, the study involves the design and fabrication of stainless steel farm tanks for anaerobic bio-digestion; upscale of laboratory experimental data for feedstock loading to produce biogas from the substrate; estimate of avoided emissions compared to other fuel sources for cooking energy; evaluate life cycle costs and return streams of biogas produced based on different scenarios; and formulate a business model.

Literature Review

In biogas production, specificity of the substrate collected usually has effects on the type of digester to be used (Christy et al. 2013). Furthermore, biodigester systems are classified based on the method of feeding and number of reactors, with the method of feeding being either batch or continuous, while the number of reactors could also either be a single stage or multi stage (Brown 2006).

The single-stage process involves three stages of the anaerobic process occurring in one reactor. In this process, fermentative bacteria rate of growth is faster than that of acetogenic and methanogenic bacteria (Brown 2006). The consequence is that it results in acid accumulation, pH falling, and methanogenic bacteria growth. For the multi-stage processes, two or more reactors are used to space out the acetogenesis and methanogenesis stages that serve as filters in the system and thus enhancing the digester's production efficiency (Manyi-Loh et al. 2013).

During batch experimental setup, feeding of the digester is only done once, which is at the beginning of the reaction, with the products of the digester being collected at the end of each cycle. However, in that of the continuous system, the feeding and discharging of organic material is continuous (Levenspiel 1999). Rajendran et al. (2012) reviewed different household digesters which are commonly used, reporting that fixed dome (cylindrical digesters) are most commonly used type of digester in

China, while the floating drum digesters are those highly recognized in India, with other digester types used being majorly tubular such as portable plug flow digesters. In terms of features, fixed dome digesters made up of the feed and digestate pipes, a fermentation chamber and a fixed dome on top of the biogas storage, while floating drum digesters are recognized for the floating drum to be at the top of the digestion chamber which separates the gas production and discharge (Neba et al. 2020). Plug flow digesters, which can operate as a household or an industrial digester, have a simple flow pattern without back-mixing. The presence of serious floating tendencies may cause clogging of the flow and prevent the escape of produced biogas in plug flow digesters, though, an inclined plug flow digester at an angle 45° is a better option (Ziyan and Xiaohua 2014; Rajendran et al. 2012). A major advantage the plug flow digester has over fixed dome and floating drum digesters is that there is no difficulty in moving an installed digester, as it is able to produce biogas at a variable pressure and constant volume. In addition, plug flow digesters are capable of managing waste with the range of 11–13% solid concentration (11–13%) (Roos et al. 2004), being always operated in the mesophilic temperature range (Krich et al. 2005).

Global climate change impact is predicted to affect energy sector as with other key sectors of the economy (Arent et al. 2015). One of the strategic approaches to addressing the future of climate change impact is the use of low-carbon energy sources (Yadoo and Cruickshank 2012). Renewables have been taunted as a major contributor to this strategy (Solaun and Cerdá 2019). Developing countries like Nigeria are quite vulnerable to climate change impact, with energy sector being one of the most vulnerable (Ogundipe et al. 2014). Schaeffer et al. (2012) did an extensive review of the vulnerability of the energy sector to climate change. The paper reported on the vulnerability of biofuels to climate change. In addition, as regards biogas production in rural setting, there are ranges of challenges to be considered, which are well documented in literature (Madriz-Vargas et al. 2018). These challenges can affect the operational outcome of renewable energy (RE) technologies as well as the sustainability of the project as a whole. These issues raise questions as regards the set of community capabilities required, appropriate project design, and enabling an external environment for sustainable community RE (CRE) projects.

To introduce the use of biogas as a low carbon strategy to energy generation in the rural areas, the use of user-centered design concept (Redström 2006) is introduced. This approach was proposed as a means to scale-up the process of developing biodigesters in rural areas for energy generation. The essence of the concept is that it takes user experiences into consideration (Redström 2006) in its design. Thus, the basic concept of the business model formulation of the RE power system is to make it be owned, operated, or maintained by a community organization. With this, technical and nontechnical problems such as the issue of social integration of RE technologies, lack of investment and maintenance capabilities, as well as end-user education (Madriz-Vargas et al. 2018; Margolis and Zuboy 2006) are eliminated.

Methodology

This section describes the approach adopted to design and fabricate the digesters, upscaling the substrate used to feed the digesters from a laboratory experiments (Adepoju 2019) conducted. The scaling up includes technical design and development of the biodigester, up-scaling biogas production from laboratory experiment, evaluation of avoided emissions, estimation of life cycle costs as well as return streams, and business model formulation.

Digester Design and Development

In the design, fabrication, and construction of the plug flow biodigester, the factors that affect the building of digester for optimum biogas yield (Jiang et al. 2011) should be taken into consideration. The principal materials to be selected for the fabrication will be stainless steel sheets because of its durability and as well as its ability to absorb heat easily, which improves mesophilic anaerobic digestion as to when compared to cement and block. The design analysis includes the design specification of the biodigester and the length of the digester is 5.96 m. The required length-to-width will be within the ratio of 3.5:1 based on the Natural Resources Conservation Service (2004) length-to-width ratio for manure in plug-flow digesters. Therefore, the dimensions of the digester are:

Length of the digester (L) = 5.96 m
Width of the digester (W) =0.71604 m
The volume of the digester = 9.6 m^3

A plug flow reactor has the following components as shown in Fig. 1:

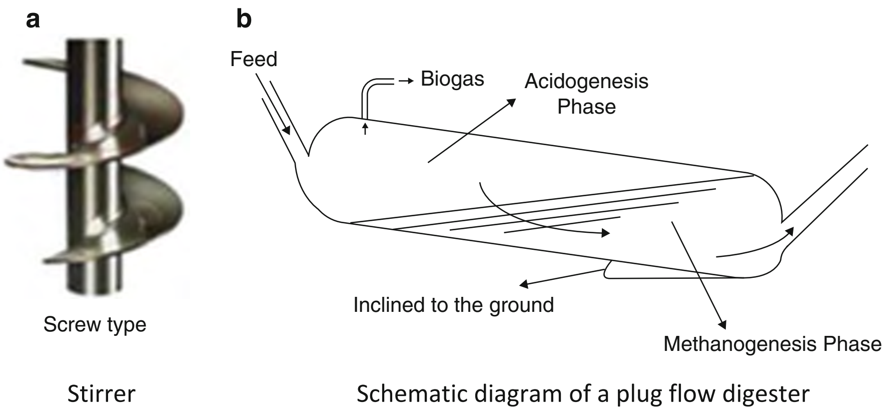

Fig. 1 Schematic diagram of a plug flow digester

Table 1 Theoretical comparison of different substrates to meet energy needs of 100 households

Substrates	Biogas potential (L/kg)[a]	Expected daily biogas production needed for 100 households (m^3)	Expected biomass (waste) for feeding (tonnes)	Expected size of biodigester (m^3)
Vegetal matter	70	39.13	133.91	67
Corn silage	200	39.13	465.83	23
Grass silage	220	39.13	423.48	21

[a]Source: Arora and Linton (2011)

1. Inlet and outlet pipes: The inlet pipe can also be referred to as the feed pipe while the outlet pipe as the digestate pipe. The pipes to be used will be of a steel rod with diameters of 500 cm and 250 cm as the inlet for feeding the substrate into the digester and outlet pipes for discharging the consumed slurry at the end of the digestion, respectively. The inlet pipe which will be at an angle of 45° for convenient channel of the substrate into the digester and the entry will be closed to prevent air from getting to the residue for easy break down of waste materials in the digester.
2. Stirrer: A screw-type, stainless material stirrer is shown in Fig. 1. The stirrer will be connected to a motor to drive it in order to create a turbulent motion of the substrates.
3. Storage tank: The storage tanks will be balloons made from high density polyethylene (HDP) or floating tank made from fiber glass for collection of biogas produced.
4. Effluent collection tank: The effluent (digestate) will be collected in a plastic tank.

The design involves the construction of seven 9.6 m^3 biodigesters. A combination of the seven farm tanks biodigesters was designed to produce approximately 39.13 m^3 of biogas daily. It is also expected that for each biodigester, about 64% of the biodigester size would be for gas accumulation. Table 1 shows different substrates with their biogas potentials, expected daily biogas production needed for 100 households, expected biomass feedstock, and expected size of biodigester. The use of grass silage as substrate for biogas production required the least sized digester at 21 m^3.

Up-Scaling Biogas Production from Laboratory Experiment

This section describes up-scaling the steps to the pilot scale from laboratory experiment. The laboratory experiment involves the use of portable 20 l plastic containers, modified as digesters, as shown in Fig. 2. Gas collection was done through water displacement method (Otun et al. 2015). Stirring was done by shaking the biodigester to prevent thickening and settling of the slurry. The experiment consists of the use of fresh waste samples of vegetables and fruits serving as feedstocks, and

Fig. 2 Laboratory-scale experiment (Adepoju 2019)

cow rumen fluid used as inoculum, collected from a food market and an abattoir. The vegetables and fruits, made up of watermelon, tomatoes, and oranges, were grinded to increase the surface area. The cow rumen fluid collected in polyethylene bags was stored at room temperature for 4 days (Elhasan et al. 2015). These were mixed with water to form slurry in the biodigester (Budiyono et al. 2014). Fresh vegetal wastes (V) mixed with cow rumen fluid (R) and clean water (W) in different V:W:R ratio and batch fed into the digester. The retention time was 30 days.

The biodigester was scaled up based on the data acquired from the laboratory-scale experiment to meet the energy needs of about a hundred (100) rural households. The energy cooking need was estimated based on Riuji (2005) and Rea (2014) that 100 l of biogas will produce 23 min of cooking time. It was assumed that a household of 5 will use 390 l of biogas for 90 min cooking time in a day. With these data, it was estimated that 100 households will require 39,130 l of biogas daily. According to Arora and Linton (2011), 1 kg of vegetal waste will produce on average 2.33 l of biogas daily and a total of 70 l biogas over a retention time of 30 days. From Arora (2011), to achieve a daily production rate of 39,130 l of biogas, will require 16,670 kg of vegetal waste without the use of inoculum, requiring an organic loading rate (OLR) of 555.67 kg daily. With the use of cow rumen as inoculum, the efficiency of the substrate is improved by 26% (Stan et al. 2018), reducing the amount of vegetal matter needed to 13,310 kg or an OLR of 443.67 kg daily. The size of the biodigester is dependent on the amount of waste needed. Using the laboratory experiment that requires 4 kg of waste for 0.02 m^3 of biodigester, the equivalent biodigester size for 13,310 kg of waste was estimated to be 67 m^3 to produce 39,130 l of biogas daily to meet the energy needs of ~100 rural households.

Avoided Emission Calculations/Climate Change Impact Reduction

The avoided emissions were estimated based on the biogas equivalent to the fossil fuel conversion method (B-Sustain 2013b), and 1 m^3 of biogas equivalent for each of the fuels is given in Table 2. The emission factors of biogas, kerosene, LPG, kerosene, and firewood were obtained from Simon et al. (2006), which was used for the estimation of the CO_2 emission. The CO_2 emission reduction potential of using biogas in relation to other fuels was evaluated by subtracting the emission from the particular fuel and that from biogas.

Estimation of Life Cycle Costs and Return Streams

In order to estimate the unit cost for the produced biogas for either cooking or electricity generation will involve life cycle analysis (Lakhani et al. 2014). For this project, a 20-year life cycle was assumed for biogas generation (Tsaganakis and Papadogiannis 2006). Based on the assumption, this life cycle cost was calculated thus:

$$Life\ cycle\ cost\ (LCC) = \frac{Total\ cost}{Energy\ derived}$$

where Total Cost = Fixed Costs + Variable Costs.

1. **Cooking**: To calculate LCC for energy derived from biogas for cooking, the assumption made is that the digester has a life cycle of 20 years and production capability of 39.13 m^3 per day. It is also assumed that the digester will work for 300 days in a year.
2. **Electricity generation**: For the energy derived from biogas for electricity, the assumption made for the life cycle is 20 years, production capacity of 849845.57 BTU/day, and 300 days of yearly operation.
3. **Digestate production**: To calculate LCC for digestate from the biodigester, the assumption made is that the digester has a life cycle of 20 years and production capability of 54.26 kg per day, with 300 working days per year.

Table 2 Biogas equivalent to fossil fuels and firewood

	Fuel	Quantity (kg)
	LPG	0.45
	Kerosene	0.6
1 m^3 of biogas equivalent to	Firewood	3.5
	Furnace oil	0.4
	Petrol	0.7
	Diesel	0.5

Source: B-Sustain (2013b)

The life cycle costs obtained were used to calculate the sales price based on the value added tax (VAT) of 5%, bank interest of 25% (assuming bank loan was secured to execute the project), sales tax of 5% (assuming sales tax will be charged), and a profit margin of 5%, which gives a sum of 40%. The sales prices were estimated by calculating 40% of the life cycle costs.

Business Model Formulation

The user-centered approach represents the concept behind the business model formulation to enable coupling of technical and economic aspects of biogas production principally for rural energy supply. This also includes issues of cash flows, access to finances, and fuel switching in rural areas of Nigeria.

The formulated business model gives potential investors an overview of typical rural energy markets, target customers, and potential return streams to be earned from a biogas production business. The adapted model is an integrated one with three domains. The first domain is the upstream side or technical input, which includes planning, R&D resources, and installation of the production process of the business that includes building of the biodigester, storage system, laying of supply pipelines, and sourcing for raw materials to be used from farms and food industries biowastes. The second domain reflects the transformation of the raw materials from the biodigester to create value for the target market. This involves anaerobic digestion to yield raw biogas and the byproduct as digestate (fertilizer), piping the biogas to connected households for cooking, and subsequently cleaning and pressurizing the biogas for electricity generation to the target customers. The last domain is the market segment of the business. This involves the marketing of biogas and digestate to target customers which include: cottage industries, residential use, commercial, and farmers.

Smallholders in rural areas usually have limited access to finance as they have to confront different challenges from bank demands, such as the complex and drawn-out procedure of documentations, high bank charges, short-term nature of the credit, and disturbing problem of mortgage for security (Abdullah et al. 2015). In the same vein is the issue of fuel switching. The Nigeria household energy mix is as shown in Fig. 3, with firewood making up 56% and sawdust being the least at 2%. To increase the proportion of clean energy sources in the form of gas such as LPG and biogas will require substantial fuel switching. The current proportion of clean energy sources in the household energy mix is barely 5%. This will even be worse in rural areas in Nigeria, where dependence on unclean sources such as firewood and kerosene are even more prevalent. For clean energy sources such as biogas or LPG to be more acceptable, the proposed business model takes into consideration the provision for household fuel switch, particularly in rural areas. The most used fuel stove currently in rural areas of Nigeria is based on firewood that depends on the traditional three-stone stoves or mud-built stoves. These stoves are grossly inefficient and unhealthy for humans and the environment due to the release of inimical particulate matter into the air (Akinbami and Momodu 2013). So tackling fuel

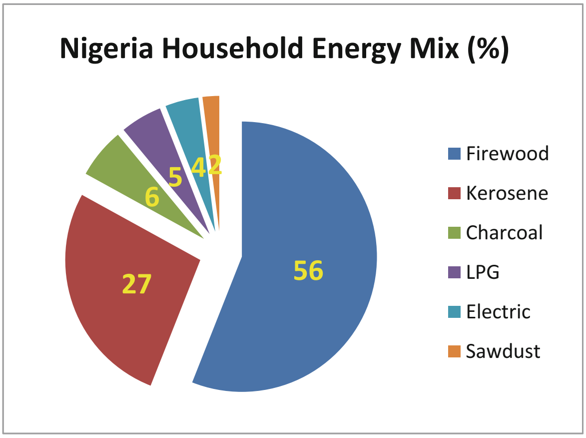

Fig. 3 Nigeria household energy mix (Source: Ministry of Petroleum Resources 2017)

switching for rural households will involve tackling the economics of fuel and stove type, respectively. Other issues to be addressed include but not limited to access conditions to fuels, technical characteristics of cook stoves and cooking practices, cultural preferences, and health impacts (Masera et al. 2000).

Results and Discussion

This section presents the results and analysis of the study. This includes the process of scaling up laboratory experiments to the field scale, avoided emission, investment cost, variable cost stream, lifecycle cost, and return streams, as well as business model formulation.

Scaled Up Biogas Production

Scaling up the biogas production to meet energy provision consists of a system of seven tanks of biodigesters that are each sized at 9.6 m^3. In this farm of biodigesters, the tanks tilted at 45° will consist of a mechanical stirrer, inlet, and outlet for feeding slurry and evacuating digestate, respectively. Biogas collection will be done using gas hoses connected to the gate valve at the top of the biodigester tanks (Arnott 1985). The raw biogas will be subjected to purification, liquefaction, storage, and transportation (Ahmad et al. 2018). The purification could be done either using water scrubber and iron filings or through cryogenic processes, depending on the level of purity required, which is determined by use. The water scrubber and iron filings will be used to clean the biogas by removing CO_2 and H_2S when the gas is needed only for cooking. On the other hand, cryogenic process is used when the gas purity is required at 94–99% level. This is an environmentally friendly biogas upgrading and

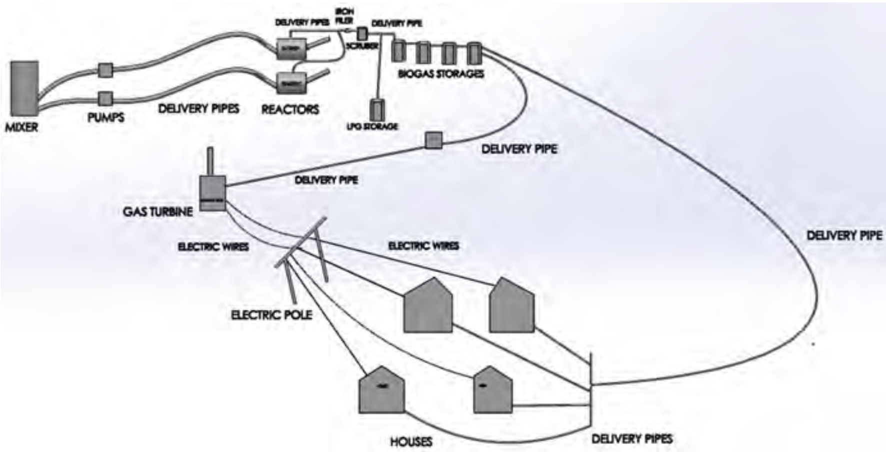

Fig. 4 Schematic layout of biogas production system for household energy and electricity generation

biomethane liquefaction system which separates pollutants and CO_2 from biogas via low-temperature (Ahmad et al. 2018). The cryogenic process will be used to purify and liquefy the biogas to be produced for the reason of storage, transportation, and high energy content gas demand of some applications. Thus, it is imperative that the concentration of methane in the biogas be increased with the removal of CO_2.

The gas will be stored in four interconnected fiber-glass tanks of 10 m^3 each. Two fiber glass tanks will supply gas for electricity generation, while the other two fiber glass tanks will be for cooking. For safety measures, there will be an inclusion of a water-cooling system for the storage tanks and regular cleaning of the pipe holes to avoid blockages and leakages and the use of several pressure relief valves along the pipeline to control the pressure of the gas. A schematic of the biogas production system is depicted in Fig. 4.

Avoided Emissions

Utilization of energy derived from biogas technology operates to reduce GHG emissions, particularly CO_2, by reducing the demand for fossil fuels and waste management (B-Sustain 2013a). The emission factors used for estimating the GHG emission from different fuel types are shown in Table 3, while Table 4 shows the total GHG emission of different fuel types. Table 5 shows that using 39.13 m^3/day of biogas produced from vegetal matter could reduce the CO_2 emission of 9.69 kg from LPG, 37.49 kg from kerosene, 23.15 kg from diesel, and 181.65 kg from firewood use. Therefore, using biogas produced from waste of vegetal matter instead of LPG, kerosene, diesel, and firewood fuels is a means to mitigate the environmental impacts of CO_2 and other GHG.

Table 3 Emission factors

Emission factors	Fuel type				
	Biogas	LPG	Kerosene	Diesel	Firewood
CO_2 (kg/MJ)	0.055	0.063	0.072	0.074	0.11
CH_4 (kg/MJ)	0.000001	0.000001	0.000003	0.000003	0.00003

Investment Cost and Variable Cost Stream

The cost stream, as shown in Table 6, itemizes the cost of materials to be used for the construction of 67 m^3 biodigester, including its civil works, the pipelines for gas evacuation and distribution, and the storage tank. The materials include stainless steel, copper pipes for connections, different sizes of valves, scrubber and iron filings, compressor, LPG cylinder, gas turbine, storage tanks, single burner cooking stoves, and rubber hoses. For purer gas needs, the materials will include cryogenic equipment.

Life Cycle Costs and Return Streams

Based on the production of biogas from the biodigesters, life cycle costs (LCC) were estimated for cooking, electricity generation, and digestate production in three different scenarios. The first scenario, called A, considered the production of

Table 6 Cost stream

Item description	Estimated unit cost	Estimated quantity	Amount (₦)
Fixed costs			
Stainless steel 9.6 m^3 tanks	1000,000	7	7,000,000
Different sizes of connecting tubes	500	160	80,000
Different sizes of valves	5000	160	800,000

Sample analysis	8000	1	8,000
Operation and maintenance costs	2,000,000	1	2,000,000
Salvage cost	700,000	1	700,000
Total			**29,093,285.60**

digestate and biogas for cooking only, in which the LCC are \$0.13/kg (₦ 44.67/kg) and \$0.14/m^3 (₦50.50/m^3), respectively. The second scenario B is the production of the digestate and biogas for electricity, while the last scenario C considers the production of digestate, 50% biogas for cooking and 50% biogas for electricity. These life cycle costs enable the cost comparison analysis of various scenarios (Table 7).

Theoretically, the investment cost is estimated as ₦29.1 million, while the return streams at different scenarios are the same, which is ₦ 40.74 million with a profit margin of ₦ 11.74 million and an average annual profit of ₦0.59 million. With the positive difference between the LCC and the return stream generated, the biogas project shows good performance with hope the business will allow for its smooth operation to enable quick cost recovery.

Business Model Formulation

The concept proposed for the rural energy biogas business, based on user-centered design, is diagrammatically shown in both Figs. 5 and 6, respectively. Figure 5 shows a simplified schematic diagram of the business model that mimics what is

Table 7 LCC and return stream

Scenario A				
	LCC (₦/kg)	**Sales price (₦/ kg)**	**Quantity (tonnes)**	**Revenue (₦) (million)**
Cooking	50.50	70.69	288.1	20.37
Digestate	44.67	62.54	325.6	20.37
Total				**40.74**
Scenario B				
	LCC	**Sales price**	**Quantity**	**Revenue (₦) (million)**
Electricity generation	0.00285 (₦/ BTU)	0.004 (₦/BTU)	5 million BTU	20.37
Digestate	44.67 (₦/kg)	62.54 (₦/kg)	325.6 tonnes	20.37
Total				**40.74**
Scenario C				
	LCC	**Sales price (₦)**	**Quantity**	**Revenue (₦) (million)**
Cooking	₦ 67.33/kg	94.25	144.04 tonnes	13.58
Electricity generation	₦ 0.0038/ BTU	0.0053	2 million BTU	13.58
Digestate	₦ 29.79/kg	41.70	325.6 tonnes	13.58
Total				**40.74**

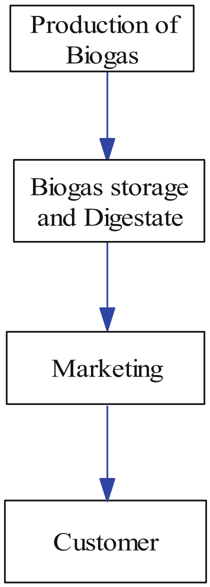

Fig. 5 Simplified schematic diagram of the biogas business model

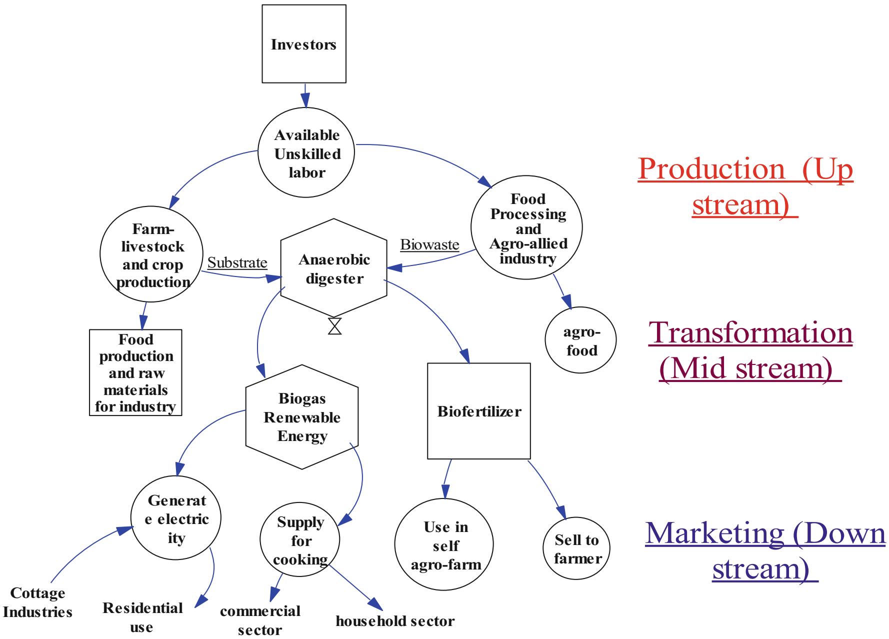

Fig. 6 Schematic diagram of the adopted business model. Source: Adapted from Yousuf et al. (2017)

obtained in traditional vertically integrated electric power systems (Walsh and Todeva 2005). Both diagrams show three distinct operations of technical inputs, storage of biogas and digestate, as well as marketing. The first domain contains most of the investment cost segment of the model. The cost stream in the business model involves investment in livestock and crop farming, food processing, agro-allied industry, and biodigester construction, while the biogas yield and bio-fertilizer will generate the return stream for the business. From the perspective of the investors, the financial feasibility of the biogas business would be assessed based on its return and cost streams as well as its ability to make profit. In Nigeria, rural areas are mostly faced with challenges in fuel switching, access to finances, and cash flows. For this project, in order to make the business model operational, the issue of fuel switching is addressed. Addressing this challenge involves adopting a user-centered approach that combines different types of business models. At inception, a niche business model would be introduced to incentivize the first few households that adopt (early adopters) the use of biogas as an energy source, where a single gas stove burner would be given to them free but have to buy the gas to be used. For other households (mid to late adopters), the razor and blade business model would be introduced, where the users will have to buy the gas stoves at graduated subsidized prices and still also have to purchase the gas for use.

Conclusions and Recommendations

Global climate change impact needs to be addressed strategically using local actions. One of such strategy is the use of low-carbon energy resource to meet energy demand. Energy supply in Nigeria is at best erratic, and this is even more pronounced in the rural areas. In addition, Nigeria, particularly her rural populace, is among the most vulnerable to global climate change impact; this is even more aggravated by Nigeria's dependence on fossil fuel usage as well as poor waste management, which two, contribute significantly to greenhouse gas emissions and influences climate change impact significantly. Using waste conversion option through biogas production to meet rural household energy demand is a local action to contribute to the global strategy. Presented are both technical and business model for using biogas production as a means of waste management measure and energy supply source. The study shows that, theoretically, scaling up of laboratory experiments for biogas production through the process of bio-waste anaerobic digestion is not only possible but also comes with a positive difference in climate change impact reduction as well as between costs and returns. First, the project will achieve avoided emissions to reduce climate change impact, which is put at 58,168.55 kg, 224,923.8 kg, 138,884.1 kg, and 1,089,906 kg, respectively, for LPG, kerosene, diesel, and firewood. In terms of costs and returns, three different scenarios are looked into, namely, Scenario A involves just cooking using the biogas produced for cooking and selling of the digestate as bio-fertilizer; Scenario B, involving using the biogas produced for electricity generation, and selling of the digestate; and Scenario C, cooking, electricity generation, and digestate sales are considered. The total cost estimated for starting the project is approximately ₦29.1 million, and the returns stream is estimated at ₦40.74 million. This gives a profit margin of ₦11.64 million for the 20-year life cycle and an average yearly profit of ₦0.59 million. It is important to note that each of the scenarios presented the same total cost though the LCC and sales price pathways were different. Biogas energy production could be effective to transforming the rural economy. Another aspect of interest that needs to be further investigated is that the CO_2 got from cryogenic processes could be channeled. This will generate some income while also removing CO_2 from the atmosphere. It is further recommended that an actual pilot scale be done with data to verify the theoretical estimation made in this study.

Abstract

Gas flaring is a key contributor of greenhouse gases that causes global warming and climate change. Adaptation measures for tackling impacts of climate change have gained much research interest. This chapter assessed vegetable farmers' perception of gas flaring and the effect of biochar remediation on the heavy metal composition of cultivated *Telfairia occidentalis.* A gas-flared area, Ohaji/Egbema L.G.A of Imo State, and a non-gas-flared area, Umudike, Ikwuano L.G.A, were selected for this research. Structured questionnaire was used to elicit information from 120 respondents. Soils were collected from the study sites and transported to the greenhouse. Five different rates, 0 t ha^{-1}, 7.1 t ha^{-1}, 13.9 t ha^{-1}, 20.9 t ha^{-1}, and 28.0 t ha^{-1}, of palm bunch biochar were applied to the soils in plastic buckets. After 2 weeks of mineralization, two viable seeds of *Telfairia occidentalis* were planted in each bucket and watered every other day for 8 weeks. The result revealed that 63% of vegetable farmers where female, while 37% were male in the gas-flared area. A total of 97% of the farmers had knowledge of gas flaring. A total decrease of 55% percent income, 90% yield, and 67% market quality of vegetable farmers was attributed to gas-flared activities. The plant height of cultivated vegetables increased every 2 weeks with greater increase in the test plant. Heavy metal concentration (Pb, and Cr) decreased with increasing biochar rate and was significantly lower for 28.0 t ha^{-1}. Biochar can enhance soil fertility and help immobilize heavy metals. The effect of biochar application on the heavy metal composition is dependent on the rate of application. Biochar use could be a cheap adaptation measure in the face of a changing climate.

Keywords

Biochar · Climate change adaptation · Gas flaring · Heavy metal · *Telfairia occidentalis*

Introduction

Natural gas is a component of petroleum that is released during crude oil exploitation (Mohammed et al. 2016). This natural gas is usually vented or flared (burnt off) (Mohammed et al. 2016). Venting has to do with a direct release of natural gas into the atmosphere without burning, while gas flaring is the indiscriminate burning of natural gas during crude oil exploitation. This practice is common in most countries of the world especially in developing countries like Nigeria where oil companies fail to acquire the needed infrastructure for trapping, storage, and use of natural gas. Gas venting and flaring are responsible for enormous waste of nonrenewable resource, pollution, and an annual release of greenhouse gases which contributes immensely to global warming and climate change (Ajugwo 2013). In 2017, World Bank Global Gas Flaring Reduction Partnership reported that more than 140 billion cubic meters (bcm) of natural gas was flared. This huge volume of gas can serve as a reliable source of energy for the African continent yearly, but on the contrary, it has remained an unprecedented source of pollution (Emam 2016; Ismail and Umukoro 2012). As commercial deposits of crude oil was discovered in Nigeria, the nation drifted from agriculture to oil exploitation as its national income base. Oil industry became the nation's gold mine as it accounts for over 80% of her earnings (Ohimain 2013a, b). The oil companies in the Niger Delta region of Nigeria provided more than 80% of funds used for allocating national budget (Ede and Edokpa 2015). Nigeria is ranked one of the ten countries of the world with abundant natural gas reserve (Orlando 2006). It has been ranked the second highest in terms of gas flaring activities and the highest in Africa having a whooping gas reserve of over 180 tcm (trillion cubic meter) that has earned it the seventh largest gas reserve worldwide (Oyedepo 2014; Shaaban and Petintin 2014). World Bank reported that Nigeria flared over 7 (seven) billion cubic meters (bcm) of gas in 2018. Nigeria produces over 2,000 billion standard cubic feet of gas yearly (Nriagu et al. 2008). This volume fluctuates regularly because of incessant unrest from militants, activities of miscreants, vandalization, leakages, and so on. Oil exploitation companies in Nigeria are unable to channel natural gas into gainful use since they consider it cost intensive to procure the facilities needed for gas capture. Gas flaring is therefore employed as a safe means to evacuate any associated natural gas during petroleum exploitation, despite its serious deleterious far reaching environmental effects. Threat of flaring gases is common in oil rigs, crude oil refineries, and plants. In advanced countries like the USA, only 1% of the associated natural gas is flared, while in Nigeria more than 60% natural gas is flared every day. This large volume of flared gas has the potential to generate substantial revenue to the government of Nigeria if properly harnessed for cooking or industrial uses (Agboola et al. 2011). The flared gas could also be used to generate (power) electricity which could end the challenge of inadequate power supply especially now that the nation is experiencing reduced oil revenues as a consequence of global decrease in oil price (Ojide et al. 2012). This will raise more revenue for Nigeria at this time when oil prices are generally low.

Nigeria losses over 1 billion naira revenue through gas flaring (Campbell 2004; Fluenta 2019) that would have contributed immensely to the nation's economy if the gas was properly captured (Buzcu-Guven and Harriss 2012). Between November 2016 and November 2017, Nigeria flared over 300 billion standard cubic feet of gas which was sold at an exchange rate of 360 naira to 1 dollar with a domestic supply rate of 1.50 USD per 1000 standard cubic feet of gas. This suggests that the nation lost a whooping sum of over 160 billion naira which could have improved her economic base (NNPC 2017). Rules and regulations governing gas flaring in Nigeria are not adequately adhered to by oil-producing companies because such laws are weakly enforced and the penalty levied on defaulters is insignificant (N10 per standard cubic feet). Oil companies in Nigeria lack modern infrastructure needed for gas capture (Okorie 2018); they perceive that such equipment is expensive, and hence its use may not be economically viable. Ironically, there has been increased preference and demand for cooking gas over other sources of fuel, yet, the colossal waste of gas flaring is still been practiced. Locally and internationally, efforts are therefore needed to ensure that regulations governing gas flaring are strictly adhered for the good of man and the environment (Otitoloju and Dan-Patrick 2010).

The composition of the flared natural gas determines the type of pollutants emitted (Fawole et al. 2016). Gas flaring emits greenhouse gases that warm the atmosphere, causing climate change (Ukala 2011); also other precursor gases, volatile organic compounds (VOCs), polyaromatic hydrocarbons (PAH), particulate matter, and black carbon from gas flares often contaminate air, soil, and water (Giwa et al. 2014). More than 200 notable toxins have been reported to emanate from gas flares including hydrogen sulfide, toluene, benzene, sulfur dioxide, nitrogen oxide, xylene, and so on (ICF 2006). Particulate matter and precursor gases are among the most toxic pollutants that affect plants and man (Giwa et al. 2014; Yaduma et al. 2013). It releases over 40 billion kilowatts of heat daily into the atmosphere (Ukala 2011). Other pollutants released during gas flaring are soot, organic carbon, particulate matter (Guttikunda and Calori 2013; Giwa et al. 2014; Zhou et al. 2014), and heavy metals (Kampa and Castanas 2008). One percent of global warming arises from gas flaring which contributes over 300 Mt of CO_2 into the atmosphere (IPCC 2014a; Amaechi and Biose 2016). Though the practice of gas flaring has been significantly reduced in some countries, Nigeria is yet to record a significant decline despite numerous government strategies (Ite and Ibok 2013); hence, its devastating effects are still felt (Giwa et al. 2014; Oyedepo 2014). Nigeria has lost so much money as a result of gas flaring since the commencement of oil exploitation (Odumugbo 2010). Nigeria loses well over 2 billion dollars as a result of gas flaring yearly (Campbell 2004). This income would have contributed positively to the nation's economy if the gas was properly captured (Buzcu-Guven and Harriss 2012). Gas flaring is responsible for loss of energy resources in oil companies. It affects art works, paints, and monuments (Abua and Ashua 2015; Amadi 2014; Anomohanran 2012; Donwa et al. 2015; Iyorakpo and Odibikuma 2015; Nkwocha and Pat-Mbano 2010; Olukoya 2015; Ubani and Onyejekwe 2013). It affects the general well-being of the Niger Delta dwellers, both psychologically and otherwise (Nriagu et al. 2008). Noise from flare stalks could also affect man and other living things residing around the area. This could lead to loss of some important species or even outright extinction. Pollutants emitted from gas flares are more concentrated at locations close to the flare site. Those farther away from flare sites have reduced pollutant concentrations (Ojeh 2012). Though gas-flared effects are majorly felt within 450 m radius of flare stack, factors like stack height, flare velocity, temperature, and wind speed affect its impact (Ojeh 2012). When there are notable variations in wind speed and direction, locations close to flare stack may have less concentration of pollutants, while farther locations may have more. Gases can be flared from either a high or low pressure valve, and this affects the concentration of gas emitted and also the noise generated. Global Emission Inventory stated that flaring releases three times more soot than gasoline-driven vehicles (Weyant et al. 2016). It is responsible for the disorientation of water bodies like seas and oceans, for example, for over 40 years now, the ice level of the artic sea has significantly diminished (IPCC 2013). This rise in sea level is a consequence of global warming (Bernstein et al. 2007).

The Niger Delta area of Nigeria occupies more than 7% of the nation's total land mass with not less than 20 million inhabitants (Tawari and Abowei 2012). The nation has onshore and offshore natural gas reserves located in nine states, namely, Abia, Akwa Ibom, Bayelsa, Cross River, Delta, Edo, Ondo, Imo, and Rivers. They comprise a total of 185 local government areas, housing over 800 oil-producing wells and gas operation facilities (Osuji and Onojake 2004). Niger Delta environment is constantly being polluted by activities such as gas flaring, crude oil pollution, pipeline and tanker leakages, and so on (Tawari and Abowei 2012). All these pollutants have over the period altered the ecosystem balance, crop development, and human health. They have also been found to affect microbial activities in the area (Sonibare et al. 2010). A greater percentage of rural dwellers in the Niger Delta engages in different agricultural activities especially fishing and farming as means of livelihood. Unfortunately, gas flaring has negatively affected their survival since it has negatively impacted soil, water, and the environment at large. Gas-flared areas have an elevated ambient temperature as a result of the huge amount of heat (above 45 billion kilowatts) that is released daily from gas-flared points (Aaron 2006). Crops cultivated 2 km away from gas-flared points are usually scorched by the heat emitted from the gas flares (Anomohanran 2012). Particulates from gas flares can spread as far as 2.61×10^6 km away from flare points (Ede et al. 2011). A study conducted by Gobo et al. (2009) revealed that these pollutants could trigger onset of eye, skin, and respiratory diseases. Prolonged exposure to gas flares has been reported to negatively affect blood hematological parameters (Adienbo and Nwafor 2010). Ovuakporaye et al. (2012) also reported presence of skin and respiratory diseases in residents of gas-flared areas as a result of long-term inhalation of gas-flared fumes. Gaseous pollutants from gas flares such as nitrogen and sulfur oxides are responsible for acid rain. Acid rain corrodes roofing sheets and walls of buildings. Smog that results from the reaction of nitrogen oxides and hydrocarbons in the presence of UV radiation creates poor visibility (Ana et al. 2009). Other diseases reported to be prevalent in gas-flare areas include respiratory disease, eye and skin disorders, skin cancers (Ana et al. 2009), lung cancer (Ana 2011), and so on. Between 2015 and 1965, a period of 51 years, it was reported that an approximate gas quantity of over 900 bcm and 17 bcm every year with carbon monoxide being the most abundant gas was emitted (Giwa et al. 2019). Elevated levels of deleterious heavy metals have been observed in the air of the Niger Delta area. For instance, Olobaniyi and Efe (2007) reported 0.56 mg/l of lead in the area. Gas flaring has been reported to reduce yield of crops (Dung et al. 2008; Odjugo 2007; Odjugo and Osemwenkhae 2009; Olisemauche and Avwerosuoghene 2015), induce soil pollution evidenced by increased PAH deposits in soils (Sojinu et al. 2010), and be responsible for various health defects (Bhatia and Wernham 2009; Ekpoh and Obia 2010). The people of the Niger Delta perceive that gas flaring affects their health status and disturbs ecosystem balance generally (Edino et al. 2009).

Living things rely majorly on plants for their survival. The much needed energy and nutrients required by human body for its biochemical processes can be majorly derived from plants. Herbivorous animals (goat, sheep, grass cutters) and omnivorous animals (rat, squirrel, mice) depend on plants for their survival. Plants also provide shelter in the form of vegetation cover for animals that live on land. Cassava and oil palm are among common plants that are often found near gas stacks. The growth (Ozabor and Obisesan 2015) and yield (Achi 2003) of these crops are often affected by gas flaring. Over 70% of the Niger Delta dwellers are convinced that gas flaring has negatively affected their agricultural activities (Adewale and Mustapha 2015), hence their income source. Data obtained from a study in an oil community, Ebedei in Delta, has shown that gas flaring is affecting production of tuber crops such as yam, potato, and cassava including plantain and okra as well (Ozabor and Obisesan 2015). Acid rain arising from gas-flared pollutants is poisonous to plants. It could even lead to death of plants and hence loss of vegetation cover (Amadi 2014). This could further expose the soil to erosion. Symptoms expressed by plants when attacked by acid rain include shedding of leaves, yellow leaves, loss of photosynthetic ability, and even early death (Efe 2011). Acid rain has a more deleterious effect on plants and vegetation that are closer to gas-flared system. Efe (2011) documented that acid rain has negative impact on growth and development of common staple food crops and even cash crops such as rubber. The soil has not been spared from the impacts of acid rain as it has led to loss of important nutrients needed for plant survival. Other researchers including Jacobson (1984), Neufeld et al. (1985), and Efe (2010) have all documented the effect of acid rain on different plant species; and water quality (Ogunkoy and Efi 2003; Efe and Mogborukor 2008). Plants are important sources of medicine because they possess phytochemicals and other bioactive compounds that are of great pharmaceutical importance (Epidi et al. 2016a, b). The medicinal potential of a plant is a function of its bioactive composition. In another study, Anacletus et al. (2014) and Ifemeje (2015) reported changes in nutritional and phytochemical content of some common edible vegetables such as fluted pumpkin, H_2O leaf, scent leaf, and bitter leaf. In a similar study, Ujowundu et al. (2013) reported changes in phytochemical (phytate, tannin, alkaloid, and cyanogenic glycoside), proximate composition (ash, moisture, carbohydrate, and proteins), micronutrients (Ca, Na, Mg, K, and P), and vitamins (A, C, and E) in African breadfruit and Bambara groundnuts cultivated near flare sites. Phytochemical (flavonoid, tannin, alkaloid, saponin) and trace metals (Pb, Fe, Cd, Zn) of fluted pumpkin could be altered by gas flaring. Okeke and Okpala (2014) reported decreased soil nutrient in two gas-flared communities (Eket and Izombe) of the Niger Delta area.

Since the era of industrial revolution, man has been faced with the challenge of handling the problems arising from excessive crude oil exploitation, gas flaring, and climate change. Methane and carbon dioxide are the most notable greenhouse gases that are responsible for global warming and climate change. Methane has been found to be the most toxic greenhouse gas because it has the ability to induce global warming (86 times) more than CO_2 (IPCC 2013). To reverse global warming temperature to below 2 °C obtained during the pre-industrialization era by the year 2050, there is need to consciously reduce the volume of crude oil exploited. A certain percentage of fossil fuel, for example, about 50% natural gas with 30% crude and 80% coal, needs to be consciously left unexploited in the earth's crust to avoid undue changes in the earth's environment (McGlade and Ekins 2015; UNFCCC 2015; Zhao and Alexandroff 2019). At the 48th Intergovernmental Panel on Climate Changes conference, following close evaluation of climate change data, scientists came up with a global warming temperature target of 1.5 °C by the 2035 (IPCC 2018). It is therefore imperative to seek urgent ways of reducing greenhouse gas emission as well as seeking other sources of energy for man (Rhodes 2019). The World Bank Global Gas Flaring Reduction Initiative (GGFR 2015) has launched several international and national programs including “Zero Routine Flaring by 2030” Initiative to reduce gas flaring rates. Other bodies that launched campaigns for reduction in gas flaring include the 1992 United Nation Convention on climate change and 1997 Kyoto protocol (Malumfashi 2007). Despite all these strategies, significant changes are yet to be recorded (Elvidge et al. 2009; Fawole et al. 2016), and climatic risk is becoming more pronounced.

Climate change has gained important recognition because of its increased risks and widespread effects. It has become an issue of concern, discussion, and debate in various news media of the world. Its effect on the agricultural sector seems to be at its peak. Farmers are more aware of its existence and risks. It has affected their livelihood and general well-being, thus making adaptation measures very imperative. Climate change is a global environmental threat that consciously or unconsciously affects living and non-living things (Patz et al. 2007). Climate change is an alteration in the state of the climate over a period of 10–30 years or more, depending on man-made activities. The United Nations Framework Convention on Climate Change (UNFCCC) stated that climate change is greatly dependent on human activities that alter the atmospheric equilibrium as well as natural climate change overtime (FAO 2008). Climate change is a global phenomenon that has affected man and his environment (IPCC 2014a, b). Climatic changes manifest in the form of weather variations in temperature and precipitation. Adaptation and mitigation strategies are needed in tackling climate change impacts. Climate adaptation has to do with the capacity to manage variations in climate to minimize possible risks, explore new opportunities, or even both. Most African countries like Nigeria are more susceptible to climate change challenges because they are less aware, suffer more exposure, and have reduced potential for adaptation. Changes in climate are greatly affecting agriculture because it is a substantial source of revenue for the nation. Low level of education, poverty, insufficient infrastructure, and poor planning has contributed to increased exposure to risks in climate. It is therefore said to be involuntary in action and not limited to any particular geographical location. It can increase the virulence of disease-causing organisms (pathogens and pests) and also introduce new alien diseases arising from man-made activities or nature. Climate change could be a short or prolonged change in weather parameters that are already being experienced or forecasted as induced by anthropogenic emissions of noxious gases such as carbon dioxide (Parry et al. 2007). Climate change effects are already being felt globally and even in Africa (Creech et al. 2014). There are variations in climate change impacts from one location to another; for example, in some African countries, there have been cases of increased rainfall pattern and drought (Creech et al. 2014). These variations affect weather forecasting as there are hardly records of regularity in pattern of climatic parameters (Keller 2009). Variations in climatic factors such as increase in temperature and CO_2 affect plant’s nutritional quality and its phytochemical composition and invariably the animals that consume such plants. It could also lead to increase incidence and severity of epidemics (EU 2015).

Farmers, their households, and stakeholders in agriculture are at greater risk of climatic change since their activities are rain dependent (Pearce et al. 1996). Agriculture is a major source of employment for Niger Delta dwellers. Adaptation to climatic vulnerability is now a major challenge to farmers, researchers, and policy makers. Most adaptation strategies are geared toward eradication of poverty among households (Mertz et al. 2009). Most farmers are already using their local and traditional practices in trying to adapt to the changes in climate with its associated risks. Climate change adaptation refers to all the steps put in place over many decades to enable a system cope with perceived or actual challenges imposed by climate change (Fankhauser 2017). There is need to put up remediative measures to help recover the ecosystem from prolonged environmental pollution and eradicate associated diseases. To enable residents of Niger Delta remain in their localities and retain their occupation as farmers, it is necessary to seek good and durable adaptation strategies. Many adaptation practices have been employed in most communities. A strategy that will likely be of immense importance is one that will improve the soil productivity of the gas-flared areas. For adaptation to be effective, the reality of climate change impacts must be appreciated (Deressa et al. 2011). The way and manner farmers view climate change determines their approaches toward handling its associated challenges. Their behavioral changes to climate change will influence adaptation options and its effects (Adger et al. 2009). Therefore, a close assessment of farmer's perception of climate risks and their specific adaptation measures will foster better understanding of their local exposure to climate risks, the farmer's adaptive capacity to cope with climate change, as well as to enhance policy formulation to tackle challenges that climate change pose on farmers. Intergovernmental Panel on Climate Change (IPCC) has postulated that the adverse effects of climate change will impact many lives globally in the years to come. Trends in rainfall are expected to drift from normal to abnormal with some areas having less rainfall while others have excess. Maturation time of crops will also be affected by increased temperatures especially in the tropics in the next 10 years. This will ultimately affect global food security and health of man (IPCC 2014a).

As a way to make agricultural activities sustainable in the Niger Delta in the face of climate risks, scientists have attempted different procedures with specific interest in those with little or no side effects to the ecosystem. Biochar is a good example of such material that has been used for soil enrichment with great potentials for soil remediation. Biochar is a biomolecule that is used to amend soils with a view to improving its biological and physical characteristics. It is made by pyrolysis of biomass at temperature range of 204–482 °C in the presence of little or no oxygen (Swanson 2013). Biochar is rich in carbon (Lehmann and Joseph 2009). It has the immense advantage of being of biological origin. Biochar improves soil physical and chemical properties, fertility, and nutrient availability (Houben et al. 2013). It reduces bioavailability of heavy metals to plants and organisms by adsorbing them (Al-Wabel et al. 2014). It also stabilizes carbon in the soil, reduces the carbon dioxide in the atmosphere (Fang et al. 2015), and reduces greenhouse gas emission (Galloway et al. 2008). Its advantage over other sources of carbon is that it keeps carbon long in the soil (Nguyen et al. 2008). Biochar is more durable and effective compared to other carbon sources; it lasts for up to 10,000 years when applied to soil. Stability of biochar depends on its pyrolysis temperature, source material, and soil type (Lehmann and Joseph 2009). Biochar helps in the breakdown of polyaromatic hydrocarbon and adsorbs heavy metals, making them biologically unavailable (Gorovtsov et al. 2018). When biochar is used as a carbon source in soils, the quantity of greenhouse gases emitted decreases by 12% yearly (Woolf et al. 2010). It is a good remediation material that reduces water loss and improves nutrients of soil (Woolf et al. 2010). Use of biochar for agricultural purposes has proven to be a good climate change adaptation practice in the face of threating global warming and climate change (Lehmann et al. 2006; Woolf et al. 2010). Biochar use is not only is environmentally friendly but also alkalinizes soil (O'Neill et al. 2009) and improves crop growth and development (Graber et al. 2010). Biochar improves soil fertility and has great potential for restructuring the ecosystem. It also increases nutrient bioavailability (Wang et al. 2012), leading to production of healthier crops as well as growth of important microorganisms (Bailey et al. 2011; Smith et al. 2010). It improves soil physicochemical properties like organic carbon, cation exchange capacity, and pH (Lehmann 2007). Under normal conditions, carbon dioxide is released from decaying plant matter and serves to balance the carbon cycle. The mechanism of action of biochar is that it forms a strong bond with carbon making it assume a very stable configuration and hence slows the process of decomposition. Biochar use traps carbon in the soil while hindering its migration into the atmosphere in the form of CO_2. This is therefore a good adaptation process for farmers in gas flaring areas of the Niger Delta region. This will reduce soil water loss and increase soil carbon concentrations and food security (FAO 2008). Biochar has the ability to adsorb toxins, making it unavailable for plant uptake (Sohi et al. 2009). Akachukwu et al. (2018) reported that biochar application enhanced the mineral content of *Telfairia occidentalis* that was cultivated on gas-flared polluted soil. This chapter compared and evaluated the farmers' perception of gas flaring and effect of biochar on heavy metal composition of *Telfairia occidentalis* leaves cultivated on gas-flared polluted soils and non-gas-flared soils.

Materials and Methods

Study Area

This research was conducted with soils collected from two locations, gas-flared area in Ohaji/Egbema L.G.A of Imo State (longitude N 05° 33.5′ and latitude E 06° 45.2′) and non-gas-flared area of Ikwuano L.G.A in Abia state (Longitude N 05° 28.5′ and Latitude E 007° 32.5′) at a depth of 0–20 cm using a sterile auger. The soil was stored in clean jut bags and transported to the greenhouse of the National Root Crops Research Institute, Umudike, Abia State. All the soil samples were collected in April.

Sociodemographic Data

Well-structured questionnaires were administered randomly to vegetable farmers in the two study sites to assess their perception of gas flaring and its effects on vegetable cultivation and farmers' livelihood.

Biochar Preparation

Biochar was prepared from sun-dried palm bunches by pyrolysis at 450 °C in a drum kiln. After cooling, it was milled to finer particles, sieved with a 3 mm^2 mesh, and subsequently stored in a clean dry bag until it was ready for use (Karamesouti and Gasparatos 2008).

Soil Preparation and Biochar Application

Four kilograms of the soil was weighed into clean plastic container. Biochar was applied to the soils at a rate of 0 t ha^{-1}, 7.1 t ha^{-1}, 13.9 t ha^{-1}, 20.9 t ha^{-1}, and 28.0 t ha^{-1} in three replicates. The soils and biochar were properly mixed, watered, and allowed to mineralize for 2 weeks.

Procurement, Cultivation, and Growth Indices of *Telfairia occidentalis*

Mature and viable seeds of *T. occidentalis* were obtained from a local market at Ndoro, Ikwuano L.G.A, Abia state, Nigeria. Two seeds were cultivated per container and watered once every 2 days. The growth parameters were measured at an interval of 2 weeks. Matured leaves were harvested after 8 weeks of germination, and samples were air-dried and used for heavy metal determination. Growth indices were measured at 2 weeks interval for 8 weeks. Plant height was measured with the aid of a ruler. Stem diameter was measured with the aid of a vernier caliper, while number of leaves was gotten by counting.

Heavy Metal Determination

A quantity of 0.2 mg of leaf sample was weighed into dry digestion tubes. Five milliliters of nitric acid was added, swirled, and allowed to stand overnight. Tubes were placed into a digestion block with the temperature gradually increasing from room temperature to 120 °C over about 2 h with periodical swirling of each tube. Thereafter, the temperature was increased to 180 °C until about 0.5 cm^3 of liquid remained. The digestion tubes were removed from the block and cooled at room temperature. The digest was diluted with ultrapure water, homogenized with a vortex mixer, and allowed to stand for a few hours prior to analysis. The heavy metal concentration was determined using an inductively coupled plasma optical emission spectrometer (ICP-OES) (Optima 8000, Perkin Elmer).

Data Analysis

The data obtained was analyzed using the Statistical Package for Social Sciences (SPSS) version 21.0 for Windows. Mean comparison was done using one way analysis of variance (ANOVA). Duncan multiple test was used to separate means. Significant values were set at $p \leq 0.05$. Data is presented as mean ± standard deviation (SD).

Results and Discussion

Figure 1 shows the result of effect of gas flaring on vegetable cultivation and farmers' livelihood. In all the study sites, more than 60% of vegetable farmers were female while approximately 40% were male. In the gas-flared area (test), almost all the farmers (97%) had knowledge of gas flaring while 62% only knew about gas flaring in the control. This could be because of the absence of gas flaring in

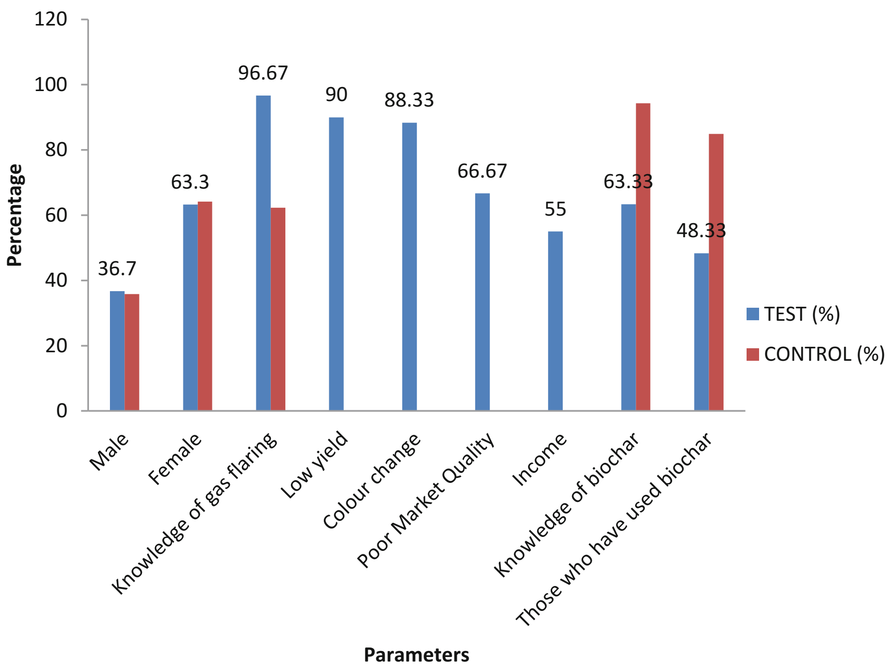

Fig. 1 Effect of gas flaring on vegetable cultivation and farmers' livelihood

the control area. Also, farmers in the test area had knowledge of biochar (94%) and had also used it (85%) unlike the control area where fewer farmers (63%) knew about biochar and had used it (48%). More than 50% of the farmers from the test area had experienced low yield, color change, poor market quality, and income reduction as a result of gas flaring activities. This could have impacted negatively on the farmers' standard of living, causing discouragement and lack of interest in farming and invariably affect food security. It could also be a subtle cause of youth restiveness that is prevalent in the Niger Delta area. There were no bar charts for control area possibly because of the absence of gas flaring in the control area.

Table 1 shows the growth indices of *T. occidentalis* grown on the gas-flared soil and non-gas-flared soil for 8 weeks. Plant height is an important physiological property useful for assessing the growth and cell differentiation in plants (Silva et al. 2019). It is also an expression of how well a plant is able to optimally utilize soil available nutrients. There was general increase in plant height as the weeks progressed from 2 to 8 weeks for vegetables grown on GFTO and NGFTO, respectively. However, the vegetables grown on the gas-flared soils (GFTO, test) showed higher plant height than those grown on the non-gas-flared soil (NGFTO, control). The 0 t ha^{-1} had no evidence of growth after the first 2 weeks. The 7.1 t ha^{-1} group had the highest initial plant height (25.77) for the test vegetable, while the 28.0 t ha^{-1} group had the highest (25.87) for the control. The pattern of plant height obtained is similar to that of maize plant treated with *Daniella oliviera* wood biochar reported by Aminu and Shamsuddeen (2019). Stem diameter of test vegetables was higher than the control in a non-dose-dependent manner and also reduced with increase in number of weeks in both the test and control vegetables; however, their differences were not statistically different. Dispenza et al. (2016) obtained a dose-dependent increase in stem diameter for substrates of *Euphorbicia* treated with 20%, 60%, and 80% conifer wood biochar. Number of leaves increased with increase in weeks (Okonwu and Mensah 2012).

Table 2 presents the heavy concentration of *T. occidentalis* leaves cultivated on biochar-remediated soils from gas-flared and non-gas-flared area. The Fe and Zn concentrations of the gas-flared *T. occidentalis* (GFTO) decreased from 13.9 t ha^{-1} to 28.0 t ha^{-1} biochar while that of the non-gas-flared *T. occidentalis* (NGFTO) decreased from 0 t ha^{-1} to 20.9 t ha^{-1} biochar. There was no significant ($p > 0.05$) difference in Fe concentration between the GFTO and NGFTO except for the 13.9 t ha^{-1} biochar group that was markedly increased in the GFTO vegetable. No significant difference was observed in Cu concentration for GFTO and NGFTO for all the groups except for the 7.1 t ha^{-1}, 13.9 t ha^{-1}, and 20.9 t ha^{-1} biochar groups that were significantly lower for NGFTO compared to the control. Lead (Pb) and Cr concentrations were significantly ($p < 0.05$) higher for GFTO from 7.1 t ha^{-1} biochar, while its concentration decreased from 7.1 t ha^{-1} to 20.9 t ha^{-1} biochar compared to their control. Cobalt concentration was highest for GFTO treated with 7.1 t ha^{-1} biochar while that of 28.0 t ha^{-1} GFTO had the least. In the NGFTO, the cobalt concentration decreased from 7.1 t ha^{-1} to 20.9 t ha^{-1} biochar. Cadmium concentration in both the GFTO and NGFTO decreased with increasing biochar concentration. Nickel concentration was highest in the GFTO-treated with 7.1 t ha^{-1}

Table 1 Effect of biochar remediation on the growth parameters of *T. occidentalis* cultivated on gas-flared and non-gas-flared soils

biochar and lowest for the 28.0 t ha^{-1} biochar-treated group, while the NGFTO treated with 20.9 t ha^{-1} biochar had the least nickel concentration. Biochar administered to the two soils reduced uptake by plants as shown by our result. Human beings are often exposed to heavy metal contamination through the food chain as they are transferred from soil to plants (Khan et al. 2010). They cause serious health challenges when their concentrations exceed the normal threshold (Al-Wabel et al. 2014). Some heavy metals are known to alter normal body metabolism, disrupt transfer of hereditary materials from parents to offsprings, and affect proper growth and development of fetus (Ali et al. 2013). Heavy metals such as chromium, copper, cadmium, and lead are well known for their toxicity when consumed at concentrations beyond the permissible limits (Dursun 2006; Kurniawan et al. 2006). Copper contamination can cause gastrointestinal cancer in humans (Turkdogan et al. 2003). Cadmium toxicity is responsible for kidney damage and can cause "itai-itai" in man. Zinc is an essential element that is toxic at higher concentrations (Baccio et al. 2005). Chromium is harmful to plants and animals; chromium (IV) ion alters soil biological activities and is carcinogenic (Javied et al. 2009). Cobalt causes bone marrow hyperplasia, acute poisoning, allergic reactions, seizures, and paralysis of nervous system. Lead is very poisonous; it affects the cardiovascular system and causes stroke and cognitive impairment (Evangelou et al. 2007). Our finding has shown that heavy metal adsorption by the *T. occidentalis* leaves decreased as the rate of biochar application increased with 20.9 t ha^{-1} being the most effective. This result suggest that using biochar to cultivate this vegetable could lead to production of better quality vegetables, reducing the prevalence of heavy metal toxicity and hence improving nutrition of the consumers.

Conclusion

The chapter has shown that vegetable farming is mostly engaged by females. Biochar use enhanced the growth parameters and reduced heavy metal uptake by the plants. Therefore, biochar use should be encouraged to remediate heavy metal polluted soils, to ensure maximum crop yield and food security. Increased sensitization is needed to encourage the use of biochar in gas flaring polluted areas to ensure that good quality vegetables are available for consumers.

Acknowledgments This research is supported by funding from the Department for International Development (DFID) under the Climate Impacts Research and Leadership Enhancement (CIRCLE) program.

Abstract

Environmental degradation, soil erosion, and desertification are some of the consequences of high rate of traditional biomass fuel use by households in developing countries. The critical issues to raise here are how can these households be encouraged to change their energy consumption behavior? What are the factors that cause the rampant use of biomass fuel in developing countries? How and to what extent can these factors be manipulated so that households in developing countries are encouraged to adopt clean energy fuel an alternative to the most widely used biomass fuel? Therefore, this chapter tries to find answer to the above questions raised, by carrying out an in depth analysis of households' use of biomass fuel in developing countries using Bauchi State, Nigeria, as the case study. Cluster area sampling technique was utilized to generate the various responses, where a total number of 539 respondents were analyzed. The study estimated ordered logit model to analyze the factors that influence the movement of households along the energy ladder from nonclean energy to the cleaner energy. Furthermore, Ordinary Least Squares (OLS) model was estimated to analyze the impacts of socio-economic, residential, and environmental factors on biomass energy consumption. It was found that age of the household head and his level of education, income, living in urban areas, home ownership, and hours of electricity supply have positive and significant impact on household energy switching from traditional biomass energy use to the cleaner energy. Therefore, policies that will enhance household income and the increase in the availability of cheap cleaner energy will encourage households switching to cleaner energy sources thereby reducing the level of environmental pollution in the study area.

Clean-energy · Households · OLS, Ordered-logit · Traditional-biomass

Introduction

Climate change which is the variation in climate overtime and its impacts on the environment and socio-economic systems now constitute the most important environmental problem facing mankind. According to UNDP (2013), climate change can affect both the human and the entire natural systems which pose a threat to human development and survival. Among the most important factors that caused climate change and environmental pollution is the wide spread use of biomass energy. Biomass fuels, which constitute animal dung, crop residues, fuel-wood, and charcoal, are among some of the most widely used fuels for cooking and heating, particularly in developing countries (Yamamoto et al. 2009). Currently, more than two billion people rely on biomass fuel globally to satisfy their basic energy needs. That is why this type of fuel accounts for about 20% of energy supply for the whole world. IEA (2011) argued that if proper measures were not taken, the number of biomass fuel users globally may increase to about 2.7 billion people by the year 2030. A large number of biomass energy users, especially in traditional ways, are found mostly in Asia and Africa. For instance, the IEA (2011) reported that biomass fuel accounts for more than 50% of Africa's energy utilization. In Nigeria, the wide use of biomass fuel at household level is more than 70%. Coming down to the state level, the rate of biomass fuel use by households is about more than 90% in Bauchi State, Nigeria (NBS 2012).

However, such wider use of biomass fuel is unwholesome for human living and their environment. For instance, when combining CO_2 emissions and other GHG in a single index, biomass fuel scores much higher than other fossil fuels like LPG and kerosene. Moreover, there is higher correlation between the use of biomass fuel and indoor air pollution (Desalu et al. 2012; Risseeuw 2012). Such indoor air pollution causes about 1.5 to 2 million losses of lives worldwide yearly. Environmental degradation, soil erosion, and desertification are some of the consequences of high rate of biomass fuel use in developing countries. In fact, Nigeria has been facing an annual average rate of deforestation over a previous decade due to high rate of biomass fuel use. Available data has shown that the nation's 15 million hectares of forest and woodland reserves could be depleted within the next 50 (Nnaji et al. 2012). In Bauchi State, the rampant use of biomass energy is so great to the extent of more than 600 kg per household monthly (Danlami et al. 2017). This has posed negative impacts on the inhabitant of the State such as the systematic destruction of the State's forest reserves and woodlands, soil erosion, and desertification whereby the State losses not less than 1 km of land yearly due to desertification as a result of high rate of felling trees (Danlami et al. 2017).

That is why the defunct United Nations Millennium Project recommended halving the number of households that depend on traditional biomass fuel by the year 2015, the target that was not complied by most of the participating countries including Nigeria (Naibbi and Healey 2013). The critical issues to raise here are that how can these households be encouraged to change their energy consumption behavior? what are the factors that cause the rampant use of biomass fuel in developing countries? how and to what extent can these factors be manipulated so that households in developing countries are encouraged to adopt clean energy fuel an alternative to the most widely used traditional biomass fuel? This is because clean fuel has greater capacity to do useful work. The use of clean fuel is an imperative to improve the standard of living of the households that heavily rely on biomass fuel (Lee 2013). Therefore, in line with the above issues raised, this chapter tries to find answer to the above questions raised by carrying out an in depth analysis of households' use of biomass fuel in developing countries using Bauchi State, Nigeria, as the case study. The remaining part of the chapter consists sections as follows. Section "Literature Review" constitutes review of related literature. Section "Theoretical Frameworks" is theoretical and conceptual frameworks of the study. Section "Methodology" highlights the methodology adopted. Section "Analysis" the discussion of findings. Section "Conclusions" highlights chapter conclusion. The last section constitutes the policy implications and recommendations.

Literature Review

Studies that analyzed energy utilization can be classified into two categories. The first group consists of those studies (Danlami et al. 2018a, 2019a) that analyze aggregate energy consumption using time series data. Most of these studies concluded that energy consumption is highly correlated with environmental degradation. However, these conclusions have limited practical applicability at a microlevel, because the energy consumption behavior of households is heterogeneous, which is usually ignored in studies that utilized time series data. Moreover, the second category of studies are those that analyzed household energy consumption using microdata approach (Lee 2013; Mensah and Adu 2013; Ozcan et al. 2013; Abdurrazak et al. 2012; Couture et al. 2012; Laureti and Secondi 2012; Onoja 2012; Oyekale et al. 2012; Song et al. 2012; Ganchimeg and Havrland 2011; Jingchao and Kotani 2011; Jumbe and Angelsen 2010; Osiolo 2010; Suliman 2010; Danlami and Islam 2020; Danlami et al. 2017; Nlom and Karimov 2014; Ogwumike et al. 2014). These studies arrived at different conclusions based on the socio-economic, demographic, home, and environmental characteristics of the households under consideration.

The composition and type of socio-demographic factors of households determine their fuel switching and consumption behavior. For instance, Laureti and Secondi (2012) indicated that households which comprise of couples with children tend to adopt less of oil and electricity and more of coal-wood when compared with a household of a single person. This is contrary to the findings by Danlami et al. (2017) which concluded that the household that is headed by a married individual has higher odd of adopting clean fuel than otherwise. Whereas some previous studies (Osiolo 2010; Jumbe and Angelsen 2010; Nlom and Karimov 2014) reported no significant relationship between the gender of the household head and its energy consumption behavior, a study by Mensah and Adu (2013) found that there is a significant negative relationship between the household head being male and the adoption of clean energy. Meanwhile, age of the household head was found to have a negative impact on the adoption of clean energy (Suliman 2010; Mensah and Adu 2013; Nlom and Karimov 2014). Households adopt less clean energy source when the head is older. Additionally, the household head level of education was found to exact a positive impact on the adoption of clean energy. The higher the level of education of the household head, the lower the probability of adopting nonclean energy (Eakins 2013; Mensah and Adu 2013; Ozcan et al. 2013). The number of a household's members (i.e., household size) affects the household's energy switching decision, the larger the size of a household, the lesser the adoption of clean energy. This assertion is supported by previous studies (Ozcan et al. 2013; Mensah and Adu 2013; Suliman 2010; Heltberg 2005).

The factors that measure the economic status of the household influence the households' fuel consumption decision. For instance, studies have established that there is a positive relationship between income and adoption of clean energy (Danlami et al. 2017; Mensah and Adu 2013; Ozcan et al. 2013; Couture et al. 2012). Poorer households especially in developing countries tend to adopt biomass fuels like firewood, plant residues, and animal dung. Furthermore, number of energy consuming appliances increases the quantity of energy consumption by households (Danlami 2017a; Eakins 2013). The higher the number of energy consuming appliances at home, the lesser the odd of adopting biomass source of energy (Danlami 2017b). Moreover, energy price has a negative relationship with energy consumption. When the price of a particular energy source is high, households switch to other alternative fuel available. This is in line with law of demand and also has been established by previous studies (Danlami 2017a; Nlom and Karimov 2014; Lee 2013).

Furthermore, the characteristics of the building in which the households live also affect their energy choice behavior. Factors such as size of the building, number of rooms in the home, share of dwelling and dwelling ownership have been established by previous studies to influence the manner of household energy consumption behavior (Danlami et al. 2017; Eakins 2013; Mensah and Adu 2013; Tchereni 2013). Lastly, environmental factors such as location of home, the extent of electricity supply, the main source of cooking, and lighting fuel in the area were found to influence the manner of household energy consumption. Households that live in the rural areas or the area whereby there is a wide spread use of biomass fuel tend to adopt biomass fuel as their main source of energy (Danlami 2017a, b; Ozcan et al. 2013).

Based on the above-reviewed literature, it can be seen that there exist inconsistences as per the findings and conclusions of previous studies on the factors influencing household energy consumption and switching behavior, from one place to another, due to differences in environmental factors, cultural factors, socio-economic settings, as well as differences in the average level of development among different regions. Therefore, additional study on household energy choice and consumption in a specific area is an addition to the existing literature as argued by the previous studies (Danlami et al. 2015, 2017).

Theoretical Frameworks

Households mostly use energy for indirect satisfaction mainly to produce another commodities or services (modified from Danlami et al. 2016). Households utilized energy from different sources for the purpose of maximizing satisfaction. This optimal level satisfaction is usually attained at the equilibrium point of particular energy consumption. For instance, equation (1) indicates a given utility function of energy consumption:

$$U = f\left(\in_c \mathrm{G}_s\ \mathcal{L}_f\ \mathcal{B}_b\right) \tag{1}$$

Subject to household budget constraint as in equation (2):

$$Y = \mathrm{P}_c \in_c + \mathrm{P}_s \mathrm{G}_s + \mathrm{P}_f \mathcal{L}_f + \mathrm{P}_b \mathcal{B}_b \tag{2}$$

where U = utility, $\in_c$ = electric energy, G_s = gas energy, $\mathcal{L}_f$ = liquid energy (i.e., fuel), $\mathcal{B}_b$ = biomass energy, Y = income of household and P = price of the relevant energy.

To find the maximum point of household energy utilization, we form Langarangian multiplier function as in equation (3):

$$L = f\left(\in_c G_s\ \mathcal{L}_f\ \mathcal{B}_f\right) + \lambda\left(Y - P_c \in_c + P_s G_s + P_f \mathcal{L}_f + P_b \mathcal{B}_b = 0\right) \quad (3)$$

Using equation (3), we can analyze the maximum point of utility for:

(i) Household that use only one of these energy sources
(ii) Households that use all of these energy sources

Equilibrium Level of Utility for Households That Use Only One of These Energy Sources

Assuming the households use only electricity as its sole source of energy, the utility maximization point will be

$$\frac{\partial L}{\partial \in_c} = f'_c - \lambda P_c = 0 \quad (4)$$

$$f'_c = \lambda P_c \quad (5)$$

Since the household utilized only single source of energy, $\lambda = 1$

$$f'_c = P_c \quad (6)$$

Equation (6) indicates the point of utility maximization from using electric source of energy where the marginal utility obtained from consuming extra unit of electricity is equal to the price of that additional unit of electricity. Any increase in the consumption of electricity above the equilibrium level implies decrease in the total utility, while consumption of electricity below the equilibrium level implies that the total utility of electricity is not maximized because additional unit of electricity consumed will lead to increase in the total utility, until the above equilibrium point is reached.

Equilibrium Point for Households That Use Gas as Their Only Source of Energy

In this case, we conduct the partial derivation of equation (3) with respect to gas. This is indicated in equation (7):

$$\frac{\partial L}{\partial G_s} = f'_s - \lambda P_s = 0 \tag{7}$$

$$f'_s = \lambda P_s \tag{8}$$

By definition, $\lambda = 1$, therefore, the utility maximization point will be

$$f'_s = P_s \tag{9}$$

that is, the point where the additional satisfaction obtained from using extra amount of gas is equal to the price of that additional unit of gas.

Derivation of Equilibrium Point for Households That Use Liquid Fuel as the Only Source of Energy

Here, we find the partial derivative of equation (3) with respect to the liquid fuel as in equation (10):

$$\frac{\partial L}{\partial \mathcal{L}_f} = f'_f - \lambda P_f = 0 \tag{10}$$

$$f'_f = \lambda P_f \tag{11}$$

Since $\lambda = 1$ (for households that use only one source of energy)

$$f'_f = P_f \tag{12}$$

Utility Maximization Point for Households That Use Only Biomass Energy

The partial derivative of equation (3) with respect to biomass energy is given by:

$$\frac{\partial L}{\partial \mathcal{B}_b} = f'_b - \lambda P_b = 0 \tag{13}$$

$$f'_b = \lambda P_b \tag{14}$$

Since $\lambda = 1$

$$f'_b = P_b \tag{15}$$

Equation (15) indicates the utility maximization point for household that utilizes only biomass energy. This is the point where the additional satisfaction obtained from using an additional bundle of biomass energy is equal to the price of that additional bundle.

Utility Maximization of Households That Use All the Four Source of Energy Together

In this situation, the utility of using energy is maximized, by consuming the energy up to the level where the ratio of extra satisfaction from using the additional amount of energy to their prices is equal. Taking back the earlier Langarangian multiplier utility function and the constraints for energy use

$$L = f\left(\in_c \mathrm{G}_s\ \mathcal{L}_f\ \mathcal{B}_b\right) + \lambda\left(Y - \mathrm{P}_c \in_c + \mathrm{P}_s\mathrm{G}_s + \mathrm{P}_f\mathcal{L}_f + \mathrm{P}_b\mathcal{B}_b = 0\right) \tag{16}$$

The partial derivatives with respect to each of the energy source are:

$$\frac{\partial L}{\partial \in_c} = f_c' - \lambda P_c = 0 \tag{17}$$

$$\frac{\partial L}{\partial \mathrm{G}_s} = f_s' - \lambda P_s = 0 \tag{18}$$

$$\frac{\partial L}{\partial \mathcal{L}_f} = f'_f - \lambda P_f = 0 \tag{19}$$

$$\frac{\partial L}{\partial \mathcal{B}_b} = f_b' - \lambda P_b = 0 \tag{20}$$

$$\lambda = \frac{f_c'}{P_c} = \frac{f_s'}{P_s} = \frac{f'_f}{P_f} = \frac{f_b'}{P_b} \tag{21}$$

That is the utility maximization point for households that use all the four source of energy is for them to consume at the point where the ratio of the extra satisfaction from using additional unit from each of the energy source to their prices are equal.

Methodology

Following Danlami et al. (2019b), the total sample size was determined based on Dillman (2011). A total of 750 questionnaires were distributed based on cluster area sampling method. Finally about 548 filled questionnaires were returned back (which is more than 70% of the total number of the issued questionnaires) out of which 9 questionnaires were discarded. Multistage cluster sampling was utilized as the sampling technique.

Model Specification

Ordered Logit Models

In order to satisfy the first objective of this chapter which is to assess the determinants of household fuel switching up the ladder from traditional biomass energy to the cleaner source of energy, ordered logit model was employed. Since household fuel switching consists of movement up the energy ladder in a hierarchical order which is the basis for ordered models (Kofarmata 2016). Therefore, due to the ordinal nature of the dependent variable, it is stated as movement in fuel the household switching from traditional biomass energy, transitional energy (kerosene), and the cleaner energy (gas and electricity sources of energy). Thus, the model can be stated as in equation (22):

$$y_i = \beta X_i + \varepsilon_i \tag{22}$$

where y_i is the observed and exact dependent variable (categories of fuel switching in hierarchical order); coded as 0, 1, ...n, X_i is the vector of the independent variables. β is the vector of parameters to be estimated and ε_i is the random variable for the ordered logit model.

If the score on the observed variable say y_i is 0, means that the household uses traditional biomass energy. However, if the household adopts the transitional fuel (such as kerosene), then $y_i = 1$; and if the household adopts cleaner source of energy (electricity/gas) then $y_i = 2$. Then the estimated empirical model is written as:

$$\begin{aligned} Y_i = {} & \alpha_0 + \beta_1 \mathrm{GEN}_i + \beta_2 \mathrm{AGE}_i + \beta_3 \mathrm{EDU}_i + \beta_4 \mathrm{HHS}_i + \beta_5 \mathrm{INC}_i + \beta_6 \mathrm{LOC}_i \\ & + \beta_7 \mathrm{NRM}_i + \beta_8 \mathrm{DSH}_i + \beta_9 \mathrm{HRSE}_i + \beta_{10} \mathrm{PFW}_i + \beta_{11} \mathrm{NCF}_i \\ & + \beta_{12} \mathrm{HAPP}_i + \beta_{13} \mathrm{HOWN}_i + \varepsilon_i \end{aligned} \tag{23}$$

Y_i = The dependent ordered variables summarized as: Traditional biomass ($y_i = 0$), Transitional energy ($y_i = 1$) and Cleaner energy ($y_i = 2$)
GEN_i = Gender of the head of household
AGE_i = Age of the head of household
EDU_i = Level of education of the head of household
HHS_i = Size of the household
INC_i = Monthly income of the head of household
LOC_i = Home location of the household
NRM_i = Number of rooms in the home
DSH_i = Size of the dwelling of the household
HRSE_i = Hours of electricity supply

PFW_i = Unit price of firewood per bundle
NCF_i = Similarity with the neighbor's main cooking fuel source
$HAPP_i$ = Home appliances
$HOWN_i$ = Home ownership

The OLS Model

Another objective of this study is to assess the determinants of household for biomass energy in Bauchi State.

Following Danlami (2014) and Lee (2013), the implicit form of the relationship between households' consumption of a particular energy and its determinants can be expressed as:

$$Y_i = \beta_0 + \sum_{i=0}^{k} \beta_i X_i \tag{24}$$

where Y_i is household i's consumption of biomass energy.

The estimated empirical OLS model for households' biomass energy consumption is expressed as:

$$\begin{aligned} ln\,\mathrm{FWD}_i = \alpha_0 + \beta_1 \mathrm{GEN}_i + \beta_2 \mathrm{AGE}_i + \beta_3 \mathrm{MST}_i + \beta_4 \mathrm{EDU}_i + \beta_5 \mathrm{HHS}_i \\ + \beta_6 \mathrm{INC}_i + \beta_7 \mathrm{PFW}_i + \beta_8 \mathrm{PKR}_i + \beta_9\, ln\,\mathrm{HAPP}_i + \varepsilon_i \end{aligned} \tag{25}$$

where
FWD_i = Quantity of firewood bundle consume monthly.
GEN_i = Gender of the head of household
AGE_i = Age of the household head
MST_i = Marital status of the head of household
EDU_i = Level of education of the head of household
HHS_i = Size of the household
Inc_i = Monthly income of the head of household
PFW_i = Unit price of firewood per bundle
PKR_i = Price of kerosene per liter
$HAPP_i$ = Number of home appliances own by household

Analysis

This study mainly analyzes two issues: household energy switching and the extent of household traditional biomass energy use. Table 1 indicates the estimated ordered logit model analyzing the determinants of household energy switching. Furthermore, Table 2 exhibits the estimated OLS model for the determinants of household

traditional biomass consumption. The analysis and discussions of the estimated models are carried out in the following sections:

Determinants of Household Energy Switching

The first objective of this study is to assess the factors that determine the household movement along the energy ladder from traditional biomass energy to the available cleanest energy (electricity) in Bauchi State. To achieve this objective, ordered logit model was estimated and the result of the estimation is indicated in Table 1.

Based on the probability value of the Chi sq (X^2), in Table 1, the estimated ordered logit model is jointly significant at 1%, thereby implying the validity of the estimated ordered model. The result indicates that the coefficient of variable Age is statistically significant at 10% level. The result indicates that there is a positive relationship between the age of the household head and the household energy switching. A 1 year increase in the age of the household will lead to a 0.023 log odd of household being in higher level of cleaner energy. This is in line with a priori expectation and conforms to the findings of Danlami (2017c). In the same vein, the coefficient of education was found to have a positive relationship with the household energy switching. The coefficient of the variable was found to be statistically significant at 5% level. The estimated result shows that an increase in the level of education of the household head increases the log odd of household switching to cleaner energy by about 0.087 units. This is in line with a priori expectation because when the household head is more educated, he will have more awareness about the negative effects of using traditional biomass energy. This result supports the findings from Danlami et al. (2018b).

Contrarily, the coefficient of household size was found to have a negative relationship with the household energy switching. This coefficient was found to be statistically significant at 1% level. Based on the estimated result, a one unit increase in the number of household size decreases the log odd of switching to cleaner energy by about 0.115 units. This is in line with the findings of Danlami et al. (2019c). The coefficient of household income was found to be statistically significant at 1% level. The estimated result indicates that a 1% rise in the household income leads to increase in the log odd of household switching to the cleaner energy by about 0.011 units. This is in line with a priori expectation because as the household income increases, the affordability of the household to substitute traditional biomass energy with a cleaner energy increases. This supports the findings of Danlami (2017a). Similarly, the coefficient of household location was found to have a positive relationship with the household energy switching and it was found to be statistically significant at 10% level. Based on the result of the estimated ordered logit model, households that reside in urban areas of Bauchi State have higher log odd of switching to cleaner energy by about 0.612 units compared to their rural counter parts. This is in line with a priori expectations that the households living in urban areas adopt cleaner energy than the households living in the rural areas mainly due to economic, social, and educational factors. The exact fact is that cleaner sources of energy are more available in urban than in rural areas, which is in line with the findings of Danlami et al. (2018c).

The coefficient of hours of electricity supply was found to be statistically significant at 1% level and it was found to have a positive relationship with household energy switching. Based on the estimated model, 1 h increase in electricity supply increases the households' log odd of switching to cleaner energy by about 0.015 units. This conforms to a priori expectation that the tendency of households to move up the cleaner energy ladder increases when the electricity supply becomes more available and reliable. This supports the findings of Danlami et al. (2018b). Finally, the coefficient of home ownership was found to be statistically significant at 5% level. Based on the estimated ordered logit model, there is a positive relationship between the coefficient of home ownership and switching to cleaner energy in Bauchi State. The households that live in their self-owned home have higher log odd of switching to cleaner energy by about 0.607 units than otherwise. This is in line with the findings of previous studies (Danlami et al. 2018b)

Determinants of Household Traditional Energy Use

Another objective of this study is to assess the factors that influence the quantity of traditional biomass energy use in Bauchi State, Nigeria. The result of the estimated model is in Table 2.

Based on Table 2, the estimated result shows that overall, the model is statistically significant at 1% level with an estimated F-value = 5.63 and the corresponding probability value Prob(F) = 0.000. The result in Table 2 has shown that the estimated coefficient of marital status is statistically significant at 5% level. On average, the households that are headed by a married person consume less traditional biomass energy by about 14% lower compared to the households that are headed by a nonmarried person. This does not conform to a priori expectation because the expectation is that when the head of a household is married, it means more number of household members which necessitates the use of more traditional biomass fuel such as firewood. However, this may be because the married household head in some cases signifies that he is at least more economically stronger to buy cleaner fuel than firewood. Based on the culture of the people in the study area, a person usually married when economically can afford the marriage responsibilities of which the purchase of cooking fuel is among. This finding supports the findings of other previous studies (Danlami 2019).

Moreover, the coefficient of level of education of the household was also found to be negative and statistically significant at 10% level. Based on the estimated OLS model, an additional year in the level of education reduces the household's use of traditional biomass energy by about 0.78%. This conforms to a priori expectation that as more educated is the household head, the more he has health consciousness and also the more he knows the risk of using traditional biomass energy thereby minimizing the use of such energy. This is in line with the findings of Danlami (2017a) and Lee (2013). On the other hand, the coefficient of household size was found to be statistically significant at 1% and positively related to household use of traditional biomass energy. Based on the result shown in Table 2, increase in the number of household by one individual increases the household's use of traditional biomass energy by about 1.68%. This conforms to a priori expectation and is in line with the findings of previous studies (Danlami 2017a).

The result also indicates that there is a negative significant relationship between traditional biomass energy use and its price. A one Naira increase in the price of firewood decreases the rate of household traditional biomass energy use by about 0.3% all things being equal. This is tally with a priori expectation because as the price of the traditional biomass energy increases, the household will switch to the use of available cheaper and cleaner energy. Similarly, when the price of a commodity rises, the purchasing power of buyers decreases, leaving the consumer with the ability to buy less of that commodity. This finding is in line with traditional law od demand which says that the higher the price, the lower the quantity demanded and also supports the findings of. Lastly, the result shows that price of kerosene has a negative impact on traditional biomass energy.

Conclusions

This study analyzes household energy switching along the energy ladder using ordered logit model. Also, the study uses OLS regression model to analyze the determinants of household traditional biomass energy use. The age of the household head and his level of education, income, living in urban areas, home ownership, and hours of electricity supply have positive significant impact on household energy switching from traditional biomass energy use to the cleaner energy. On the other hand, household size was found to have a negative relationship with household energy switching. Furthermore, the estimated OLS model indicates that household size has a positive and significant impact on traditional biomass energy use, the higher the household size, the high the quantity of traditional biomass energy consumption all things being equal. Marital status, household head level of education, and the price of the traditional biomass energy have negative significant impact on household use of traditional biomass energy.

Policy Recommendations

Having conducted empirical investigation of household energy switching and traditional energy consumption in Bauchi State, Nigeria, the following recommendations were offered based on the study findings, in order to encourage households to switch to cleaner energy in the study area. Since increase in income was found to have significant impact in encouraging households' energy switching up to cleaner energy, policies and programs aimed at raising income earnings of individuals should be embarked upon to discourage the adoption and use of traditional biomass energy. Income can be increased via employment generation, wealth creation, increase in government expenditure, empowering small and medium scale industries, and skills acquisition and development programs.

The study finds that households that live in urban areas have higher probability and odd of switching to cleaner energy. In line with this finding, government should try to make cleaner energy available and affordable to rural dwellers as is in the urban areas. All the facilities that will ensure the availability of cheap cleaner energy in rural areas of the State should be established in order to encourage households to switch to cleaner energy in rural areas of the State.

The findings revealed that the level of formal education attainment by the household head has significant influence on switching to cleaner energy, the higher the level of education of the household head, the higher the odd of switching to the cleaner energy. Therefore, government should embarked upon policies to encourage higher education attainment of people leaving in the study area, especially rural areas whereby there are a large number of illiterate people. High rate of school enrolment can be increased via policies like free universal basic education programs, higher education enrolment at a subsidized rate, construction of more schools near to the people especially in rural areas, provision of more scholarships at higher levels, employing adequate number of teachers to meet the growing number of pupils, and increase in expenditure on educational facilities. The curriculum of the educational system should emphasize on the danger of high rate of environmental pollution and contamination especially in rural areas whereby the rate of awareness is very low.

Lastly, the study has found that adequate supply of electricity has significant impact on household switching to cleaner energy use. Therefore, provision of cheap and adequate electricity supply to households will encourage many households to use electricity as their main source of cooking and lighting, thereby reducing the rate of traditional biomass energy use.

Abstract

Agricultural production systems, for example, conservation agriculture, climate smart agriculture, organic agriculture, sustainable landuse management, and others, summarized under the term “sustainable intensification,” have been introduced in African countries to increase productivity and to adapt/mitigate CC (CCAM). But the productivity of smallholder farming systems in Africa remains low. High erosion, contaminated water, threatened human health, reduced soil water, and natural resources functionality, that is, ecosystems services, and decreased biodiversity dominate. Low support in the farm environment is also responsible for this situation.

It is hypothesized, based on the huge body of literature on CCAM, that the implementation of already existing arable and plant cultivation methods like crop diversity, alley crops, forage legume-based crop rotations, mulching, organic matter recycling, and reduced tillage intensity will increase CCAM performance and also farm productivity and income. Based on a brief analysis of CCAM relevant arable and plant cultivation methods and agricultural production systems potentials and challenges, this chapter offers guidance for further transforming climate robust African farming systems.

Keywords

Agricultural production systems · Arable and plant cultivation methods · Climate change adaptation and mitigation · Institutional environment · Smallholder farmers practices in Africa

Introduction

In this brief review, the discussion focuses on factors making smallholder farmers vulnerable to CC induced drought and floods and how they are able to cope with CC. The chapter refers to the farms internal management, the relevance of the diverse arable, and plant cultivation methods that are differently organized and highlighted in today’s agricultural production systems, which might contribute to adapt/mitigate climate change (CCAM), and how the institutional environment impacts a farmer’s capacity to apply CCAM.

This chapter summarizes contributions to CCAM with reference to the diverse mixed farming systems in East Africa. This region is so far of interest as it entails a broad range of African farming systems. Those farming systems with an annual rainfall between approx. 800 mm and 2.000 mm, annual or bi-annual rainfall patterns, and farm sizes between approx. 0.5 and 2.0 ha have been selected. With that the study excludes farming systems from mainly drought regions that however are asking for partly different farming solutions, which would open an additional chapter to discuss. So far, the review will offer a part of the whole picture on farm internal management strategies and relevant environmental (institutional) conditions specifically under East African conditions.

There is evidence that specifically Africans agricultural systems are challenged by climate change (IPCC 2018). To reach the SDG2 targets in the next decade, investment costs to reduce hunger in Africa for the next decade are tremendous (Mason-D'Croz et al. 2019). Such future pictures are based on mainstream agricultural practices, combined with all kinds of single agricultural practices, borrowed from latest discussed agricultural production systems (Gonzalez-Sanchez et al. 2019; Porter et al. 2019; Senyolo et al. 2018; Zougmoré et al. 2018).

The hypothesis, which is framing the analysis, argues that the systemic implementation of already existing arable and plant cultivation methods like crop diversity, alley crops, forage legume-based crop rotations, mulching, organic matter recycling, and reduced tillage intensity will increase CCAM performance and also farm productivity, and as a consequence also the income. The majority of recommendations to cope with CC on smallholder farms commonly involve single methods, such as diversified crop rotations, intercropping, relay cropping, alley cropping and silvo-pastoral systems, compost and manure management, pH regulation, mulching, and low tillage intensity. These methods are summarized as arable and plant cultivation methods, but are also discussed as "agroecological" methods. If properly managed, these methods can increase biodiversity and biomass production; close carbon and nutrient cycles, as well as optimize mineralization processes and increase carbon sequestration; decrease soil erosion; and optimize regulation of the micro- and mesoclimate and the water household. They can also be classified as the backbone of sustainable production, and as such, operate as ecosystems services. The single methods (crop rotation, mulching, . . .) arise in different combinations and partly different "accentuations," in specific agricultural production methods described with the terms "climate smart agriculture, sustainable landuse management, or organic agriculture" and summarized under the term sustainable intensification.

Literature corpus on this topic is huge. Most of the methods are mentioned in the latest report on CC (The IPCC' Special Report on Climate Change and Land. What's in it for Africa? (Dupar 2019 #156). But what is missing in this report is a systemic view and integration of the diverse practices that would make farming systems robust against CC. In other words, to clearly indicate that adoption of farming systems is no longer the adequate reaction on the dramatic situation driven by CC. Instead, there is need for a huge transformation of farming systems as a whole.

For discussing the hypothesis, a selection of reviews and empirical studies seems adequate, using the terminology of arable and plant cultivation, that is, agroecology methods, and selected agricultural production systems (e.g., climate smart agriculture, conservation agriculture and others) within the context of CCAM as key words. Main literature was selected between the years 2010 and 2020 by Google scholar including reviewed papers and grey literature (Majumder 2015), to make visible how far in the last decade, where conservation agriculture, climate smart agriculture, agroecology, or sustainable intensification became prominent in the debate, CCAM was discussed. There are some exceptions, where identified literature informed about earlier relevant sources. Using cropping systems as an example, for all sections with a specific topic, search was defined as follows: Smallholder farming AND cropping systems AND Climate change AND Africa/Review AND Smallholder farming AND cropping systems AND Climate change AND Africa. Following a stepwise saturation in a certain field of knowledge, that is, explicit, reproducible, and leads to minimum bias, further papers that indicate mainly same messages have been excluded (Grant and Booth 2009).

A quantification of applied CCAM is critical due to the fact that there is huge diversity of agroecological conditions and farming practices and that there is no empirical basis available for making such an assessment. Instead, a qualitative assessment of the impact of CCAM methods is applied to primarily understand specific characteristics in their context (see the methodological approach chosen by Dale 2010). For that a set of methods both single arable and plant cultivation methods as well the agricultural production systems have been selected that are well known to be relevant for CCAM.

CCAM Practices and Barriers for Their Implementation

This section reviews the most relevant single methods, their potential to contribute to CCAM, and farm productivity, and the barriers that hinder farmers from implementing them are discussed. Drought adapted varieties, irrigation, and water management technologies are not mentioned specifically. It is assumed that they are part of any CCAM approach.

Crop Diversity and Crop Rotations

In many farming systems, crop diversity in crop rotations is low. Currently, maize is the dominant crop in most crop rotations in Africa. The other land is planted mainly with cereals, grain legumes, and root crops and in some cases intercropped maize and grain legumes (Table 1) (Rusinamhodzi et al. 2012). These one-sided systems, with open soils with low root (< 1 t DM ha-1 a-1) and above ground biomass (< 2 t DM ha-1 a-1), lead to highly vulnerable soils over the whole African continent, continuously loosing fertile soils and the capacity to store water and nutrients. The key crops for moving to higher CCAM relevant ecological functions of cropping systems are forage legumes and forage-grain legumes with high root (> 2 t DM ha-1 a-1) and above ground biomass (> 4 t DM ha-1 a-1) that currently can only be found in some selected regions in pure stands or in combination with maize, known as push and pull system. The latter is a combination of Maize with undersown/intercropped

Table 1 CCAM relevant ecological functions of crops and cropping systems

[a]intercropping of cereals and grain legumes would increase the ecological functions of both crop groups with values between grain legumes and forage grain legumes

[b]crops with high biomass and grain production (e.g., cow pea, grass pea, lablab, mucuna, mung bean)

[c]alfalfa, centrosema, clover, desmodium, and others

desmodium and Napier grass as a trap crop to control stemborer and striga, a chemical ecology-based integrated pest management technology (Khan et al. 2016).

The transformation of cropping systems towards forage legume-based systems can increase the potential of CCAM (Forage legumes > Forage grain legumes > Intercropping systems), through relatively high below (3–6 t DM ha-1 a-1) and above ground biomass (5–15 t DM ha-1 a-1) and nitrogen fixation (50–300 kg N ha-1 a-1) of forage legumes (Kumar et al. 2018), efficiently reducing soil erosion (Sheaffer and Seguin 2003) and with positive impact on following cash crop yields (Traill et al. 2018). Nutrient acquisition and nutrient utilization are species and genotype specific and differ between crop families of grasses and legumes and between legumes (Gómez-Carabalí et al. 2010). Of relevance is the % lignin, C:N ratio, (lignin + polyphenol): N and C-to-N ratios (Thomas and Asakawa 1993). Evidence is also given that this crop group increases animal performance, where similarly the mentioned ratios are of relevance for the digestibility of forage legume feed (Schultze-Kraft et al. 2018).

The implementation of this crop group however is challenging for several reasons: the availability of seed material; the lack of knowledge about the potential impact of plant based nitrogen on the following crop performance; the idea that humans cannot eat forage legumes, and therefore cropping forage is a short-term loss of land for assuring food security, but one that overlooks the contribution of farm yard manure to increased crop yields as well as to the production of milk and meat.

It appears that forage legumes are not offered by either seed breeders, seed wholesalers, advisory services or researchers and policies, with some exceptions of selected species and regions. In the same way, farmers multiplication of seed material is an exception. The diversification of crop rotations with nonmainstream crops is limited because there is no demand by the markets, but also because of traditional food habits. Intercropping and relay cropping – two submethods of crop rotations – likewise can increase yield and income and are rarely implemented.

Mulching Strategies and Green Manure Cover Crops

It is commonly argued that mulch material contributes significantly to the ecological functions and CCAM (Table 2). Already small amounts of mulch material positively impact soil parameters (Mchunu et al. 2011). However, most smallholder farms have no left-over organic matter from their arable fields. All the straw and weeds are consumed by animals after harvest, or burned. As a result, soils are open and this contributes to a further loss of the first most fertile millimeter of humus via wind and water erosion, and leads to a continuous reduction of soil functions. Collecting mulch material outside the farm is for several reasons not a sustainable approach. First, in many regions, biomass is limited, but also requires significant labor, estimated to be 5 to 12 days per acre (Bunch 2017). Furthermore, it does not fit for a community or catchment approach if all farmers would collect biomass, competing also the feed demand of grazing animals, that are mainly far beyond

Table 2 CCAM relevant ecological functions of agroecological practices

a including a broad range of types from stable manure up to liquid forms

the carrying capacity of the communities available pasture land (Wall 2017). Further relevant source for mulch material is branches from alley crops with an annual biomass productivity of 2 to 10 t DM ha-1, dependent on the tree species, variety, as well as the planting density and well-managed ratooning (Wilson et al. 1986).

Green manure cover crops are mainly planted in the short rainy season and used also for food and feed purposes. Green manure cover crops (GMCC) include any species of plant, mainly leguminous crops, whether it is a tree, a bush, a climbing vine, a crawler, a grain legume, forage-grain legumes, or close to water a water born plant (Wall 2017). GMCC like Lablab beans (*Dolichos lablab* or *Lablab purpureum*), runner beans (*Phaseolus coccineus*), mucuna (*Mucuna spp*.), ratooned pigeon peas (*Cajanus cajan*), jack beans (*Canavalia ensiformis*), and many other GMCC species like tephrosia (*Tephrosia vogelii* or *T. candida*) produce high amounts of biomass and increase C-sequestration (above and below ground biomass) (Branca et al. 2013; Hobbs and Govaerts 2010). Nitrogen fixation of leguminous crops varies in a broad range of approx. 80 and 250 kg N ha-1 a-1, according to species, variety, soil and climatic conditions, and crop management (Monegat 1991). Assuming a loss of 50% via volatilization and use of grains (Bunch 2017), there are still more than 40 kg ha-1 a-1 N for the following crop with a reference value of 2 t ha-1 a-1 wheat.

Seriously managed, CMCC, combined with minimum soil tillage, can reduce soil erosion by more than 90% (equivalent to a means of 850 kg ha-1organic matter, approximately 50 kg nitrogen ha-1 and 8 kg phosphorus ha-1). GMCC provides nitrogen and offers weed control (Elwell and Stocking 1988), as well as other benefits, including the amelioration soil compacted (Scopel et al. 2004). But GMCC for compost or mulch is only partly a solution because farmers argue that all land should be used for food production, and this hinders them from investing in these crops, which asks for an answer. With forage grain legumes, an alternative exists that can fulfill both ecological functions, but also offer food and feed, and keep relevant parts of the fixed nitrogen in the field. Barriers to their implementation are costs (seeds) and lost harvest of a catch crop income. So, farmers often prefer intercropping of, or rotation with, grain legume crops rather than GMCC (Nandwa et al. 2011).

Farm Yard Manure

Farm yard manure (FYM), which is an un-normed mixture of dung, slurry, straw, and feed residues, is an organic material with many relevant ecological functions (Table 2) (Teenstra et al. 2015). FYM is potentially available on a farm for redistribution to the fields, if there is any form of zero grazing or animals fenced for certain times in a kraal. Systematically applied, FYM manure can increase biomass production by 100% (Ndambi et al. 2019). In many cases, its impact on yields is comparable with that of medium mineral fertilizer inputs; or the combination of 5 t ha-1 FYM with 30 kg N ha-1 a-1 is able to produce equivalent maize yields in comparison with 200 kg N ha-1 a-1 (Achieng et al. 2010).

Practically each smallholder farm should have some FYM. One ox, one or two cows, and in some cases approx. Five sheep or goats and 10–20 chickens are a classical set of animals for a 1 ha farm. A tropical livestock unit is calculated with 250 kg, which is 50% of the Western standard. Additional feed comes from communal pastures, feed along pathways, and from shrubs. Milk productivity with this feed is rather low (378.6 kg cow a-1 in 2018 in East Africa; http://www.fao.org/faostat/en/#data/QL). As a result, the production of farm yard manure is low as well as their nutrient content. Moreover, this limited manure production is often used for house construction or for cooking purposes. In addition, most farmers do not apply manure management practices, such as roofed animal housing, with water-proof floor or covering manure during storage in order to prevent large nutrient losses during manure storage, increasing greenhouse gas emissions, and reducing the quality of the manure as a fertilizer and its positive impacts on ecological factors, that is, contributions to CCAM (Ndambi et al. 2019).

To conclude, farm yard manure contribution in current smallholder systems to strengthen CCAM or productivity is seriously low or nonexistent. Hurdles for an adequate collection and use of FYM are lack of knowledge in general about the value of this organic matter, techniques for cut and carry feed, investment for zero grazing units, that is, kraal fencing, and techniques for the adequate distribution of the manure in the field. Furthermore, it seems neither in the focus of advisory services nor of research or policy agendas (ibid).

Soil Tillage

Soil tillage functions include, among others, to loosen the soil, to provide technical aid for in depth growth of roots, to homogeneously mix organic matter with the soil, and to prepare seed beds.

Current partly excessive soil tillage systems often lead to soil compaction, soil aggregate break down, soil dust, and rapidly decomposing organic matter. High rates of topsoil loss contribute to downstream sedimentation and degradation of local and regional water bodies (Tully et al. 2015). While soil compaction reduces the seedbed quality and thus hinders the germination of seeds, soil dust gets irreversibly lost via water and wind erosion. Thus, the current type of so-called plowing tillage systems in combination with maize dominated cropping systems weakens several ecological functions relevant for CCAM.

In general soil tillage systems follow a continuum from conventional inversion moldboard plow up to disc opener no-till planter into dead residue (Reicosky 2015). Alternative soil tillage systems have been developed over the years to reduce tillage intensity, including stubble mulching, to reduce or eliminate tillage, and to retain plant residue on the soil surface to alleviate wind and water erosion. These practices led to what became known as conservation tillage, culminating in no-till systems that avoid any soil disturbance. No-tillage, reduced-tillage, mulch-tillage, and strip-tillage are some of the diverse CA tillage approaches.

The combination of green mulch cover crops (GMCC) is expected to significantly increase ecological functions and contributions towards CCAM (Table 2). GMCCs can also control weeds by covering, that is, suppressing upcoming weeds. Potential yields through combining mulching and low soil tillage exceed 100%. But it must be remembered that the quantity of additional organic carbon in the soil under no-till is relatively small. The main effects are relevant for other ecological functions and indirectly contribute to CCAM. Over the years it also has become evident, that after a period of low tillage interventions, this system must be interrupted for 1 year with a more intense tillage approach, in order to loosen natural soil compaction effects in the below ground, as well as to regulate the weed pressure (Powlson et al. 2014).

Soil tillage systems technologies with reduced intensity are only available in some regions and the optimal approach which depends on soil type, rainfall, share of skeleton, precrop and the following crop, as well as above ground biomass is still not identified for many agroecological situations. If not managed properly, nonadequate technique applied, and rotations without forage legumes, as well as limited or lack of mulch material, there is high risk of weed pressure, reduced crop yields. If weeds take over farmers then tend to misinterpret the approach increasing the application of fertilizer inputs and herbicides with negative environmental impact (Giller et al. 2011). A certain number of weeds however can provide also positive ecological functions, as discussed in OA (Hillocks 1998). Missing finances for the technical equipment and knowledge gaps might be other reasons for low adaptation rates of reduced tillage systems in Africa.

Agroforestry

The multifunctions of the diverse agroforestry systems are highly relevant for CCAM (Lasco et al. 2014), but also serve as forage or for other diverse purposes (fuel, construction, apiculture, food, forage), and provide positive contributions to reduce concentration of carbon dioxide (CO2) and other greenhouse gases (GHGs) (Awazi and Tchamba 2019) and to regulate microclimate (Mbow et al. 2014). Specifically, alley-crop-systems contribute to multiple ecological functions (Table 2). They contribute to a reduction of inorganic inputs (Wilkins 2008), to pest and disease control (Murthy et al. 2013), biodiversity (Murthy et al. 2016), and regulation of microclimate (Schroth et al. 1995). What makes them specifically attractive is their use of subsoil layer nutrients and water resources and photosynthesis above the main crops, well adapted to soil and climate conditions, simulating partly the original vegetation cover before once turned the land from natural forest to arable land.

Alley branches can be used directly as mulch, or as a protein feed for animals, filling the protein gap and leading to higher animal manure production. Trials of alley crops with rows all 4–8 m document the high positive impact on cash crop growth. A weakness in the majority of trials are monocropping alleys with an increased risk of pest and diseases, while diverse alley crops provide more resistance, multiple functions for arable pest and disease control, and a diversification of forage qualities and adaptability towards CC (e.g., *Faidherbia spp*.).

On smallholder farms, their integration is challenged if the land is scattered. Otherwise, already the limited area of the homestead would offer space for implementation. Biomass productive hedges are often not in place and also the technique of ratooning, for example, in case of pigeon pea, and other management practices are missing and are limited in biomass production with all its positive impact on CCAM. Further hurdles for smallholder farmers to integrate a diverse cropping scheme with alley crops are the limited availability of seedlings, lack of knowledge how to prune shrubs and to integrate into feed ratios, as well as investment costs and workload for their management.

(Silvo-) Pastoral Systems

Pastoral systems are usually the backbone of animal systems. By nature, grassland is rich in root biomass and humus content is seriously higher than in arable systems with permanent soil tillage. However, in most African countries, pastures are overused, sward management is low, erosion is high, and productivity is not high enough to feed animals with energy and protein rich crops. Irreversible loss of land via erosive processes/land-slides is point on the agenda explaining the critical situation (Wynants et al. 2019). Land distribution and ownership patterns coupled with continuous fragmentations are further drivers of the current system and are challenging farmer towards sustainable grassland management (Tesfa and Mekuriaw 2014). Provision towards ecological functions, that is, contributions towards CCAM, is low if not negative.

Limited availability of seeds, lack of labor for establishing pasture systems, the cost of fencing and knowledge gaps, as well as missing management and knowledge at community level, as well as missing management at the community level, hinder and limit the production of pasture biomass and thus also their CCAM.

As an alternative silvopastoral system, a combination of pastures with leguminous shrubs and trees provide relevant contributions to ecological functions towards CCAM (Table 2) and an enormous increase of biomass production (Sarvade et al. 2019). The forage legume trees cover a high share of the protein gap limiting the animal production. Forage production can be seriously increased with a strong impact on the level of fattening and milk production and less GHG emissions per animal unit (Broom et al. 2013). For that grassland management needs to reorganize, including regulations for use, awareness on traditions, and fenced or otherwise controlled areas (Ochieng and Waiswa 2019).

Impact of Arable and Plant Cultivation Methods on pH Regulation

The pH of soils with substantial ecological functions and specifically high impact on biomass production is influenced by several of the arable and plant cultivation methods and therefore is summarized in this subsection. The pH of many East African soils is below 5.0, virtually no available phosphorus and toxic levels of aluminum (Bunch 2017) and therefore out of the optimum for a productive crop growth and biomass production, which is between 5.8 and 6.5, while crop specific in a broader range. Mineralization processes, the optimal living conditions for microorganisms responsible for many soil functions, and growth conditions for crops are limited with low pH, leading to lower crop yields, that is, less positive impact on CCAM. Under acid soil conditions, phosphorous is tied up in a short time and does not provide more than 0.5% soil phosphorous in forms that are available to plants. The general low P content of African soils increases the dilemma.

Mulch and compost material mainly from grass provide a large C/N and therefore will not feed the crops. A high share of legumes instead offers a C/N which boosts the growth of microorganism that are functioning as storage but also deliver nutrients towards crops through the decomposition of mulch material. Phosphorous becomes available as a slow floating source. Farm yard manure (approx. pH 7), slurry (approx. pH 8), and compost (approx. > 7 pH) with high pH values would positively influence nutrient availability and thus crop productivity. Current systems are lacking these effects due to the low availability of manure, slurry, and compost, which at least causes the inefficient landuse and low productivity of crop and animal production. Also, alley crops have the potential to increase the pH via litter fall, through re-transporting leached Ca, however depends on tree species, and the presence of a subsoil of suitable quality, that is, clay enriched and with high Ca saturation (Vanlauwe et al. 2005).

Using lime is an option, so far locally available and transportable. But liming runs the risk of increased mineralization, that is, humus decomposition beyond what is needed, and there are cost factors.

Cattle, Dairy, Sheep, and Goat Systems

Ruminants play an intermediate position between crops and manure. Current feeding ratios are often of low quality. Overgrazed grassland, lack of any forage crops in the crop rotation, alley crops, and hybrid grasses (*Pennisetum spp.*; *Brachiaria spp.*) are the explaining factors. Specifically, protein deficits explain also the low performance in dairy production. Intense use of straw and stubble after crop harvests – a main forage source – reduces the humus level of soils, specifically if organic manure is not recirculated to the fields, which is in manure farms the practice and is increasing soil erosion. Without a forage management including access to water, positive outcomes of breeding programs cannot be transferred into practice. To add cereals or grain legumes in the feed ratios compete directly with human food and cannot be recommended as a key strategy, except the use of leftovers.

Ruminant demand for forage legumes, hybrid grasses (Ghimire et al. 2015), forage trees/alley crop branches (Franzel et al. 2014), and silvopastoral systems fit with the CCAM strategies, due to the fact that they all contribute to an increase of biomass production, farm internal nitrogen supply, and milk productivity per land unit. As a result, the organic manure nutrient content and quantities increase, which can serve as a valuable fertilizer for crops and for supporting soil functions.

Agricultural Production Systems Contributions to CCAM

This section first discusses diverse agricultural production methods and how they relate to each other in order to identify communalities and differences. As seen in the description of single CCAM relevant methods, they often refer to CA and OF. Table 3 informs about differences and similarities within an African context.

Sustainable Intensification – Some Terminological Clarifications

Most prominent agricultural production methods in recent years can be summarized as “Sustainable intensification (SI),” which is defined as meeting the growing demand for agricultural production while conserving land and other resources, “from the same area of land while reducing the negative environmental impacts

and at the same time increasing contributions to natural capital and the flow of environmental services" (Khan et al. 2017). This term also accounts for the human condition, nutrition, and social equity. In their review, Smith et al. (2017) conclude, using a broad range of socio-, cultural, and socio-economic measures, that most current agricultural practices fall into this category. SI does not explicitly exclude any farming practice or requires an obligatory production framework, as, for example, the case for conservation agriculture with minimum tillage and mulching, or organic farming that excludes some farming and processing inputs. Mahon et al. (2017) conclude that SI is an oxymoron, underpinned by a productivist agenda, and that it is lacking a clear rationale. In their review, Xie et al. (2019) identify the reduction of yield gap as the main target of SI. But the intense use of mineral fertilizers is also not excluded (Holden 2018). Yet others, like Mdee et al. (2019), understand SI to be based on agroecological methods, or to classify integrated pest management as a core activity (Pretty and Bharucha 2015).

Definitions of CA do not explicitly exclude mineral fertilizers, herbicide and pesticide applications, but keep them at an option. Consequently, Vanlauwe et al.

(2014b) summarize three conceptual pathways for intensification paradigms: (i) integrating soil fertility management ending up in conservation agriculture, (ii) push and pull systems (Khan et al. 2008b), and (iii) evergreen agriculture (agroforestry-based systems) (Garrity 2017). All of these systems contribute to high soil health status and productivity through somewhat different pathways. In contrast to the overall definition of SI, which includes overlaps of sustainable and ecological intensification (Wezel et al. 2015), these pathways are classified as being only part of ecological intensification and thus only cover partially what is discussed under the term SI.

Another concept, Climate Smart Agriculture (CSA), is defined by the FAO as "agriculture that sustainably increases productivity, resilience (adaptation), reduces/removes greenhouse gases (mitigation), and enhances achievement of national food security and poverty reduction" (Nyasimi et al. 2014). CSA refers to food security and rural livelihood improvement through agricultural concepts that facilitate climate change adaptation and provide mitigation benefits (Scherr et al. 2012). Arable and plant cultivation methods applied refer to many of the field-based and farm-based sustainable agricultural land management practices identified as part of SI. As Zougmoré et al. (2016) suggest in their analysis of CCAM relevant approaches, CSA is a farming method like CA.

"Sustainable land (use) management (SLM)" as the last approach, which should be mentioned in this brief analysis, is a compilation of methods that summarizes many of the activities already introduced above. Gurtner et al. (2011) define SLM as "the adoption of land use systems that, through appropriate management practices, enables land users to maximize the economic and social benefits from the land whilst maintaining or enhancing the ecological support functions of the land resources." Arable and plant cultivation methods of SLM include soil fertility and crop management, soil erosion control measures, organic fertilization, minimum soil disturbance, and incorporation of residues, terraces, water harvesting and conservation, and agroforestry, grazing and forest management (Branca et al. 2013; Cordingley et al. 2015). But scholars highlight different specific methods. Dale (2010) defines SLM mainly as a technology approach to cope with erosion via mainly technical interventions and less one defined by crop-based systems.

Conservation Agriculture

Conservation agriculture (CA) integrates three principles (FAO) (www.fao.org/ag/ca): (i) avoiding or minimizing mechanical soil disturbance; (ii) enhancing and maintaining a permanent mulch cover with organic matter on the soil surface; and (iii) diversifying species (Kassam et al. 2017). Today CA is associated with three other agricultural production systems.

Push and pull system discussed as a core subsystem of CA, but also described as a climate smart technology that combines maize with undersown forage legumes and Napier grass, and with a minimum tillage approach (Midega et al. 2015), fulfills many of the ecological functions that contribute importantly to CCAM (Table 3) and enables sustainable cereal crop and livestock production intensification through ecosystem or agroecological approaches based on natural biological processes (Khan et al. 2014). In the face of CC, new drought-tolerant trap (e.g., *Brachiaria* cv. *Mulato*) and intercrop (drought-tolerant species of desmodium, e.g., *D. intortum*) plants have been studied to further develop the push and pull system (Khan et al. 2017). Another approach is Evergreen Conservation Agriculture, a subtype of CA, which focuses specifically on the integration of trees into crop and livestock production systems (Garrity 2017). Close to this system are agroforestry systems that include inter-planting of a broad range of leguminous shrubs (Pratt et al. 2002). For erosion control in combination with other conservation measures, for example, dense hedges of vetiver grass on contours are recommended (Bunderson et al. 2015).

The positive impacts of CA on yields are well documented (Mkonda and He 2017), with yield increases compared to traditional methods, for example, from 1 t ha-1 to 3.5 t ha-1 per cropping season (Khan et al. 2006) as well as increased milk production (Khan et al. 2008a; Khan et al. 2008b; Midega et al. 2014). As a result, CA is shown to contribute significantly to higher economic returns for the farmer (higher returns to both land and labor than conventional farmers' practices), thereby allowing reduced, and sometimes none, use of nitrogen fertilizers, herbicides, and pesticides. CA contributions towards carbon sequestration further underline their high contribution to CCAM (Gonzalez-Sanchez et al. 2019; Sommer et al. 2014).

Organic Farming

Organic farming (OF), as described by internationally accepted guidelines, is designed to be followed for farmers who are approved by certification processes and want to market their products as organic. OF also embodies a set of ethical principles that serve to orient all the subsystems of this agricultural production system. OF relies on (agro-) ecological processes, biodiversity at all levels (species, genotype, habitat, landscape...), and nutrient and carbon cycles, and high contributions to reduce agricultural GHG emissions (Scialabba and Müller-Lindenlauf 2010). All CCAM methods are recommended (see also FAO 2011), while other methods with often critical impact on the environment, but also for CC are limited (Table 3).

A key characteristic of organic farming is the focus on soil fertility, as a result of diversified crop rotations with forage legumes, catch crop and intercropping, and organic manure, which is the basis of a healthy and sustainable production (Meyer 2010). These diversified crop rotations largely replace the functions of excluded inputs like soluble mineral fertilizers, herbicides, and pesticides (Freyer 2019). Forage legume-based crop rotations, agroforestry, and nutrient and carbon recirculation are of high relevance. From a systems perspective, all of these methods must be implemented to enable a productive system. Tillage systems follow the idea to avoid the mix of fertile above ground soil layers with less fertile in lower layers. How far tillage intensity can be reduced depends on precrop – following crop relations, produced above and below ground biomass, organic manure type and amount, and the demand for weed control or to initiate mineralization processes, therefore cannot be generalized (Koepke 2003). At this point the difference between OA and CA becomes relevant which is the exclusion of many external inputs in the OA system. Functions of these excluded inputs must be partly taken over by the tillage system.

Other characteristics of OA are the inclusion of traditional knowledge, material, and methods (Müller and Davis 2009). Also, local seed collection and use is an intrinsic part of organic agriculture (Forster et al. 2012). Such seeds might be an advantage to adapt under certain climatic conditions and contribute to maintaining agro-biodiversity.

Africa hosts the majority of organic farms worldwide, with almost 2.1 million hectares of certified organic agricultural land (2017), and at least 815,000 producers (Willer and Lernoud 2019). But what is currently missing is an evaluation of the practices in these organic farming systems. Annual farm certification only partially informs the extent and quality of CCAM applications.

Moreover, research lacks a convincing organic systems approach. If trials include amounts of organic fertilizers that are going beyond the production capacity or what is currently known on that in practice, crop rotation principles are ignored, and alley cropping is not integrated (Adamtey et al. 2016; Musyoka et al. 2017). Such trials are of low relevance for identifying the real potential of OA to CCAM. This limited availability of research trials hinders a more in-depth assessment of the organic approach. Specifically, in comparison to CA, the gap is huge.

In African countries, OA is often equated with traditional practices – whatever they are – less mechanized, and minimum use of chemical fertilizers and pesticides. The low input systems neither fulfill the organic principles of health, ecology, fairness, and care, are not in line organic guidelines, nor would survive any organic farming certification process (Nalubwama et al. 2011).

Discussion

This section summarizes and provides an orientation to the interdependence of CCAM relevant methods. It informs the challenges of farmers to adopt and refers to farmers' perspectives, agroecological, social, livelihoods, and the surrounding conditions for implementing CCAM, as well as how to interpret communalities and differences between CA and OA.

The Logic of CCAM Practices

The interdependence of CCAM relevant methods is a key to understand their efficiency, success, or failure, not only for CC, but also their impact on productivity. Methods can be classified into two levels:

- First level: Methods that provide biomass and nitrogen: Legume based Agroforestry systems, silvopastoral systems, forage legume-based/green manure cover

crop, relay crop and intercrop-based crop rotation systems, and perennial productive high breed grasses.
- Second level: Methods that depend on the productivity and management of first level methods: mulching, manure and compost production, minimum tillage, pH regulation, biodiversity for pest and disease regulation.

Of course, isolating the yield effects of individual practices is complicated (Branca et al. 2013), but without optimal management of first level methods, second level methods cannot be activated or are weak in their performance. In other words, if methods in the first level are not well established, second level methods cannot be put in place. In organic farming, the application of CCAM relevant methods is obligatory to enable productivity with limited input from outside. Exclusion of one method would weaken the whole system. Of high relevance is the management quality of applied methods which allow that, even with very low amounts of residues, increases in the productivity with respect to conventional farming practices (Sommer et al. 2012). This fact is often overlooked. OA is very clear on this point – there are no half measures – if so, the system would fail both in CCAM and in productivity.

Barriers for Adoption CCAM from a Production Perspective

In recent decades, extensive efforts to promote CA, CSA, or SLM have been undertaken. Despite extensive past efforts by governmental, nongovernmental, and research organizations to promote SLM to smallholder farmers in SSA, adoption remains low (Cordingley et al. 2015). What are the barriers to establish these methods from a production perspective?

- Crop specific: forage legume seeds, agroforestry seedlings and tree management, hybrid grass seeds, pasture seeds, weed control.
- Technically specific: soil tillage and seed technology, technology for cut and carry systems, stable construction, water management, storage, transportation and distribution of organic manure and compost.

Challenges to implement CCAM approaches are obviously not essentially different between CA and OA. The difference lies in the accessibility of nitrogen fertilizer, herbicides (Wall 2017), and pesticides that all can be applied as “emergency” methods in CA, while not in OA, These inputs provide CA farmers a set of methods that can be used when the crops are in a critical stage (lack of nitrogen, high weed pressure, expected outbreak of pest and diseases).

The differences between CA and OA can be identified largely in the so-called “other methods” (Table 3). Neither soluble mineral fertilizers nor herbicides and pesticides are allowed in either to bridge critical weather conditions, weed, or pest and disease development. Nitrogen fertilizer is the most relevant input with high impact on GHG emissions.

The application of these inputs is also controversially discussed in CA. While some argue that the three CA principles are sufficient to guide CA practices (Sommer et al. 2014; Wall 2017), Vanlauwe et al. (2014) identified a fourth principle, the application of mineral fertilizers. Many farmers believe that CA cannot be undertaken without specific inputs and tools, a message commonly conveyed to them by extension staff (e.g., hybrid seed, fertilizers, herbicides, knapsack sprayers, jab planters,. . .) (Bunderson et al. 2015). For farmers, the exclusion of "other methods" would limit the acceptance of CA and its scale on farms. Farmers also fear an increased abundance of termites and earthworms as harmful, whereas in fact they can have beneficial effects on the soil and crops (ibid). But there are also voices from the organic side that agriculture in Africa without herbicides and synthetic fertilizers is not possible and vote for their integration into the organic guidelines (Lotter 2015). The result would be simply CA. Other surveys report that farmers' perceptions indicate that CA without external inputs, such as fertilizers, herbicides, pesticides, or compost, can improve yields relative to conventional agriculture. This argument is supported by the observations of scientists that a large proportion of soils in sub-Saharan Africa can be described as nonresponsive (Tittonell and Giller 2013), in which mineral fertilizer applications do not result in higher crop yields, while already the application of the three CA principles led to serious higher yields in comparison to the conventional input driven approach (Ngwira et al. 2013; Thierfelder and Wall 2010). Also, effective weed management is possible without the use of herbicides, since all three CA practices contribute to integrated weed control, also experienced in organic farming, if crop rotation and weed management are organized following latest knowledge. These observations are a clear reference about the OA system that also builds besides other methods on the three CA principles. These experiences are also showing that subsidizing of inputs is not a necessary precondition to CA use and uptake (Bunderson et al. 2015; Lalani et al. 2017).

According to FAO (2012), 80% of all farms in Africa have an agricultural area of <2 ha. These fragmented small land holdings preclude the effectiveness of large machinery in fieldwork, specifically for cut and carry systems, mulch-seeding systems/zero-tillage direct seeders, or the distribution of farm yard manure or mulch from outside the field, or from alleys (Sims et al. 2017; Sommer et al. 2014). In contrast, Lalani et al. (2017) observed that manual forms of CA can be attractive for farmers, particularly those with very small plots of land (0.5 ha or less), observing that mulching systems can reduce weed pressure.

Labor for biomass management is discussed as a barrier to the adoption of some CA methods, while others like seed varieties that are drought tolerant and early maturing are classified as the most suited technologies for smallholder farmers to respond react to CC (Senyolo et al. 2018). To define the CA approach only with drought resistant seed material, optimized irrigation and mineral fertilizers fail the overall idea, which could be also titled with "CA by default" or a conventionalized CA; of course it is less complex to apply a hand full of fertilizers and a herbicide instead of developing diversified crop rotation, mulching, and agroforestry systems.

A further barrier of CA/OA systems with the CCAM approaches is that they cannot be put in place in one season. Often the starting points for transforming the system are poor soil fertility, land degradation, pests, and erratic rainfall that are challenging the adoption (Sietz and Van Dijk 2015). It is therefore not only about implementing new farming methods, but also to “repair” the damaged natural system. There is a conversion period of 2 to 3 years as it is also for OA, where farmers primarily have to invest in the transformation of the system. This requires a period of labor and financial investment, and patience by farmers until trade-offs of the new system become visible in an increase of productivity (Lalani et al. 2017).

In addition to these relevant hurdles, it is to keep in mind that weed and pest and disease control are a challenge for all farmers, irrespective of the CCAM methods, and not specific for CA/OA, like diversified crop rotations, in comparison to maize monocropping (Thierfelder et al. 2013; Thierfelder and Wall 2010); however, the high increase of pest and diseases provoked by monocropping and biodiversity poor landscapes underlines that farmers on the long run have no other choice than to modify their system, independent from CC.

Markets, Policies, and Education for a Diversified Production

The implementation process of CCAM methods still lacks a clear conceptual understanding (Partey et al. 2018). The poor understanding of CA/OA, its CCAM methods, and suspected contradictions over what it means reflect the absence of an overall educational training program for teachers, extension officers, and students (Bunderson et al. 2015). Field trials should not lack of first level CCAM approaches (see the example of (Thierfelder et al. 2013, 2016); without training programs for farmers, chances for successful adoption of CCAM will continue slim (Erenstein et al. 2012).

Diversified production is also not possible without a policy and market enabling crop diversity and rewarding the contributions toward biodiversity and CCAM. Sustainable out-scaling of CCAM and to achieve large-scale landscape adoption depends on linkage to functional markets for inputs and outputs (Sommer et al. 2014). There is need for more attention via policy and extension on value chains, and more focused development resources from donors, governments, nongovernmental organizations (NGOs), and national and international research and development organizations to support participatory dissemination and upscaling of CCAM approaches (Friedrich et al. 2012). Investment policies should focus along value chains from technology at farm level, up to processing, and the availability of specifically forage legume seeds and tree seedlings.

Certification, that is, labeling of CCAM based agriculture, might be an option to support their implementation if linked with subsidies. In case of OA certification, schemes protecting the production status is currently only a half solution to increase the share of CCAM approaches in practice, due to the fact that only farmers with products for export are able to partly cover the relatively high certification costs. For local markets, certified products with a premium price are not adapted to the economic conditions of local population. Apart from specific investment costs, the successful implementation of CCAM methods would increase production and thus farmers income, making additional price premiums less important. An ecosystem services-based payment scheme might be an option; however, the administrative costs can be currently higher than the money reaching the farmers pocket.

To make an impact, integrated participatory catchment strategies are expected to be most efficient in terms of adoption of CCAM methods, via technology, advisory and financial support, and the implementation of an impact monitoring (Scherr et al. 2012).

Sensitivity must be given of the vulnerable and marginalized (women and poorer households, for instance) to avoid the exclusion and a social gradient (Feder et al. 2010). Multiple communication tools are discussed as a precondition for successful implementation of CCAM (Leeuwis and Aarts 2011). To bring together broad experience for learning and encouraging innovation, communication platforms should be established including farmers' organizations, advisory services, and universities. Social acceptance by referents, and shared learning processes, plays a key role in this regard (Lalani et al. 2017).

National policies have to frame this process, for example, to strengthen the establishment of a seed and seedling sector specifically for forage legumes and legume trees, while regional land locally sensitive policy instruments serve for finetuning of product specific value chains (Zougmoré et al. 2016).

Conclusions

This chapter summarizes the status and potential of smallholder farmers' application of CCAM practices and some observations on the institutional environment, with reference mainly to the subtropical/tropical environments of East African smallholder farming.

Lessons learned are that many CCAM relevant arable and plant cultivation methods are available, but most of these are still not in place. It is obvious that all CCAM methods contribute to an increase of productivity, with minor exceptions, where systems need further development.

With respect to agricultural production systems where the integration of CCAM methods is far advanced, conservation agriculture (CA) builds on the use of farm inputs including nitrogen fertilizer, soluble mineral fertilizers, herbicides, and chemical pesticides, while organic agriculture (OA) excludes these inputs. To what extent these inputs are a precondition for successful CA management is a matter of controversy. CCAM methods are practically similar in both approaches – CA and OA – while the degree of their implementation and favored methods might be different.

The amount of biomass production and nitrogen by nitrogen fixing crops is a key driver of CCAM and an increase of farm productivity. Both can serve as general indicators to assess farms, that is, catchments in their progress to cope with CC and to boost productivity, while it is less the share of mineral fertilizer. Most relevant crop groups with highest impact are forages legumes, forage grain legumes, and leguminous alley crops, but also biomass rich hybrid grasses, that profit indirectly from the forage legume nitrogen, for example, via slurry. These crop groups are the ones that increase soil fertility, reduce soil erosion and increase water holding capacity, biological pest and disease control, provide the feed biomass for animal husbandry systems, and guarantee an increase of cash crop yield and quality. Critical is the low supply of specifically forage legumes in seed markets.

There are still open questions, specifically concerning the GHG of mulching systems, pest and disease management and weed control, adapted technology for small scale farming and catchment strategies for a synergetic and efficient management. But those aspects are more part of a site and farm specific fine tuning than of fundamental lack of knowledge, which currently characterizes one of the main innovation barriers.

The dramatic negative trends of soil quality, biodiversity, and CC speak a clear language that the agricultural systems must bid farewell to one-sided systems. There is a need for a fundamental change, that is, resetting of the current farming practices, in other words, adaptation is no longer the appropriate term but the comprehensive transformation of the farming system as a whole. This is only possible if there is an enabling institutional and policy environment that supports agricultural research, advisory services, and education oriented to farmers' needs to adapt their farming system, making it more robust against drought and floods through the establishment of biomass and nitrogen producing cropping systems, and is reducing the farm specific negative impact on CC. This transformation process depends on assuring that best practices, adapted to local conditions, can demonstrate a reduction of labor, and a serious increase of farm income. It is recommended to apply a more systemic view in developing farming systems and related value chains, instead of focusing on single methods, that is, products. Transformation towards biodiverse crop rotations and biomass management also asks for the respective markets, consumer demands, and processing units, for example, for an increased milk production as a result of increased forage production, a dairy structure, and adaptions, that is, transformations of human diets. These final remarks clearly inform about the need for systemic transformation of food systems for successful CCAM management.

Abstract

The global rise in human population has led to the intensification of agricultural activities to meet the ever-rising food demand. The potato (*Solanum tuberosum* L.) is a crop with the potential to tackle food security issues in developing countries due to its short growth cycle and high nutrient value. However, its cultivation is heavily dependent on artificial fertilizers for yield maximization which culminates in global warming and other environmental problems. There is need, therefore, for its alternative fertilization technologies to mitigate climate change. This study evaluated the potential of indigenous rhizobacteria for potato cropping in Tanzania. Ten potato rhizobacterial isolates belonging to *Enterobacter, Klebsiella, Citrobacter, Serratia,* and *Enterobacter genera* were obtained from a previous collection from different agro-ecological areas in Tanzania. The isolates were characterized culturally, microscopically, biochemically, and by their carbohydrate utilization patterns. Their *in vitro* plant growth-promoting (PGP) traits such as nitrogen fixation, solubilization of phosphates, potassium, and zinc, and production of siderophores, indole acetic acid, and gibberellic acids were then evaluated. Lastly, sterilized potato seed tubers were bacterized with the inoculants and grown in pots of sterile soil in a screen-house using untreated plants as a control experiment. The potato rhizobacterial isolates had varying characteristics and showed varying *in vitro* PGP activities. The screen-house experiment also showed that the rhizobacterial treatments significantly ($p < 0.05$) enhanced different parameters associated with potato growth by up to 91% and established the potential of most of the isolates as alternative biofertilizers in potato cropping systems in Tanzania.

Keywords

Potato · Biofertilizer · Plant growth promoting rhizobacteria (PGPR) · Climate change · Sustainable agriculture

Introduction

Potato (*Solanum tuberosum* L.) is an important crop for food and economic security in developing countries (FAO 2008). However, its cultivation is heavily dependent on the application of synthetic fertilizers (George and Ed 2011). The general recommendations of synthetic fertilizers for this crop are 120, 123, and 149–199 kg ha^{-1} of nitrogen (N), phosphorus (P), and potassium (K), respectively, for an average fresh tuber yield of 30 t ha^{-1} (Manzira 2011). Nevertheless, these generous fertilizer applications do not always produce the desired results because the crop's rooting system is too shallow for the efficient recovery of fertilizers (Hopkins et al. 2014).

Attempts to establish suitable alternative fertilization mechanisms for crops to minimize environmental impacts and mitigate climate change are quickly gathering momentum worldwide (Kumar et al. 2018). In this context, plant rhizospheres have been the center of attention worldwide for decades. Plant roots secrete nutrient-rich exudates that attract plant growth-promoting rhizobacteria (PGPR) that contribute to plant growth promotion (PGP) directly or indirectly, for instance, through the production of phytohormones and siderophores, solubilization of phosphates, and biological nitrogen fixation (BNF) (Kumar et al. 2018).

Biofertilizers are PGPR-cultures which are developed for use as inoculants to improve soil fertility and plant productivity (Aloo et al. 2019). The PGPR of different crops like legumes have extensively been studied as biofertilizers, but the potato rhizobacterial communities are not yet fully understood, yet they could extremely be important as alternative biofertilizers for this crop. Understanding their interactions with the potato to unravel their PGP potentials for sustainable potato cropping is equally important. It is now known that indigenous PGPRs of specific crops can make better biofertilizers because they are completely adapted and established in specific environments and can be more competitive than introduced inoculants (Sood et al. 2018). Cognizant of this, the present study was designed to explore the PGP functions of indigenous rhizobacterial strains selected from a previous study that had isolated, and identified rhizobacteria from potato rhizospheres and tubers from different agro-ecological regions in Tanzania. The selected rhizobacteria were studied culturally, microscopically, biochemically and based on their carbohydrate (CHO)-utilization patterns. Their *in vitro* PGP functions and effects on various growth parameters of potato in pot experiments were investigated under screen-house conditions, using un-inoculated potato plants as controls. Understanding these bacteria and their functions can enable the identification of suitable inoculants for the development of sustainable potato cropping systems in Tanzania and provide deeper insights into the overall mitigation of climate change in Africa.

Materials and Methods

Rhizobacterial Cultures

Ten rhizobacterial cultures that had previously isolated from potato rhizosphere soils growing in various regions in Tanzania and identified using their 16S rRNA gene sequences (Aloo et al. 2020) were selected for the present study. The strains, sources, and species of these rhizobacterial cultures are displayed in Table 1.

Table 1 Strains, sources, and species of the potato rhizobacterial isolates used in the study

SN	Strain code	Source	Strain identity
1	*LUTS1*	Luteba	*Klebsiella grimontii LUTS1*
2	*LUTS2*	Luteba	*Enterobacter tabaci LUTS2*
3	*MWAKS1*	Mwakaleli	*Klebsiella oxytoca MWAKS1*
4	*MWAKS5*	Mwakaleli	*Enterobacter asburiae MWAKS5*
5	*MATS3*	Matadi	*Enterobacter tabaci MATS3*
6	*MPUS2*	Mpunguti	*Enterobacter tabaci MPUS2*
7	*KIBS5*	Kibuko	*Serratia liquefaciens KIBS5*
8	*MWANS4*	Mwangaza	*Citrobacter freundii MWANS4*
9	*BUMS1*	Bumu	*Enterobacter ludwigii BUMS1*
10	*NGAS9*	Ngarenairobi	*Serratia marcescens NGAS9*

Cultural, Microscopic, and Biochemical Characterization of the Rhizobacterial Cultures

The morphological characterization of the rhizobacterial colonies was performed based on their sizes, shapes, colors, margins, opacity, elevation, and texture as described by Somasegaran and Hoben (1994). The determination of Gram staining properties was performed using the 3% potassium hydroxide (KOH) string test (Pradhan 2016). Rhizobacterial smears were prepared and stained with safranin and observed under oil immersion ($\times$100) on a fluorescence microscope (Optika B-350) to determine the cell shapes. Evidence of flagella motility was checked in a motility test medium (MTM).

The qualitative assessment for the production of organic acids was determined using the methyl red (MR) (Sambrook and Russell 2001). The catalase test was used to identify isolates that produced catalases and the citrate test was used to detect the ability of the rhizobacterial isolates to utilize citrate as the sole source of carbon and energy on Simmons citrate agar (Simmons 1926). The ability of the isolates to produce hydrogen sulfide (H_2S) was checked on sulfur indole motility (SIM) agar tubes, and the oxidative-fermentative (O-F) test medium was used to evaluate the oxidative and fermentative abilities of the isolates. The production of indole by the isolates was also performed on SIM cultures using Kovac's reagent. Lastly, the CHO utilization patterns of the isolates were glucose, sucrose, mannitol, maltose, dextrose, lactose, fructose, dulcitol, sorbitol, trehalose, cellobiose, and ribose as described by Hugh and Leifson (1953).

In vitro Experiments

The rhizobacterial cultures were screened for various *in vitro* PGP activities. Pikovskaya's medium containing tricalcium phosphate (TCP) (Wahyudi et al. 2011) and Aleksandrov's medium containing potassium alumino-silicate (Sindhu et al. 1999) were used to evaluate for P and K solubilization by the rhizobacterial strains, respectively. Zinc solubilization assays were performed using ZnO as the insoluble Zn source (Fasim et al. 2002). For the quantitative estimation of P, K, and Zn solubilization, the optical densities (OD) of culture supernatants from Pikoskaya's, Alexandrov's, and ZnO broths were determined spectrophotometrically at A_{690}, A_{799}, and A_{399}, respectively, using a multimode reader (Synergy HTX – Biotek). The quantities of solubilized P, K, and Zn in mg L^{-1} were subsequently calculated from standard curves of KH_2PO_4, KCl, and $ZnSO_4$, respectively. The halozones around the bacterial colonies on the plates of respective insoluble compounds were measured and used to compute the solubilization index (SI) for each compound using Eq. 1 (Edi-Premona et al. 1996).

$$\text{Solubilization index (SI)} = \frac{\text{Colony Diameter (cm)} + \text{Halozone Diameter (cm)}}{\text{Colony Diameter (cm)}} \tag{1}$$

The production of IAA and GA by the isolates was evaluated as previously described by Vincent (1970) and Holbrook et al. (1961), respectively. The nitrogenase activities of the isolates were checked on solid and liquid N-free media (NFM). The formation of brown or yellow colors in the NFM broth cultures indicated NH_3 production, and its OD was measured spectrophotometrically at 435 nm. The concentration of NH_3 was then estimated by comparing the absorbance of samples with a standard curve of ammonium sulfate in the range of 0.0–10 mg L^{-1} (Goswami et al. 2014). The siderophore production abilities of the isolates were assessed using chrome azurol S (CAS) liquid assays and agar plates as described by Schwyn and Neilands (1987). In the liquid CAS assays, the percent siderophore units (% SU) per isolate were calculated from the absorbance measurements of samples and reference solutions using Eq. 2 (Payne 1993).

$$\%\text{Siderophore units } (\%\text{SU}) = \frac{\text{Reference absorbance} - \text{Sample absorbance}}{\text{Reference absorbance}} \times 100\% \tag{2}$$

For the solid CAS assays, each experiment was performed in triplicates and the diameters of the orange or yellow halozones were used to calculate the siderophores production index (SI) using Eq. 3 (Batista 2012).

$$\text{Siderophore production index (SI)} = \frac{\text{Orange halozone (cm)}}{\text{Colony diameter (cm)}} \tag{3}$$

The Potted Experiment

The rhizobacterial cultures were grown in 50 mL universal bottles filled with 25 mL Tryptic soy broth in a rotary shaker (200 rpm) for 16 h at 28 °C. The absorbance of the bacterial suspensions was evaluated spectrophotometrically at 600 nm using a multimode reader (Synergy HTX – Biotek), and each culture was diluted in sterile distilled water to a final concentration of 1×10^6 CFUs mL^{-1}. The cells were harvested by centrifugation at 4000 rpm for 20 min at 4 °C and resuspended in 100 mL of 7% Carboxy Methyl Cellulose (CMC) solution to help bind the cells to the tubers. Potato seed tubers sourced from a nearby local market were surface-sterilized (using 3% sodium hypochlorite for 3 min and rinsing four times in sterile distilled water). The tubers suspended in the prepared bacterial suspensions for 30 min and sown in plastic pots (20 cm wide) containing 250 g of 24-h oven-sterilized soil with pH: 7.33, electrical conductivity (EC): 207.33 μS cm^{-1}, soluble salts: 0.07%, organic carbon (OC): 0.89%, organic matter (OM): 1.53%, N: 0.08%, zinc (Zn): 35.62 mg kg^{-1}, P: 231.64 mg kg^{-1}, K: 7.59 mg kg^{-1}, iron (Fe): 1.31 mg kg^{-1}, sand: 68.67%, clay + silt: 29.44% and gravel: 1.88%. The experiment was set up in a completely randomized block design with three replicate potato pots per treatment, giving a total of 93 pots for 90 bacterized tubers (10 isolates in three triplicates) and three nonbacterized tubers. The screen house conditions were naturally maintained at 20–22 °C with a day length of 12 h and watered every 48 h using sterile distilled water (150 mL pot^{-1}).

The number of days to emergence (DTE) and flowering (DTF) per treatment was recorded and 90 days after planting (DAP), the crops were harvested and data obtained on the number of tubers, length and weight of shoots, and the average weight and size of tubers per plant. To obtain the average size of tubers per plant, the diameter of each tuber from each potato plant was measured using a measuring tape, and the diameter of tubers per plant obtained by dividing the total diameter of tubers per plant by the number of tubers from that plant. The average radius of tubers per plant was obtained by diving the average diameter by two and used to determine the potato tuber size per plant (Eq. 4).

$$\text{Average tuber size} = \frac{4}{3}\,\pi\ \text{x}\ (\text{Average radius})3 \tag{4}$$

The potato rhizospheric soils were evaluated for various physicochemical properties. The pH and EC of the soils were analyzed by the saturated paste method as proposed by Jackson (1973) and Chi and Wang (2010), respectively. The (%) OC in the soils was determined by the potassium dichromate ($K_2Cr_2O_7$) wet digestion method and the (%) OM of the samples was derived from the (%) OC using Eq. 5 (Walkley and Black 1934).

$$(\%)\ \text{Organic Matter} = (\%)\ \text{Organic Carbon} \times 1.724 \tag{5}$$

The N content in the rhizospheric soils was determined following the micro-Kjeldahl method (Bremmer and Mulvaney 2015). The Mehlich III method was used to extract the soil P and Zn (Tran and Simard 1993), while the extraction of K was performed using the ammonium acetate method (Jackson 1973). The 1, 10-phenanthroline complex method described by Chaurasia and Gupta (2014) was used for the extraction of Fe in the samples. The quantitative estimation of P, K, Zn, and Fe in the soil extracts was performed by determining the OD spectrophotometrically at A_{690}, A_{799}, A_{399}, and A_{510}, respectively, using the multimode reader (Synergy HTX – Biotek) and subsequently calculating their concentrations from standard curves of KH_2PO_4, KCl, $ZnSO_4$, and ferrous ammonium sulfate, respectively.

The potato tuber nutrient contents were evaluated per plant from single well-developed tubers. The tubers were surface-sterilized using 2% sodium hypochlorite and rinsed four times with sterile distilled water. Next, they were chopped into small pieces using a clean knife and dried in the oven (80 °C) for 5 days. Particle size reduction was performed by mechanically grinding, crushing, and milling them into fine amorphous powders. The P, Fe, and K in them were extracted using 50 mL of 2% acetic acid on 0.2 g of samples, followed by filtering (Miller 1995). The Mehlich III method was used to extract Zn in the powdered potato tuber samples (Tedesco et al. 1995). All sample extracts were subjected to quantification of P, K, Zn, and Fe by absorbance measurements using the multimode reader (Synergy HTX – Biotek), and the respective concentrations were obtained using the standard graphs as previously described for soil analysis. The analysis of total %N in potato samples was performed using the micro-Kjeldahl process (Bremmer and Mulvaney 2015), and their crude protein contents were estimated using Eq. 6 based on the assumption that N constitutes 16% of protein (AOAC 1995).

$$\text{Crude protein content } (\%) = \text{micro} - \text{Kjeldahl N content } (\%) \times 6.25 \qquad (6)$$

Statistical Analysis

All statistical analyses were performed using the XLSTAT (Version 2.3, Adinsoft) at a 95% level of confidence. The Shapiro-Wilk test was used to test for normality of data and multiple comparisons of variances were performed using Multivariate Analysis of Variance (MANOVA). Variables with significantly different means were subjected to post hoc analysis using Tukey's Honest Significant Difference (HSD) test. Spearman's correlation was used to evaluate relationships between potato nutrient contents, rhizosphere soil properties, and potato biometrics in the screen house experiment. The percent increase/decrease in levels of different response/dependent variables was calculated from the field experiments using Eq. 7 to assess the differences between treatment and control experiments.

$$\frac{\text{Treatment} - \text{Control}}{\text{Treatment}} \times 100\% \qquad (7)$$

Results

The Cultural, Microscopic, Biochemical, and Carbohydrate Utilization Properties of the Potato Rhizobacterial Isolates

The cultural, microscopic, biochemical, and the CHO utilization properties of the potato rhizobacterial isolates are displayed in Table 2. All colonies were round in form except for *E. tabaci* MPUS2 and *S. liquefaciens* KIBS5 which were spreading in form and *C. freundii* MWANS4 which had a rhizoid appearance. They portrayed different colors, textures, and margins and most were opaque. All were rod-shaped

and Gram-negative. Similarly, all strains were motile except for *S. marcescens* NGAS9, *E. asburiae* MWAKS5, and *K. oxytoca* MWAKS1 and all were MR-positive except for *C. freundii* MWANS4, *E. asburiae* MWAKS5, *K. oxytoca* MWAKS1, and *E. ludwigii* BUMS1.

Except for *E. asburiae* MWAKS5, the rest of the studied isolates were catalase-positive, with some isolates like *E. ludwigii* BUMS1, *K. oxytoca* MWAKS1, *S. liquefaciens* KIBS5, and *S. marcescens* NGAS9 exhibiting strong catalase activities than the rest of the isolates. Half of the isolates exhibited H_2S production abilities but indole production and O-F tests were positive for all of them. *Klebsiella oxytoca* MWAKS1, *K. grimontii* LUTS1, and *S. marcescens* NGAS9 metabolized all the tested sugars. *Enterobacter ludwigii* BUMS1, *E. tabaci* MATS3, *E. asburiae* MWAKS5, *C. freundii* MWANS4, *E. tabaci* MPUS2, and *E. tabaci* LUTS2 could not metabolize lactose. Additionally, *E. tabaci* MPUS2 and E. tabaci MATS3 could not metabolize cellobiose, *E. tabaci* LUTS2, *E. tabaci* MPUS2, and *S. liquefaciens* KIBS5 could not metabolize sorbitol and *S. liquefaciens* KIBS5 could not metabolize dulcitol.

In vitro Plant Growth Promoting Abilities of the Potato Rhizobacterial Isolates

The results of *in vitro* solubilization of P, Zn, and K by the 10 potato rhizobacterial isolates are portrayed in Fig. 1a–f. Significant differences among the isolates were observed for ZSI in the qualitative assays and quantities of solubilized P ($p = 0.026$), Zn ($p = 0.031$), and K ($p = 0.031$) in the quantitative assays. However, no significant differences were noted for PSI ($p = 0.885$) and KSI ($p = 0.524$) in the qualitative assays. The averages of PSI, ZSI, and KSI were 3.628 ± 0.420, 1.783 ± 0.764, and 3.619 ± 3.563, respectively, while those for quantities of solubilized P, Zn, and K were 100.33 ± 19.90 mg L^{-1}, 67.897 ± 55.46 mg $L^{-1,}$ and 62.897 ± 55.46 mg L^{-1}, respectively. The best P solubilizers were *E. tabaci* LUTS 2, *E. tabaci* MPUS2, and *S. liquefaciens* KIBS5 which recorded average quantities of 115.88, 112.59, and 117.43 mg L^{-1} of solubilized P, respectively. Similarly, *S. marcescens* NGAS9, with average ZSI of 2.94 and *E. ludwigii* BUMS1, with an average of 130.26 mg L^{-1} of solubilized Zn, exhibited the best Zn solubilization abilities in the qualitative and quantitative

Fig. 1 *In vitro* nutrient solubilization abilities of the potato rhizobacterial isolates. On the X axes, 1 = *Enterobacter ludwigii* BUMS1, 2 = *Enterobacter tabaci* LUTS2, 3 = *Serratia marcescens* NGAS9, 4 = *Enterobacter tabaci* MPUS2, 5 = *Citrobacter freundii* MWANS, 6 = *Serratia liquefaciens* KIBS5, 7 = *Klebsiella grimontii* LUS1, 8 = *Enterobacter asburiae* MWAKS5, 9 = *Klebsiella oxytoca* MWAKS1 and 10 = *Enterobacter tabaci* MATS3. Fig. 2 (continued)

assays, respectively. Only two isolates, *C. freundii* MWANS4 and *E. ludwigii* BUMS1 exhibited good K solubilization abilities in the quantitative assays by yielding an average of 112.98 and 125.26 mg L^{-1} of solubilized K, respectively.

The quantity of IAA produced by the potato isolates *in vitro* was not significantly different ($p = 0.080$) (Fig. 2a). Nevertheless, *E. tabaci* LUTS2 yielded the highest quantity of IAA (10.86 μg mL^{-1}) and the average quantity of IAA produced by all the isolates was 5.57 ± 4.51 μg mL^{-1}. Interestingly, the isolates exhibited significantly different ($p = 0.027$) abilities to produce GA (Fig. 2b). The average quantity of GA produced by the isolates was however only 0.423 ± 0.420 μg mL^{-1} and the best GA producer was *E. tabaci* MATS3 with an average of 1.27 μg mL^{-1}. The isolates exhibited significantly different ($p < 0.0001$) N_2-fixation abilities *in vitro* (Fig. 2c, d). The average N_2 fixation zones and quantities of ammonia (NH_3) recorded for them were 1.153 ± 0.440 cm and 27.97 ± 21.09 mg L^{-1}, respectively. *Serratia marcescens* NGAS9 which recorded an average N_2 fixation zone of 1.70 cm and *E. ludwigii* BUMS1 with an average of 79.84 mg L^{-1} produced NH_3 yielded the best results from the two tests used to assess for *in vitro* N_2 fixation. The isolates exhibited significant differences ($p = 0.021$) with regards to the SI averages (Fig. 2e), but no significant differences ($p = 0584$) were observed with regards to the SU averages (Fig. 2f). The average SI and SU recorded for the isolates were 2.79 ± 1.66 and 26.14 ± 18.25%, respectively. The highest average SI of 6.13 was yielded by *E. ludwigii* BUMS1 and the rest of the isolates yielded significantly lower SI averages ranging from 1.67 to 2.71.

Effects of the Rhizobacterial Treatments on Potato Growth Parameters and Rhizobacterial Soils in the Screen House Experiment

The effects of rhizobacterial treatments on various growth parameters related to potato growth in the screen house experiment are shown in Table 3. Although the DTE averages were not significantly different for the different treatments in this experiment ($p = 0.960$), treatment with some rhizobacteria such as *K. oxytoca* MWAKS1, *E. tabaci* LUTS2, and *E. asburiae* MWAKS5 still resulted in DTE reduction by 7.53%, 3.41%, and 7.53%, respectively. Treatment of the potato seed tubers with the various rhizobacterial isolates significantly ($p = 0.027$) improved the DTF of treated plants in comparison to the untreated controls which recorded the

highest DTF of 46. The rhizobacterial treatments reduced the average DTF of potato plants by approximately 6–33%. The DTF reduction by *C. freundii* of 32.68% was significantly higher than all other rhizobacterial treatments.

Although the number of tubers was not significantly different ($P = 0.121$) across the different rhizobacterial treatments and the un-inoculated control, the rhizobacterial treatments still resulted in crops with increased tuber yields above the control which recorded an average tuber number of 8.67. The greatest average number of tubers of 14.67 was observed from the treatment with *S. marcescens NGAS9* corresponding to a 91.21% increase relative to the control plants. Significant differences were observed for tuber weight ($p = 0.010$) and diameter ($p = 0.027$) among the different rhizobacterial treatments and the uninoculated control plants.

The highest average tuber weight of 19.93 g corresponding to a 91.21% increase above the control was recorded for potato plants from the treatment with *S. marcescens* NGAS9. This particular treatment also yielded the largest tuber diameter of 3.87 cm corresponding to a 44.96% increase over the control which recorded an average tuber diameter of 2.13 cm.

No significant differences ($p = 0.189$) were observed for tuber sizes for the different treatments and the control experiment. However, treatment with *S. marcescens* NGAS9 produced an average tuber size of 40.08 cm^3 corresponding to an increase of 87.23% above control treatments. The average shoot lengths of potato plants observed for different rhizobacterial treatments in this study were not significantly different ($p = 0.169$). However, all rhizobacterial treatments except for *E. ludwigii* BUMS1 resulted in increased shoot lengths of the potato plants by between 36% and 54% relative to the un-inoculated controls. The treatment with *E. tabaci* MATS3 gave the maximum shoot weight of 46.33 and the highest increment of 61.86% relative to the un-inoculated control. Interestingly, treatment with *E. ludwigii* BUMS1, though not significant, resulted in shoots with lower weights and lengths in comparison to the un-inoculated control. Similarly, the average shoot weights of potato plants observed for different rhizobacterial treatments in this study were not significantly different ($p = 0.126$). However, the treatments still resulted in increased shoot weights of potato plants by up to 82% relative to the control experiments where the average shoot weight was 2.32 g.

The properties of potato rhizospheric soils from the screen house experiment are provided in Table 4. Significant differences ($p < 0.05$) were among the rhizobacterial treatments and the un-inoculated control for all the studied soil properties except for Fe ($p = 0.077$), P ($p = 0.109$), and pH ($p = 0.493$). The treatment with *E. tabaci* MPUS2 resulted in the highest OM content of 3.56% corresponding to a 60% increment over the un-inoculated control. *Klebsiella grimontii* LUTS1 also yielded the best results in terms of EC, salts, and K contents with averages of 1467.33 uS cm^{-1}, 0.51%, and 31.79 mg kg^{-1}, respectively, corresponding to increments of 48.8%, 49.7%, and 75.3%, respectively, above the un-inoculated control. Treatment of potato plants with *E. asburiae* MWAKS5 also yielded significantly higher averages of OM (2.22%), OM (3.83%), and Zn (92.28 mg kg^{-1}) corresponding to increments of 68.3%, 68.4%, and 66.7%, respectively, over the un-inoculated control.

Except for pH, EC, and salt contents, where some treatments resulted in reduced contents and others, increased contents in rhizospheric soils of the treated potato plants, the quantities of the rest of the soil properties increased as a result of the rhizobacterial treatments. Although no significant differences ($p = 0.077$) were noted among the potato rhizobacterial treatments and the un-inoculated control with regards to Fe contents of the rhizospheric soils, all rhizobacterial treatments resulted in increased Fe contents of between 99.0% and 99.8%. The effects of different rhizobacterial treatments on the nutrient concentration in potato tubers in the screen house experiment are provided in Table 5.

[a]Un-inoculated control experiment

All the studied nutrients in the potato tubers were significantly different ($p < 0.05$) across the different rhizobacterial treatments and the un-inoculated control. The greatest N, protein, and P increments (>85%) were observed for the treatments with *S. marcescens* NGAS9, *E. tabaci* MATS3, and *E. asburiae* MWAKS5. For K, *E. tabaci* MWATS 3 yielded the highest average of 2741.86 mg kg^{-1} corresponding to an 82.3% increment over the un-inoculated control for which the average K content was 486.33 mg kg^{-1}. Similar results were observed for Fe quantity in potato tubers where the same treatment resulted in tubers with an average Fe content of 6.63 mg kg^{-1} corresponding to a 96.7% increment over the control which recorded an average Fe content of 0.126 mg kg^{-1}. Interestingly, the rhizobacterial treatments resulted in tubers with improved Zn content to a great extent over the un-inoculated controls by between 90% and 97%. The highest Zn content of 6429.97 mg kg^{-1} was recorded for the treatment with *E. tabaci* MATS3, an increment of 97.6% over the control whose tubers had an average Zn content of 155.95 mg kg^{-1}.

Discussions

Cultural, Microscopic, Biochemical, and Carbohydrate Utilization Properties of the Isolates

The rhizobacterial isolated exhibited a broad range of morphological features in terms of their colony forms, indicating their relative diversity. All isolates were Gram-negative, agreeing with other reports that that plant rhizospheres are predominantly colonized by Gram-negative bacterial communities. For instance, in a recent study by Mujahid et al. (2015), up to 90% of all studied rhizobacterial isolates from various crop fields, respectively, were also Gram-negative.

Only 3 out of the 10 potato rhizobacterial isolates in this study did not exhibit any form of motility in the MTM. Rhizobacterial motility is an important property that enables bacteria to reach the plant root exudates and flagella-driven chemotaxis is very critical for successful root colonization (Turnbull et al. 2001). Half of the isolates were MR-positive, indicating their ability to produce organic acids which are important in the solubilization of inorganic P (Adeleke et al. 2017). Similarly, the rhizobacterial isolates were all positive for catalase production and some isolates exhibited very strong catalase activities. Catalases are enzymes that act as defense mechanisms for bacteria to detoxify, neutralize, repair, or escape oxidative damages and bactericidal effects of reactive oxygen species like H_2O_2 (Mumtaz et al. 2017). Except for *K. oxytoca* MWAKS1, all the isolates also exhibited citrate utilization which is thought to play a significant role in competitive root colonization and maintenance of bacteria in the rhizosphere (Turnbull et al. 2001).

Half of the potato rhizobacterial isolates exhibited H_2S production. The reduction of sulfide and other sulfate compounds into H_2S is thought to diminish sulfur availability in the soil for plants and is thus not a desirable trait for soil fertility (Choudhary et al. 2018). The isolates all exhibited indole-production in tryptophan-amended cultures, showing their corresponding abilities to produce tryptophanases (Das et al. 2019). Similarly, the rhizobacterial isolates were all positive for the O-F test, indicating their saccharolytic nature which is an important trait for rhizosphere colonization.

The rhizobacterial isolates exhibited varying capacities to metabolize different CHO. A number of them were capable of metabolizing all the sugars but some could not metabolize lactose, sorbitol, and dulcitol. The rhizosphere is generally a nutrient-rich microenvironment due to the presence of rhizodeposits and root exudates with different chemical compositions (Kumar et al. 2018). This can explain the diverse ability of the isolates to utilize different substrates for growth as may be provided for in their natural environments. Substrate preference may confer certain selective advantages in the rhizosphere and multisubstrate utilization may enable rhizobacteria to diversify their nutrient sources for efficient rhizosphere colonization (Zahlnina et al. 2018).

In vitro Plant Growth-Promoting Activities of the Potato Rhizobacterial Isolates

The potato rhizobacterial isolates exhibited varying P, Zn, and K solubilization capacities. The average quantities of solubilized P ranged from 60.96 to 163.47 mg mL^{-1} which is higher compared to previously reported averages for potato rhizobacterial isolates, for example, in studies by Naqqash et al. (2016) where the averages ranged from 30.71 to 141.23 mg L^{-1}. The best P solubilizers were *E. tabaci* LUTS 2, *E. tabaci* MPUS2, and *S. liquefaciens* KIBS5 with average quantities of 115.88, 112.59, and 117.43 mg L^{-1} of solubilized P, respectively. The solubilization of P is proposed to occur through acidification by organic acids and results in the production of di- and mono-basic phosphates which are the only plant-available P forms (Awais et al. 2019). The production of organic acids by the rhizobacterial strains in the present study was evidenced in the biochemical assays and can explain their P solubilization abilities and illustrate how valuable they can be in improving potato P nutrition.

Serratia marcescens NGAS9, with average ZSI of 2.94 and *E. ludwigii* BUMS1, with an average of 130.26 mg L^{-1} of solubilized Zn exhibited the best Zn solubilization abilities in the qualitative and quantitative assays, respectively. Although Zn is a micronutrient, its adequate supply is required for proper potato yields (Vreugdenhil 2007). Since only a small portion of Zn occurs in plant-available forms in most soils, Zn solubilizing bacteria (ZSB) such as the ones identified in the present study have the potential of improving the Zn utilization in potato grown soils (Aloo et al. 2019).

Except for a few isolates, the K solubilization abilities of the potato rhizobacterial isolates followed similar trends to P and Zn solubilization abilities. Two isolates *C. freundii* MWANS4 and *E. ludwigii* BUMS1 particularly showed good K solubilization abilities in the quantitative assays by yielding averages of 112.98 and 125.26 mg L^{-1} of solubilized K, respectively. Evidence suggests that about 98%

of K occurs in soils in fixed forms and only about 2% is available in plant-accessible forms (Meena et al. 2018). As such, efficient KSB such as the ones identified in the present study can significantly enhance potato K nutrition.

All the potato rhizobacterial isolates produced IAA in tryptophan-amended culture media similar to reports by Naqqash et al. (2016). Indole-3-acetic acid is a rhizobacterial PGP hormone that is important for the proliferation of lateral roots and root hairs and enhancement of plant mineral nutrients uptake (Kumar et al. 2018). The average IAA quantity produced by the isolates in the present study was 5.57 ± 4.51 μg mL^{-1}. In a recent study by Jadoon et al. (2019) in Pakistan, lower IAA average quantities of only 2.09 μg mL^{-1} were reported but geographical differences could explain this variation. The isolates generally produced lesser quantities of GA with an average of only 0.423 ± 0.420 μg mL^{-1}. The best GA producer was *E. tabaci* MATS3 with an average of 1.27 μg mL^{-1}. Unlike IAA, reports on rhizobacterial GA production are scanty (Amar et al. 2013), yet GA production is one of the rhizobacterial PGP mechanisms (Aloo et al. 2019).

The average N_2-fixation zones and quantities of NH_3 were 1.153 ± 0.440 cm and 27.97 ± 21.09 mg L^{-1}, respectively. *Serratia marcescens* NGAS9, with an average N_2 fixation zone of 1.70 cm and *E. ludwigii* BUMS1, with an average NH_3 of 79.84 mg L^{-1} yielded the best results in this assay. The diazotrophic abilities of the potato rhizobacteria established in the present investigation indicate the critical role they could be playing in the potato rhizosphere. Although diazotrophy is a common trait in legume symbioses, nitrogenase genes are present in diverse bacterial taxa (Gyaneshwar et al. 2011). Such traits can be optimized and exploited to promote N nutrition in nonlegumes such as the potato using the diazotrophic strains identified in the present study.

The potato rhizobacterial isolates were all capable of producing siderophores which are important metabolites with a high affinity for binding Fe and promoting its availability to plants (Mhlongo et al. 2018). Interestingly, the present isolates showed higher siderophore production abilities than has been reported in other studies for potato rhizobacteria. For instance, the average SU obtained for the isolates in the present investigation was $26.14 \pm 18.25\%$ while in studies by Pathak et al. (2019), potato rhizobacteria produced lower SU means (< 11.97%). Very few potato rhizobacteria have been associated with the siderophore production trait (Aloo et al. 2019), and these siderophore-producing rhizobacterial isolates are important candidates for potato biofertilization.

Effects of the Rhizobacterial Treatments on Growth and Yield of Potted Potatoes

The present study also evaluated the effects of indigenous rhizobacterial treatments on various growth parameters of potted potato under screen house conditions. The results showed that most of the rhizobacterial treatments reduced the DTE and DTF of the potato plants by up to 7.35% and 32.68%, respectively, relative to the un-inoculated controls. Increased germination rates and seedling vigor in plants following inoculation with beneficial rhizobacterial strains are advanced to occur as a result of phytohormone production that enhances growth by stimulating root elongation and development (Ahemad and Kibret 2014).

Except for the number and weight of tubers in the present study, the rest of the potato growth parameters were not significantly different across the treatments and the control treatment. Nevertheless, the rhizobacterial treatments still resulted in increased growth attributes of the plant. For instance, the potato shoot weights were increased by 22–88% upon rhizobacterial inoculation. Such results can also be attributed to the stimulation of root development and nutrient uptake by rhizobacterial PGP hormones (Kumar et al. 2018), whose production was also established for the present rhizobacterial inocula. Contrary to the expectation, *E. ludwigii* BUMS resulted in average potato shoot length and weight that were less than those of the un-inoculated control by 3.94% and 5.94%, respectively. The failure of rhizobacterial inocula to produce the desired results during *in planta* investigations is probably due to the inabilities to establish themselves in the rhizosphere (Istifadah et al. 2018).

The potato rhizospheric soils were also greatly influenced by the rhizobacterial treatments. Most treatments resulted in reduced pH levels relative to the control and increased N, P, K, Zn, and Fe contents in the potato rhizospheres, signifying rhizosphere acidification which is commonly associated with the solubilization of nutrients in the soil. The increased availability of N and P in the rhizospheric soils may be attributed to N_2 fixation and P solubilization by the rhizobacterial inocula as advanced by Sood et al. (2018). The Fe contents in the potato rhizospheric soils increased by up to 99.7% relative to the un-inoculated control following rhizobacterial inoculation, signifying the excellent Fe-mobilization abilities by the rhizobacterial inocula. The soil OC and OM contents also increased significantly for most of the treatments relative to the un-inoculated control.

The present study established that most of the rhizobacterial treatments resulted in tubers with increased nutrient contents, demonstrating improved nutrient uptake and accumulation by the treated plants. This can mostly be attributed to the multitrait inoculants used to treat the potato plants. For instance, the increased uptake and accumulation of N and P may have been due to increased fractions of the minerals in the rhizospheric soils mediated by the rhizobacterial treatments through N_2 fixation and P solubilization, respectively, as similarly observed in wheat by Sood et al. (2018). The inoculation of seed potato tubers with *S. marcescens* NGAS9, *S. liquefaciens* KIBS5, and *E. asburiae* MWAKS5 resulted in tubers with significantly higher N and protein contents, a clear indication of their efficient diazotrophic roles. Interestingly, the treatment of potato seed tubers with *C. freundii* MWANS4 and *K. grimontii* LUTS1, despite exhibiting N_2 fixation abilities in the *in vitro* studies, did not lead to significant increments on the average concentration of N and protein in the potato tubers relative to the un-inoculated control, probably due to the inability to establish adequately themselves in the potato rhizosphere.

Conclusions

The study establishes the importance of indigenous rhizobacterial communities in the biofertilization of potato which can be exploited for its sustainable cultivation. The selected potato rhizobacterial isolates demonstrated efficient N_2-fixing, P-solubilizing, and IAA, siderophores producing abilities. All these characteristics are important PGP traits and have been found effective in positively improving the growth of potted potato plants under screen house conditions. In sustainable crop production, the focus should not only be on increasing crop productivity but also the nutritional value of the food produced for food security. Apart from improving the potato growth parameters relative to the control, the rhizobacterial treatments also enhanced nutrient availability in the rhizospheric soils and improved the potato tuber nutrient contents. The studied isolates are, therefore, potential candidates in future field applications and sustainable cropping of potato in Tanzania.

Climate Change Adaptation Among Smallholder Farmers in Rural Ghana

72

Peter Asare-Nuamah and Athanasius Fonteh Amungwa

Contents

Abstract

Climate change has the potential to disrupt sustainable development initiatives, particularly in developing economies. A substantial body of literature reveals that developing economies are vulnerable to climate change, due to high dependency on climate-sensitive sectors, such as agriculture. In Ghana, a growing body of literature has revealed multiple adaptation strategies adopted by smallholder farmers to respond to and reduce climate change impacts. However, there is a dearth of literature on the effectiveness of adaptation strategies. This chapter explores the adaptation strategies of smallholder farmers and analyzed the predictors of effective adaptation. Through the technique of simple random

sampling, 378 smallholder farmers were selected, and data was collected using a questionnaire survey. Descriptive and inferential statistics were performed using the SPSS software. The findings indicate that smallholder farmers adopt multiple adaptation strategies to reduce the impact of climate change. In addition, it is revealed that marital status, years of farming experience, knowledge of climate change, and education are significant predictors of adaptation. Moreover, the chapter found that marital status, weedicide application, change in staple food consumption, and planting of early-maturing crops are good predictors of effective adaptation. The chapter recommends the need to intensify adaptation strategies through agricultural extension programs and interventions that improve rural food security and livelihood. In addition, the chapter recommends strengthening the capacity of farmer organizations and rural institutions, particularly agricultural extension and advisory services.

Climate change · Climate change adaptation · Effective adaptation · Smallholder farmers · Ghana

Introduction

Background

Climate change adaptation is defined as the adjustment in a system to respond to, recover from, and exploit opportunities, to reduce the impact of climate change. Adaptation has gained center stage in global development debates and discourse (IPCC 2018; World Bank 2018). The heightened attention of adaptation stems from the fact that climate change affects every component of the earth's system, particularly the biosphere and essential life-dependent resources (IPCC 2018). More importantly, climate change affects agriculture, thereby increasing the vulnerability of developing countries, whose economies are largely dependent on climate-sensitive sectors, including agriculture (AGRA 2014; IPCC 2018). According to the Intergovernmental Panel on Climate Change (IPCC) (2014, 2018), adaptation strategies are very important in developing economies in Africa and Asia, as the impact of climate change is already felt in extreme in these regions. For instance, climate-related disasters, such as floods and droughts, are predominant and extreme in Africa and Asia. Moreover, El Nino Southern Oscillation (ENSO) has been reported in Southern and West Africa, with prolonged dry season in Ghana (see Hirons et al. 2018; IPCC 2014, 2018). Consequently, a large body of literature has focused on examining the adaptation strategies adopted particularly by smallholder farmers to respond to these changes, with little or no attention on the effectiveness of adaptation as a conduit for food security and livelihood, which this chapter seeks to address. Dankelman (2010) asserts that adaptation strategies, particularly in developing countries, are ineffective and unsustainable, as they are practiced in a resource-constrained environment, which calls for the need to examine effective adaptation strategies employed by smallholder farmers to enhance their food security and livelihood.

According to the European Environment Agency (EEA 2013), effective adaptation requires holistic, concrete, and process-based measures and approaches, whereas the German Development Agency (GIZ 2014) and IPCC (2007, 2014) argue that effective adaptation strategies have the potential to increase adaptive capacity and offset the negative impact of climate change, by decreasing sensitivity and exposure to climate change. Globally, farmers have adopted adaptation strategies to reduce vulnerability and respond to climate shocks and stresses, such as erratic rainfall, high temperature, flood, drought, and pests, among others (IPCC 2007, 2014, 2018). Adaptation strategies may be self-induced or externally planned; proactive, reactive, or concurrent; planned or spontaneous; and tactical or strategic. In addition, they may occur at different scales, such as local, regional, or international; by agents of adaptation including but not limited to individuals, communities, governments, the private sector, and non-governmental/civil society organizations (Antwi-Agyei et al. 2014a; Bryant et al. 2000; Smit et al. 2000; Smit and Skinner 2002; IPCC 2014). To ensure an effective adaptation, it is essential for adaptation agents to adopt planned adaptation behaviors, which are typical of disaster preparedness, as well as ensure effective response and recovery to disasters (World Bank 2018b).

A growing body of literature has revealed that farmers have adapted to climate change through multiple on-/off-farm adaptation strategies such as climate-smart agricultural practices, to enhance their livelihood and food security, which depend largely on the environment (Antwi-Agyei et al. 2014a; Gyampoh et al. 2009; Pearce and Ford 2015; Yaro et al. 2014). In Ghana, for instance, crop and livelihood diversification; pesticide, weedicide, and fertilizer application; water harvesting; and planting of early-maturing and drought-resistant crops have been reported in the literature (Antwi-Agyei et al. 2014a, b; Fosu-Mensah et al. 2012; Gyampoh et al. 2009; Osumanu et al. 2017; Yaro 2013a, b; Yaro et al. 2014). Nevertheless, Sarpong and Anyidoho (2012) argue that the adaptation strategies in Ghana are not effective due to poor policy environment, whereas Connolly-Boutin and Smit (2016) and the IPCC (2014) argue that poor natural resource management, low adaptive capacity, and poverty make the adaptation strategies ineffective in Africa.

According to the GIZ (2014) and Turner et al. (2003), entitlement, access, and endowment influence the adaptive capacity to climate change. This corroborates the assertion that the assets owned, used, and/or available to communities and households enable them to adapt to climate change (IPCC 2007, 2014). Similarly, studies have demonstrated that adaptation is dependent on multiple socioeconomic factors, such as age, gender, years of farming experience, assets, level of education, household size, and technology (Adu et al. 2018; Fosu-Mensah et al. 2012; Lopez-Ridaura et al. 2018). The present study aims to achieve the following objectives: explore adaptation strategies of smallholder famers and predict factors that promote adaptation and effective adaptation. The rest of the paper presents the methods, results, and conclusion.

Description of the Study Area and Methodology

Study Area

The study was conducted in the Adansi North District, located in the Ashanti Region of Ghana on longitude 1.50 W, latitude 1.4 N and longitude 1.5 W, latitude 6.30 N. It covers about 853.63 km^2, which is equivalent to 4.7% of the surface area of the region. It also has a total population of about 107,109, with 54,036 (50.5%) females and 53,055 (49.5%) males (GSS 2010, 2014). The dependency ratio in the district is high, with males found to be more dependent than females (GSS 2014). Located in the semi-equatorial climate, the district experiences high temperature and rainfall, with a mean rainfall of 1250 mm to 1750 mm and temperature of 27 °C. The district has bi-modal rainfall patterns, comprising of major and minor rainy seasons. February is the hottest month in the district, and agriculture is the major economic activity, employing about 77% of the labor force, followed by services (15%) and manufacturing (8%) (GSS 2014). The district has rich ochrosols, which favor agriculture and forest vegetation. The major food crops produced here include cassava, plantain, cocoyam, maize, yam, and cash crops, such as cocoa and oil palm. As a rural district, poverty, low income, and lack of access to basic socioeconomic assets are dominant in the district (GSS 2014).

Research Methods

Study Site Selection and Sampling Method

A total of 15 communities from 7 operational areas were selected via multistage sampling techniques comprising of cluster and simple random sampling. The district has 15 operational areas which served as the clusters from which 7 were randomly selected. A sample of 378 farm household heads was randomly selected using the district census data as the sample frame. Krejcie and Morgan's (1970) statistical table for sample size selection led to the selection of 378 respondents from the household population of 23,863.

Data Sources and Collection Methods

The chapter used quantitative primary data. Data collection lasted for 6 months, starting from April to September 2018. Prior to data collection, the Institutional Review Committee of the Pan African University, Cameroon, approved the study. The data collection instrument was questionnaire survey. The questionnaire was divided into sections to collect data on the respondents' demographic characteristics, access to essential assets, and adaptation strategies.

Data Analysis

Primary data was analyzed using the Statistical Package for Social Sciences (SPSS) version 20. Data cleaning was performed through frequency analysis to identify the missing data. Preliminary analyses, such as outliers and normality tests, were

Table 1 Variables description and coding

Variable description	Variable coding
Dependent variable	
Have you adapted to climate change?	Yes = 1 No = 0
Independent variables	
Sex	Male = 1 Female = 0
Age	Years (Number)
Household size	Number
Education	Yes = 1 No = 0
Marital status	Married = 1 Else = 0
Access to land	Yes = 1 No = 0
Access to extension	Yes = 1 No = 0
Access to market	Yes = 1 No = 0
Knowledge of climate change	Yes = 1 No = 0
Access to technology (e.g. phone)	Yes = 1 No = 0
Farming experience	Yes = 1 No = 0

Source: Fieldwork, 2018

conducted using box and scatter plots as well as line graphs (Pallant 2016). Two binary logistic regression models were specified for the analysis. The first binary logistic regression model explored factors that predicted the respondents' climate change adaptation strategies. The dependent variable in the first model was adaptation that was operationalized as whether or not a respondent has adapted to climate change using any of the strategies available to them. The independent variables comprised of categorical and continuous variables, such as age, sex, household size, farming experience, marital status, access to land, access to technology (phone), access to market, extension service, and knowledge of climate change. Table 1 presents the variable coding and description.

The use of the preliminary regression model without the predictor variables resulted in an overall percentage of 59.2% in terms of whether respondents have adapted or not, which served as a baseline for comparison with the regression model that included predictor variables (Pallant 2016). The Omnibus Tests of Model Coefficient, which determines the "goodness of fit" of the regression model resulted in a significance level of 0.006 (p <0.05). The Omnibus goodness of fit test also resulted in a chi-squared value of 26.193, with 11 degrees of freedom. In addition, the Hosmer–Lemeshow goodness-of-fit test resulted in a chi-squared value of 6.701

with 8 degrees of freedom and a significant value of 0.569. Pallant (2016) asserts that for the Hosmer–Lemeshow test to be significant, the significant value must exceed 0.05. The significant value of 0.569 exceeded 0.05, which is indicative of the goodness of fit of the model. The Cox and Snell R-squared and Nagelkerke R-squared indicated that the predictor variables account for 26.7% and 29.1% of variation in the dependent variable, respectively. In addition, the percentage accuracy in classification (PAC) table (Pallant 2016) resulted in an overall percentage of 62.3%, which exceeded the initial value of 59.2%. This chapter computed for the sensitivity of the model. According to Pallant (2016), the sensitivity of the model is defined as the percentage of the respondents who have or have not adapted to climate change, which has been accurately identified by the model. It is computed by dividing the number of cases predicted by the total number predicted and multiplied by 100 (Pallant 2016). The positive predictive (true positive) value indicates the percentage of respondents who have adapted to climate change and has been accurately identified by the model. The positive predictive value is 57.5%. Conversely, the negative predictive value (true negative) is the percentage of respondents who have not adapted and has been accurately identified by the model. The computation resulted in 61.8% for the negative predictive value.

In the second model, a binary logistic regression analysis was conducted to understand the adaptation strategies that effectively improve the respondents' food security and livelihood. The dependent variable was "whether or not adaptation strategies effectively enhance food security and livelihood of respondents." The independent variables consisted of categorical variables of 24 different adaptation strategies adopted by the respondents. In addition, the predictors of adaptation from the first model were included in the second model. Table 2 presents the coding and description of variables used in the second regression model.

The initial regression model without the predictor variables resulted in an overall percentage of 88.9% in terms of whether or not adaptation enhances food security and livelihood. The Omnibus Test of Model Coefficient resulted in a significance level of 0.018 (p <0.05), with a chi-squared value of 45.858 and 28 degrees of freedom. The Hosmer–Lemeshow goodness-of-fit test resulted in a chi-squared value of 7.085 with 8 degrees of freedom, at a significant value of 0.527. The Cox & Snell R-squared and Nagelkerke R-squared values were 0.114 and 0.227 respectively, indicating that the predictor variables account for 11.4% and 22.7% of the variation in the dependent variable, respectively.

The PAC table resulted in an overall percentage of 89.4%, exceeding the initial value of 88.9%. In addition, the chapter computed for the sensitivity of the model, which is the percentage of the respondents accurately identified by the model as those who indicated that adaptation enhances or does not enhance food security and livelihood. Sensitivity is computed by dividing the number of cases predicted by the total number predicted and multiplied by 100 (Pallant 2016). The positive predictive value (true positive) indicates the percentage of respondents who indicated that adaptation effectively enhances food security and livelihood. The positive predictive value was 89.8%. The negative predictive value (true negatives) is, however, the

percentage of respondents who were accurately identified by the model to have indicated that adaptation does not enhance their food security and livelihood. The negative predictive value was 66.7%.

Results and Discussion

Adaptation Strategies Employed by Smallholder Farmers

The respondents in the study have adopted multiple adaptation strategies as presented in Table 3. The dominant adaptation strategy of the respondents is crop diversification, as reported by 93.4% of respondents. Antwi-Agyei et al. (2014a) similarly reported that majority of smallholder farmers in the Bongo District in the Upper East Region of Ghana practice crop diversification, as a response to climate change. Crop diversification is a traditional farming practice where multiple crops are planted on the same plot of land. The system enables farmers to harvest different crops throughout the year, thereby increasing food security. The practice may be influenced by the different maturity periods of crops, nutrient requirement, and demand on the market. Majority of the respondents have resorted to delay farming (70.1%), fertilizer application (68%), planting of early-maturing crops (42.1%), improved crop varieties (33.9%), and multiple-cropping season (51.3%). About 51.1% of the respondents reported of extension services. Studies have reported that extension services enable farmers to adapt to climate change through the transfer of knowledge and emerging farm practices (Boyaci and Yildiz 2016; Morrison and Sarris 2007).

Aside from extension services, the Government of Ghana's agricultural interventions, such as cocoa spraying and cocoa pollination, were also reported by 42.1% and 34.7% of the respondents, respectively, as adaptation strategies. It is interesting to note that some farmers are turning to the application of chicken dropping (17.5%) as an alternative to chemical fertilizer, which they hinted to be expensive. Unique to the findings of this chapter is the application of "So-Klin," a washing detergent used

Table 3 Respondents' adaptation strategies

Indicators	(%)	N (378)
Migration	8.3	33
Fertilizer application	68.0	257
So Klin application	44.4	168
Planting of early-maturing crops	42.1	159

Farm expansion	38.4	145
Joining in farm-based organizations	3.7	14
Chicken dropping application	17.5	66

Source: Fieldwork 2018

to control fall armyworm invasion. Some respondents indicated that they use both "So-Klin" and pesticides to control fall armyworms. It is reported that fall armyworms cause significant crop loss, particularly maize, sorghum, and millet (FAO 2018; Wild 2017). In Ghana, about 1.4 million ha of maize and cowpea have been destroyed by fall armyworms, whereas about 6400 ha of cocoa farms have been invaded (African Union 2017; Mpofu 2017; OCHA 2017). Loss of maize from fall armyworms in Africa has been estimated at US$3 billion (African Union 2017). About 57.4% of the respondents have diversified their livelihood. Livelihood diversification has been reported in by Antwi-Agyei et al. (2014a, b) as a conduit to climate change adaptation. Table 3 demonstrates that the respondents have resorted to diet-related adaptation strategies as a response to climate change. For instance, respondents reported reduction in meal size (66.4%), change in diet/staple food (52.4%), and reduction in the number of diets (57.4%), which are consistent with the literature (Giannini et al. 2016; Quaye 2008). Other adaptation strategies include help from family and friends (40.5%), pesticide (34.7%) and weedicide (43.2%)

application, change in livestock (35.3%), farm expansion (38.4%), irrigation (26.7%), and planting of drought-resistant crops (18.3%).

Predictors of Adaptation Strategies

The output of the binary logistic regression analysis is presented in Table 4. The beta (β) values represent the change in the logit of the outcome variable (the log odds ratio) with a unit change in the predictor variable. The β value for years of farming experience, for instance, is −0.616, which indicates that an increase in the experience of a respondent by 1 year will result in a decrease in the adaptation of the respondents to climate change by 0.616. Put differently, the finding indicates that as the years of experience of a respondent increase, there is less likelihood that the respondent will not adapt to climate change. An increase in education increases climate change adaptation by 0.581, whereas access to market and marital status also increase adaptation by 0.178 and 0.583, respectively. Respondents with knowledge of climate change are more likely to adapt to climate change by 1.715. These findings are consistent with the literature (Osumanu et al. 2017; Tessema et al. 2018). For instance, as the level of education increases, farmers are likely to increase their climate change knowledge and become more concerned of the need to adapt. In addition, education increases farmers' knowledge of available and emerging adaptation strategies, including technology and climate-smart agriculture.

The Wald statistic with a chi-squared distribution demonstrates whether or not the β values for predictor variables are significantly different from zero (Mensah 2008). From Table 4, household size, for instance, has a Wald statistic of 2.171, which is significantly different from 0. However, the contribution of household size to the model is statistically insignificant at a p-value of 0.141 (thus, p <0.05). From the model, years of experience, education, marital status, and knowledge of climate

Table 4 Binary logistic regression of the predictors of climate change adaptation

Variables	β	Wald	Significance	Exp(β)
Sex	−0.112	0.176	0.675	0.894
Age	0.008	0.728	0.393	1.008
Household size	0.037	2.171	0.141	1.037
Experience	−0.616	3.752	0.050*	0.540
Education	0.581	4.738	0.030*	1.789
Marital status	0.583	4.085	0.043*	1.792
Access to land	−0.520	1.582	0.208	0.594
Access to technology	−0.443	1.712	0.191	0.642
Access to extension services	−0.028	0.012	0.914	0.973
Market	0.178	0.451	0.502	1.195
Climate change knowledge	1.715	4.739	0.029*	5.559
Constant	−2.310	5.263	0.022	0.099

Source: Computed from fieldwork 2018

change have Wald statistics of 3.752, 4.738, 4.085, and 4.739, respectively, which are statistically significant at p-values of 0.050, 0.030, 0.043, and 0.029, respectively. Marital status, for instance, plays a significant role in climate change adaptation, as it promotes pool of resources. In addition, married household heads are more likely to adapt due to their responsibility to feed their families and cater for their wards. Studies have revealed that the farming experience and knowledge of climate change significantly influence climate change adaptation (Osumanu et al. 2017; Tessema et al. 2018).

Another important statistic presented in Table 4 is the Exp(β). These values, which are the odd ratios of the predictor variables, show the odds of the outcome variable occurring as a result of a unit change in the predictor variable. Statistically, the odd of an event is the probability of that event occurring divided by the inverse or the probability of that event not occurring (Mensah 2008). Exp(β) values greater than 1 means that an increase in the predictor variables results in an increase in the odds of the outcome variable, whereas Exp(β) values less than 1 show an inverse relationship between the odds of the outcome and the predictor variable. For instance, knowledge of climate change has Exp(β) value of 5.559, which indicates that there is a positive relationship between adaptation and knowledge of climate change. As such, it can be interpreted that increasing the knowledge of climate change of a respondent increases the respondent's adaptation to climate change. Table 4 demonstrates that age, household size, education, marital status, and market increase adaptation to climate change, whereas sex, experience, access to land, technology, and extension service reduce adaptation to climate change. It can be concluded from the model that years of experience, education, marital status, and knowledge of climate change are significant predictors of climate change adaptation, which is consistent with the previous studies (Osumanu et al. 2017; Tessema et al. 2018). The equation of the model can be written as Logit(Adaptation) = −2.310(Constant) −0.112*Sex + 0.008*Age + 0.037*Household size −0.616*Experience + 0.581*Education + 0.583*Marital status − 0.520*Land − 0.443*Technology − 0.028*Extension + 0.178*Market + 1.715*Climate change knowledge.

Predictors of Effective Adaptation

Table 5 presents the output of the binary logistic regression estimation. The β value is the change in the logit of the outcome variable (the log odds ratio) as a result of a unit change in a the predictor variable. The β values indicate that improved crop varieties, weedicide application, and change in staple food consumption, for instance, increase food security and livelihood by 1.130, 1.315, and 1.333, respectively. It can be asserted that improved crop varieties, weedicide application, and change in staple food consumption have positive relationships with food security and livelihood. The more a respondent adopts these adaptation strategies, the more likely food security and livelihood of the respondent will improve. Other adaptation strategies, such as cocoa spraying, multiple-cropping season, and drought-resistant crops, are positively related to food security and livelihood as a unit increase in these strategies

Table 5 Binary logistic regression of the predictors of effective adaptation

Variables	β	Wald	Significance	Exp(β)

Source: Computed from fieldwork 2018

improves food security and livelihood by a margin of 0.474, 0.531, and 0.884, respectively. Among the predictors of adaptation, years of farming experience (0.154) and marital status (0.749) have a positive relationship with food security and livelihood.

The Wald statistic demonstrates whether or not the β values for predictor variables are significantly different from zero (Mensah 2008). Predictor variables such as marital status, chicken dropping application, planting of early-maturing crops, livelihood diversification, pesticide application, weedicide application, reduction in the number of diets, and change in staple food consumption, for instance, are significantly different from zero with Wald statistics of 3.582, 3.465, 3.918, 2.212, 2.138, 3.444, 3.432, and 7.111, respectively. The significance column in the table presents the level of significance of the predictor variables in predicting effective adaptation. The model indicates that effective adaptation is significantly predicted by planting early-maturing crops (0.048), weedicide application (0.050), change in staple food consumption (0.008), and marital status (0.053). The Exp(β) values are the odds of the outcome variable occurring as a result of a unit change in the predictor variable. Statistically, the odd of an event is the probability of the event occurring divided by the inverse or the probability of that event not occurring (Mensah 2008). Exp(β) values greater than 1 indicate that an increase in the predictor variables result in an increase in the odds of the outcome variable, whereas Exp(β) values less than 1 show an inverse relationship between the odds of the outcome and the predictor variable.

For instance, planting of drought-resistance crops, change in staple food consumption, weedicide application, and improved crop varieties have Exp(β) values greater than 1 which indicates a positive correlation between effective adaptation (food security and livelihood) and these predictors. Marital status (0.001), planting of early-maturing crops, (0.266), and pesticide application (0.372), for instance, have Exp(β) values less than 1 which indicates an inverse or negative relationship with effective adaptation (food security and livelihood). It can be summed up from the model that planting of early-maturing crops, weedicide application, change in staple crop consumption, and marital status significantly predict effective adaptation (food security and livelihood). The equation of the model can be written as Logit(EffectiveAdaptation) = 20.933(Constant) + 0.035*Migration + 0.016*Fertilizer application + 0.418*So Klin application −1.325*Planting of early-maturing crops + 1.130*Improved crop varieties −0.705*Livelihood diversification + 0.221*Help from family and friends + 0.246*Crop diversification −0.655*Delayed farming + 0.531*Multiple-cropping season −1.117*Pesticide application + 1.315*Weedicide application + 0.2008*Cocoa pollination + 0.474*Cocoa spraying −1.156*Reduced number of diets − 0.357*Reduced meal size + 1.333*Change in staple food − 0.308*Irrigation + 0.176*Extension − 0.843*Change in livestock + 0.884*Planting of drought-resistant crops − 0.008*Farm expansion − 1.145*Joining in farm-based organization − 0.822*Chicken dropping application + 0.154*Experience − 0.365*Education +0.749*Marital status − 18.547*Climate change knowledge.

Conclusion and Recommendations

Ghana’s ability to promote food security, livelihood, and rural and pro-poor economic development is largely dependent on agriculture and hence smallholder farmers who constitute the bulk of the labor force in Ghana and contribute about 80% of the food produced. The agriculture sector, in particular, and smallholder farmers, in general, are vulnerable to climate change, due to subsistence and climate-dependent nature of agriculture and low adaptive capacity of smallholder farmers, in addition to high poverty and less access to essential assets. Nevertheless, smallholder farmers in Ghana are adapting to climate change through multiple self-induced and externally supported adaptation strategies. This chapter, which sought to explore smallholder famers' adaptation and examine the predictors of adaptation and effective adaptation, found that smallholder farmers in the rural Adansi North District of Ghana use multiple on-/off-farm and diet-based adaptation strategies to respond to climate change. The chapter also found that marital status, years of farming experience, education, and knowledge of climate change significantly influence adaptation, whereas marital status, weedicide application, change in diet/staple food, and planting of early-maturing crops significantly enhance effective adaptation (food security and livelihood) of smallholder farmers.

While farmers are adapting to climate change, most adaptation strategies of smallholder farmers do not necessarily enhance their food security and livelihood, which may be due to the resource-constrained environment and low adaptive capacity. As such, it is imperative that social intervention programs and policies that promote resource distribution and access must be strengthened, particularly in rural communities, to increase smallholder farmers' access to essential socioeconomic assets, thereby increasing adaptive capacity, improving adaptation strategies, and reducing climate change impacts. In addition, mass education of farmers on climate change must be intensified to improve climate change knowledge/perception, reduce misconceptions associated with climate change, and ensure effective adaptation, as farmers' climate change perception strongly influences climate change adaptation. Farm-based organizations can play a significant role in climate change education and must be promoted particularly in rural communities. Moreover, local institutions, particularly those that provide extension and advisory services, must be intensified and resourced with technology, personnel, and infrastructure to provide services that enable farmers to adapt effectively to climate change through skills and knowledge transfer.

While this chapter limited its geographic scope to only the Adansi North District, the chapter could do better if it covered a wider geographic scope across different ecological zones in Ghana, to deepen the understanding of how different communities are adapting to climate change, which is very important for fit-for-purpose climate change policies. Hence, further studies must consider larger population with a wider geographic location to better understand climate change adaptation in Ghana. In addition, a combination of quantitative and qualitative data on climate change adaptation can greatly improve an understanding of climate change and advance the debate on adaptation. This chapter used only quantitative data, but future studies must go further to include qualitative lived experiences of smallholder farmers. Nevertheless, the chapter has made significant contributions to climate change discourse and has provided insights, with the potential to shape climate change policies in Ghana, in particular, and Africa, in general.

Abstract

Biomass Burning (BB) aerosol has attracted considerable attention due to its detrimental effects on climate through its radiative properties. In Africa, fire patterns are anticorrelated with the southward-northward movement of the intertropical convergence zone (ITCZ). Each year between June and September, BB occurs in the southern hemisphere of Africa, and aerosols are carried westward by the African Easterly Jet (AEJ) and advected at an altitude of between 2 and 4 km. Observations made during a field campaign of Dynamics-Aerosol-Chemistry-Cloud Interactions in West Africa (DACCIWA) (Knippertz et al., Bull Am Meteorol Soc 96:1451–1460, 2015) during the West African Monsoon (WAM) of June–July 2016 have revealed large quantities of BB aerosols in the Planetary Boundary Layer (PBL) over southern West Africa (SWA).

This chapter examines the effects of the long-range transport of BB aerosols on the climate over SWA by means of a modeling study, and proposes several adaptation and mitigation strategies for policy makers regarding this phenomenon. A high-resolution regional climate model, known as the Consortium for Small-scale Modelling – Aerosols and Reactive Traces (COSMO-ART) gases, was used to conduct two set of experiments, with and without BB emissions, to quantify their impacts on the SWA atmosphere. Results revealed a reduction in surface shortwave (SW) radiation of up to about 6.5 W m^{-2} and an 11% increase of Cloud Droplets Number Concentration (CDNC) over the SWA domain. Also, an increase of 12.45% in Particulate Matter (PM_{25}) surface concentration was observed in Abidjan (9.75 μg m^{-3}), Accra (10.7 μg m^{-3}), Cotonou (10.7 μg m^{-3}), and Lagos (8 μg m^{-3}), while the carbon monoxide (CO) mixing ratio increased by 90 ppb in Abidjan and Accra due to BB. Moreover, BB aerosols were found to contribute to a

70% increase of organic carbon (OC) below 1 km in the PBL, followed by black carbon (BC) with 24.5%. This work highlights the contribution of the long-range transport of BB pollutants to pollution levels in SWA and their effects on the climate. It focuses on a case study of 3 days (5–7 July 2016). However, more research on a longer time period is necessary to inform decision making properly.

This study emphasizes the need to implement a long-term air quality monitoring system in SWA as a method of climate change mitigation and adaptation.

Introduction

Biomass Burning (BB) is one of the major sources of aerosols in Africa after Saharan dust. In the form of submicron accumulation mode BB pollutants are mainly composed of organic carbon (OC) and black carbon (BC) aerosols and carbon monoxide (CO), hydrocarbon, and nitrogen oxide (NO_x), as gaseous pollutants. During the previous decades, an increasing number of studies have investigated the impacts of BB aerosols on radiation, weather, and climate. In general, the African fire pattern is strongly associated with the southward movement of the intertropical convergence zone (ITCZ) (N'Datchoh et al. 2015; Swap et al. 2002). BB occurs as a result of anthropogenic activities, such as land management, livestock grazing, and crop production (Bowman et al. 2011; Stowe et al. 2002; Mbow et al. 2000). BB is an important source of aerosols and trace gases in the atmosphere, with an estimated burned biomass of 3260–10,450 Tg a^{-1} for tropical areas (Barbosa et al. 1999). Hao and Liu (1994) estimated that there was an amount of 2500 Tg a^{-1} (46% of the tropics in total) over the tropical regions of Africa, to which the savanna contributes up to 1600 Tg a^{-1} (30% of the total amount over the tropics).

BB affects the radiative energy budget of the Earth by absorbing and scattering solar radiation and modifies the properties of clouds as they serve as cloud condensation nuclei (CCN) or ice nuclei (IN). The global mean direct radiative effect of BC and OC from BB was quantified as being 0.155 W m^{-2} for their overall effect, with 0.25 W m^{-2} for BC (absorption) and −0.005 to +0.4 W m^{-2} for OC (Jiang et al. 2016). BC traps a significant part of solar radiation in the atmosphere, thus reducing the surface incoming radiation as well as low surface sensible and latent heat fluxes (Huang et al. 2016). A modeling study by Walter et al. (2016) investigated the impact of the Canadian forest fires that occurred in July 2010 on SW radiation and temperature using the regional climate model, Consortium for Small-scale Modelling – Aerosols and Reactive Traces gases (COSMO-ART). Downwelling surface SW radiation was found to be reduced by up to 50% below the biomass plume under cloudless conditions due to absorption in dense smoke layers, furthermore leading to a decrease of up to 6 K of 2-m temperature. Surface cooling, as well as a warming in elevated layers, led to an increase in atmospheric stability, which induce a decrease of precipitation.

Thornhill et al. (2018) analyzed 30-year simulation to assess the impact of BB on the regional climate of South America. The simulations found a decrease in the downwelling clear-sky and all-sky SW radiation at the surface by 13.77 W m^{-2} and 7.37 W m^{-2}, respectively. Mean surface temperature was reduced by 0.14 ± 0.24 °C and a mean precipitation decrease of 14.5% was found in the peak region of BB. The authors found that, if BB increases during a particular dry season, the resulting decrease in precipitation may in fact exacerbate drought. Pani et al. (2016) estimated the direct aerosol radiative effects of BB aerosols over northern Indochina from observed ground measurements of the optical properties of such aerosols. They found that the overall mean aerosol radiative forcing was $-8\ W\ m^{-2}$ and $-31.4\ W\ m^{-2}$ at TOA and at the surface, respectively.

Similarly, Huang et al. (2013) investigated the impact of direct radiative forcing of BC on West African Monsoon (WAM) precipitation during the dry season, and concluded that there was a reduction in precipitation in the WAM region due to the radiative effect of BC. They demonstrated that aerosols from the southern African hemisphere significantly reduced convective precipitation, particularly during the boreal cold season, when BB smoke was prevalent. They also highlighted that BB can affect local weather and climate over West Africa. These results suggest that reductions in cloud amount, cloud top height, and surface precipitation are due to a high BC aerosols load in the atmosphere.

During the airborne measurement campaigns of the Stratospheric Ozone Experiment (STRATOZ) of March 1985 and the Tropospheric Ozone Experiment (TROPOZ) of December 1987, Marenco et al. (1990) discovered that large CO concentrations are present over the mid-Atlantic Ocean as well over West Africa, which is evidence of the lofting of BB from Central and Southern Africa. The plumes arising from agricultural burning fumes mix in a 3–4 km deep boundary layer over Africa as a result of convergence, before overriding moister and cooler air and being advected westward over the Atlantic Ocean (Chatfield et al. 1998). In another study, it was shown that BB plumes from Central and Southern Africa are transported each year during the WAM season and carried westward by a jet located at 700 hPa between 2 and 4 km altitude (Barbosa et al. 1999; Mari et al. 2008). In addition, Real et al. (2010) found ozone plumes in the mid- and upper troposphere over the Gulf of Guinea as a result of the long-range transport of BB from Central Africa. Using backward trajectories, Mari et al. (2008) demonstrated that the intrusion of BB into the upper troposphere of the Gulf of Guinea and the northern hemisphere was controlled by the active and break phases of the southern hemisphere's African Easterly Jet (AEJ) during the summer monsoon (July–August 2006).

The number and size distributions of BB aerosols in southern West Africa (SWA) are dominated by the accumulation mode (Haslett et al. 2019). Likewise, according to a modeling study by Menut et al. (2018), BB from Central and Southern Africa has increased the level of air pollution in urban cities, such as Lagos and Abidjan (approximately $150\ \mu g\ m^{-3}$ for CO, $10–20\ \mu g\ m^{-3}$ for O_3, and $5\ \mu g\ m^{-3}$ for $PM_{2.5}$). The contribution of BB in $PM_{2.5}$ concentrations from Central Africa increased from ~10% in May to ~52% in July (Deroubaix et al. 2018). Haslett et al. (2019) found a significant aerosol mass concentration in the SWA boundary layer, both over the ocean and over the continental background, with similar chemical properties. They suggested that the upstream (Gulf of Guinea) aerosols originated from Central African BB, and demonstrated that these aerosols affected cloud optical properties but were less sensitive to precipitation.

Although there have been studies, like the above, on the distribution and impact of BB in various regions the impact of BB aerosols from Central and Southern Africa on the meteorology and climate over SWA specifically has not yet been fully investigated.

Research during these past decades has shown that BB aerosols injected into the atmosphere have adverse effects on radiation and climate. Remote pollution from the long-range transport of BB appears to affect the levels of atmospheric aerosol pollution over SWA during the summer monsoon. It originates from Central and Southern Africa as a result of agricultural activities, land management, livestock grazing, and crop production. It is carried westward by the African Easterly Jet (AEJ) toward the tropical Atlantic Ocean, the Gulf of Guinea, and SWA, aloft at the mid-level troposphere (2–4 km). Recently, an intensive field campaign within the framework of Dynamics-Aerosol-Chemistry-Cloud Interactions in West Africa (DACCIWA) in SWA, observed large amounts of the BB as background concentration in the Planetary Boundary Layer (PBL), dominated by OC (Haslett et al. 2019).

In this chapter, then, the changes in atmospheric variables (precipitation, clouds, solar radiation) due to BB aerosols are examined. During a case study of 3 days (5–7 July 2016), two sets of simulations are performed: with and without BB. The differences make it possible to quantify the impacts of BB on the state of the atmosphere. The following research questions are addressed in this work:

- What is the relative contribution of BB aerosols to the atmospheric composition of the SWA region?
- What is the effect of BB on the climate of SWA?
- What are the practical behaviors and actions to be taken in order to reduce the level of pollution over SWA?

Description of the Study Area and Methodology

This section describes the study area, where the data was obtained (section "Study Area"), and the methodology used (section "Methods") to obtain the results.

Study Area

The study domains comprise an outer domain, that is, D1: West Africa, and a nested domain, that is, D2: southern West Africa (SWA), spreading from 3°N to 10°N and 9°W to 4°E (Fig. 1). The latitudinal extent of D1 (18°W–26.6°E; 20°S–24.6°N) covers the Sahel region, as well as the eastern Atlantic Ocean and Central Africa. The wide spatial coverage of D1 allows us to account for the long-range transport of aerosols, such as dust aerosol from the Sahel and the Sahara Desert and BB from Central Africa. The nested domain D2 (9°W–4°E; 3°–10.8°N), located in SWA, is characterized by tropical forest in the South and grassland and savanna in the North. The climate is that of typical tropics zones governed by the North-South shift of the Intertropical Convergence Zone (ITCZ) or the Intertropical discontinuity (ITD) (over the land), which determines the rainy/dry seasons. During the period under

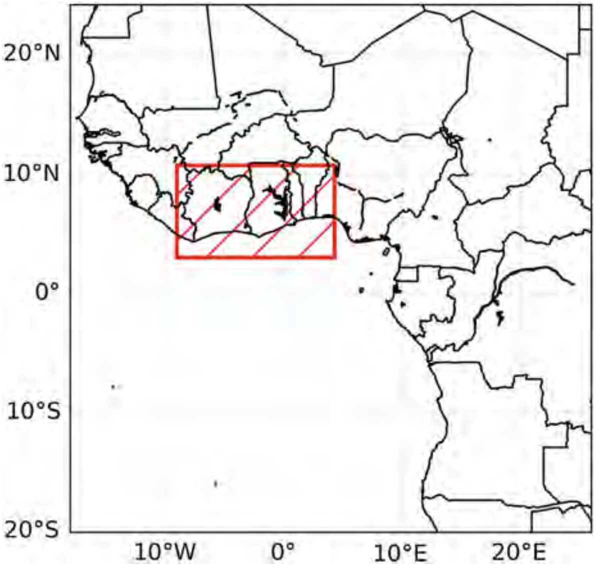

Fig. 1 Model domains D1 (outer domain) and D2 (nested domain) hacked in red. The horizontal resolution in case of D1 is 5 km and in case of D2 is 2.5 km

investigation (July 2016), the WAM was prevalent in the study domain. The WAM is generated by the temperature gradient between the Atlantic Ocean, which is cool (monsoon), and the north (the Sahara Desert), which is warm.

Methods

This section describes the model setup (section "Model Setup") and the biomass burning experiment (section "Biomass Burning Experiment").

Model Setup

Simulations were performed with the regional scale model COSMO-ART (Vogel et al. 2009) at a spatial resolution of 5 km for D1 and nested to 2.5 km for D2 with 50 and 80 levels up to 30 km altitude above ground level (AGL), respectively. Simulations were run for 9 days over D1 (29 June–7 July 2016), and 3 days (5–7 July 2016) were analyzed over D2 as a case study for detailed investigation. COSMO-ART allows for the treatment of the aerosol dynamics, atmospheric chemistry, feedback with radiation, and cloud microphysics (Athanasopoulou et al. 2013; Bangert et al. 2012; Knote et al. 2010; Vogel et al. 2009). A gas flaring emission parameterization of the area of interest in SWA has been developed by Deetz and Vogel (2017), using a combination of remote sensing observations and physically based combustion equations to better reproduce the atmospheric chemistry of the area of interest. The implementation of a 1 D-plume rise model of BB aerosols and gases into COSMO-ART was realized by Walter et al. (2016), which calculates online the injection height (top and bottom limit) of the BB plume. For this study, several emission datasets from different sources have been used. The BB emissions data were obtained from the Global Fire Assimilation System (GFAS) version 1.2 (Kaiser et al. 2012). It is a satellite retrieved dataset of daily fire radiative power (FRP) measurements from the Moderate Resolution Imaging Spectroradiometer (MODIS) Terra and Aqua. Anthropogenic emissions were provided by the Emission Database for Global Atmospheric Research Hemispheric Transport of Air Pollution version 2 (EDGAR HTAP_v2) dataset (Edgar 2010) for 2010 with a 0.1° grid mesh size. In addition, the new gas flaring emission from Deetz and Vogel (2017) was used for this study. Biogenic emissions, sea salt, and mineral dust are calculated online within the model, and mean dimethyl sulfide (DMS) monthly fluxes are prescribed after Lana et al. (2011). The initial and boundary conditions for the meteorology were provided from the global Icosahedral Nonhydrostatic (ICON) model of the German Weather Service (Zängl et al. 2015). The boundary data for gaseous and particulate compounds were derived from the Model for Ozone and Related Chemical Tracers (MOZART) (Emmons et al. 2010). The simulation setup used was similar to the one described in Deetz et al. (2018).

Biomass Burning Experiment

In order to assess the effects of BB over SWA, we carried out two sets of simulations: one with BB emissions (hereafter called Fire) and another one ignoring BB emissions (hereafter called No Fire) for the period under investigation. The experiment with BB includes real-time MODIS observations of fire emissions. Figure 2 presents surface CO emissions for the two case scenarios under investigation.

Due to its long lifetime and its reactivity, CO is used as a surrogate for BB detection. Moderate CO emissions are observed in SWA mostly over the city plumes (Abidjan, Accra, Cotonou, and Lagos) due to local anthropogenic emissions.

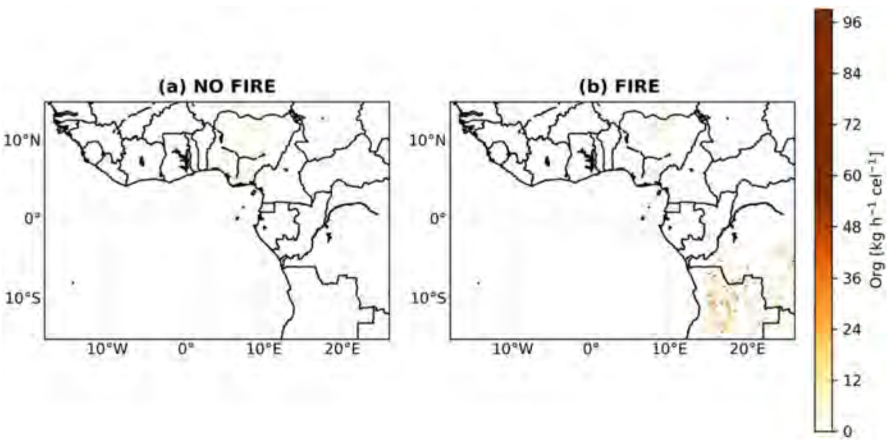

Fig. 2 Biomass burning July fire emissions for the No fire (**a**, 2016) and Fire (**b**, 2016) at the surface

Moderate CO emissions are also observed in the Niger Delta (in southwestern Nigeria), probably as a result of gas flaring activities, as well as in northern Nigeria. The peak of the CO emission is observed in Central and Southern Africa, where the BB is taking place.

Results and Discussion

This section presents the results obtained with regard to BB, by focusing on the impact on meteorology of the study area (section "Impact on Meteorology"), the impact on the atmospheric composition (section "Impact on the Atmospheric Composition"), and the adaptation and mitigation strategies proposed (section "Adaptation and Mitigation Strategies") as being helpful in reducing the impact of BB in the SWA region.

Impact on Meteorology

Our period of investigation is July 2016, which was characterized as the post-onset rainy season in SWA (Knippertz et al. 2017), thus favoring an undisturbed monsoon condition. During this period, long-range transport of BB is advected across the Eastern Atlantic Ocean and the Gulf of Guinea by a jet at around 700 hPa. In order to obtain quantitative results, a domain average over D2 (9°W–4°E; 3°–10.8°N), and the difference and relative change between the Fire and No Fire cases were analyzed. The effects of BB on the meteorological field in general (precipitation, temperature, and cloud droplets number) and on surface shortwave (SW) radiation were examined. Table 1 presents the mean effects over the SWA domain according to the variables for Fire and No Fire.

The results revealed a decrease in SW radiation at the surface and top of atmosphere (TOA) by 6.5 W m^{-2} and 5 W m^{-2}, respectively, a slight decrease in precipitation, and an increase in the Cloud Droplets Number Concentration (CDNC) over SWA. The decrease of surface SW radiation was expected, as aerosols directly reflect or scatter radiation, thus leading to a cooling effect, which in turn reduces the

Table 1 Mean values of meteorological fields for the Fire and No Fire scenarios, the difference (F-NF) and the change in percentage averaged over the nested domain D2 (9°W–4°E; 3°–10.8°N)

Field	Fire (F)	No Fire (NF)	Difference	% change (F-NF) *100/F)
Precipitation (mm day^{-1})	4.15	4.26	−0.11 ± 0.008	−2.7
SW down surface (W m^{-2})	83.43	89.95	−6.51 ± 0.0	−7.8
Cloud droplet number (CDNC) concentration (cm^{-3})	94,767	85,542	10,225 ± 853	10.78
TOA net downward SW (W m^{-2})	184.61	190.28	−5 ± 0.0	−3.07

atmospheric stability and, thus, the surface fluxes called semi-direct effects. This result agrees with the findings of Thornhill et al. (2018).

The increase in the CDNC from our model results verifies the Twomey effect (Twomey 1977), which states that an increase in the amount of aerosols leads to a reduction in the cloud droplets size distribution that is associated with an increase in the number concentration.

Our finding corroborates with that of Haslett et al. (2019) which demonstrated that BB aerosols reduce droplet size and increase their number concentration over SWA but less sensitive to precipitation. As a result, more aerosols are competing for water uptake, leading to a reduction in precipitation (known as the Albrecht effect). This result is in agreement with the findings of Thornhill et al. (2018) regarding the impact of BB on precipitation. According to the latter an increase in the number of cloud droplets and a decrease in their size would lead to a decrease in precipitation in the absence of strong convection; however, the decrease here is less compared to their findings.

Impact on the Atmospheric Composition

In addition to investigating the impact of BB on the local climatology of SWA, this study also examined the relative contribution of BB to the atmospheric composition of SWA. The spatial distribution of the surface CO mixing ratio (ppm) is presented in Fig. 3, over both domains, D1 and D2.

The two upper panels (a, b) depict the contribution of BB in CO concentration; it is marked by high values over Central and Southern Africa where BB occurred (Fig. 3b). Low values of traces of CO concentration can be observed over the Atlantic Ocean. The signature of anthropogenic activities is shown by moderate CO values (0.6 ppm) over Lagos and the Niger Delta in southern Nigeria. The simulated CO concentration over D2 in the lower two panels (c, d) clearly illustrate the plumes above the cities (Abidjan, Accra, Cotonou, Lomé, and Lagos); they show moderate values, expect for Lagos, which exhibits the highest CO concentration from both experiments (No Fire and Fire). Kumasi (Ghana), a metropolitan area, also shows a moderate CO concentration as a result of anthropogenic activities. It is worth noting that Kumasi, a city with the third highest population in SWA (3.065 million inhabitants), is one of the most populated area in Ghana (UNO 2018). The CO concentration in SWA cities along the coast is the result of urban pollution. Figure 3d highlights the contribution of BB plumes to the region by showing moderate CO concentrations (0.3 ppm) over the Gulf of Guinea. This is the result of the intrusion of BB air masses into the atmosphere. Indeed, Mari et al. (2008) have shown that BB aerosols are carried aloft and advected westward by a jet at roughly 700 hPa. Layers of BB across SWA, the Gulf of Guinea, and the tropical eastern Atlantic are present during this period of the year (i.e., July 2016) (Chatfield et al. 1998; Mari et al. 2008). The presence of CO from BB in the marine boundary layer mainly arises from subsidence of the aerosols being carried aloft, due to the high pressure area to the west of the African continent (Adebiyi and Zuidema 2016; Flamant et al. 2018). A recent study by Dajuma et al. (2020, in press) demonstrated

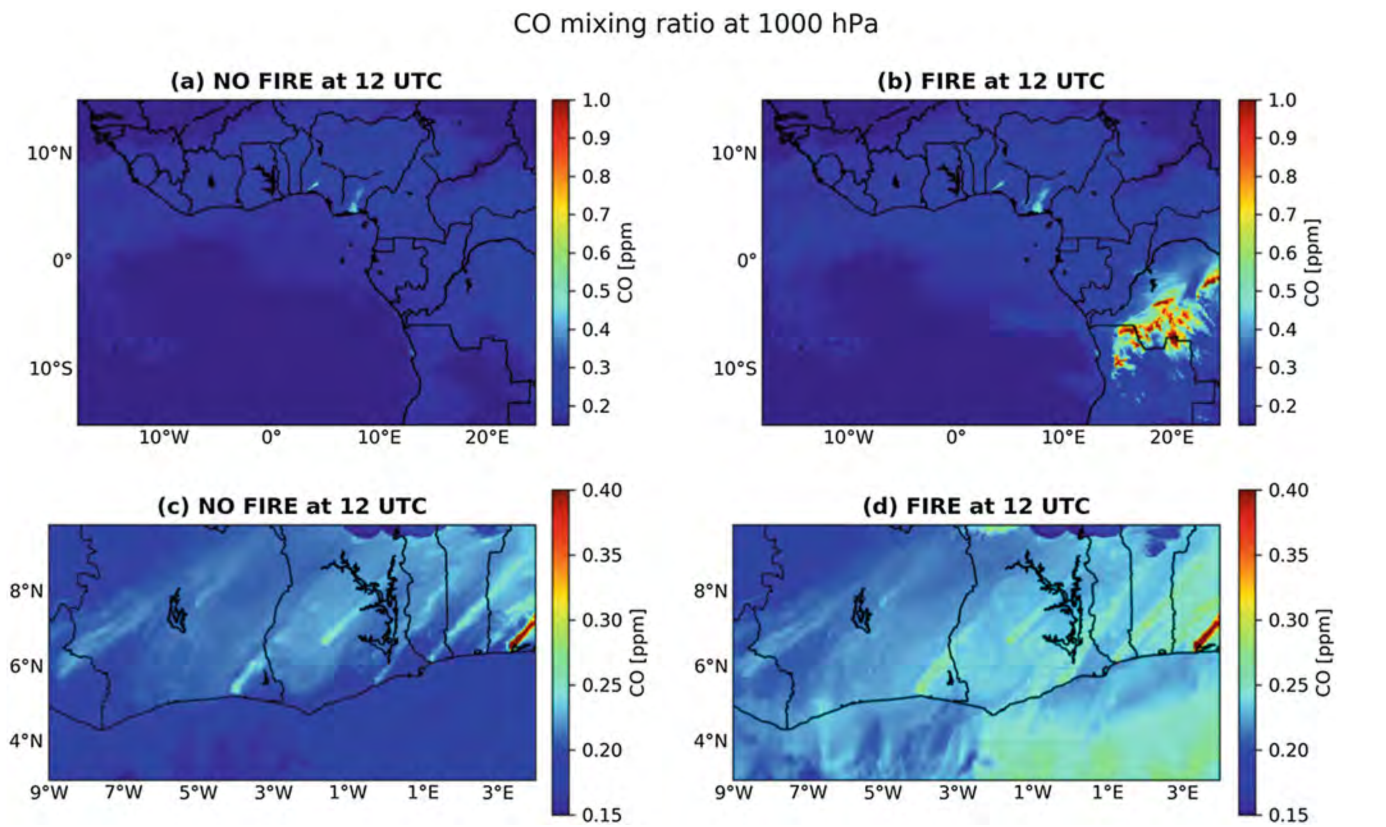

Fig. 3 Surface CO spatial distribution over domain D1 (**a**, **b**), respectively, with No fire emissions (**a**) and Fire emissions (**b**), and over Domain D2 (**c**, **d**), respectively, with No fire emissions (**c**) and Fire emissions (**d**) simulated with COSMO-ART

that convective cumulus clouds located over the Gulf of Guinea play a role in the downward mixing of aerosols located at the mid-level troposphere into the PBL. The southerly monsoon flow in the PBL below 700 hPa carries both BB aerosols and urban gases and aerosols northward (Deroubaix et al. 2019; Knippertz et al. 2017).

The relative contribution of BB to the PM_{25} over urban cities was also examined in our study. Time series of surface concentrations of PM_{25} examined for the period simulated over four SWA cities. The results, as illustrated in Fig. 4, are presented for Abidjan, Accra, Cotonou, and Lagos, for simulations with No Fire, Fire, and the difference between the two scenarios (Fire – No Fire).

The diurnal cycle shows a peak of PM_{25} concentration in the early morning around 6 UTC, which begins to decrease after sunrise. The increase of the PBL height results in a mixing of aerosols, highlighted by a decrease with a minimum value around 15 UTC (Fig. 4a). After sunset, the aerosols start to accumulate again. The impact of BB aerosols appears after only 1 day of simulation (from 6 July 2016). For all four cities, the impact of BB has the same order of magnitude, underscoring the wide extent of long-range BB over SWA. The maximum contribution found was 9.75 μg m^{-3}, 12.45 μg m^{-3}, 10.7 μg m^{-3}, and 8 μg m^{-3}, respectively, in Accra, Abidjan, Cotonou, and Lagos. Menut et al. (2018) quantified the contribution of BB to the PM_{10} concentration to be about 5 μg m^{-3} in two SWA cities (Lagos and Abidjan). Although PM_{25} and PM_{10} are composed of the same type of aerosols, only at different sizes, it is expected that the contribution to PM_{25} will be higher (double) than that of PM_{10}. This confirms that BB aerosols are dominated by the submicron mode, as observed by Haslett et al. (2019).

Our model allowed us to quantify the contributions from each type of aerosol and gases as well. Table 2 thus summarizes the contribution of BB to OC, BC, CO, NO_x, OZONE, and the Aerosol Optical Depth (AOD).

The relation between AOD and aerosol increase is clearly shown. A 36% increase of AOD from BB contribution is simulated by COSMO-ART highlighting the positive relationship between BB aerosols and AOD, in agreement with the findings of (Reddington et al. 2015). Thus, according to our model results, BB significant effect on AOD.

From the analysis of Table 2, it can be seen that BB plumes increased the atmospheric composition of both gases and aerosols concentrations in SWA. The major contribution of aerosols is from OC, representing a 70% increase due to BB, followed by BC, which accounted for 24.5%. These results agreed with the observations made during the DACCIWA campaign, which showed that 80% of the aerosol mass concentration in the monsoon layer (below 1.9 km) in SWA was that originated from Central and Southern African BB (Haslett et al. 2019). Also, Menut et al. (2018), through modeling with the Weather Research and Forecasting model coupled with Chemistry (WRF-Chem), found that the contribution of PM_{10} from BB in Central Africa was mainly composed of primary organic and particulate matter (PM).

Among the gases, the ozone contribution from BB was 16%, followed by CO at 11%, then NO_x at roughly 8%. Real et al. (2010) found that the BB plume over Central Africa was a source of ozone in the mid-level and upper troposphere. Moreover, Mari et al. (2008), tracing BB aerosol from the southern hemisphere

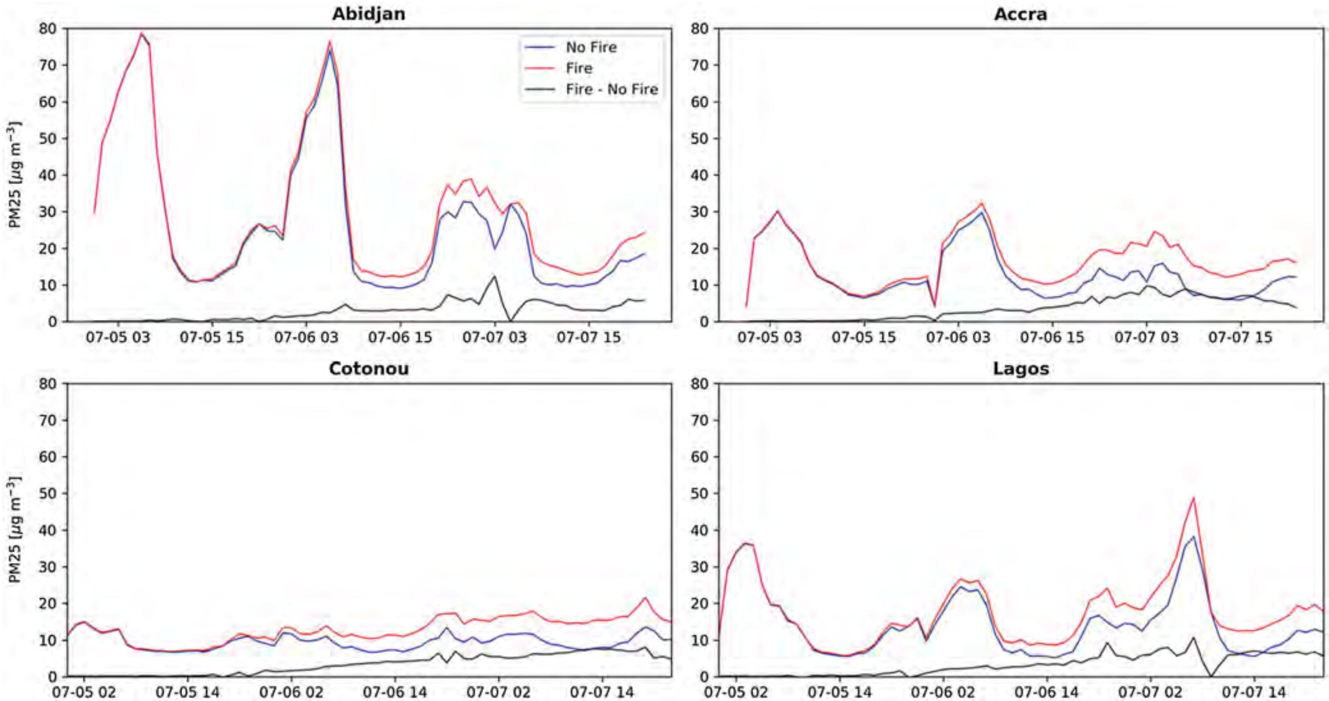

Fig. 4 Time series of surface concentrations (in μg m^{-3}) of PM25 for Abidjan, Accra, Cotonou, and Lagos: Fire in red, No Fire in blue, and the difference (Fire -No Fire) in black

Table 2 Mean values of aerosols mass concentration and gas mixing ratio for the Fire and No Fire scenarios, the difference (F-NF), and the change in percentage averaged over the nested domain D2 (9°W–4°E; 3°–10.8°N)

Concentration	Fire (F)	No Fire (NF)	Difference	% change (F-NF)*100/F
AOD	0.39	0.25	0.14 ± 0.01	36
CO (ppb)	225	199	26 ± 1	11.5
OZONE (ppb)	39	33	6 ± 0.3	16
NO_x (ppb)	26.18	24.1	2.07 ± 0.3	7.98
SOOT (μg m^{-3})	0.196	0.148	0.05 ± 0.004	24.5
OC (μg m^{-3})	3.15	0.93	2.21 ± 0.14	70.32

during the summer monsoon, found ozone production to vary, depending on the meteorological conditions associated with the active and break phases of the southern hemisphere jet.

The presence of BB in the PBL increases the level of air of pollution which increases pollution-related diseases (Lelieveld et al. 2015). Intensive measurements during the DACCIWA campaign in both the dry and wet seasons confirmed that carbonaceous aerosols (OC and BC) were major contributions to particle fractions in Abidjan and Cotonou (Adon et al. 2020). The high content of organic aerosol from BB also has adverse effects on population health throughout the region. For instance, a study by Mauderly and Chow (2008) indicated that organic fractions of ambient PM have adverse respiratory and cardiovascular health outcomes.

Adaptation and Mitigation Strategies

The detrimental effects of air pollution are recognized worldwide, particularly in West Africa (Knippertz et al. 2015), as this region appears to suffer most from climate change as a result of anthropogenic activities. Increasing levels of local pollution and pollution from remote aerosol sources, such as BB from Central Africa and mineral dust from the Sahel and the Sahara, are increasing the aerosol burden over the SWA region. Consequently, poor air quality exposes the population to serious health risks, particularly people living in the coastal cities. Since urbanization is increasing worldwide, there is a need to implement effective management plans and policies to improve adaptive capacity and mitigate the effects of anthropogenic induced air pollution in SWA. An air quality monitoring network should be established in SWA in order to regulate air quality throughout the region over the long term, as suggested by the DACCIWA policy brief (Evans et al. 2019). This will also help to spread awareness among the population of areas of high pollution thus reducing the prevalence of respiratory illnesses, such as asthma. Local populations should be encouraged to shift from using wood and charcoal for cooking to instead using electricity or gas in order to reduce local emissions. For instance, Adon et al. (2020), focusing on local sources domestic fires in Abidjan, showed that 75% of the total PM are carbonaceous aerosols.

Regionally, negotiations are necessary between Central Africa and West Africa in order to reduce both regions' BB emissions, as recommended by the DACCIWA policy brief (Evans et al. 2019). It is furthermore important to develop air pollution policies in SWA. Weather forecasting is an essential tool to mitigate air pollution-related effects. There is a need to improve weather forecasting in SWA, not only in the meteorological field but also to account for aerosols, as these interact with the climate.

Another recommendation is to promote the use of renewable energy, such as solar, for use in industries to reduce the consumption of fossils fuels, which are also exacerbating air pollution. With regard to transportation, the traffic fleet in the SWA region is dominated by old cars (Doumbia et al. 2018). Regulations should be implemented to ban the use of old cars and to improve the public transportation systems in SWA, as both are major sources of pollutants.

By means of climate education and the promotion of green lifestyles the local community could be educated, assisted, and encouraged to participate in the mitigation of climate change. And lastly, it is also recommended that increasing observational networks over SWA and improving modeling tools (e.g., cluster) and human capacity would be effective and efficient ways of tackling issues related to climate change.

Conclusions

It has been found in our study that remote pollution from the long-range transport of BB appears to affect the atmospheric aerosol pollution over SWA during summer monsoon. BB plumes originate from Central and Southern Africa as a result of agricultural activities, land management, livestock grazing, and crop production. They are carried westward by a jet toward the tropical eastern Atlantic Ocean, the Gulf of Guinea and SWA in the mid-level troposphere. BB aerosols were shown to increase the concentration of PM over four coastal cities in SWA in the same range of magnitude. Increase in PM_{25} of 12.45 μg m^{-3}, 9,75 μg m^{-3}, 8 μg m^{-3}, and 10.7 μg m^{-3} was simulated, respectively, for Abidjan, Accra, Lagos, and Cotonou. Observational studies have shown that PM_{25} aerosols measured in the ADF, for instance, have exceeded the limits set by the World Health Organisation (WHO) limit (Djossou et al. 2018).

Relative contributions of BB to gaseous pollutants such as NO_x, CO, and Ozone are, respectively, 7.98%, 11.5%, and 16%. As far as aerosols are concerned, OC is the dominant contributor to the atmospheric composition from BB with a 70% increase, followed by BC with a 24% increase. The AOD change as a result of BB aerosol is estimated at 36%.

Regarding the effect on climate, it was found that SW radiation decreased by 6.5 W m^{-2} at the surface and 5 W m^{-2} at the TOA. The mean domain average of CDNC increased by 11% from the No Fire to the Fire case scenario, followed by a slight decrease in precipitation. It is worth noting that this experiment was conducted only over a few days. However, the results do emphasize that there is a need to explore further and obtain more robust results by performing long-term simulations. Based on the results obtained with our model, it is obvious that BB aerosols from the southern hemisphere of Africa are interacting with the WAM dynamics; these interactions need to be investigated in future studies.

In addition, there is a need to implement an air pollution monitoring system to tackle health problems related to pollution and increase the adaptive capacity of West Africa to climate change by limiting local pollution. Moreover, there is a need to implement transboundary agreements in policies making, for example, by collaborating with countries in Central Africa to reduce their emissions from vegetation fires, as suggested by the DACCIWA policy brief (Evans et al. 2019).

Abstract

It is commonly accepted that the Earth's climate is changing and will continue to change in the future. Rising temperatures are one of the direct indicators of global climate change. To investigate how the rising global temperature will affect the spatial pattern of rainfall in West Africa, the precipitation and potential evapotranspiration variables from ten Global Climate Models (GCMs) under the RCP8.5 scenario were driven by the Rossby Centre regional atmospheric model (RCA4) from the COordinated Regional Climate Downscaling EXperiment (CORDEX) and analyzed at four specific global warming levels (GWLs) (i.e., 1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C) above the preindustrial level. This study utilized three indices, the precipitation concentration index (PCI), the precipitation concentration degree (PCD), and the precipitation concentration period (PCP) over West Africa to explore the spatiotemporal variations in the characteristics of precipitation concentrations. Besides, the analysis of the effect of the specified GWLs on the Consecutive Dry Days (CDD), Consecutive Wet Days (CWD), and frequency of the intense rainfall events allowed to a better understanding of the spatial and temporal patterns of extreme precipitation in West Africa. Results reveal that, for the projections simulations and at each GWL, the rainfall onset starts one month earlier in the Gulf of Guinea in response to the control period. To encourage adaptation to the various changes in climate in general, and particularly in respect of rainfall, this study proposes several adaptation methods that can be implemented at the local (country) level, as well as some mitigation and adaptation strategies at the regional (West African) level.

Precipitation concentration index (PCI) · Precipitation concentration degree (PCD) · Precipitation concentration period (PCP) · Adaptation strategy · Global warming

Introduction

Precipitation variability and concentration are two important climate factors with an impact on society, agriculture, and the environment, as increased precipitation variability can reduce agricultural yields (Rowhani et al. 2011). Also, precipitation variability is strongly connected to extreme wet and dry events, floods, and droughts, which pose threats to the environment and to society, and can also have devastating consequences on ecosystems, food supplies, and economies at the local, regional, and global scale (Easterling et al. 2000). In its 5th report, the Intergovernmental Panel on Climate Change (IPCC) stresses that there is an increase in the number of extreme weather events for the twenty first century due to climate change (IPCC 2014). As temperatures rise, the amount of water vapor in the atmosphere also increases and the spatiotemporal distributions of precipitation change, resulting in significant differences in precipitation across the world (Chou and Lan 2011;

Gao et al. 2014). Obtaining real-time information and facilitating earlier predictions by decision makers can be an efficient tool to adapt and to mitigate the impacts of climate events. However, this is an especially challenging task over data-sparse regions as West Africa, where unreliable monitoring networks and generally low institutional capacity limits the spread of timely information (Sheffield et al. 2014).

To assess the spatial and temporal variability of precipitation, various methods were adopted and documented. Precipitation concentration plays an important role, firstly, with regard to the annual total precipitation amount days and, secondly, with regard to the time and degree of concentration of the yearly total precipitation within a year. This variable has the potential to cause floods and drought events, both of which are expected to put considerable pressure on water resources (Zhang and Qian 2003; Zhang et al. 2009). Several studies have been interested in the importance of precipitation concentration indices. The present study adopted three of them: (i) the precipitation concentration index (PCI), which was developed by Oliver (1980); and years after was modified by De Luis et al. (2011). It has been used by Shi et al. (2015) as an indicator of the rainfall concentration for annual and seasonal scales, and Ezenwaji et al. (2017) to investigate the implications of the concentration and variability of rainfall on flooding over Awka Urban Area (Nigeria). (ii) The precipitation concentration degree (PCD) and (iii) the precipitation concentration period (PCP), which were redefined by Zhang and Qian (2003) in a study of droughts and floods in the Yangtze River valley (China). The basic concept behind the PCD and PCP is that the monthly total precipitation is a vector quantity with both magnitude and direction (Li et al. 2011; Wang et al. 2013).

In order to investigate and understand future climates, scientists refer to climate scenarios to provide a plausible explanation of how the future may evolve with respect to a number of variables, including socioeconomic change, technological change, energy and land-use, and the emissions of greenhouse gasses (GHGs) and air pollutants (Van Vuuren et al. 2011). Many factors are taken into account in order to predict how future global warming will contribute to climate change. A key variable is future GHG emissions. Some studies over West Africa (e.g., Egbebiyi 2016; Haensler et al. 2013; Sylla et al. 2012) have shown that projected increases in global GHG concentrations will lead to an increase in the frequency and intensity of extreme rainfall events (Klutse et al. 2018). So, for the meeting by the Intergovernmental Panel on Climate Change (IPCC) in 2007, four RCP radiative forcing levels were retained (Moss et al. 2008). The Representative Concentration Pathway (RCP) is defined as the trajectories relating to GHG concentrations, and was projected by the IPCC in 2014. The four Representative Concentration Pathways (RCPs), namely, RCP2.6, RCP4.5, RCP6, and RCP8.5, are labeled after a possible range of radiative forcing values up to the year 2100 (2.6, 4.5, 6.0, and 8.5 W/m^2, respectively).

In 2010, the sixteenth session of the Conference of the Parties (COP16) adopted the Cancun Agreement for keeping the global temperature rise below 2.0 °C (UNFCCC 2010). A few years later, in 2015, at Paris, the COP21 proposed an ambitious target, which is to keep the increase in global average temperature to well below 2.0 °C above preindustrial levels, while pursuing efforts to limit the temperature increase to 1.5 °C. The rate of climate change is an important issue for mitigation and/or adaptation policies (Watkiss et al. 2015). Many studies have recently examined regional risks for the whole of Africa, as well some of its regions, such as Southern Africa and West Africa, at various global warming levels (GWLs). Recently, Déqué et al. (2017) suggested a classification of global warming for all the RCPs and for GWLs from 1.5 °C to 4 °C. Based on Déqué et al.'s (2017) suggestion, several studies (Abiodun et al. 2019; Klutse et al. 2018; Kumi and Abiodun 2018; Maúre et al. 2018; Nikulin et al. 2018) were done to assess the impact of different GWLs on various climate variables.

Mitigation and adaptation are two fundamental societal response options to deal with the problem of climate change (IPCC 2001; Füssel 2007; Locatelli 2011). The community of climate change scientists has focused mainly on mitigation rather than adaptation; for a long time, the latter has been ignored in the debate on climate change (Füssel 2007; De Perthuis et al. 2010). Mitigation policies have already been adopted at the international level, since it is clear that the global climate is already changing and will continue to change in the future due to anthropogenic GHG and aerosol emissions; it is thus important to make adjustments all the more urgently, especially at a local level (Füssel 2007; De Perthuis et al. 2010). In addition, though, there is a need to focus the debate on adaptation measures to climate change in order to prepare communities, especially the most vulnerable ones, to cope with its impacts (Kpadonou et al. 2012).

Identification of a suitable methodology to assess the spatiotemporal precipitation distribution is vital for planning effective adaptation and mitigation strategies to overcome potential drought and flood situations. Selecting the optimal methodology or tools may be useful for planning disaster management and preparedness to respond to droughts and floods, and to mitigate their effects on the activities in different sectors of the economy. Therefore, this study aims to use the analyses of PCI, PCD, PCP, consecutive dry days (CDD), and consecutive wet days (CWD) to explain the spatial and temporal variability of precipitation in West Africa in the context of GWLs 1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C.

Description of the Study Areas and Methodology

This section describes the study area and the data used (section "Study Area and Data Sources"), and the methodology that was applied (section "Methodology") to arrive at the results.

Study Area and Data Sources

The study area lies in West Africa, which is located between latitudes 0°N and 20°N and longitudes 20°W and 20°E (Fig. 1). This region is bordered in the South by the Gulf of Guinea, in the north by Mauritania, Mali, and Niger; the Cameroon highlands form the eastern boundary, while the Atlantic Ocean forms the western limit. The annual mean temperature is about 18 °C, but the monthly mean can be more than 40 °C over the southern part of the Sahara. Rainfall patterns over this region are mostly affected by ocean currents and local features, such as topography.

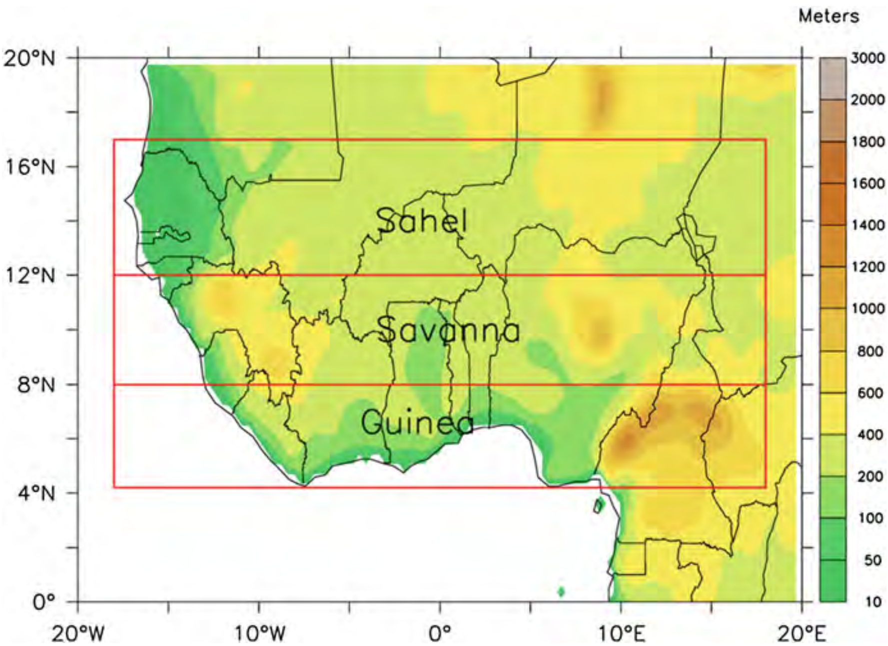

Fig. 1 Study domain showing the West African topography and the area of focus, which comprises the Gulf of Guinea (Guinea), the Savanna, and the Sahel zones (Diasso and Abiodun 2015)

In terms of climatic zones, West Africa can be divided into three different regions. The first region covers the Sahel and is characterized as a semiarid zone ranging from western Senegal to eastern Sudan, between 12°N and 20°N. The second region is the Sudano-Sahelian zone, while the last and the third comprises the Guinea coast, which is characterized by a bimodal mode driven by the Intertropical discontinuity (ITD).

Precipitation and potential evapotranspiration variables from CORDEX are used in this study. Data from CORDEX are driven by RCA4 at daily and monthly timesteps. The simulated dataset used was collected from the coordinated regional climate downscaling experiment (CORDEX) (Nikulin et al. 2012), and has a horizontal resolution of 0.44° × 0.44°. The period of 1971–2000 was extracted from the simulated dataset as the historical period, while the period of 2006–2100 was used for projections. This study focuses specifically on the GWLs of 1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C above the preindustrial levels and under the RCP8.5 scenario. The 30-year projection according to each GWL can be found in Table 1.

Methodology

The PCI is calculated in the section "Calculation of Precipitation Concentration Index (PCI)" to classify how the rainfall is spatially distributed, and the PCD and PCP in the section "Computation of Precipitation Concentration Degree (PCD) and Precipitation

Concentration Period (PCP)" were designed to determine, respectively, the period (months) and the degree of the concentration of the precipitation during the year.

Calculation of Precipitation Concentration Index (PCI)

The PCI, which was developed by Oliver (1980), modified by De Luis et al. (2011) and also used by Shi et al. (2015), was used as an indicator of rainfall concentration for annual and seasonal scales (wet and dry seasons). In our study, the PCI was tested to identify future trends in respect of the spatial distribution of rainfall. According to Oliver (1980), PCI values of less than 10 represent a uniform precipitation distribution (i.e., a low precipitation concentration), values between 11 and 15 denote a moderate precipitation concentration, values from 16 to 20 denote an irregular distribution, and values above 20 represent a strong irregularity of precipitation distribution (i.e., a high precipitation concentration). The following equations were used on each grid point to calculate the PCIs:

$$\mathrm{PCI}_{\mathrm{annual}} = \frac{\sum_{i=1}^{12} P_i^2}{\left(\sum_{i=1}^{12} P_i\right)^2} \times 100 \tag{1}$$

$$\mathrm{PCI}_{\mathrm{wet}} = \frac{\sum_{i=1}^{nw} P_i^2}{\left(\sum_{i=1}^{nw} P_i\right)^2} \times \frac{100 * nw}{12} \tag{2}$$

$$\mathrm{PCI}_{\mathrm{dry}} = \frac{\sum_{i=1}^{nd} P_i^2}{\left(\sum_{i=1}^{nd} P_i\right)^2} \times \frac{100 * nd}{12} \tag{3}$$

Equation 1 was used for annual PCI, while Equations 2 and 3 were utilized for seasonal scales (rainy and dry seasons, respectively); *nw* and *nd* represent, respectively, the number of rainy and dry season months, and P = precipitation of the i^{th} month. In order to investigate changes in the PCI, a 30-year period was considered both for historical and future periods. Table 1 shows the projection periods used for each GWL; the historical 30-year period is 1971–2000.

Computation of Precipitation Concentration Degree (PCD) and Precipitation Concentration Period (PCP)

The PCD and PCP were proposed by Zhang and Qian (2003) to measure the distribution of rainfall and the peak of its concentration date. The basic principle is based on the vector of daily or monthly total precipitation. The assumption can be made that at a time scale (daily, 5-day, weekly, decade or monthly) total precipitation is a vector quantity with both magnitude and direction and can be illustrated as a circle (360°). According to Li et al. (2011) and Zhang and Qian (2003), the indices were calculated as follows:

$$\theta_j = \left(360^\circ * \frac{j}{n}\right) \tag{4}$$

$$R_i = \sum r_{ij} \tag{5}$$

$$R_{xi} = \sum_{j=1}^{N} r_{ij} * \sin\theta_j \tag{6}$$

$$R_{yi} = \sum_{j=1}^{N} r_{ij} * \cos\theta_j \tag{7}$$

$$\mathrm{PCD}_i = \frac{\sqrt{R_{xi}{}^2 + R_{yi}{}^2}}{R_i} \tag{8}$$

where i is the year (e.g., for the historical period $i = 1971, 1972, \ldots, 2000$), j represents the time scale (**daily**, 5-day, weekly, decade, or **monthly**) of that year, R_i is the amount of rainfall of a year, r_{ij} is the precipitation of the j^{th} time scale in the i^{th} year, n is the number of time scales per year (e.g., daily: for a non-leap year, $n = 365$, while in a leap year, $n = 366$)

$$\alpha_i = \tan^{-1}\left(\frac{R_{xi}}{R_{yi}}\right) \tag{9}$$

$$D_i = \begin{cases} \alpha_i \ (R_{yi} > 0, R_{xi} \geq 0) \\ \alpha_i \ (R_{yi} > 0, R_{xi} < 0) \\ \alpha_i \ (R_{xi} < 0) \end{cases} \tag{10}$$

$$\mathrm{PCP}_i = D_i * \left(\frac{n}{360^\circ}\right) \tag{11}$$

The next section discusses the results obtained with regard to the three indices above mentioned.

Results

This section presents the results obtained from the study. Based on the variability between the historical period (1971–2000, also referred to as the control period, CTL) and the various GWLs periods the section "Annual Precipitation Concentration" shows the annual precipitation concentration patterns, while the section "Seasonal Precipitation Concentration" focuses on the seasonal PCI variabilities. The section "Evaluation of the Models' Robustness" investigates the robustness of the models to assess the PCI over West Africa. The period and the degree of the concentration of the rainfall are evaluated in the section "Variability of PCD and PCP", while the section "Daily Precipitation Variability" shows the daily consecutive precipitation variability. Finally, the adaptation processes proposed are explained in section "Adaptation Strategies."

Variability of PCI

The variability of the PCI is investigated in sections "Annual Precipitation Concentration" and "Seasonal Precipitation Concentration," respectively, for the annual and seasonal time scales.

Annual Precipitation Concentration

The variability of the PCI computed across West Africa at an annual scale is between 12 and above 20 (Fig. 2a–e). According to a classification established by Oliver (1980), this high variability of the PCI values over West Africa illustrates the existence of a seasonal rainfall regime. Lower values (between 12 and 13) are noticed for the simulation of the historical period over the Gulf of Guinea, which means that this region of the study domain has a moderate precipitation concentration when interested in the distribution at the annual scale. The seasonality is more pronounced in the Savanna with PCI range between 17 and 18 (according to Oliver's (1980), this explains how the precipitation is irregularly distributed both spatially and temporally). Lastly, the Sahel region recorded a high precipitation concentration (PCI>20), which means that the precipitation is strongly irregularly distributed. For the specified GWLs, it is illustrated in Fig. 2a–e that for the Gulf of Guinea and the Savanna, the precipitation concentration is irregularly distributed except for some countries like Côte d'Ivoire and Liberia which have a low PCI.

Seasonal Precipitation Concentration

There are two major seasons over the study area. For the purposes of this analysis, the rainy season is assumed to last from early May to the end of September (MJJAS).

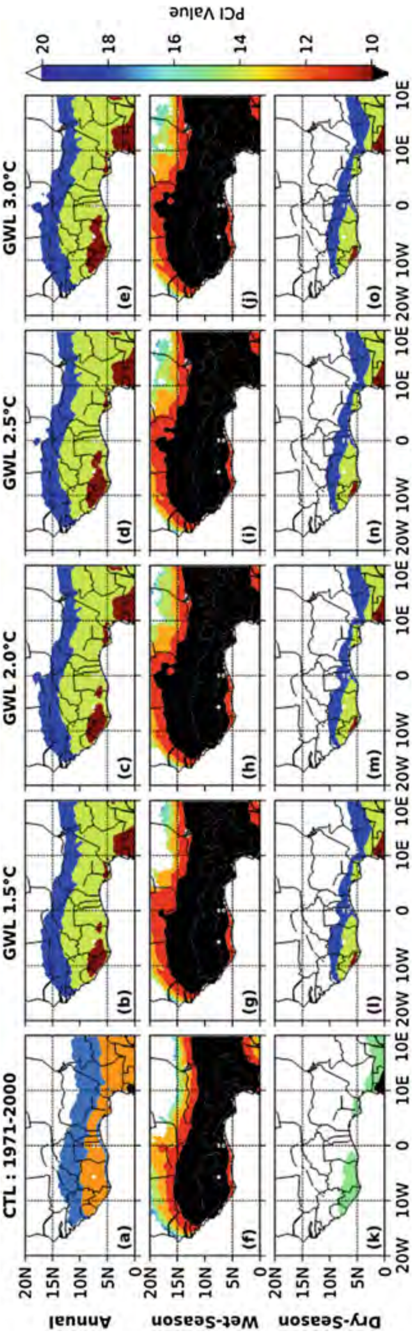

Fig. 2 Variability of Precipitation Concentration Index (PCI) at annual and seasonal scales for the historical period (CTL: 1971–2000) and for projections of GWLs 1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C

The PCI computed for the seasonal scale over West Africa indicates complex spatial patterns of precipitation distribution. Therefore, Fig. 2f–j shows that precipitation is uniformly distributed (i.e., almost the same amount of precipitation occurs in each month) over the Gulf of Guinea and the Savanna. For the studied GWLs, when compared with the historical period, it can be noticed that the uniform precipitation distribution extends a little toward the Sahel. So, the precipitation concentration is irregularly distributed (i.e., $PCI \in [16, 20]$ according to Oliver 1980) over the northern region of West Africa during the rainy season.

Figure 2k–o presents the PCI for the dry season. It illustrates an irregular precipitation concentration distribution over the Gulf of Guinea. This is obvious, because there is almost no rain during this period of the year, and the irregular distribution noticed might be due to some isolate rains recorded after some particular meteorological phenomena. The precipitation in the Savanna and Sahel is strongly irregularly distributed (i.e., $PCI > 20$ during the rainy period, according to Oliver 1980), which means that the total of significant precipitation occurs within a short period (1–2 months).

The analysis of simulations presented in Fig. 2 (with regard to annual and seasonal evaluation) establishes that in West Africa, the precipitation is uniformly well distributed during the period May–September (MJJAS) in the Gulf of Guinea and the Savanna. A northward gradient is well noticed because the highest values of the PCI are located in the Sahel, whereas the lowest are identified around the Gulf of Guinea. Despite the global warming effect for all levels, the precipitation concentration does not change over the Gulf of Guinea and the Savanna; on the contrary, it extends toward the northern region of the study domain.

Evaluation of the Models' Robustness

Figure 3, which presents the differences between the projected PCI in respect of the historical period, shows that the level of variability is similar from one GWL to another. The annual and seasonal concentrations reduce gradually from the Sahel to the Gulf of Guinea, and confirm the variability illustrated by Fig. 2, which shows the regression of irregular and strong irregular precipitation concentrations. Figure 3 also illustrates the robustness of the simulations. At least 80% of models (indicated here with vertical green strips) demonstrate that the precipitation concentration over the eastern part of the study area has changed. This change, which increases according to the GWLs, is also shown over several countries, such as Niger during the rainy season. At least 80% of the models demonstrated that the change is significant (as indicated by the horizontal blue strips), with a confidence level of 95%. Here too, Niger and Nigeria are projected to experience significant changes, which will increase with the GWLs. The red cross (+) is observed in the area where at least 80% of the simulations agree with regard to the change, and where these changes have a 95% confidence level. Therefore, during the rainy season and under GWL3.0, countries such as Ghana, Togo, and Burkina Faso present a more uniform precipitation distribution, in contrast to variabilities for the historical period and the projections (Fig. 2).

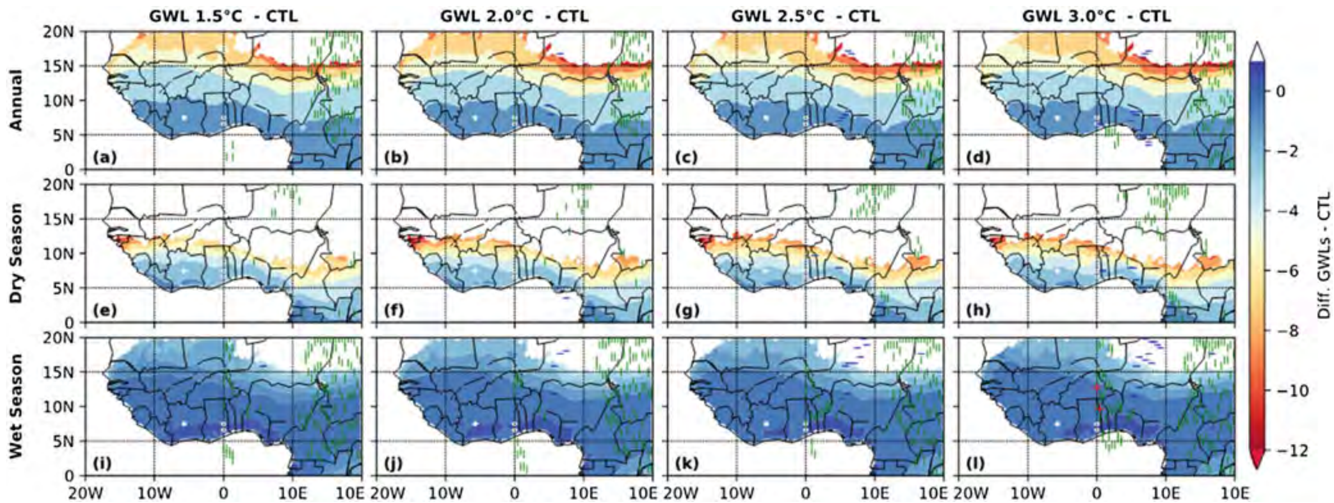

Fig. 3 Evaluation over West Africa of the difference between the changes at 1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C GWLs of PCI using the CORDEX Africa ensemble. The vertical green strip (|) indicates where at least 80% of the models agree on the sign of the changes, while horizontal blue strip (–) indicates where at least 80% of the simulations agree that the projected change is statistically significant with 95% as confidence level. The red cross (+) indicates where both conditions are satisfied

Variability of PCD and PCP

Figure 4 presents the PCP and PCD. Figure 4a–e shows that the variability over the entire West Africa of PCPs both for historical and projected periods is a range between 7 ± 2. This indicates that the yearly mean precipitation concentration over West Africa occurs between June and September. The analysis corroborates with the current knowledge about the period of the West African precipitation producing system, which is led by the West African Monsoon (WAM). The high values during the control period are observed in the north-western of West Africa, while regarding the projected period, the highest values are recorded over the Sahel. The finding indicates that the wet season starts earlier in the southern regions, followed by the Savanna before reaching the Sahel in the North. The variability of the yearly mean PCDs (shown in Fig. 4f–j) is between 0.17 and 0.90, indicating the high spatial variability of the precipitation concentration in the study domain. When looking at the historical period simulations (Fig. 4f), it can be observed that the computed PCDs increase northwardly. Lower values (0.17–0.60) are located around the Guinea coast, and the highest (>0.80) in the Sahel. This denotes the existence of a gradient across the Gulf of Guinea and the Sahel. This gradient informs that precipitation during the rainy season is more concentrated in a few months across the Sahel compared to the Gulf of Guinea. For the projected simulations, the same gradient Gulf-of-Guinea-Sahel is observed, although here the magnitude of the PCD is less in response to the control period. The lower values lie between 0.17 and 0.50, and the higher range between 0.5 and 0.6. During the projected period, there is globally a decrease of precipitation concentration compared to the historical period, leading both the Sahel and the Savanna having the same precipitation distribution for all GWLs studied. Furthermore, the projections indicate a shift in time for the starting of the rainy season. Therefore, comparing the projected and the present period, it is noticed that the wet season will state earlier. The highest concentration of precipitation will occur from May to July for the Gulf of Guinea and the Savanna, and in August for the Sahel.

Daily Precipitation Variability

The consecutive wet days (CWD) and consecutive dry days (CDD) were calculated over the study domain to evaluate the daily variability of the precipitation distribution. CWD and CDD also indicate extremes in rainfall. CDD is furthermore a useful indicator for studying short-term droughts (Frich et al. 2002) and drought tendencies (Orlowsky and Seneviratne 2012), as it could indicate enhanced dryness and high risk for seasonal droughts (Klutse et al. 2018). Changes in CDD and CWD can lead to uneven temporal distributions of rainfall, which could have a significant consequence for agricultural practices (Barron et al. 2003; FAO et al. 2015; Wiebe et al. 2017). The CDD was calculated both at annual (cdd) and seasonal scales (in this study, May–September: MScdd), in order to evaluate both dry and wet spells within the rainfall season; knowing this is very important for agricultural practices in the region (Klutse

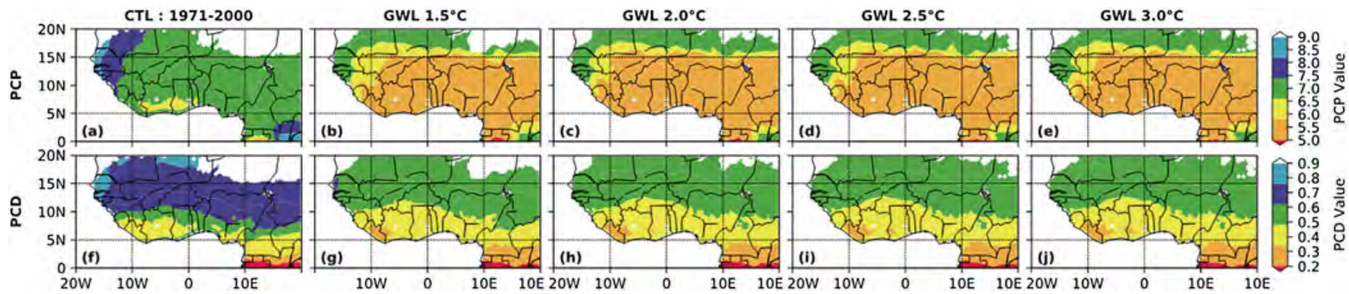

Fig. 4 Spatial distribution of yearly mean Precipitation Concentration Degree (PCD) and Precipitation Concentration Period (PCP) for the historical period (CTL: 1971–2000) and at projections of GWLs 1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C

et al. 2018). Figure 5 shows the variability between the projection of different GWLs and the selected historical period. High values of CDD are noticed in the north of West Africa, and higher CWD values around the coast of Gulf of Guinea. The comparison between the results of (Figs. 5a–d, i–l) shows both for annual and rainy season periods a decrease of CDD about 10 ± 5 days over the north-eastern of West Africa. Around the northern area of the study domain, an important variability of dry days is noticed within the rainy season (e.g., a decrease in CDD over the north-eastern part and an increase in CDD over the north-western part), which demonstrates that the north-eastern of West Africa is wetter under GWLs, while the north-western region is drier. Over the Gulf of Guinea, for both annual and rainy season scales a slight variability of CDD for all GWLs is noticed. The results of the GWLs 1.5 °C, 2.0 °C, and 2.5 °C indicate a pattern of CDD with same spatial variability, and for the GWL 3.0 °C (on Fig. 5i), a significant increase in the annual CDD is observed. The CDD is projected to increase for 4–5 days over the Gulf of Guinea; in Mauritania and Senegal, the increase is projected to be 10 ± 2 days as showed by Quenum et al. (2019). Some Sahel countries like Niger and Chad (which are characterized by a dry north-easterly flow crossing the Sahara desert) are projected to record a dwindling of CDD between 10 and 14 days. This finding agrees at GWLs 1.5 °C and 2.0 °C, with Klutse et al. (2018), who showed a reduction for GWLs 1.5 °C and 2.0 °C, in terms of the number of CDD in the wet season over our study domain, and also the results of Sultan and Gaetani (2016), who concluded a decrease in the number of CDD over central Africa.

In contrast to the CDD analysis over West Africa, the CWD did not show important variability. Its variation is very slight and ranges between 0 ± 3 days. Nonetheless, some high variations could be observed at several specific points. On the projected simulations illustrated in Fig. 5e–h), the CWD decreases about 10 ± 2 over the South Benin and Nigeria. A slight augment in CWD of up to 2 days is likely to be noticed in the Sahel.

In order to investigate the spatial variability of extreme rainfall events, which plays an important role in the availability of water resources and agriculture, etc., the frequency of intense rainfall events (RxD10 mm: $R \geq 10$ mm/day), very intense rainfall events (RxD20 mm: $R \geq 20$ mm/day), and heavy rainfall events (RxD25 mm: $R \geq 25$ mm/day) were calculated; they are displayed in Fig. 6. These variables indicate whether there were changes in the amount of precipitation received over consecutive 5 days with the highest precipitation. Figure 6a–d illustrate that, compared to the control period, each GWL detects an increasing RxD10 mm over the orographic regions and the ocean boundary (Gulf of Guinea). There is a very slight increase in the number of RxD10 mm over the Savanna and Sahel zones. In general, the results clearly show that as the GWL increases, the more the projected RxD10 mm increases too (e.g., for GWL 1.5 °C, the increase is about 7 ± 2 over the Gulf of Guinea and 1 ± 1 for the Savanna and Sahel, while for GWL 3.0 °C, the increase is about 9 ± 2 over the Gulf of Guinea and 3 ± 1 for the Savanna and Sahel). In the case of RxD20 mm and RxD25 mm, the general increase in response to increasing GWLs is noticed too. Only the coastal countries record significant increases in RxD20 mm and RxD25 mm, which could be due to the south-westerly moist flow from the Gulf of Guinea inland.

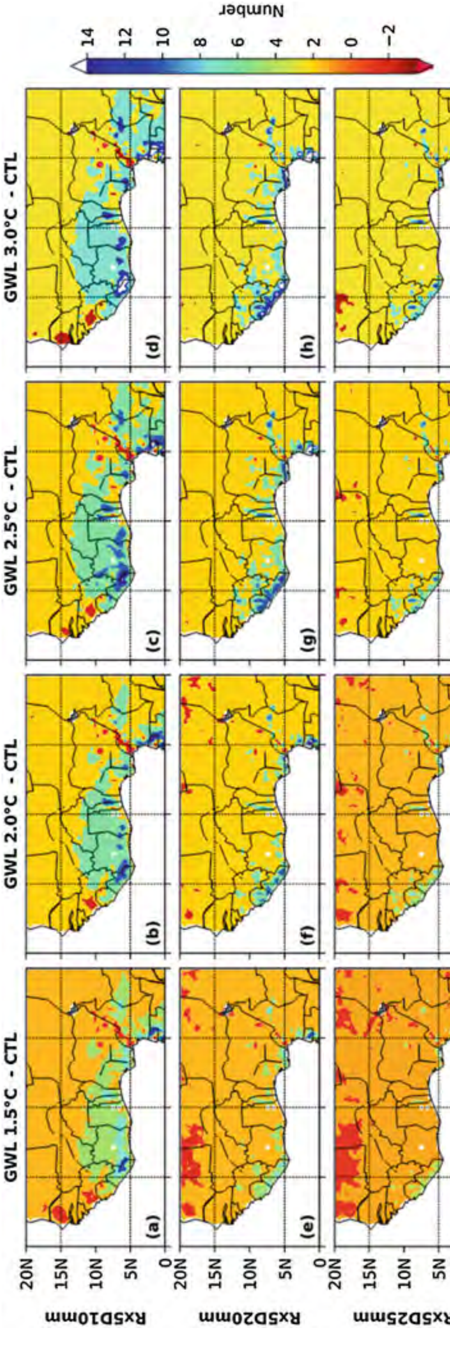

Fig. 6 Spatial distribution of the change in frequency of intense rainfall events (RxD10 mm), very intense rainfall events (RxD20 mm), and heavy rainfall events (RxD25 mm)

Adaptation Strategies

Since the spectacular drought events of the 1970s, it has become clear that the high variability in precipitation constitutes one of the major challenges faced by the West African region. Agriculture is one of the major economic activities of West Africa, and thus significant changes in rainfall due to climate change will negatively affect the entire region. These concerns have generated ongoing scientific, social, and political debate. Moreover, some parts of West Africa (mostly along the Guinean Coast) have recorded recurrent flood events since 2000. Thus, both climate variability and increasing trends in droughts and floods and other severe weather events pose a challenge for the primarily rain-fed agriculture systems in West Africa (Sultan and Gaetani 2016). Therefore, any adaptations must enable inhabitants to cope successfully with short-term climate variability as well as to reduce the long-term negative impacts of climate change (Lobell 2014; Saba et al. 2013). Households and communities must become accustomed to and able to respond creatively and effectively to disruptions of their livelihoods. Indeed, in order to be successful, adaptations must be anchored in all processes affecting life. Some of the possible adaptation strategies, especially relating to floods, droughts, and food crops, are illustrated in this study.

According to the results above, at increasing GWLs, precipitation over the Gulf of Guinea and the Savanna will shift and start earlier (in May) and that the highest precipitation concentration will occur in May–June over that area. In addition, intense rainfall events and consecutive wet days will increase in frequency, which can expose the Gulf of Guinea and Savanna to flood events from June onwards. This confirms the results from Donat et al. (2016), which showed that the intensification of the hydrological cycle both in recent decades and in future projections will lead to an increased risk of flooding in dry regions as the climate warms. Groundnut, cassava, and maize are important crops for the Gulf of Guinea, especially for Nigeria, southern Mali, Benin, Ivory Coast, Burkina Faso, Ghana, and Senegal, while over the Savanna, the main crops are yam, millet, and sorghum. Therefore, to inform farmers about short-term coping and adaptation practices, scientists are encouraged to simulate crop models and to assess their uncertainties according to the shift in the times of the projected precipitation distribution and the increase in the soil temperature. Alternative strategies, such as constructing infrastructure or irrigation systems, could also be used to mitigate the impact of exposure.

Regional provisions and strategies that include all West African countries should be developed to meet the challenge of combating GHG production. The framework agreements must link and bind countries to ensure strict compliance with community-based adaptation measures. At the local level, moreover, each country will have to develop precautionary flood and drought warning systems to limit the loss of human life. Scientific community frameworks need to be developed at the local level to improve the seasonal prediction of rainfall models that must be updated frequently in order to generate reliable information. Better research findings are needed to increase knowledge of how information structures could be framed and used to reduce the power of parochial conflicting benefits and overcome inertia, apathy, and lack of political drive. Finally, communication systems geared toward achieving specific targets (e.g., to assist farmers) will have to be developed. Informing media platforms about climate sciences and adaptation strategy policies and discussions, for instance, would educate the public about the impacts of global warming, the importance of reducing GHG emissions, and the need for developing and implementing mitigation and adaptation strategies.

Discussion and Conclusion

It is widely demonstrated in the literature that West Africa is vulnerable to climate change due to its high climate variability and high reliance on rain-fed agriculture. It does not have an institutional capacity to respond and to adapt climate variability and climate change (Quenum et al. 2019). In order to reduce risks and suggest reliable adaptation strategies for predicted climate change, this study focused on determining the variability of precipitation both in the present time and under various future scenarios. The findings obtained with regard to the PCI showed that in West Africa the period summarizing the main rainfall activity is between May and September. For the historical period, simulations show over the Gulf of Guinea and the Savanna a uniform precipitation distribution, and in the Sahel both moderate and irregular distribution of precipitation. Under future scenarios, i.e., at all the GWLs (1.5 °C, 2.0 °C, 2.5 °C, and 3.0 °C in this study), the magnitude of the simulated PCIs over West Africa reduced and became close to $PCI<10$. This demonstrates that under the selected GWLs, the precipitation concentration of West African becomes more uniformly distributed except for some countries in the north-eastern areas (Niger and Chad), which are least dry at all four GWLs. To get further details on the temporal patterns of the precipitation concentration in the study domain, the PCP variable is computed, which reveals that the magnitude of the PCI increases northwardly materializing a south-north precipitation gradient. The highest precipitation concentrations during the control period occur in July–August and cover the Gulf of Guinea and the Savanna regions, whereas the Sahel records the peaks of its precipitation concentration in September. The PCP too changed in response to increasing GWLs. Therefore, the precipitation for the projected period becomes more concentrated in June–July over the Gulf of Guinea and the Savanna, and in August for the Sahel region. Thus, the rainfall concentration starts one month earlier in the future period compared to the historical (which is very important and needed information for the agricultural sector). Globally, it also noticed that the Savanna-Sahel region recorded a high magnitude of PCD. This means that the total yearly precipitation recorded in this region occurs in a short time, due to the WAM system, which is led by the back-and-forth movement of the Inter-Tropical Discontinuity (ITD) between south and north. Indeed, this movement creates an increased precipitation concentration in the Savanna-Sahel area, which is immediately followed by the southward movement of the ITD. This establishes a long time record of precipitation concentration, which is highlighted by the PCD values over this area. A significant reduction in the CDD is recorded over the north-east (i.e., Niger and Chad), and a slight increase in the number of CWD over the Sahel.

Additionally, based on the results from PCI and PCP, Niger and Chad are projected to experience more wet condition under increasing GWLs. The 5-day cumulative rainfall variable shows that the Gulf of Guinea is projected to experience more intense, very intense, and heavy rainfall events under increasing GWLs. All these results together show how much West Africa will be exposed to higher variability of climate change and also to future heavier rainfall and wet conditions.

To cope with such changes, reduce loss of life, and better manage the impact on inhabitants of this region, some adaptation strategies are necessary under continual climate change. Two types of strategies are required: a regional framework agreement and local coping strategies. The regional agreement is very important because it forces each stakeholder (country) to respect the framework agreement; this is mostly in line with mitigation of climate change at the regional scale. Local strategies are important in two ways: Firstly, local strategies should enable West African countries to respect the regional framework agreement. Secondly, they should encourage countries to look for and develop adequate adaptation possibilities, by responding to the contributions of scientists and decision makers, which represent an important factor in development. They are the ones who have to provide reliable information to the population, and particularly to farmers, for better management of crops in order to ensure food security.

In summary, this study has investigated precipitation variability and change in West Africa under increasing GWLs, and identified an earlier onset of rainfall, especially over the Gulf of Guinea. It has found that the variability of CDDs and CWDs under increasing GWLs is considerable, and that even the intensity of rainfall has increased. Such significant information is useful for farmers and decision makers to ensure the survival and prosperity of the population.

Abstract

As the Green Climate Fund continues to make concerted efforts to leverage funding for resource-constrained communities in the global south under the aegis of increasing climate change impacts in sub-Saharan Africa, there is urgent and compelling need for tools that assist organizations to track the effectiveness of adaptation interventions in reducing vulnerability. This chapter offers a cost-effective methodology to track adaptation by using a case-study-based identification of communities with diminishing coping capacities in Raymond Mhlaba Local Municipality in the Eastern Cape Province of South Africa. Multistep geostatistical techniques were utilized in the ArcGIS 10.5 software environment to rank and spatialize changes in adaptation by using demographic census data for the years 2001 and 2011. Results of the analysis revealed that 12 communities had declining or static adaptive capacities between 2001 and 2011, while 10 communities had long-term decrease in adaptive capacities from 2001 to 2011 from a sampling universe of 134 communities. These findings are important because they demonstrate that the methodology can be effectively used to provide actionable information on the prevalence of low adaptation capacities at appropriate temporal and spatial scales, in order to guide the allocation of limited resources to the most deserving communities.

Introduction

Africa is one of the most vulnerable continents to climate change (Sarkodie and Strezov 2019; IPCC 2014; World Bank 2014) due to high dependence of livelihoods on climate-sensitive sectors such as agriculture and forestry, poor infrastructure, and limited adaptive capacities to cope with adverse impacts (Ford et al. 2015). In an effort to overcome these constraints, the Paris Agreement and the Katowice Climate Package have been urging all parties to take more climate action by encouraging the adoption and documentation of appropriate adaptation strategies. Adaptation has been getting increasing recognition as a fundamental component of global-level climate change strategies and investigations (Leal Filho and de Freitas 2018; Brooks 2011; Biesbroek et al. 2010), with sub-Saharan Africa emerging in the limelight (Fox et al. 2018; Jiri and Mafongoya 2017; Leal Filho et al. 2015; Leal Filho et al. 2017; Ziervogel et al. 2014; Dinar et al. 2012) because of growing apprehension of climate risks. This apprehension explains why the Green Climate Fund (GCF) has been increasing levels of adaptation funding to many countries in Africa in order to fulfill the Paris Agreement (Pauw et al. 2018; Tompkins et al. 2018; Georgeson et al. 2016) by enhancing their capacities to mitigate the adverse effects of climate change (Mukarakate 2016). This commitment is demonstrated by the recent extension of support to as many as four climate change adaptation projects in South Africa alone (https://www.greenclimate.fund/countries/south-africa). The GCF is part-implementation of the Paris Agreement in the context that "Developed country Parties shall provide financial resources to assist developing country Parties with respect to both mitigation and adaptation in continuation of their existing obligations under the Convention." Because adaptation funding is increasing, tracking progress in its effectiveness is essential in order to identify constraints that need to be addressed and successes that require further strengthening and improvement.

Adaptation tracking is a part of intervention monitoring and assessment that helps to capture the effectiveness with which coping strategies are translated into tangible courses of action that reduce vulnerability to climate change (Berrang-Ford et al. 2019; Lesnikowski et al. 2017). It is also useful in the governing of adaptation actions by providing a baseline for continuous monitoring and evaluation of progress over time (FAO 2017). Although necessity to monitor the advancement of climate change adaptation is gaining increasing recognition, effective tracking continues to be undermined by lack of objective indicators for scoping how adaptation takes place (Ford et al. 2013). This challenge is aggravated by difficulties in quantifying the expression of adaptation tracking due to lack of reliable tools that can be used to identify trends and gaps in adaptation responses. With climate projections pointing to relatively strong rates of warming over Africa (Engelbrecht et al. 2015) and global temperatures rising by an estimated 1.5 °C above preindustrial levels, it is apparent that there is immediate need to meaningfully embrace climate friendly adaptation strategies (IPCC 2018; New 2018). As atmospheric greenhouse gas concentrations increase in South Africa, an analysis of climate trends, using observations between 1980 and 2016 and IPCC-validated model-simulations up to 2050, projected an increase in global temperatures by 0.02 °C/year up to 2050, and a possible increase to 0.03 °C/year in future (Jury 2019). These scenarios have severe implications for South Africa's climatically vulnerable communities, and there is convincing evidence to support the view that the need to formulate innovative techniques that can be used to monitor the translation of adaptation plans into implementable interventions is long overdue.

In South Africa, Limpopo and Kwa-Zulu Natal provinces are extremely vulnerable to climate change-related problems due to their high dependence on climate-sensitive sources of livelihood (Rankoana 2019; Hlahla et al. 2018; Ncube et al. 2016; Gbetibouo et al. 2010). Out of the country's nine provinces, the Eastern Cape is recognized as the most vulnerable (Zhou et al. 2016) because of its susceptibility to consecutive droughts (Ngqakamba 2019; Ndamase 2019; ADM 2010, 2012, 2017; IFRC 2004) with one of the most severe outbreaks being experienced in Amathole District Municipality's (ADM) Raymond Mhlaba Local Municipality (RMLM) during the 2018/19 season (Ndamase 2019). The severity of this drought is demonstrated by four of the six local municipalities under ADM's jurisdiction namely: RMLM, Mbhashe, Mnquma, Ngqushwa that received two water trucks each, while the remaining two; namely Great Kei and Amahlathi, received one truck each (Dwesini 2018). Despite the increasing incidence of droughts in RMLM, the implementation of effective climate change adaptation strategies is still ineffective and continues to be undermined by conspicuous absence of reliable adaptation tracking techniques (ADM 2017). These bottlenecks and challenges justify the need for a methodology that can be used to effectively track adaptation. Although demographic indicators provided in numerical format are useful measures of adaptation (Gamble et al. 2013; van Aalst et al. 2008; Wall and Marzall 2006), they are often inadequately exploited because they require a lot of computational manipulations before they can be translated into spatially intelligible information which can be used to direct attention to areas in need of support (Qiu et al. 2019; de Sherbinin 2016; Schensul et al. 2013).

This limitation is aggravated by the fact that most national-level reports on adaptation tend to present critical information in the form of spatially disjointed metrics that can be used more effectively by presenting them in coherent formats that are capable of directing practitioners to specific target areas when action is required. A structured consolidation of these fragmented regional scale observations into discrete geographical localities is therefore essential and helpful because it provides for bottom-up scientific investigations in which the local informs the regional by facilitating exhaustive interrogation of cause-and-effect relationships and identification of areas where action is needed (Hamandawana et al. 2008). The strength of this approach is demonstrated by the Paris Agreement's adoption of an inclusive agenda on what countries can do with climate change (Conway et al. 2019; Kuwornu 2019) by using grassroots strategies that promote effective implementation of adaptation strategies (Keskitalo and Preston 2019). Mindful appreciation of this inclusiveness is demonstrated by Chari et al. (2018); Bouroncle et al. (2017); Weis et al. (2016); and Juhola and Kruse (2015) who provide useful examples of approaches that can be used to promote adaptation by aiding objective identification of communities that are vulnerable to the adverse effects of climate change.

Although RMLM has not been very successful in attracting support for adaptation initiatives, evidence suggests that local communities in this area are increasingly being exposed to climate-driven short-term variabilities that are considered to be more important stimuli to adaptive responses than long-term changes in climate (Berrang-Ford et al. 2011). Unfortunately, it has not been possible for resource-poor communities in this area and others elsewhere to access meaningful assistance due to lack of local-level information that can be used to delimit localities in need of external support (Taylor 2016). This chapter attempts to demonstrate how this gap can be bridged by providing an adaptable and spatially explicit case-study-based methodology to track the extent to which local communities in RMLM have been able to meaningfully embrace climate-friendly adaptation.

Materials and Methods

Study Area

Raymond Mhlaba (Fig. 1) is a sparsely populated (~24 people/km^2) countryside local municipality comprising 23 wards that cover approximately 6,358km^2 (ADM 2017).

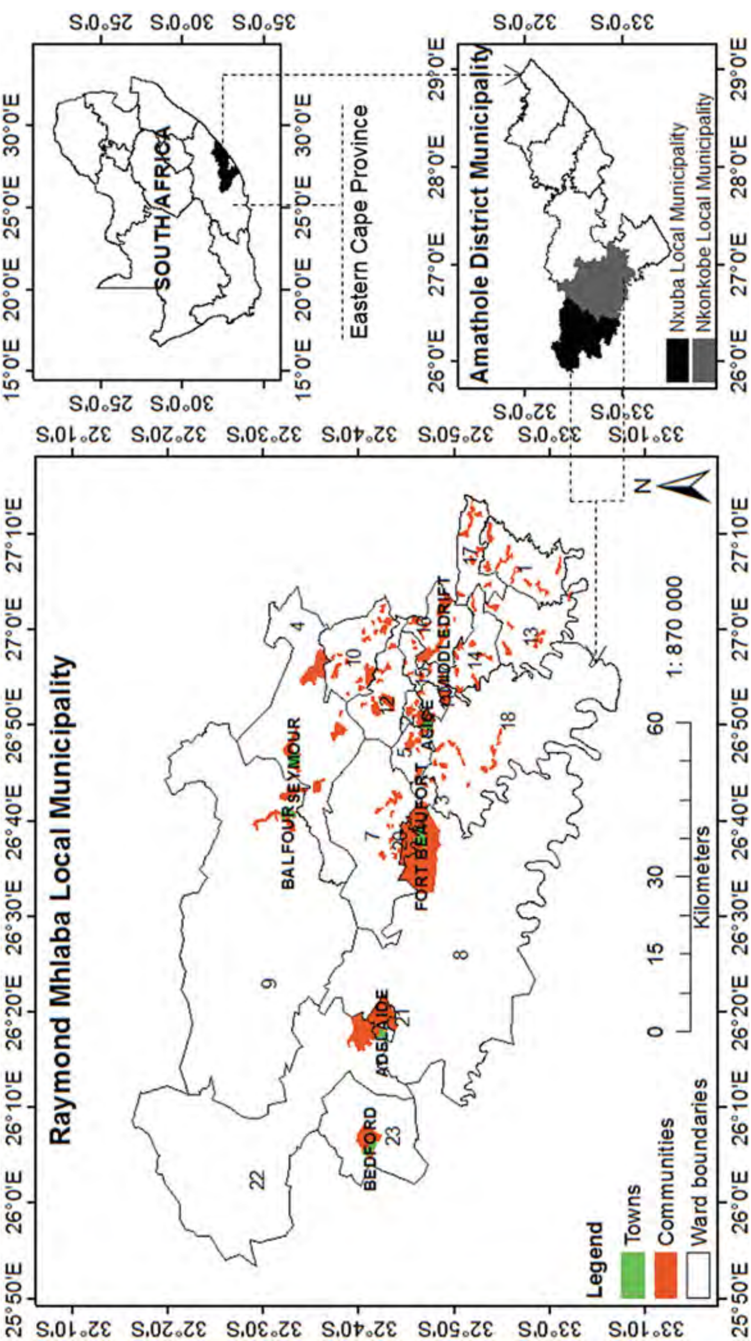

Fig. 1 Location of Raymond Mhlaba Local Municipality. (Source: Chari 2020)

It became the largest of ADM's six local municipalities when it was established by merging Nkonkobe and Nxuba Local Municipalities after the August 2016 local elections (Local Government Handbook 2016). The majority of villages in this area are situated in the immediate peripheries of Fort Beaufort (Fig. 1) with this positioning being largely influenced by accessibility to the latter's urban amenities and availability of arable land for subsistence farming. The entire municipality has a semiarid climate that is characterized by a) unreliable seasonal autumn rainfall which does not exceed 600 mm/annum with the lowest (~7 mm) and highest (~66 mm) amounts occurring in July and March, respectively, and b) average mid-day temperatures that range from 19.3 °C in June to 28.3 °C in January (www.statssa.gov.za). The abilities of this area's local communities to adapt to deteriorating climatic conditions are severely undermined by unreliable rainfall which makes rain-fed subsistence crop production extremely risky. This limitation and the municipality's documented failure to attract substantial adaptation funding and its positioning in a hotspot area with resource-poor households that are projected to experience widespread climate-change induced decrease in crop yields (Ncube et al. 2016) make it a suitable target for a case study-based exploration of novel techniques that can be used to boost adaptation tracking.

Data

The datasets that were used in this study were compiled by sourcing information from different sources over different time periods between January 2017 and May 2019. These datasets include (a) a shapefile that captures the distributions of local communities in RMLM as compiled by Statistics South Africa (StatsSA) in 2011, (b) 2001 and 2011 census data in a raw Microsoft Excel table format that was provided by the same source, and (c) insights of expert informants that were used to verify the reliability and appropriateness of the municipal-level data that was used in this study. Availability of census data for the years 2001 and 2011 was judged to be timely because these records provided demographic indicators over a 10-year period which was reasoned to be long enough for individual households to translate climate-change-induced coping strategies into quantifiable indicators of adaptation. These datasets were also considered to be reliable because in South Africa, StatsSA is the custodian of official multilevel planning statistics (www.statssa.gov.za).

Methods

A hybrid approach comprising a multistep GIS-based mapping and analysis of aggregated indicators was used to track the adaptation of resource-poor communities to climate change with adaptive capacity indicators being purposefully selected to accommodate representative inclusion of different communities and the singular geographical and socioeconomic distinctions of their localities. The Nkonkobe Integrated Development Plan (IDP) of 2012–2017 was used to aid the identification of communities with different livelihood activities because most of the communities in RMLM reside in the former Nkonkobe Local Municipality (Fig. 1). The selection of assessment indicators was based on the definition of adaptive capacity provided by Heltberg and Bonch-Osmolovskiy (2011) and the type and level of demographic data available for the municipality with further refinements being made by using ancillary information that was solicited from expert informants. Overall, the indicators listed and described in Table 1 below were finally selected on the basis of the logic described above and used to assess and map adaptive capacities in the municipality.

Prior to analysis, spreadsheets with information on sub-places/communities were cleaned by (1) deleting unnecessary details from all Excel datasets and (2) selecting matching names in the 2001 and 2011 census records to facilitate the execution of

Table 1 Description of demographic indicators used for assessing and tracking adaptation

Narrative indicator	Rationale	Ranking/classification of communities
Literacy levels	Specified adaptive capacity within the communities on basis of highest education level. *Reclassified from 21 classes to 6 classes*.	Scores of 0 to 5 were allocated as follows on the basis of level of education: No schooling = 0, Some Primary = 1, Completed Primary = 2, Some Secondary = 3, Completed Secondary = 4, Higher = 5.
Income levels	Communities with low incomes have low resilience because they are unlikely to have access to credit. *Reclassified from 12 classes to 5 classes*.	Scores of 0 to 4 were allocated depending on income profiles. Wards with the lowest incomes were allocated a score of 0. Groups were segregated according to annual income as follows: No income = 0, R1 – R9 600 = 1, R9 601 – R19 200 = 2, R19 201 – R38 400 = 3, $\geq$ R38 401 = 4.
Age profiles	Used to identify communities with low resilience to climate change by virtue of being economically inactive due to predominance of children and/ or old people in the population. *Reclassified from 18 classes to 4 classes*.	Scores of 0 to 3 were allocated and communities segregated into three age groups as follows: 0–14: Child (score of 0), 15–39: Young (score of 2), 40–59: Old (score of 3): *Senior citizen 60+ (score of 1).
		* *This categorization is based on age criteria used by South Africa Social Security Association (SASSA) to identify beneficiaries of social security assistance*
Water access by source type	Specified adaptive capacities of individual communities on the basis of most used water sources. *Reclassified from 7 classes to 4 classes*.	Other sources = 0, Surface water = 1, Ground water = 2, Regional water scheme = 3.

Source: Adapted from Chari et al. (2018)

valid geospatial analysis operations. To avoid join operation errors in ArcGIS 10.5, all communities that were founded after year 2001 and all extra spaces in the attribute tables of the community names field (key fields) were omitted from the spreadsheet of 2011. Thereafter, shapefiles were created by linking each input indicator's Excel table to the attribute table of the digitized-communities shapefiles and the Join operation used to translate these datasets into spatial layers that were combined with other layers to provide thematic map-portrayals of adaptive capacity ranks. The demographic data from StatsSA was analyzed at community level because this was the lowest level at which required data was available. The combination of layers was followed by turning off repeated fields in the output attribute tables in order to mute field redundancies when the data was exported to the geodatabase. In the final step the following Python script (Script 1) was used to automatically assign scores to communities in the income levels attribute table, and the three indicators (Literacy levels, Source of water, Age profiles) for census years 2001 and 2011 after changing their table names, field names, and row numbers, following the criteria in Table 1.

Script 1 Script That was Used to Automatically Assign Scores for Community Income Levels

```
##Name of script: Income2001.py
##Purpose: Automated allocation of scores to communities for the
2001 income levels data
#Importing system modules
import arcpy
#Input data and input fields and their lengths
table = "E:/GIS/RayMhlaba.mdb/Income_2001"
fields = ["No_income", "R1_R9600", "R9601_R19200", "R19201_R38400",
"R38401_more"]
#Adding fields to input table to store maximum and field names
maxfield = "HIGHEST"
maxname = "HIGHEST_name"
scores = "In2001_score"
arcpy.AddField_management(table, maxfield, "TEXT")
arcpy.AddField_management(table, maxname, "TEXT")
arcpy.AddField_management(table, scores, "SHORT")
#Adding created fields to the array
fields2 = fields[:] # Shallow copy
fields2.extend([maxfield, maxname, scores])
#Checking and updating of fields
with arcpy.da.UpdateCursor(table, fields2) as cursor:
  for row in cursor:
    arrayVals = [row[0], row[1], row[2], row[3], row[4]]
    highest = max(arrayVals)
    row[5] = highest
    row[6] = fields[arrayVals.index(highest)]
    if row[6] == "No_income":
        row[7] = 0
        cursor.updateRow(row)
    elif row[6] == "R1_R9600":
        row[7] = 1
```

```
        cursor.updateRow(row)
    elif row[6] == "R9601_R19200":
        row[7] = 2
        cursor.updateRow(row)
    elif row[6] == "R19201_R38400":
        row[7] = 3
        cursor.updateRow(row)
    else:
        row[7]= 4
        cursor.updateRow(row)
["No_income","R1_R9600","R9601_R19200","R19201_R38400",
"R38401_more"]
py.AddField_management(table,maxfield,"TEXT")
py.AddField_management(table,maxname,"TEXT")
AddField_management(table,scores,"SHORT")
extend([maxfield,maxname,scores])
arcpy.da.UpdateCursor(table,fields2) as cursor:
    cursor:
    arrayVals = [row[0],row[1],row[2],row[3],row[4]]
    highest = max(arrayVals)
    row [5] = highest
row[6] = fields[arrayVals.index(highest)]
    if row[6] == "No_income":
    row[7] = 0
cursor.updateRow(row)
    elif row [6] == "R1_R9600":
    row[7] = 1
cursor.updateRow(row)

    row[7] = 2
cursor.updateRow(row)
    elif row[6] == "R19201_R38400":
    row[7] = 3
cursor.updateRow(row)
    else:
    row[7] = 4
cursor.updateRow(row)
```

Script 1 was executed by using the Python `execfile` command to generate a map for each of the four indicators in ArcMap 10.5 for years 2001 and 2011 on the basis of the assigned scores in order to reveal spatial variations in each indicator with communities that had the lowest scores for each indicator being identified by examining all attribute tables. Adaptive capacity scores for both census years (Table 2) were automatically determined by generating a new shapefile and attribute table into which the previously calculated scores from the four indicators for each community were imported and automatically summed up by using Script 2 and Script 3. Although all indicators were weighted equally because of limited availability of indicator data for the municipality, this relaxation did not compromise the reliability of results because information obtained from expert informants and the Nkonkobe IDP for 2012–2017 (Nkonkobe Local Municipality 2012) confirmed that

Table 2 Evaluation of adaptive capacity in the attribute table for each of the census years

Village	Ward number	Access to water	Literacy levels	Income levels	Age profile	Adaptive score	Adaptive capacity
V_1	W_1	3	5	4	3	15	HIGH
V_2	W_2	S_1	S_2	S_3	S_4	.	.
.	.	.	.	.	.	.	.
.	.	.	.	.	.	.	.
V_{134}	W_{23}	3	3	2	0	8	MEDIUM

$V_1 \ldots V_{134}$ – community names; W – ward numbers; S_1, S_2, S_3, S_4 – indicator scores. Adaptive scores ranged from 1–15
Source: Adapted from Chari et al. (2018)

all indicators were equally important for adaptive capacity assessment. Adaptive capacities for the census years 2001 and 2011 were calculated in the attribute table (Table 2) by using the following formula:

$$\text{Adaptive score} = \left(\sum_{n=s1}^{s4} n\right) \tag{1}$$

Where S_1, S_2, S_3, S_4 are scores for each of the four indicators

The following Python script (Script 2) was used to automatically create a new shapefile and attribute table and to join, Age_Profile scores to the IndicatorScores table. The same script was also used to join the remaining three indicator scores to the IndicatorScores attribute table by using community name as the linking field.

Script 2 Script That was Used for Automated Creation of a New Shapefile and Attribute Table and Joining of Age_Profile Scores to the IndicatorScores Table

```
##Name of script: ScoreInput2001.py
##Purpose: Automated creation of a new shapefile and attribute table
for saving an integration of the four indicator scores and
automated joining of the remaining 3 indicator scores to the
IndicatorScores table using MP_NAME as the linking field.
#Importing system modules

```

Since the highest attainable adaptive capacity score from addition of the four highest indicator scores was 15 (Table 1), the computed adaptive capacity scores were ranked into low-medium-high adaptive capacity as follows: 1–5 = LOW, 6–10 = MEDIUM, and 11–15 = HIGH by using the Python `execfile` command to run the following Python script (Script 3) which automatically added a field for the ranked adaptive capacity scores attribute table.

Script 3 Script That Was Used for Joining of the Remaining 3 Indicator Scores to the IndicatorsScores Table Using MP_NAME as the Linking Field

```
## Name of script: AD2001.py
## Purpose: Automated summation and ranking of the four indicator
scores for year ## 2001
#Importing system modules
import arcpy, math
#Importing scores from indicator attribute tables into the Adaptive
capacity shapefile
table = "E:/GIS/RayMhlaba.mdb/Ind_Scores2001"
fields = ["A2001_score","In2001_score","Lit2001_score",
"W2001_score"]
# Adding fields to input table to store maximum and field name
total = "AD2001_Score"

    #Joining of Adaptive capacity 2001 field to the Adaptive capacity
    2011 field to create one table
arcpy.JoinField_management
("AD_Diff","MP_NAME","Ind_Scores2001","MP_NAME","AD2001_Score")
```

Changes in adaptive capacity scores between census years 2001 and 2011 (Table 3) were calculated by using the following formula:

$$\text{Change in adaptive capacity} = \left(\begin{matrix} 2011 \\ \sum_{n=s1}^{s4} n \end{matrix}\right) - \left(\begin{matrix} 2001 \\ \sum_{n=s1}^{s4} n \end{matrix}\right) \quad (2)$$

The adaptive capacity scores were automatically ranked into no change, decrease, and increase as follows: Difference of 0 = NO CHANGE; Difference of ≤ -1 = DECREASE; Difference of ≥ 1 = INCREASE by using the following Python script (Script 5) that was run by executing the Python `execfile` command which also generated fields for differences and ratings of adaptive capacity scores for the two census years and automatically added them to the attribute table.

Script 5 Script That Was Used for Calculating Changes in Adaptive Capacities Between 2001 and 2011

```
## Name of script: Diff.py
## Purpose: Calculating changes in adaptive capacities between
years 2001 to 2011
#Importing system modules
import arcpy, math
# Selecting fields of interest from attribute table in shapefile
table = "E:/GIS/RayMhlaba.mdb/AD_Diff"

cursor.updateRow(row)
```

A map showing changes in adaptive capacities was produced in ArcMap 10.5 based on the rankings and another map showing communities with low adaptive capacities by year 2011 produced from the 2011 adaptive capacity attribute table. Thereafter, the same attribute table and platform were used to generate a list of communities with decreased adaptive capacities over the 10 years between 2001 and 2011.

Presentation of Results

Results of this study are presented in the form of (1) maps that were purposefully designed to illustrate how tabulated data can be portrayed in a visually comprehensible manner that facilitates better tracking of adaptation compared to conventional presentation of this important information in the form of tables and histograms that do not capture the spatial dimension (Figs. 2, 3, and 4) and (2) tables that summarize communities that were identified as having declining/static adaptive capacities and

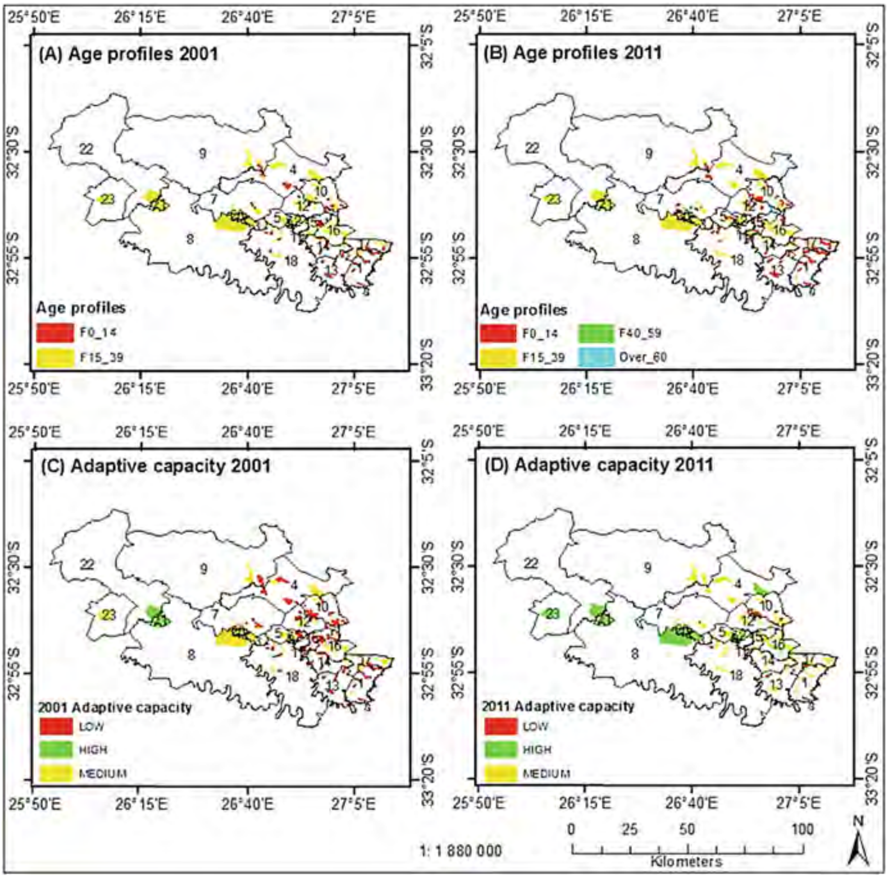

Fig. 3 Age profiles and adaptive capacities of communities in RMLM in 2001 and 2011. (Source: Chari 2020)

those that were identified as having long-term decrease in adaptive capacities (Tables 4 and 5, respectively).

Maps That Were Produced from Data on Water Access, Literacy Levels, and Annual Income Levels That Were Used to Assess Adaptive Capacity for Years 2001 and 2011

Figure 2 shows spatial distributions of access to water by source type, literacy levels, and annual incomes that were mapped for individual communities in RMLM on the basis of census data for the years 2001 and 2011. Figure 3 shows age profiles for the same communities and their adaptive capacities on the basis of the three-point scale (LOW-MEDIUM-HIGH) that was used to rank the uptake of adaptation interventions by individual communities. The last map (Fig. 4) shows spatial variations in

Tables That Show Adaptive Capacity Levels for Individual Communities by Year Period

Tables 4 and 5 show communities that were identified as having (a) declining (medium – low) and static (low) adaptive capacities in the 2001 and 2011 census surveys and (b) communities that were identified as having a long-term decrease in adaptive capacity in the 10 years between 2001 and 2011.

Discussion and Conclusion

Discussion

This section discusses the results of this initiative by placing the major findings in a broader context with emphasis being given on the responsiveness of communities to climate change on the basis of the extent to which individual communities were able to access the three indicators that were singled out for investigation and how age profiles influence their adaptive capacities. The section concludes the chapter by stating the methodology's limitations and highlighting its usefulness in tracking adaptation.

Access to Water

Sources of water by source type in wards 1–23 (Fig. 2a and b) affect the resilience of communities (not shown in Fig. 2a and b) by influencing the availability of water. In 2001 (Fig. 2a), two communities (Teba and KwaNgwevu in ward 7) were severely water stressed and obtained water from two nonnatural sources comprising water vendors and water tankers. By 2011 (Fig. 2b), three communities (Msobomvu in ward 12, Allandale in ward 13, and MnqabaJames in ward 1) were identified as severely water stressed, although they still depended on water from the same nonnatural sources as they did in 2001. The increase in the number of communities depending on nonnatural sources from 2 to 3 is indicative of how deteriorating climatic conditions are reducing natural availability of water which is corroborated by the observed occurrence of consecutive droughts in the Eastern Cape province in 1992, 2004, and 2009 (ADM 2010, 2012; IFRC 2004). These scenarios strongly suggest that in this environment, water scarcity is a persistent problem that requires exploration of alternative water sources and a judicious mix of different water saving techniques in order to reduce dependence on costly supplies provided by government and commercial operators.

Literacy Levels

Figure 2c and 2d indicates spatial variations in levels of schooling. In 2001 (Fig. 2c), two communities (NgqolowaA and Dhlawu) in ward 13 and six communities (Ndindwa, Gqumashe, KwaMemela, Lower Hopefield, Mavuvumezini, and Calderwood) in wards 1, 2, 3, 10, 14, and 18, respectively, were identified as having no formal schooling. By 2011, only two communities (Mdeni B in ward 5 and Lebanon in ward 13) were identified as having the majority of the population without formal schooling (Fig. 2d). This observation is not only commendable but interesting because it suggests that awareness of climate change issues is increasing as the number of people gaining access to formal education increases. Unfortunately, awareness alone does not automatically translate into increased uptake of actionable adaptation strategies in the absence of enabling factors that facilitate the translation of recommended actions into tangible climate friendly activities because knowing alone without inspiration and capacity to act is inadequate (Adger et al. 2009). Ability to act requires capacity in the form of resources which in the case of RMLM is evidently lacking because of poverty. This asseveration is supported by the 2011 census data which shows that 48.1% of the people in Nkonkobe and 42% in Nxuba were unemployed (StatsSA 2014). In view of this consideration and the documented prevalence of poverty in this area, it is not unreasonable to suggest that although literacy improved, effective implementation of climate change adaptation strategies continues to be constrained by lack of a holistic approach that embraces a wide range of enabling factors that determine the ability of communities to meaningfully embrace climate-friendly interventions.

Annual Income Levels

Figure 2e and 2f indicate communities with and without income, respectively, with the latter being destined to be susceptible to most climate change-induced shocks due to lack of access to credit. In year 2001, 51 communities emerged as being dominated by people without any income (Fig. 2e) while 5 communities (Seymour, MdeniA, Magxagxeni, Koloni, and kwaSawu) in wards 4, 7, 10, 17, and 15, respectively, were identified as the poorest in the municipality (Fig. 2f). These results are in agreement with the 2011 census data which shows that the majority of people in these communities do not have any sources of income (StatsSA 2014). The nationwide prevalence of this limitation is supported by many researchers (Mkuhlani et al. 2019; Rusere et al. 2019; Mpandeli and Maponya 2013) who report that in the Lambani, Tshakhuma, Rabali, and Tshiombo communities in Limpopo province, most households find rain-fed crop production extremely risky because they cannot afford supplementary irrigation and do not qualify to get external support in the form of agricultural insurance due to widespread lack of reliable sources of income.

Influence of Age Profiles on Resilience

The identification of communities with different levels of resilience on the basis of age profiles (Fig. 3a and 3b) was based on the reasoning that children and old people have limited capacities to assimilate and implement adaptation strategies by virtue of being economically inactive compared to their economically active counterparts of intermediate age. In year 2001 (Fig. 3a), 37 communities were identified as having the majority of the people in the ages between 0 and 14 years. By year 2011 (Fig. 3b), a total of 46 communities were identified as having the majority of people in the ages between 0 and 14 years with 2 of these communities having the majority of people above 60 years of age while 68 communities had low adaptive capacities in 2001 (Fig. 3c). Although 54 of these communities had improved from low to medium and high adaptive capacities by 2011, this apparent improvement falls short of the desired situation because the downward trend in capacities of two of these communities (eMgwanisheni and MnqabaJames) is actually indicative of the system's inability to effectively mitigate the adverse effects of climate change with additional support for this observation coming from the fact that between 2001 and 2011, ~7.5% of the communities in RMLM were identified as having low or decreasing adaptive capacities (Table 5).

The results presented here are useful because they demonstrate that objectively based geostatistical techniques can be used to aid disaster management by creating space for timely and reliable identification of communities that can be targeted as recipients of appropriately informed adaptation strategies at multiple temporal and spatial scales. In a broader context, the methodology is potentially capable of enhancing adaptation tracking because of its ability to accommodate wide-ranging demographic datasets that are often provided in different and unstandardized formats. This proficiency makes it adaptable to suit different areas of interest and capable of being used to support different stakeholders such as the Global Commission on Adaptation and many others which seek to ensure that adaptation action and support reaches the most vulnerable communities.

Conclusion

Although the methodology presented in this chapter is admittedly far from being capable of offering a universal solution due to gaps in the availability of data at appropriate spatial and temporal scales and lack of a single unit of analysis that can be used to measure or compare adaptation, accessibility of demographic data in most countries still makes it a usable option worth considering because the acquisition of fine-scale data can be prohibitively expensive and time consuming. Even though these challenges are likely to persist for some time into the future, one of the major strengths of the methodology is that it provides an ideal entry point to adaptation tracking at both the national and sub-national levels because its bottom-up basis and firm grounding in a GIS-based framework can accommodate consistent and contextually focused multilevel assessment at different spatial and temporal scales. The other strength of the methodology is that its bottom-up inclination confers a sense of involvement in the decision-making process by creating space for the incorporation of inputs from key stakeholders who are directly involved in and affected by the implementation of adaptation projects. In addition, the methodology's ability to provide a spatially explicit presentation of adaptive capacities offers additional advantages by enabling those interested in adaptation tracking to identify trends in the assimilation and implementation of climate friendly adaptation interventions. The major insight from this initiative is that although data scarcity is often singled out as one of the major constraints confronting adaptation tracking, the geostatistical methodology presented in this chapter provides a workaround approach that can be tapped and used to maximize the utility of different and readily accessible datasets from disparate sources. The take home message is that practitioners, policy–makers, and other stakeholders interested in fast-tracking and enhancing the effectiveness of adaptation interventions stand to benefit by adopting this methodology because it can be easily adapted to effectively track the adoption of adaptation under wide-ranging situations.

Acknowledgments The authors would like to thank the Water Research Commission's K5/2496/4 project and National Research Foundation (NRF) of South Africa for funding.

Abstract

The South African Lowveld is a region of land that lies between 150 and 2000 m above sea level. In summer the region is characterized by the maximum mean daily ambient temperature of 32 °C. The purpose of the study was to characterize

indoor thermal environments in low-cost residential dwellings during summer seasons as climate is changing. Indoor and ambient air temperature measurements were performed at a 30-min temporal resolution using Thermochron *i*Buttons in the settlement of Agincourt. 58 free running low-cost residential dwellings were sampled over the summer seasons of 2016 and 2017. Complementary ambient air temperature data were sourced from the South African Weather Service (SAWS). Data were transformed into hourly means for further analysis. It was found that hourly maximum mean indoor temperatures ranged between 27 °C (daytime) and 23 °C (nighttime) for both living rooms and bedrooms in summer 2016 while in 2017, maximum mean indoor temperatures ranged between 29 °C (daytime) and 26 °C (nighttime) in living rooms and bedrooms. Pearson correlations showed a positive association between indoor and ambient temperatures ranging between $r = 0.40$ (daytime) and $r = 0.90$ (nighttime). The association is weak to moderate during daytime because occupants apply other ventilation practices that reduce the relationship between indoor and ambient temperatures. The close association between nighttime ambient and indoor temperature can also be attributed to the effect of urban heat island as nighttime ambient temperature remain elevated; thus, influencing indoor temperatures also remain high. These findings highlight the potential threat posed by a rise in temperatures for low-cost residential dwellings occupants due to climate change. Furthermore, the high level of sensitiveness of dwellings to ambient temperature changes also indicates housing envelopes that have poor thermal resistance to withstand the Lowveld region's harsh extreme heat conditions, especially during summer. The study findings suggest that a potential risk of indoor overheating exists in low-cost dwellings on the South African Lowveld as the frequency and intensity of heat waves rise. There is therefore a need to develop immediate housing adaptation interventions that mitigate against the projected ambient temperature rise for example through thermal insulation retrofits on the existing housing stock and passive housing designs for new housing stock.

Introduction

Climate change has triggered a rise in external summer air temperature posing a threat to human indoor thermal comfort and health (Mavrogianni et al. 2010) with cities facing a heightened risk of extreme heat from climate change (Araos et al. 2016). On a regional scale temperature rise in sub-Saharan Africa is expected to be higher than global mean temperatures (Webber et al. 2018; Hoegh-Guldberg et al. 2018) as Southern Africa is expected to rise at 2 °C compared to a global mean of

1.5 °C (Hoegh-Guldberg et al. 2018). Incidences of extreme weather events around the world are increasing as a consequence of climate change with projections showing an increase in the number of warm days/nights putting low-icome earners at risk of physical health threats (Hoegh-Guldberg et al. 2018). The most severe effects of global warming will be reflected through an increase in the frequency and intensity of extreme events such as heatwaves (IPCC 2007; White-Newsome et al. 2012; Dosio 2016). Low-income earners who live in substandard housing are likely to feel the full wrath of temperature rises as they cannot adapt quickly to climatic change.

According to the Chartered Institution of Building Services Engineers (CIBSE Guide A), sleep impairment can be experienced at temperatures above 24 °C (Mavrogianni et al. 2010). Low-cost residential dwellings that have poor thermal insulation can overheat if exposed to extreme heat. High indoor temperatures also drive energy consumption via the occupants' demand for cooling (Kavgic et al. 2012). Low-cost residential dwellings in South Africa are poorly insulated exposing them to extreme heat effects (Chersich et al. 2018). During hot spellslow-cost structures may be 4–5 °C warmer than outdoor temperatures (Chersich et al. 2018). Indoor overheating is a function of dwelling thermal insulation levels as well as ventilation practices of occupants (Mavrogianni et al. 2010). Overheating occurs when the indoor operative temperature is over 3 °C the thermal comfort temperature (Mavrogianni et al. 2010) which the WHO pegged at 24 °C for indoor environments.

Similar studies on summer indoor temperature monitoring include studies by Summerfield et al. (2007) which monitored 29 dwellings in the United Kingdom (UK) during the summer of 2005–2006 and estimated mean indoor temperatures for living rooms to be 19.8 °C and 19.3 °C for bedrooms while Firth and Wright (2008) monitored 224 dwellings in the UK estimating mean living room temperatures at 21.4 °C and bedroom temperature at 21.5 °C. On the other hand, Mavrogianni et al. (2010) monitored 36 dwellings in London during the summer of 2009. Daytime means in living rooms rose above 28 °C in three dwellings out of the total 36 sampled while average indoor temperatures in 53% of living rooms were above indoor thermal comfort temperatures of 25 °C.

The human thermoregulatory mechanism endeavors to maintain a constant core temperature for the body, which commonly requires that the internal heat generated by metabolism be transferred through the skin and lungs to the surrounding environment (Robinson 2000) with the human body temperature being normally maintained at approximately 37 °C by the anterior hypothalamus through thermoregulation (Hifumi et al. 2018). Heat-related illness develops when the pathological effects of heat load cannot be eliminated from the human body (Szekely et al. 2015) manifesting through excessive loss of water which can induce dehydration and salt depletion (Hifumi et al. 2018). In the event of exposure to extreme high indoor temperatures, removal of excess waste from the body is impeded triggering the core temperature to rise and physical health problems can begin (Robinson 2000). Healthy humans have sufficient heat regulatory which cope with increases in temperature up to a particular threshold; however, beyond a certain point the thermoregulatory system can collapse (Kovats and Hajat 2008).

Climate change has the potential to result in more heat-related illnesses as the mean global temperatures rise (White-Newsome et al. 2012). Occupants with pre-existing diseases, children, and the elderly face the greatest risk from extreme indoor heat (Wright et al. 2017). The WHO estimates the global burden of disease from climate change risk factors to have caused 160,000 premature deaths particularly from heatwaves and floods (Myers et al. 2011). The chronically ill, elderly, and children spend considerable time inside dwellings thus making them more vulnerable to indoor heat exposure (Smargiassi et al. 2008; White-Newsome et al. 2012). Past studies show that Southern Africa is expected to be a climate change hotspot (Hoegh-Guldberg et al. 2018). Most experimental indoor temperature monitoring studies have been done in the Global North hence the study sort to fill this knowledge gap on the threat of climate change on indoor thermal environments in Africa. Adaptation techniques are needed immediately for the housing sector to deal with the impacts of extreme heat on indoor environments (Kinnane et al. 2016). The purpose of the study was to characterize summer indoor thermal environments in low-cost housing units on the South African Lowveld. The chapter is structured as follows: section "Materials and Methods" describes the materials and methods, section "Results" presents results, section "Discussion" presents a discussion of the study, while section "Conclusion" presents conclusion and plans for future work.

Materials and Methods

This section outlines the materials and methods used during the study. A brief description of the study site is given followed by a highlight of the indoor sensors used to gather indoor and ambient data.

Description of the Study Site and Sampled Dwellings

Agincourt/Matsavana (24.8279S: 31.2197E) is a low-income residential settlement on the Lowveld valley and is located in the town of Bushbuckridge Local Municipality in Mpumalanga Province (Wittenberg and Collinson 2017). All sampled dwellings in the study were of a detached nature and were constructed as standalone structures. Dwellings selected were constructed from either hollow block or clay standard bricks or standard cement and sand bricks with no wall plastering and no ceilings and were free running without any mechanical indoor temperature mechanisms but rather depend on occupant ventilation behaviors. Figure 1 represents the study site.

Figure 1 shows the settlement of Agincourt located in the Bushbuckridge Local Municipality in the Lowveld region of South Africa.

Figure 2 shows images of sampled dwellings for the study. The majority of dwellings were detached, roofed from iron corrugated iron sheets, none plastered with no ceilings. The left image represents low-cost dwellings, the middle image

Fig. 2 Low-cost housing units sampled for the study

shows iButtons hanged inside a dwelling wall, and the right image shows the data downloading process.

Description of Indoor Temperature Monitoring Sensors: (*Thermochron iButton*)

Indoor air temperatures were measured using Thermochron iButton (DS1922L) manufactured by Maxim Integrated Products formerly Dalls Semiconductor (USA) as shown in Fig. 3. Thermochron iButton has a diameter of 17.35 mm and a thickness of 6 mm (Johnson et al. 2005). These sensors can measure air temperature range of −40 °C to 85 °C. Thermochron loggers are rugged, water-resistant, and self-sufficient sensors that measure temperature and record the result in a protected memory section (Hubbart et al. 2005). Figure 3 shows the image of a Thermochron *i*Button used in the study.

Indoor Air Temperature Measurements (T_{ai})

In each dwelling, two occupied spaces were identified: living rooms and bedrooms with a single sensor (Thermochron iButton) being installed in each room. Living rooms were chosen as this is the space where occupants spend considerable time during the daytime while the bedroom is mostly occupied at night. Air temperature in living rooms space was used as a proxy indicator or for occupant daytime exposure to extreme temperature while the bedroom air temperature was used as a proxy indicator for nighttime extreme indoor temperature exposure. Indoor sensors

Fig. 3 Thermochron *i*Button used for indoor and ambient temperature measurement

were placed at a standard height of 1.5 m–1.6 m above ground as applied in Healy and Clinch (2002), Yohanis and Mondol (2010), Newsome et al. (2012), Kane (2013), Lee and Lee (2015) and Magalhaes et al. (2016). Precautions were taken to make sure that sensors were not obstructed by furniture away from direct sunlight, heat, or any form of heat radiation (Malama and Sharpless 1996; Mavrogianni et al. 2010; Loughnan et al. 2015; Lee and Lee 2015; San Miguel-Bellod et al. 2018). Measurements were done continuously over a 24-h cycle at a 30-min temporal resolution.

Ambient Air Temperature Measurements (T_{air})

Ambient air temperature measurements were done using the same sensors as indoor temperatures (Thermochron *i*Button DS1922L). Similar to indoor measurements loggers were set to collect data at a 30-min temporal resolution over a 24-h cycle. Before deployment, all sensors were calibrated and tested for accuracy in the laboratory by the manufacturer (Matandirotya et al. 2019). Supplementary ambient air temperature data were obtained from the South African Weather Service (SAWS) nearest weather station.

Table 1 shows the number of summer indoor monitoring days during the 2016 and 2017 surveys. In 2016 indoor monitoring was done for a total of 17 days while for 2017 monitoring was done for 37 days.

Data Analysis

The study defined daytime as 8:00 am to 8:00 pm while nighttime was staggered from 9.00 pm to 7 am. For each room, hourly mean temperatures were calculated for the whole monitoring period. To establish the association/relationship between indoor and ambient temperatures at different times of day, indoor and ambient temperature were correlated using simple linear regression. Pearson values were used as a proxy indicator of insulation material strength. Section "Results" presents the results of the study.

Results

This section presents the results of the study. Tables 2 and 3 highlight the descriptive of indoor and ambient temperatures during the indoor monitoring campaigns.

Table 1 Indoor temperature monitoring times

Study site	From	To	Number of monitoring days
Agincourt 2016	13 April 2016	30 April 2016	17
Agincourt 2017	1 February 2017	9 March 2017	37

Table 2 Descriptive statistics for summer 2016

	Minimum (°C)	Maximum (°C)	Mean (°C)	Std. Deviation
Ambient daytime	17	38	27	5
Living room daytime ($n = 31$)	21	33	27	3
Bedroom daytime ($n = 19$)	20	34	27	2
Ambient nighttime	16	26	21	2
Living room nighttime ($n = 31$)	20	29	24	2
Bedroom nighttime ($n = 19$)	18	28	23	2

Table 3 Descriptive statistics for summer 2017

	Minimum (°C)	Maximum (°C)	Mean (°C)	Std. Deviation
Ambient daytime	19	41	29	7
Living room daytime ($n = 27$)	21	36	29	4
Bedroom daytime ($n = 27$)	21	37	29	4
Ambient nighttime	18	28	22	2
Living room nighttime ($n = 27$)	21	33	26	3
Bedroom nighttime ($n = 27$)	21	33	26	3

Table 2 represents descriptive statistics of indoor and ambient temperatures during the summer of 2016. The daytime ambient mean was higher than the nighttime mean by 6 °C. The trend was also observed for indoor temperatures during day and nighttime. The occupied spaces bedrooms and living rooms had similar means during daytime at 27 °C, while at nighttime there is 0.6 °C difference between living rooms and bedrooms with living rooms being slightly warmer. Living rooms are occupied spaces during daytimes so there was a potential of thermal discomfort as a result of temperatures exceeding the WHO maximum indoor temperature guideline of 24 °C. During the nighttime, there was also a marginal chance of thermal discomfort as the bedroom temperatures were close to breaching the 24 °C mark.

Table 3 represents descriptive statistics of indoor and ambient temperatures during summer 2017. A similar trend to 2016 was observed as mean daytime ambient temperatures were higher than nighttime temperatures by a 7.4 °C. Occupied spaces (living rooms and bedrooms) showed similar daytime and nighttime behaviors. Daytime differences between bedrooms and living rooms were by 0.2 °C, while at nighttime the difference was by 0.4 °C. There were very marginal differences between the rooms sampled. Figure 4 represents the density distribution of indoor temperatures in bedrooms during the summer of 2016.

Figure 4 represents indoor temperature density distribution in bedrooms during the summer of 2016. Throughout the summer monitoring period, all bedrooms had median temperatures above 24 °C beyond the WHO maximum temperature

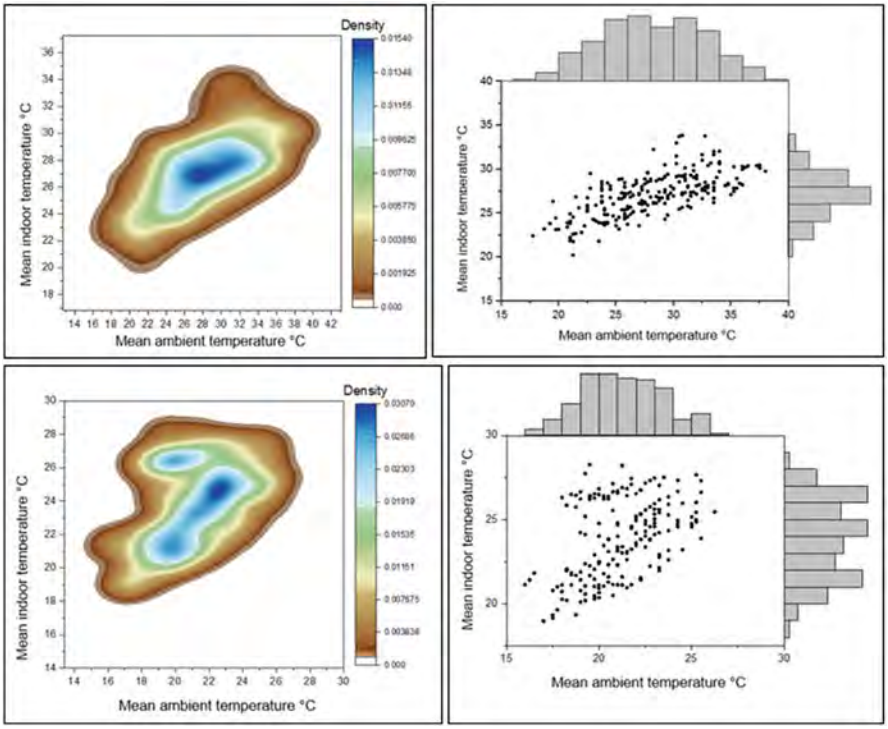

Fig. 4 Density distribution and marginal histograms of indoor temperatures in bedrooms during the summer of 2016. Top-row represents daytimes while the bottom row represents nighttimes

guideline for thermal discomfort. High bedroom temperature beyond the prescribed 24 °C has the potential to cause sleep impairment especially at night when space is used for night resting. Besides causing sleep impairment high indoor temperatures can cause excessive sweating that ultimately can cause dehydration as well as heat exhaustion. Figure 5 shows the density indoor temperature distribution for bedrooms during the summer of 2017.

Figure 5 shows indoor temperature density in bedrooms during the summer of 2017. During daytimes, indoor temperatures were in the region above 25 °C with minimum hourly mean temperatures being above 20 °C in all bedrooms sampled. The study assumed that this space is not occupied during the daytime; therefore, no risk was anticipated to occupants. According to Fig. 4, temperatures remained high at nighttime with minimum mean nighttime temperature remaining above 20 °C. The high indoor temperatures are mainly from solar radiation absorption which happens during the day which spills over into nightime since occupants do not have mechanisms to artificially regulate their indoor environments. The impact of these high nighttime indoor temperatures is that occupants are likely to suffer sleep impairment with a potential to loose fluids. With these high ambient temperatures, there is a likelihood of indoor overheating during both daytime and nighttimes.

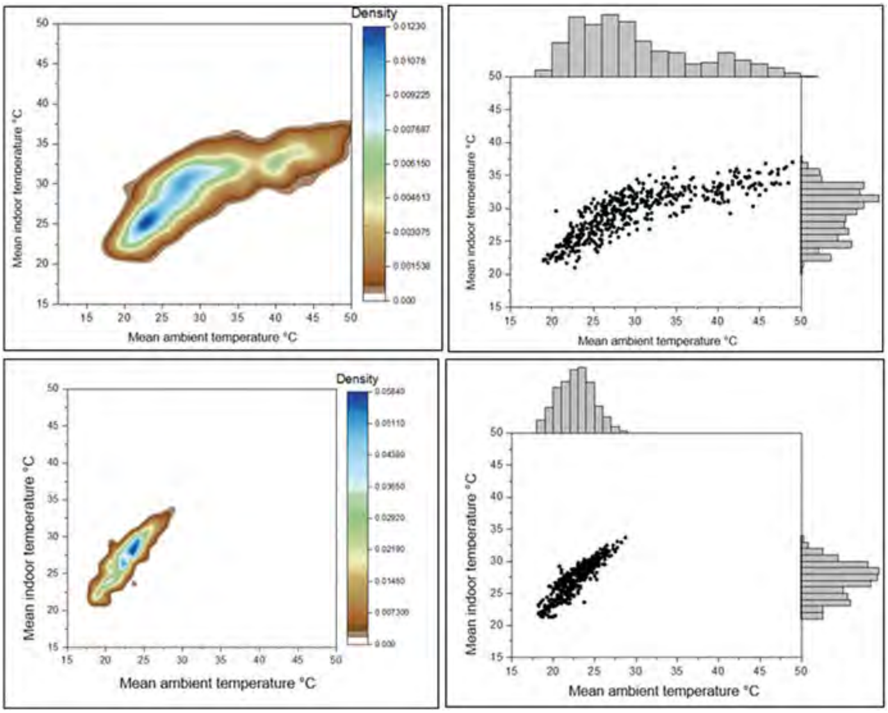

Fig. 5 Density distribution and marginal histograms of indoor temperatures in bedrooms during the summer of 2017. Top-row represents daytime while the bottom row represents nighttime

Figure 6 shows indoor temperature density distribution in living rooms during the summer of 2016.

Figure 6 shows the density distribution and marginal histograms of indoor temperatures in living rooms during the summer of 2016. The study assumed that living rooms are occupied in space during the daytime. The highest concentration was recorded at mean indoor temperatures of 26 °C during the day, while at night the highest concentration was at 24 °C. The biggest threat to human indoor thermal comfort came from daytime occupation of living rooms as temperatures were at the most time above 24 °C the prescribed thermal comfort temperatures by the WHO. The impact on occupants is that they are likely to lose a lot of bodily fluids from this exposure to high temperatures.

This trend was similar to that observed in bedrooms over the same summer monitoring period. A threat to human thermal comfort can only be experienced in this space during the day as people are expected to be occupying this space while on the other hand if the temperatures breach the 24 °C threshold at night it is a threat to those households that use living space for sleeping purposes thus sleep impairment can happen. Concerning thermal insulation material, the high indoor temperatures

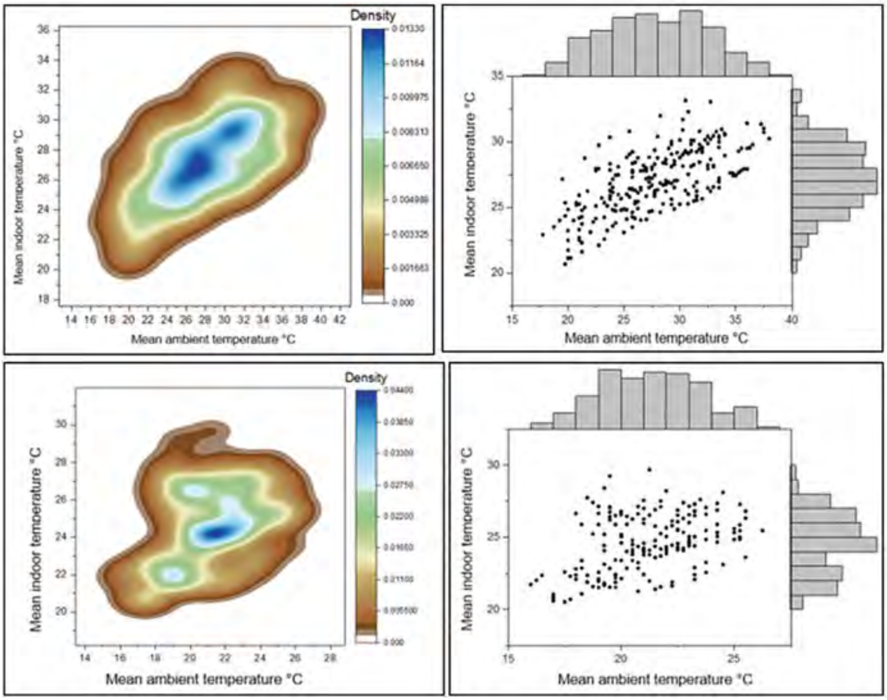

Fig. 6 Density distribution and marginal histograms of indoor temperatures in living rooms during the summer of 2016. Top row represents daytime while the bottom row represents nighttime

indicate that the thermal material is of poor thermal capacity. Figure 7 shows indoor temperature density distribution in living rooms during the summer of 2017.

Figure 7 shows the density distribution of indoor temperatures during the day and nighttimes. A similar trend was observed as in the summer of 2016 where the daytime minimum mean temperatures were recorded at above 20 °C while at nighttime they remained high with the minimum mean recorded in living rooms being at 21 °C. The impact on occupants was expected during the daytime as the study expected occupants to be occupying this space. Negative thermal effects are expected in living rooms if the indoor temperatures are above 24 °C during the day as people are expected to be occupying this space while it can have negative thermal impacts if occupants use this space for sleeping purposes during the night. The high indoor temperatures show that the thermal material used is weak in comparison to the high ambient temperatures experienced in the region thereby exposing occupants to extremely high indoor temperatures. It, therefore, implies that dwellings need to be constructed from a thermal material with the appropriate R-value and resistance capability to withstand the high levels of solar radiation. Measuring R-values of the building material was beyond the scope of this thesis but can be a future line of

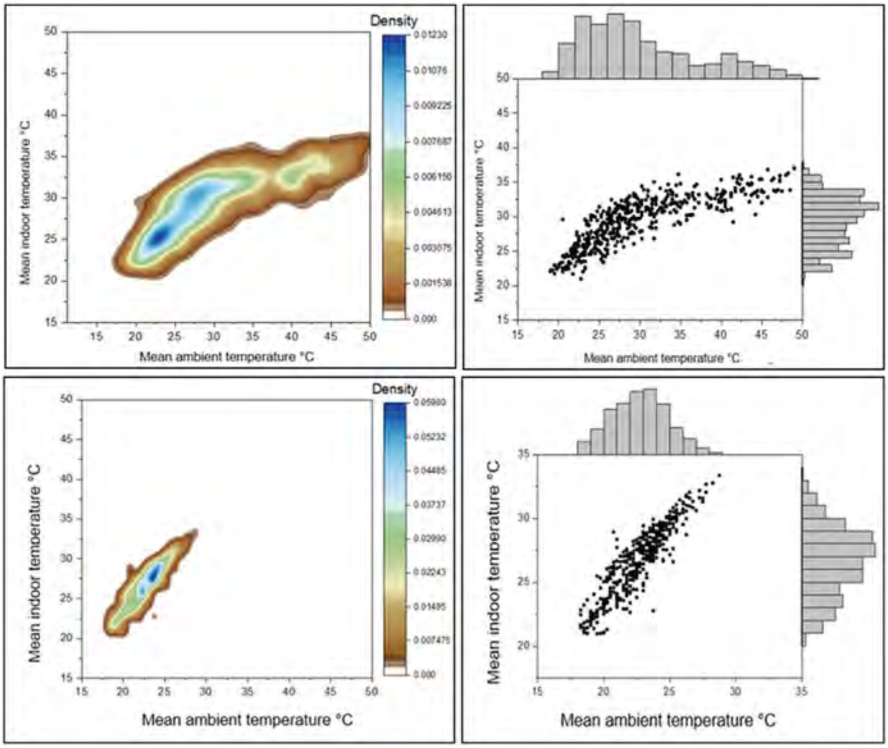

Fig. 7 Density distribution of indoor temperatures and marginal histograms in living rooms over the summer 2017 monitoring period. Top-row represents daytimes while the bottom row represents nighttimes

research. Figure 8 shows simple linear regression results for mean indoor and ambient temperatures in bedrooms during the summers of 2016 and 2017.

Figure 8 shows the simple linear regression results in bedrooms during the 2016 and 2017 indoor monitoring surveys. During both surveys, ambient temperatures were a good predictor of indoor temperatures with the strongest association being observed during the nighttime of 2017 monitoring ($r = 0.90$), while the least association was observed during nighttime of 2016 ($r = 0.47$). The strong relationship between ambient air temperatures and indoor temperatures shows the weakness in the thermal fabric of the material used to construct the sampled dwellings. Figure 9 shows simple linear regression results for mean indoor and ambient temperatures in living rooms during the summers of 2016 and 2017.

Figure 9 shows simple linear regression results of mean indoor and ambient temperatures in living rooms. The strongest association was observed during the night of 2017 monitoring ($r = 0.90$) while the least association was observed during nighttimes of 2016 at $r = 0.40$. The strong relationship indicates that these low-cost dwellings are highly sensitive to ambient temperature changes.

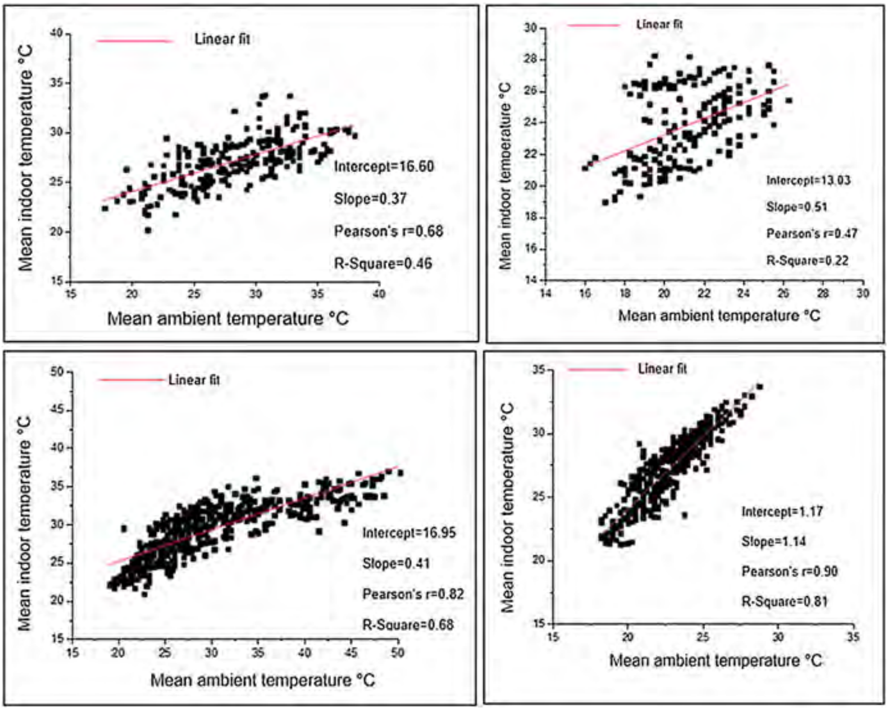

Fig. 8 Regression results for mean indoor and ambient temperatures in bedrooms. Top-row represents bedrooms 2016, while the bottom row represents 2017. The left image represents daytime while right image represents nighttime

Discussion

During summer 2016, the study observed that 100% of bedrooms had mean daytime temperatures above 24 °C through the monitoring period, while 53% of the same bedrooms recorded night temperatures exceeding 24 °C. In 2017, during both daytime and nighttime, 100% of bedrooms had daytime mean temperatures above 24 °C. The implication of being exposed to such indoor temperatures for a long time is that occupants lose a lot of fluids that can lead to dehydration. At night sleep impairment can also be experienced due to the high indoor temperatures. The population likely to be negatively affected most are young children and the elderly. Young children suffer from high heat exposure because their thermoregulatory system will not have developed much while for the elderly the thermoregulation system starts to suffer from dysfunction as sweating glands get blocked with aging hence not much sweat is generated to cool off the body. In both instances, it results in heat build-up within the body thereby putting a strain on the core. A strained core can end with such heat-related negative illnesses such as heat strokes, heat cramps, or heat exhaustion (Myers et al. 2011).

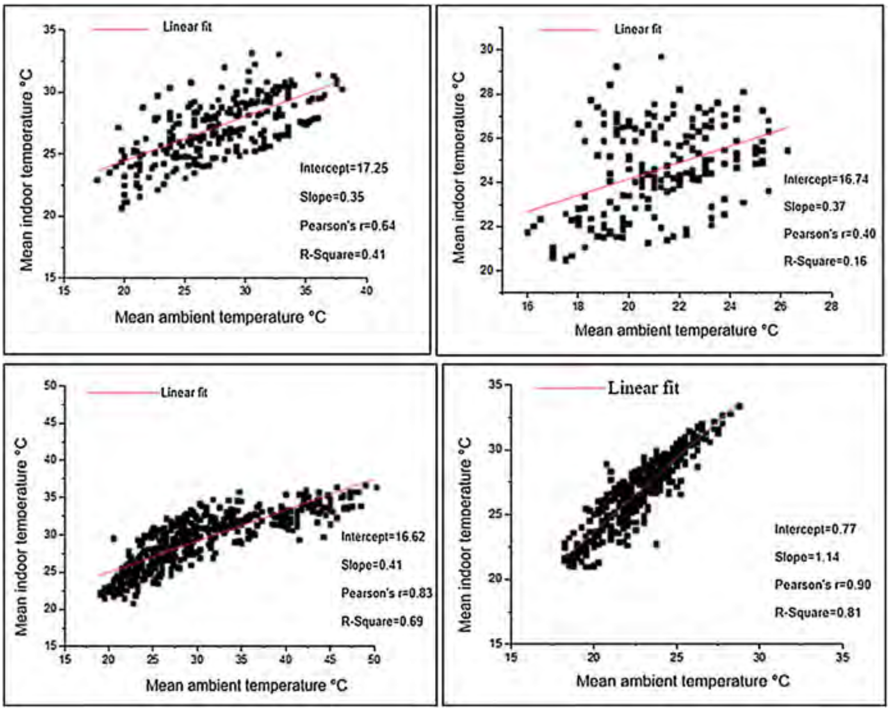

Fig. 9 Regression results of mean indoor and ambient temperatures in living rooms. The top row represents living rooms during 2016 while the bottom row represents living rooms 2017. The left image represents daytime, while right image represents nighttime during summer 2017

A similar trend to bedroom indoor temperature variations was observed in living rooms wherein 100% of living rooms in 2016 breached the 24 °C threshold, while at night 87% of sampled dwellings had mean temperatures above 24 °C. In 2017, the study observed that 100% of living rooms had mean daytime and nighttime indoor temperatures above 24 °C providing ideal conditions for indoor overheating. The high indoor temperatures recorded by the study during 2017 can be attributed to the monitoring period wherein temperature monitoring was done during the peak of summer season in February unlike the 2016 survey where temperature monitoring was done in April which is towards the period of transition to winter on the South African Lowveld. For living rooms, the study anticipated the greatest threat to indoor thermal comfort during daytime as people are occupying this space unlike at night where occupants shift to bedrooms. Prolonged exposure to high indoor temperatures can have devastating effects on those occupants already having underlying health conditions which can worsen.

The study also established that the sampled structures were highly sensitive to ambient temperature changes as confirmed by the strong positive Pearson correlations between indoor and ambient temperatures. The sensitiveness was observed for both day and nighttimes. This confirms that the thermal fabric of sampled dwellings is weak with an inability to regulate indoor temperatures as desired. If the thermal insulation is fully functional, it could act as a barrier to incoming solar radiation during the day and also be complemented by various ventilation practices put in place by occupants. Since the dwellings sampled were free running, occupants had no opportunity to artificially regulate indoor thermal environments. An increase in heat weather events in South Africa is likely to increase exposure to elevated temperatures for the poor which can be classified as a climate-related health threat (Wright et al. 2017). With ambient temperatures expected to continue on an upward trajectory as a result of climate change, there is a need to improve the thermal fabric of low-cost dwellings which can be achieved through thermal insulation retrofits for existing housing stock while for a new housing stock passive designs can be integrated. These two adaptation strategies can be of help to regulate indoor thermal conditions. The study findings concur to studies by Makaka and Meyer (2005), Naicker et al. (2017), Matandirotya et al. (2019) which also estimated that low-cost dwellings are sensitive to ambient temperature changes because of poor insulation. In a study by Mavrogianni et al. (2010), 53% of livingrooms average indoor temperatures were above thermal comfort levels of 24 °C while 86% of recorded temperatures could result in sleep impairment. Residents of low-cost dwellings are therefore at risk of being exposed to indoor thermal discomfort as temperatures continue to rise as a consequence of climate change.

Extreme high indoor temperature as a result of climate change is bringing several challenges for the built environment as people spend considerable time indoors; hence, the effects are likely to belong-lasting if appropriate adaptation interventions are not introduced especially for the poor marginalized populations who already occupy substandard housing. The study, therefore, brings to the fore the current existing indoor thermal environments in low-cost housing in the context of climate change. One of the possible immediate mitigation measures includes thermal insulation retrofits for the existing housing stock while for new housing stock passive designs can be incorporated. These measures improve the ability of housing structures to regulate indoor thermal environments. Furthermore, greening programs, urban planning, and housing are also other strategies that can be used to mitigate against devastating health threats from climate change (Wright et al. 2017). Future work will focus on measuring the thermal resistance capacity of building materials used for the construction of low-cost dwellings on the South Africa Lowveld region.

Study Limitations

The study had single sensors deployed in each room during monitoring; therefore, there was no mechanism to account for indoor vertical and horizontal temperature gradients. To mitigate this limitation, the study had to position sensors at the center of rooms where possible without interfering with occupants' daily activities. The study also could not take into account other indoor sources of radiant heat or ventilation practices that could impact on indoor temperatures. Additionally, the other limitation was that the study could not measure humidity which could facilitated the calculation of apparent temperatures which is an indicator of thermal sensation. Future studies will take into account these factors.

Conclusion

The study estimated that there is a risk of indoor overheating in low-cost dwellings on the South African Lowveld as a consequence of poorly insulated dwellings and a rise in temperatures from climate change. Occupants were exposed to indoor temperatures which breached the WHO maximum thermal guideline of 24 °C subjecting occupants to various physical health threats in the event of prolonged exposure. It is therefore imperative that adaptation and mitigation strategies on the existing housing stock are applied in order to reduce the effects of climate change on occupants. Future work will focus on community participation in the development of housing designs that are climate resilient and suit the changing climatic conditions of Southern Africa.

Acknowledgments Acknowledgments go to Brigitte Language who did data collection for the study working under the Prospective Household Observational cohort study of Influenza, Respiratory Syncytial Virus and other respiratory pathogens community burden and Transmission dynamics in South Africa (The PHIRST Study) supported by a grant from the United States Centre for Disease Control and Prevention and conducted by the National Institute for Communicable Disease of the National Health Laboratory Service. Ethical approval for the PHIRST study was obtained from the University of Witwatersrand, Johannesburg HREC (150808). Acknowledgments are also extended to South Weather Service for the provision of ambient temperature data.

Contents

Abstract

Weather information is needed for smart decisions because uncertainties in weather phenomena are beyond capacity of smallholders for autonomous responses. The study analyzed determinants of farmers' use of weather information as smart adaptation strategy. Arable crop farmers were sampled in the derived

savannah agro-ecology area of Ondo State, Nigeria. Heckman probit model estimates show that gender and agricultural extension services were significant positive drivers of farmers' access to weather information. Should weather information becomes an alternative adaptation strategy, access to credit was found as the major driver of farmers' propensity to use weather information before taking climate smart agricultural decisions. Further results reveal that increasing knowledge of onset date, large farm size, and access to agricultural extension services significantly reduced farmers' propensity to use improved weather information for smart decisions in the dry savannah area.

Extreme weather · Weather information · Adaptation responses · Smart decisions · Heckman Probit · Ondo State

Introduction

Climate change is a particular threat to continued economic growth and livelihoods of vulnerable populations (UNEP 2018). The United Nations Development Programme (2011) confirms that Africa faces considerable challenges in adapting to the long-term impacts of climate change and extreme climate events. Extreme events have led to severe economic losses over the years and have increase farmers' needs for weather forecast information that will enable predictions beyond the timeline of indigenous knowledge in decision-making processes. Agricultural stakeholders have to contend with the high vulnerability due to low levels of adaptive capacity and poor weather services across many developing economies. Ensuring that decision makers and end users especially smallholders are able to respond to the medium- and-long-term implications of climate change is important in promoting climate-resilient development (Ziervogel and Zermoglio 2009).

Jones and Carabine (2013) observed that the need for medium- and long-term climate information to support climate-resilient development planning in Africa is clear to generate long-term strategies for loss and damage, adaptation finance, climate resilient agricultural practices, and other variants such as climate-compatible development. In the Sub-Sahara Africa, farming systems are highly reliant on prevailing environment, and the existence of traditional knowledge offers elements of resilience (FAO 2011).

In managing the adverse impacts of extreme climate events and climate variability, local farmers have to adjust to harsh weather conditions by relying on weather forecast services which would help moderate potential damage and adverse consequences. The accessibility and usefulness of weather information are therefore critical factors that will affect farmer's ability to adapt (Alston 2013; Serna 2011; Bryan et al. 2009).

In Nigeria, the agricultural production system is predominantly rain-fed, hence highly vulnerable to seasonal variability which affects agricultural livelihood of smallholders and landless laborers who depend on agriculture, as one of the most vulnerable countries among developing African economies (Vermeulen et al. 2012). The impacts of long droughts and deficit rainfall will be mostly felt by the rural population who represent over 80% of the Nigerian population who have less means to adapt and/or diversify their livelihoods (World Bank 2013). Nigeria may lose about 11% of GDP ($460 billion) to drought risk event by 2020 and about 25% by 2050.

Smallholders usually depend on traditional weather predictions in taking production decisions (Mugabe et al. 2010). A variety of traditional indicators have been developed in taking decisions weather-dependent farm management decisions. Over time, some traditional weather and climate indicators consequently are no longer patterned base on existing climate behavior (Sanni et al. 2012). Variability in weather parameters has resulted into significant changes in agricultural production cycle such that farmers can no longer accurately predict start and duration of rainfall seasons by relying on indigenous knowledge (Awolala 2018; Madzwamuse 2010). Weather information has shown potential for improving resilience of agriculture to climate shocks and uncertainty, as a fundamental basis upon which smallholders will adapt to effects of climate change (Food and Agriculture [FAO] 2013, 2015).

Nigeria plans “Climate-Smart Agriculture” under the Nigeria’s National Determined Contributions of COP21 Paris Agreement for which weather and climate information services are foremost safety nets. Adapting to impacts through access to timely weather forecasts and other adaptive mechanisms are foremost in Africa’s policy dialogues and socio-economic development agendas (Oyekale 2015).

Policy makers’ have thus considered several alternatives for enhancing farmers’ adaptive capacity in the face of changing climatic parameters. A national strategy towards climate resilience, therefore, is to strengthen local resilience and adaptive capacity of vulnerable smallholders to facilitate their investments in Climate Smart Agriculture National Adaptation “Action” Plan towards a resilient agricultural sector (IFAD 2017; CCAFS 2015). One of the strongly identified pathways to meet this Action Plan is the utilization of weather and climate information to facilitate smallholder decisions for adaptation planning. Despite the inherent uncertainties that are associated with climate science and weather forecasting in making informed decisions on agricultural investments aimed at optimizing use of scarce resources available, there is no enough evidence of understanding gaps in the uptake of weather forecast information for long-term strategies of climate resilience, particularly in the Sub-Saharan Africa including Nigeria (African Climate Policy Centre [ACPC] 2011).

While studies in developed countries reveal that farmers benefit substantially from using seasonal forecasts (Mjelde et al. 2000), seasonal weather information has nevertheless been found to have very minimal impacts as it remains largely unutilized by smallholder farmers in Nigeria despite facing food deficits (Awolala 2018). This study analyzed major drivers of farmers’ use of weather information as basis for adaptation decisions in the savannah area of Ondo State, Southwest of Nigeria.

Materials and Methods

The study site was the Derived Savannah agro-ecology of Akoko North-West Local Government Area of Ondo State, Nigeria. Akoko North-West is located between latitudes 7° 38′ and 7.6° 27.6′ N and longitudes 5° 47′ and 5.8° 38.4′ E of the equator with an elevation of 486 m in Guinea Savannah agro-ecological zone (accessed from Google maps, 2017). Akoko North-West Local Government Area has an estimated population of 213,792 and covers a total area of 512 km^2 (National Population Census 2006). Ondo State is located in the Southwest of Nigeria, entirely within the tropics with tropical climate broadly classified into rainy season (April–October) and dry season (November–March). Temperature throughout the year ranges between 21 °C to 30 °C and humidity is relatively high. The annual rainfall varies from 2,000 mm in the south to 1,150 mm in the north. Ondo State enjoys luxuriant vegetation with high forest zone (rainforest) in the south and subsavannah forest in the northern fringe (accessed from http://www.coastalnews.com/profile/government-profile profile) (Fig. 1).

Cross-sectional data used for this study were obtained using a structured questionnaire administered during a farm field survey of arable food crop farmers. Multistage sampling technique was used to select the respondents. In the first stage, Akoko North-West Local Government Area (LGA) was

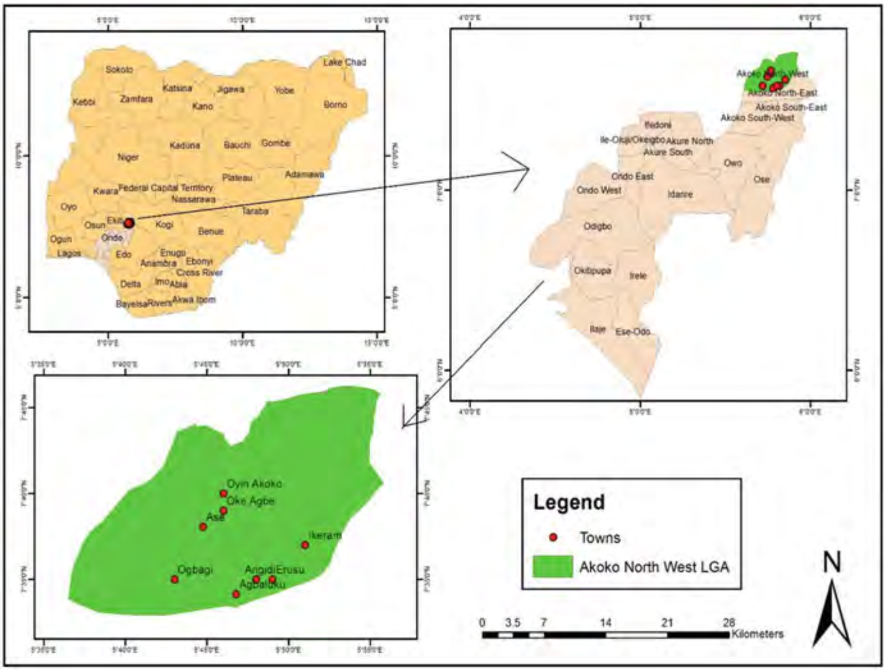

Fig. 1 Map of Akoko North-West showing selected villages in Ondo State

purposively selected in guinea savannah agro-ecological zone of Ondo State given its dominance of major production of cereals and high dry vegetation. This zone is characterized by low rainfall and long dry period. The savannah area, however, has the potential for producing major food staples in meeting consumption and export requirement towards 2023 National Food Security Agenda in the State. In the second stage, eight farming communities were randomly selected from Akoko North-West LGA using a simple random sampling technique. The final stage involved the random sampling of 20 respondents in each farming community which resulted into a total of a hundred and sixty respondents sampled for the study.

Econometric Model

Heckman Two-Step Procedure

Heckman Probit Model was used to Analyse Determinant of Smallholders' Use of Weather Information in decision making processes. When a decision process by farmers to adopt an innovative strategy requires more than one step, models with two-step regressions are usually used to correct for the selection bias generated during the decision-making processes which implies the use of Heckman's Sample Selectivity Probit Model (Heckman 1976; Maddison 2006). For model specification, the first step involved the analysis of determinants of access to weather forecast information (selection model) and the second step was the smart decision taken, conditional on the first stage of access to weather information (outcome model), adapted from Awolala et al. and Oyekale (2015). The Probit model for sample selection assumes that there exists an underlying relationship. The latent equation is given by:

$$y_j^* = x_j\beta + u_{1j} \tag{1}$$

Such that the binary outcome is only observed given by the Probit model as:

$$y_j^{probit} = \left(y_j^* > 0\right) \tag{2}$$

The dependent variable is observed only if the observation "j" is observed in the selection equation:

$$y_j^{select} = \left(z_j\delta + u_{2j} > 0\right) \tag{3}$$

$$u_1 \approx \mathrm{N}(0, 1)$$
$$u_2 \approx \mathrm{N}(0, 1)$$
$$corr(u, u_2) = \rho$$

where, x is a k- vector of regressors, z is an m-vector of regressors; u_1 and u_2 are error terms jointly normally distributed, independently of x and z with zero expectations. When $\rho \neq 0$, standard Probit techniques apply to Eq. (3) give biased results. Hence, the Heckman Probit provides consistent, asymptotically efficient estimates for all parameters in such models (StataCorp 2003). Therefore, to analyze the determinant of farmers' utilization of weather forecast information in taking specific adaptations decisions, the marginal effects of a unit change in an independent variable on the probability $P(Z = 1| X = x)$ were obtained given that all other variables are held constant. It is mathematically expressed as:

$$\frac{\delta P(Z_i = 1|x_i)}{\delta x_i} = \frac{\delta E(Z_i = 1|x_i)}{\delta x_i} = \varphi(x_i'\beta) \quad (4)$$

Table 1 presents variables that were analyzed in the Heckman two-step econometric model.

Table 1 Variable list for the econometric analysis

Variables	Descriptions	Measurements
Dependent variables		
Agricultural smart decisions	Smart agricultural decisions taken by farmers, given weather information received (Yes =1)	Yes = 1; 0 if otherwise
Farmer's access to weather information	Farmer has access to weather information	
Independent variables		
Gender	Gender of farmer	Female = 1; 0 if otherwise
Farming experience	Farming experience of household head	Number
Farm size	Farm size cultivated	Hectares (ha)
Credit	Access to agricultural credit finance	Yes = 1, 0 if otherwise
Agricultural extension access	Access to agricultural extension services	Yes = 1, 0 if otherwise
Farmers Group membership	Hold membership of Farmers Group	Yes = 1, 0 if otherwise
Access to weather forecasts	If farmer receives weather information	Yes = 1, 0 if otherwise
Weather information		
Rainfall onset date	Rainy season onset date	Yes = 1, 0 if otherwise
Cessation date	Rain cessation date	Yes = 1, 0 if otherwise
Agricultural decisions		
Taking Smart Agricultural decisions	Has taken smart adaptation practices	Yes = 1, 0 if otherwise

Results and Discussions

Drivers of Farmers' Use of Weather Information for Smart Decisions

The result from the Heckman two-step regression estimates result in Table 2 reveals that access to credit is a major driver increasing farmers' propensity to adapt with climate-smart practices at 5% level of significance while increasing access to information onset date, farm size, access to extension reduce farmers' their ability to take climate-smart actions in the derived savannah area. However, gender and access to agricultural extension service were major drivers positively facilitating access to weather information while farmers' experience negatively influence farmers' access to weather information in the derived savannah area of Ondo State, Nigeria.

Access to credit has a positive coefficient with the adoption of climate-smart practices ($p<0.05$). An increase in access to credit will increase the likelihood that farmers would adopt climate-smart adaptation practices conditional on access to weather forecast information. It is viewed that with credit facilities, interested farmers will be able to bear the cost associated with climate smart practices. For instance, when there is a forecast that rainfall is likely to be unusually low, farmers can grow crops that are drought resistant and sensitive to water availability

Table 2 Heckman estimates of major drivers of farmers' use of weather information

to improve profit unlike farmers who also received forecast information but lack access to credit. Therefore, credit facility should be strengthened for smallholders' adoption of climate-resilient technology adaptation actions in the derived area.

Seasonal rainfall onset date and farm size both have negative coefficients with the adoption of climate-smart adaptation practices ($p<0.05$). An increase in access to seasonal rainfall onset date, likewise increase in farm size, will reduce the likelihood that farmers would adopt climate-smart adaptation practices conditional on access to weather forecast information. These are important policy drivers that should be addresses because they signal danger to farmers' adaptation with climate-smart practices conditional on access to weather forecast information. There are certain socioeconomic and cultural factors which might be responsible for such findings. It is also believed that medium and large-scale farmers might be reluctant in taking climate-smart decisions due to the huge costs involved.

The positive coefficient of gender and access to extension service are both significant at 5% level ($p<0.05$). The result implies that male farmers are more likely to have access to scientific weather forecast information unlike their female counterparts. It thus becomes obvious that this male farming population should be given attention as major pathway to ensure farmers' resilience with regards to utilization of scientific weather forecast information.

Likewise, increase in access to agricultural extension service, it will be more likely that farmers would have access to weather forecast information in the study area. This is because the role of agricultural extension is critical to move weather forecast information from weather service providers especially the Nigerian Meteorological Agency (NiMet) and other weather forecast agencies in other to ensure a return on investment by translating new knowledge into innovative practices which will enhance farmers' resilience.

Further results explained the negative coefficient of farmers' experience with access to weather forecast information ($p<0.05$). As farmers' experiences increase, there is a declining likelihood that they will have access to scientific weather forecast information. This might be attributed to their over reliance on traditional experience and knowledge of monitoring weather with local indicators in the study area. This is another important policy variable indicating that there should be improvements in farmers literacy and awareness campaign to encourage the use of scientific-based weather forecasts information to help facilitate climate-smart adaptation actions other than traditional forecasting techniques in the dryland. Table 2 presents the econometric results of factors influencing the use of weather information for smart decisions in the study area.

Conclusions and Policy Recommendations

Access to rainfall cessation date has a positive significant effect on farmers' use of improved weather information. Increasing access to seasonal rain probabilities forecast through information sharing increases the likelihood that farmers will use improved weather information for smart production decisions. Weather services such as rainfall forecasts and advisory planting calendars based on length of growing season should be location specific and timely communicated by the Nigerian Meteorological Agency (NiMet) in a mode that is understood at farmers' level. Such information on rainfall cessation date is considered significantly helpful for farmers adaptation planning and resilience.

Credit also significantly facilitates farmers' use of weather information in taking climate-smart decisions. It is viewed that with credit facilities, interested farmers will strengthen their adaptive capacity to afford whatever transaction cost that might be associated with climate smart practices if they have adequate financial assistance. Better incentive-based credit facility should be developed as a farmer-oriented financial product to strengthen smallholders' decisions for climate-resilient technology actions in the dry land area. Similarly, Policy makers should ensure functioning financial institutional services especially rural access to bank credits and informal credits are available to help farmer's withstand unforeseen circumstances that may arise from investing in innovative climate smart practices.

In terms of access, male farmers were found to have more access to weather information. Agricultural decisions are traditionally considered as responsibility of the household head, and most of the times, it is the male gender. Therefore, weather information utilization could be more guaranteed when male farmers are used as an entry point to allow for quick and wider coverage among farmers given their strong influence as decision makers. Policy makers and agricultural stakeholders at the federal, state, and local government levels must ensure that rural education is provided for male household heads to fast-track local uptake of improved weather information as weather risk adaptation strategy.

Better access to agricultural extension services also increase farmers' likelihood to have access to weather forecasts. Agricultural Extension Department at the Ministry of Agriculture and Rural Development must ensure that periodic extension education and training services serve as opportunities to share updated information on weather with farmers and provide advisory services on smart agro-weather management technologies. A functional and effective extension service system has great potential in facilitating early action on weather risk management through climate smart practices by the increasing farming population in the derived savannah area of Ondo State, Nigeria.

These drivers should be considered for a review as strategies for implementing the National Climate Smart Agriculture Adaptation Plan (NCSAAP) in Ondo State, Nigeria, as stated in the revised National Agricultural Policy which targets agricultural livelihood resilience towards meeting the 2030 National Food Security Agenda.

Contents

Abstract

Farmers in most parts of Africa and Asia still practice subsistence farming which relies minly on seasonal rainfall for Agricultural production. A timely and accurate prediction of the rainfall onset, cessation, expected rainfall amount, and its intra-seasonal variability is very likely to reduce losses and risk of extreme weather as well as maximize agricultural output to ensure food security.

Based on this, a study was carried out to evaluate the performance of the European Centre for Medium-range Weather Forecast (ECMWF) numerical Weather Prediction Model and its Subseasonal to Seasonal (S2S) precipitation forecast to ascertain its usefulness as a climate change adaptation tool over Nigeria. Observed daily and monthly CHIRPS reanalysis precipitation amount and the ECMWF subseasonal weekly precipitation forecast data for the period 1995–2015 was used. The forecast and observed precipitation were analyzed from May to September while El Nino and La Nina years were identified using the Oceanic Nino Index. Skill of the forecast was determined from standard metrics: Bias, Root Mean Square Error (RMSE), and Anomaly Correlation Coefficient (ACC).

The Bias, RMSE, and ACC scores reveal that the ECMWF model is capable of predicting precipitation over Southern Nigeria, with the best skill at one week lead time and poorest skills at lead time of 4 weeks. Results also show that the model is more reliable during El Nino years than La-Nina. However, some improvement in the model by ECMWF can give better results and make this tool a more dependable tool for disaster risk preparedness, reduction and prevention of possible damages and losses from extreme rainfall during the wet season, thus enhancing climate change adaptation.

Introduction

Background

Weather and climate affect man in diverse ways which greatly impact agriculture, food security, housing, transportation, health, engineering structures, water resources, military operations, oil exploration and exploitation, environment, livelihoods, etc. (Ugbah 2016). These impacts are usually associated with extreme weather and seasonal hazards such as tropical cyclones, heavy rainfall, flooding, etc., which occur more frequently (IPCC 2018). For these reasons, scientists have continued to invest great time and resources in trying to understand and predict the processes that lead to changes in the atmosphere associated with these hazards. One of such investment is the international project known as the subseasonal to seasonal (S2S) prediction project set up in 2013 by the World Meteorological Organization (WMO), World Weather Research program (WRWP), and World Research and Climate program (WRCP) to provide a common platform for sharing of data and knowledge between countries, National meteorological Agencies, and researchers which will enhance our understanding of seasonal and subseasonal variability and also help to improve the skill and accuracy of long range forecast (weeks–months) and likely extreme events in different parts of the world (Takaya 2015).

In most parts of Asia and Africa and in developing countries such as Nigeria, farmers still practice subsistence farming which relies mainly on seasonal rainfall for Agricultural production (Siegmund et al. 2015; Hansen 2002). Farming, out of all human activities, is the most weather-dependent (Hanson 2002). A timely and accurate prediction of the onset, cessation, expected rainfall of the monsoon season, and its intra-seasonal variability is very likely to reduce losses and risk of extreme weather (Vitart et al. 2016) as well as maximize agricultural output to ensure food security. This is one of the purposes for which the S2S project was set up.

The time range for subseasonal forecast lies between 2 weeks and 60 days (Vitart et al. 2016) within the rainy season and it is meant to "bridge the gap between the medium range forecast" (at most 2 weeks) and seasonal forecast (3–6 months) [Vitart et al. 2016; Molteni et al. 2016]. The Madden Julian Oscillation (MJO), among other factors such as El-Nino Southern Oscillation (ENSO), stratospheric influence, Ice and snow cover, soil moisture, ocean conditions, and tele-connection between the tropics and extra tropics, is said to be the main source of predictability for subseasonal time range (Vitart et al. 2016; Inness and Dorling 2010); this may not be unconnected with the fact that MJO plays a significant role in initiating or terminating equatorially trapped waves (Kelvin waves) and Rossby waves (Maclachlan et al. 2015) which influence ENSO phenomena. The choice of the ECMWF forecast rather than others is based on the high skill displayed by the model in simulating MJO over the tropics and extra tropics, and the continuous improvement in skill of predicting subseasonal variability and events up to lead time of 10 days, since 2002. This is attributed to the improvement in the ECMWF model characteristics (resolution, initial conditions, physics, etc.) made possible because of the advancement in information technology which has led to the production of better computers with higher computational capabilities, capacity, and speeds in recent times. This development gives a ray of hope to those who depend on subseasonal to seasonal rainfall for production, planning, decision making, disaster preparedness, and socioeconomic development, thus the need to embrace the S2S project.

This study was done in 2016 with the aim of assessing the skill of ECMWF subseasonal ensemble forecasting system in simulating subseasonal rainfall variability in terms of pattern and amount of rainfall in Nigeria up to lead time of one month specifically over southern Nigeria where annual rainfall is highest and the risk of flooding from excessive rainfall also high. The area is highly threatened by sea level rise especially during the rainy season. This work also investigates how good the S2S model ensemble is, in predicting the likelihood of extreme rainfall that may cause flooding over the region.

The scope of this work is limited to southern Nigeria only where risk of flooding is highest and does not cover the entire country. Also it does not include evaluation of how the model can simulate or predict rainfall onset, cessation, or length of season but rainfall amount and pattern. It is expected that findings from this research will not only help to improve the quality and accuracy of S2S forecast, but will also help in updating the seasonal forecast of Nigerian Meteorological Agency and provide useful information and early warning system for disaster preparedness and risk reduction against extreme weather and climate events such as flooding.

Review of ECMWF Subseasonal to Seasonal Forecasting

In 2002, Frederic Vitart started the ECMWF medium range (monthly) forecast of precipitation as an experimental phase which became fully operational by 2004. It was integrated with the ensemble prediction system in 2008 following results of improved skill in simulation of weekly surface temperature, precipitation, mean sea level, and MJO observed during the period over the extra-tropics (Vitart 2005, 2014; Vitart et al. 2016). The model is run two times in a week to produce a daily forecast in real time for lead period up to 32 days, with a 1 hourly high resolution retrieval, and a reforecast (hindcast) for more than 12 years (Molteni et al. 2016; Vitart et al. 2016). The forecast consists of 51 ensemble members while the reforecast has 11. According to Vitart et al. (2016), it is structured to allow better coupling of the atmosphere (IFS model) and ocean (NEMO model) compared to models used in NOAA and UKMet office. Representation of model physics and physical processes has also been improved in very recent version. Some of the improvements include the increase in frequency of the S2S forecast from every 14 days in 2002 to twice a week from 2013 to date. The horizontal resolution has also evolved from T159 which had a lead time up to 32 days in 2002, through T255, T319, and presently T639 with lead time of up to 46 days. Vertical resolution has also improved from 40 atmospheric levels with top at 10 hPa in earlier versions to 91 atmospheric levels with top at 1 Pa in 2016. Re-forecast size now has 11 ensemble members as against 5 members in earlier versions (Molteni et al. 2016).

Work by Vitart (2005; Vitart et al. 2016) in trying to evaluate the skill of ECMWF subseasonal forecast showed higher weekly scores for lead times greater than 10 days and better skills when compared to persistent forecast and climatology (Vitart 2005; Vitart et al. 2016; Haiden et al. 2015). In another work, verification of the ECMWF subseasonal forecast model was done using metrics such as anomaly **coefficient of correlation (ACC) and root mean square error RMSE and probabilistic skills (**Vitart 2004**).** This approach is very popular and it is in line with the WMO recommendation on verification of deterministic forecast (Inness and Dorling 2010). **Vitart's result showed decreased correlation in the weekly anomalies with increasing lead time; the highest correlation value was observed in the first week forecast.** The skill was found to be greater than skill of the persistence forecast. For the ensemble probability forecast, the relative operative characteristics (ROC) scores which show the ratio between the Hit rate and false alarm were determined using the contingency table. ROC value of 0.5 means "no skill forecast" while values above 0.5 suggest good skill of forecast. The ROC values obtained from Vitarts work showed that forecast of 12–18 days was better than persistence forecast of 5–11 days. His work in 2014 also confirms this, with highest skill for week 1 (0.8) decreasing to 0.6 during week 3 (Vitart 2014). Brier score of ECMWF subseasonal forecast was 0.04 which suggested that model performed better than climatology (Vitart et al. 2016). The result of evaluation of the ECMWF subseasonal forecast showed better performance than other global centers as seen from the studies of Vitart over the extra tropics and consistent with other centers (Haiden et al. 2014). He pointed out that there could be variability in scores from one region to another and so, it would be wrong to conclude that the African region with a different climate, weather and geomorphology, will produce same skill as the extra-tropics without carrying out studies to compare and make valid conclusions, hence the justification for this study over Nigeria.

Li and Robertson (2015) also carried out studies to evaluate precipitation forecast from global ensemble prediction system at submonthly timescales using hind cast data from three global prediction centers (ECMWF, NCEP, and JMA) during May to September for the period 1992–2008. Statistical metrics used were the Correlation of Anomalies (CORA), and the Mean Square Skill Score (MSSS). The results showed good skills from all the three models during the first week compared to lead times of 2–4 weeks. The skill from ECMWF forecast was however better than the other two. Anomaly correlation skill scores were found to be high at lead times 1–4 over the equatorial Pacific while values of 0.2–0.3 were found to be statistically significant over tropical Atlantic at lead 1 only. The skills over land areas were generally poor even at lead time of one week over Africa. The result also showed very good correlation between ENSO and the submonthly prediction with ACC skills for ENSO years higher than neutral years. Biases in mean weekly precipitation forecast were large particularly in the NCEP model over the Atlantic, West Africa, and the Sahel regions.

Studies by Hamill (2012) on verification of the ECMWF probabilistic precipitation forecast, TIGGE National Centers for Environmental Prediction (NCEP) model, Canadian model, and UK Met Office (UKMO) forecast models during June–November 2002 to 2009 over the United states of America showed that ECMWF had the best skills with better scores for higher precipitation. These works confirm the leading standard of the ECMWF model forecast which has been chosen for this study.

Description of the Study Areas and Methodology

Study Area

Nigeria is located towards the coast of West Africa on latitude 4.0^{o}N–14.0^{o}N and longitude 2.45°E–15.5°E (Fig. 1). It occupies a landmass of about 924,000 Km^2 and population of about 133 million as at 2006 which grows at a rate of 2.8% (Ayanlade et al. 2013). The study area is the southern part of the country shown in the red box (Fig. 1) defined by latitude 4.0^{o}N–8.0^{o}N and longitude 2.0°E–11.0°E estimated from the figure which is sourced from Eludoyin and Adelekan (2013). It covers an area less than 50% of the country and is bounded in the South by the Atlantic Ocean (Gulf of Guinea). The area is bounded in the East and West by two countries: Cameroun and Benin Republic, respectively.

Climatology and Sources of Subseasonal Predictability in the Region

The study area lies within the mangrove swamp, tropical rainforest, and Guinea Savanna vegetative zones which experience two major seasons: Wet (late February

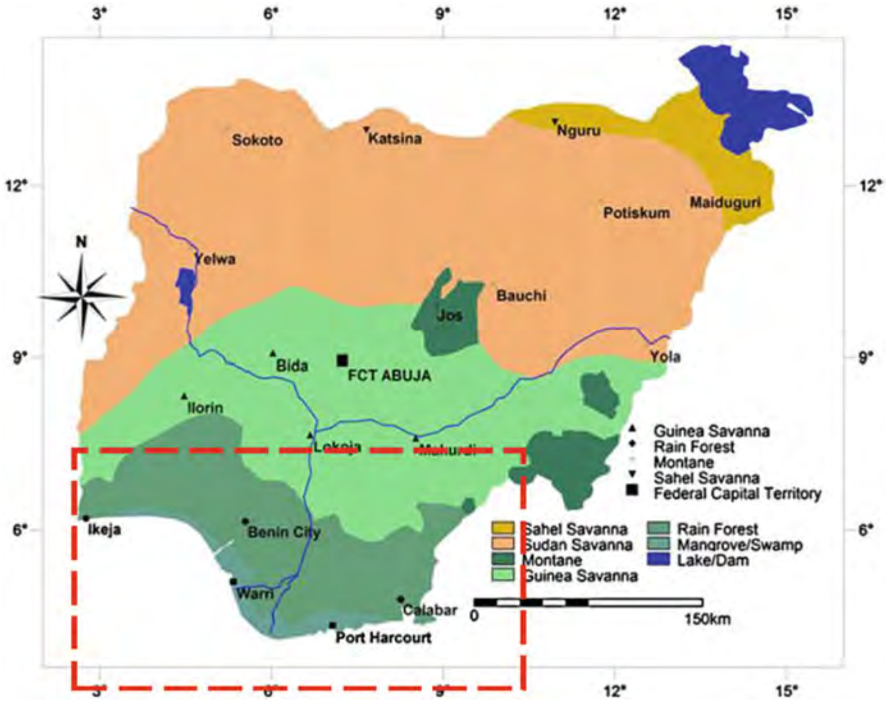

Fig. 1 Map of Nigeria showing study area in rectangular box (Source: Eludoyin and Adelekan 2013, springer publishers)

to November) and the dry (December to mid-February) as reported by Eludoyin and Adelekan (2013). The unequal distribution of rainfall from month to month within these two major seasons further distinguishes the season into long rainy season (March–July), short dry season or August break (Late July–early August), short rainy season (early September–mid-October), and the long dry season (late October–early March) (Chidiezie and Shrikant 2010). The wet season is said to have a bimodal pattern of rainfall and a longer period which lasts about 200–300 days (NiMet 2013, 2014). It is characterized by moist southwesterly winds also known as the tropical maritime air mass (mT) which blow landwards from the Atlantic Ocean and is predominant during the rainy season. The dominant winds during the short period of dry season (Harmattan season) are the dry dusty northeasterly trade winds from the desert also called the tropical continental air mass (cT) which find their way to the South from the North (Eludoyin & Adelekan 2013). Annual rainfall total ranges from 1500 to 3000 mm over most of the South but can reach about 4000 mm over the southeastern part where rainfall is highest (Ayanlade et al. 2013, Chidiezie and Shrikant 2010). Mean air temperatures are in the range of 25.0°–30.0 °C during summer and 20.0–30.0 °C during the harmattan season (Ayanlade et al. 2013)

Research Methods

Study Site Selection and Sampling Methods

The study area covers all locations in southern Nigeria which lie between latitude 4.0 and 8.0 N and longitude 2.0 and 11.0 E which are Bayelsa, Rivers, Akwa-Ibom, Cross-river, Ebonyi, Enugu, Abia, Anambra, Imo, Delta, and Edo states. Others are Ondo, Lagos, Ogun and southern part of Osun, Oyo, Benue, and Kogi states. The selection of the area is intentional for only areas which experience high annual rainfall of 1500 mm and above and prone to high risk of flooding due to the heavy rainfall and proximity to the Atlantic Ocean. The area is also close to rivers Niger and Benue and selected based on three agro-climatic zones: mangrove swamps, tropical rainforest, and Guinea Savanna only. This means that a combination of purposeful and stratified sampling was employed in selecting the study area.

Data Sources and Collection Methods

Secondary data was used for this study and includes forecast and observed precipitation data for 21 years from 1995 to 2015 over Nigeria. This is the period for which reforecast data was available. The forecast data is the ECMWF ensemble reforecast precipitation data in mm/day downloaded from the S2S data website hosted by ECMWF and it is available up to lead time of 40 days from 11 ensemble members. The mean ensemble precipitation forecast data provided at a resolution of $1.5° \times 1.5°$ grids (IRI 2016) was used for this study. The observed rainfall data is the CHIRPS reanalysis of daily precipitation provided at a resolution of 0.05×0.05 grid which is higher than the resolution of the forecast data. It was downloaded from the IRI website earlier discussed and credited to Funk et al. (2014).

No missing data was observed in the data sets as it is likely that any existing missing data may have been filled during reanalysis/homogenization before making the data available for users on the websites.

Weekly precipitation totals and climatological averages of observation and forecast from May 14 to September 24 (20 weeks) for the 21 year period (1995–2015) was extracted and used to study the intra-seasonal changes in precipitation. The choice of the seasonal period (May–September) is based on the enormous rainfall usually experienced during this period. ENSO years within the period were selected based on the Oceanic Nino index (ONI) provided by NOAA at http://www.cpc.ncep.noaa.gov/products/analysismonitoring/ensostuff/ensoyears.shtml

Data Analysis

Codes were written first, to read all the data files which were in NetCDF format, and then to convert the time variable which was in Julian days in CHIRPS data to the normal calendar dates to enable easy extraction of weekly totals of precipitation from May 14 to September 24. This was then followed by extraction of weekly means and climatological averages of precipitation over southern Nigeria from which temporal plots were made. Time series were plotted as average weekly while the climatological average was determined from the weekly totals averaged over 21 years. Bias and RMSE between forecast and observed precipitation was calculated accordingly.

Anomalies were determined by subtracting the climatological mean from the weekly mean precipitation and the anomalies correlated to determine the ACC skill of the forecast at different lead times. All plots as well as calculations were made using Python.

The ECMWF forecast data, unlike CHIRPS, had a land-sea masked file for measurements over land and ocean. This masked file was used to mask out the ocean precipitation values in order to extract only values over land. The step is taken to isolate the land grid boxes when calculating precipitation averages and totals to enable a fair comparison between the data sets.

The observed precipitation for the previous week was persisted for the following week to produce the one week lead time persistent forecast for the 20 weeks period (May 14–September 24). This was then compared with the observed climatology and forecasts at weekly lead times of one, two, three, and four weeks referred to as lead 1, 2, 3, and 4. The El Nino and La Nina events were identified by averaging the five consecutive Oceanic Nino Index (ONI) values of months AMJ, MJJ, JJA, JAS, ASO, and the average was compared with the threshold that defined an ENSO event, that is, ONI values greater or equal to +0.5 °C define an El Nino while values less or equal to −0.5 is La Nina (NOAA 2016). These months were chosen to be consistent with the season (May–September) for which forecast is made. The flow chart (Fig. 2) summarizes the procedure involved.

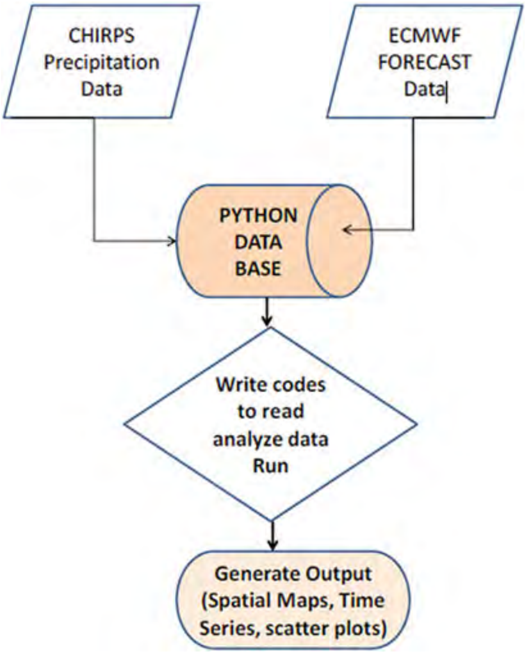

Fig. 2 Flow chart of methodology. (Source: Ugbah 2016)

Results and Discussion

Comparison Between Observation and Forecast at Different Lead Times

Weekly totals of the forecast and observed precipitation covering the twenty weeks period (May 14 to September 24) from 1995 to 2015 were plotted to compare the extent to which the observation agrees with or deviates from the forecast at different lead times. The result is shown in Fig. 3.

It can be seen from Fig. 3 that both the forecast and observation follow a similar pattern during the season and depict the two peaks (bimodal) of rainfall in early July and in September. The short period of the little dry season known as “August break” is also shown by the precipitation minimum around late July/August. At initial start dates up to June11 and towards the end of the season in September, the precipitation values all seem to be in close agreement, having only small differences, but beyond the week starting June 11, the forecasts start to deviate significantly from the observed with the largest differences around the period of the little dry season after which the lines begin to converge until the end of the season (Fig. 3). It can also be seen that the differences in precipitation amount increase with increasing lead

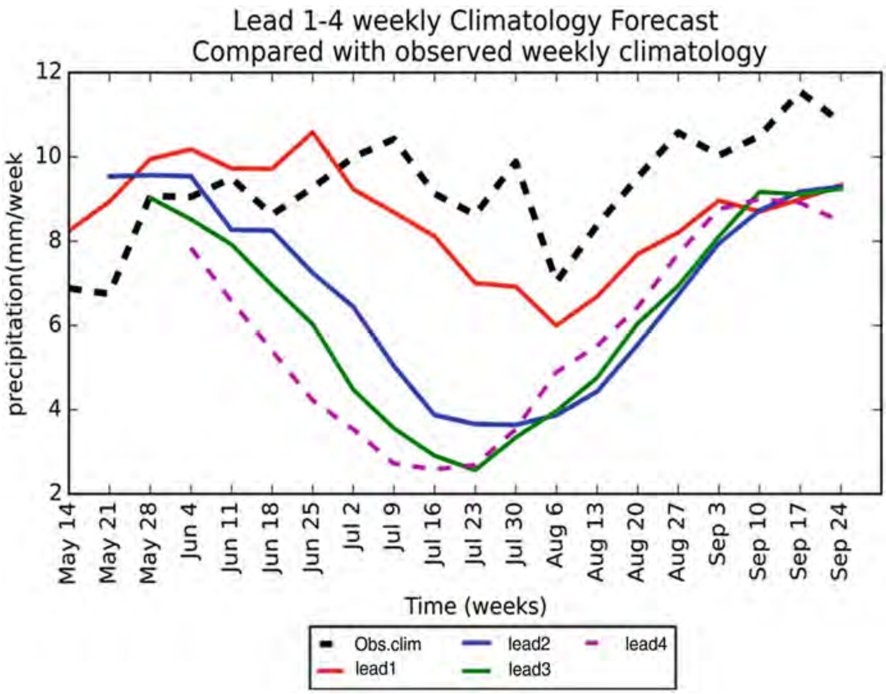

Fig. 3 Forecast at different weekly lead times (wk1-wk4) indicated with colored lines and Observed weekly climatology (black dotted line) compared (Source: Ugbah 2016)

time as depicted by lead 1 forecast (red line) which lies closest to the observation (dotted black line) throughout the season. Forecast of lead 2, 3, and 4 show larger departures from the observed climatology (Fig. 3) with the largest departure seen in the lead 4 forecast (purple dotted line). These large departures possibly arise from the inability of the model to properly simulate the little dry season phenomenon and related subseasonal processes. Correction of these differences is likely to improve the performance of the model. The plot also shows that the predicted precipitation at all the different lead times is lower than the observed implying an underestimation by the model. This can also be corrected to improve the model.

Evaluation of the Forecast Skill: Metrics

It is important to explain some of the different scores that are used for evaluating this forecast as there are different types of metrics used for verification of forecast and the choice of a particular type depends on the objective of the verification. Some of the popular metrics used by scientists and recommended by WMO for use in verification of precipitation forecasts include bias, root mean square error (RMSE), and anomaly correlation coefficient (ACC). These metrics have been selected for this study to provide a common standard for comparing the results with those of other scientist and meteorologist on related works.

Bias

The bias refers to the differences between the forecast and the observation mean. It is a measure of the extent to which the ECMWF model under-estimates or over-estimates precipitation. Bias information is useful in correcting errors in models which are likely to improve its performance (Inness and Dorling 2010). Mathematically it is defined as:

$$\text{Bias} = \sum_{i=1}^{n} \frac{(f - O)}{N}$$

where f = forecast, O = observation, and N = total number of events.

A larger bias shows large differences or disagreement between forecast and observation while smaller values suggest closeness or similarities. Such closeness may not necessarily mean that the forecast is perfect because observations could be wrong and therefore give misleading results. Bias can be positive when forecast is over-estimated or negative when under-estimated.

The biases were computed at the four different lead times and then averaged over the twenty weeks period from May to September (Table 1). Negative biases can be seen for leads of 1, 2, 3, and 4 weeks. The biases increase with lead time from week one (−0.69) to week four (−3.10). This is consistent with findings from Vitart 2004, 2014, and Li and Robertson (2015). At lead times of 2 to 4 weeks, the dry bias is particularly strong from late June through July. This suggests difficulty by the model

Table 1 1995–2015 ECMWF forecast vs observed precipitation scores at weekly lead times

Scores of the ECMWF subseasonal weekly forecast over Southern Nigeria				
Lead time scores	Week 1	Week 2	Week 3	Week 4
BIAS	−0.69	−2.30	−2.7	−3.10
RMSE	1.64	3.33	3.78	3.98

to forecast at a period when reduced rainfall is experienced in the West African Monsoon (WAM) and when the Inter-Tropical Convergence Zone (ITCZ) also called ITD is at its most northward position from the area of study. Such biases may be necessary to correct only if other metrics also provide evidence in support of poor model performance. This is because bias alone is inadequate in evaluating the performance of a model as it only tells only the differences and does not give weight to errors like the RMSE. That is why the use of only one metric is not recommended but a combination of two or more.

Root Mean Square Error (RMSE)

RMSE can be defined as the square root of the sum of the squares of all errors (biases) between a given set of data as shown below (Chai and Draxler 2014).

This metric is good for use in evaluating the performance of a model because it represents normally distributed errors better than uniformly distributed errors common in models (Chai and Draxler 2014). It gives more weight to large errors than smaller errors and has a tendency of showing some bias towards datasets without large errors, but it still remains one of the oldest and most popularly used metric among scientists in model evaluation. Large RMSE values imply large error distribution while smaller values suggest smaller errors. RMSE of zero means that the forecast is without errors or bias.

$$\text{RMSE} = \sum_{i=1}^{N} \frac{(f - O)2}{N}$$

where f = forecast, O = observation, N = total number of events.

The results of RMSE also show that errors increased with lead time, and were lowest (1.64) at lead time of one week and highest (3.98) at lead time of four weeks (Table 1).

Anomaly Correlation Coefficient (ACC)

ACC was used to evaluate the potential skill of the forecast. It is considered a potential skill because it is only one metric out of the several others that need to be considered to arrive at the final or perfect skill of a forecast. It may not be exhaustive, but it provides very useful information for assessing model performance and a pointer to the likely overall skill. Correlation between forecast and CHIRPS observed daily precipitation data was done using python program scripts written to incorporate the mathematical formula for ACC defined by Maue and Langland (2014) as:

$$\mathrm{ACC} = \frac{\sum_{m=1}^{m} f' * O'}{\sqrt{\left(\sum_{m=1}^{m} (f')2 * \sum_{m=1}^{m} (O')2\right)}}$$

where $f' = fm\text{-}Cm$, is the forecast mean (fm) – climatological mean of forecast (Cm) $O' = Om\text{-}Cm$, is the mean of observed (Om) – Observed mean Climatology (Cm).

The climatological average values of forecast and observation for the 21 year period was first calculated and then subtracted from each weekly forecast and observed precipitation to get the desired result. Correlation values generated from linear regression analysis of these anomalies also produced similar results when compared. This served as a check for possible computational errors from code written to calculate this metric. One advantage with this metric is the consideration of errors averaged over a longer period than for short period averages which are usually highly variable. This advantage, on the other hand, also constrains the metric in its ability to significantly reflect changes in the mean values over shorter time ranges.

The results of the correlation for weekly start dates during the season and at lead times of the 1, 2, 3, and 4 weeks indicated are further discussed in section "Performance of the S2S Model Precipitation Forecast During Rainfall Peaks and Period of Little Dry Season". There are 20 weekly start dates in the season starting with the first on May 14, then May 21, May 28, . . . up to the last date on 24th September.

A forecast can be produced on any of these dates for lead times up to 40 days in advance, but in this study, only lead times up to 4 weeks are considered. This is because such a time period is relatively reliable and adequate for use by farmers especially in Nigeria to plan and make decisions about farming practices such as planting, weeding, fertilizer application, etc. It should be noted also that at longer lead times, forecasts tend to lose accuracy (Inness and Dorling 2010), and so, the weekly to one month lead time forecast chosen is likely to be more reliable than lead time more than one month. In this study, forecast made with a lead time of one week (referred to as lead1) means the forecast is produced on a particular week and is valid for one week (up to the following week). It is also possible to produce a lead 1, 2, 3, or 4 forecast on any of the 20 start dates from May 14 to September 24. The choice of any of the start dates depends on the period of interest within the season and the goal which the user or client wants to achieve or satisfy.

The correlation between the observed and forecast anomalies (ACC) at different lead times and with persistence forecast is shown in Fig. 4.

Seasonal mean ACC values tend to be generally poor and less than 0.5 but weekly values tend to be better in some weeks at different lead times. For example, start dates of week 8 (July 2), week 12 (July 30), week 13 (August 6), week 14 (August 13), and week15 (August 20) for lead 1 forecast have the highest and best ACC values of 0.71, 0.84, 0.75, 0.72, and 0.65, respectively, which suggest a strong positive relationship between forecast and observation. These values are all significant at 0.01 level while the ACC value of 0.54 in week 11 (July 23) is significant at 0.05 level. High ACC scores were also observed for a few start dates at lead times 2, 3, and 4. The scores generally decreased with increasing lead time (Fig. 4) and the poorest scores were

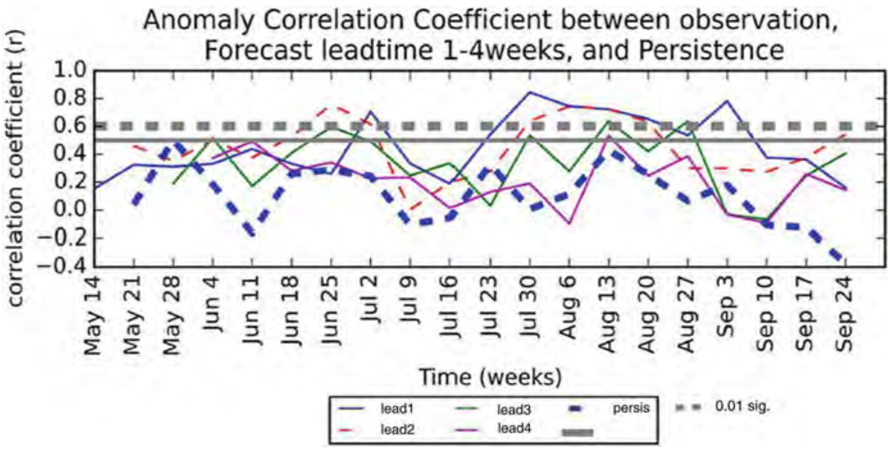

Fig. 4 Anomaly Correlation between forecast at different lead times compared with persistence forecast. Topmost thick horizontal grey dotted line indicates ACC values that are statistically significant at 0.01 while the solid grey line represents values that are significant at 0.05 level (Source: Ugbah 2016)

observed in lead 4 forecasts with a few negative correlations. This is consistent with Li and Robertson (2015). A statistical test to determine the level of significance of these values was done using the Statistical Package for Social Sciences (SPSS) software.

Persistence is also a baseline, like mean climatology, used to compare with forecasts in order to determine their quality. The persistence forecast for lead 1 was produced by persisting observation of the present week for the following week's forecast. The result was then correlated with the forecast at different lead times. It is often said that the long time range involved in subseasonal forecasting has made it difficult for it to beat Persistence forecast (Vitart 2014) but result from this study has proven otherwise as the forecast at the different lead times beat persistence in most of the weeks This approach according to Jolliffe and Stephenson (2003) only performs well for short range forecast, but result from this work support the view that it can also perform well for medium ranged forecast as shown (Fig. 4).

Comparison Between Observed and Forecast during El Nino and La Nina Years

ENSO and MJO both interact in modulating subseasonal to seasonal precipitation. It is assumed that since the ECMWF model is known for its high skill in simulating MJO events, it is also likely to accurately simulate subseasonal rainfall variability during different phases of ENSO. Based on this, it will be good to look at how the model forecast for precipitation during El Nino and La Nina years either agree or differ from the lead 1 forecast for the 1995–2015 period. Only lead one forecast is chosen because it shows the least bias with observed climatology compared to lead times of two, three, and four weeks. El Nino and La Nina years were identified using the Oceanic Nino Index (ONI) as earlier discussed. Four La-Nina (1998, 1999, 2000, 2010) and Five

El-Nino events (1997, 2002, 2004, 2009, 2015) were identified and the forecast for these years extracted and plotted for comparison. The selection of 1997 El Nino and 1999 La Nina events is in agreement with Enso events between 1963–1999 identified by Joly and Voildoire (2009). The strength of ENSO usually weakens towards the end of first quarter of the year and reaches maximum strength around December to February (Joly and Voildoire 2009). A strong African monsoon is linked to La Nina events which are observed in April, May, or June (Joly and Voildoire 2009).

The result of analysis shows that both La Nina and El Nino years forecast are in reasonable agreement with observed precipitation during the first eight weeks (May14–July2) and show a wetter bias, but begin to show marked differences beyond this period particularly in mid-July and in August (Fig. 5) when the little dry season is usually experienced in the study area.

The differences between them were calculated as bias and compared with the 1995–2015 climatology shown in Table 2.

The seasonal mean biases were all negative suggesting underestimation of precipitation by the model compared to observation and was higher (−0.97) during La Nina years than El Nino (−0.41). The 1995–2015 period as a whole, however, showed lower bias compared to the La Nina years. It is likely that the larger bias might be by chance rather than a certainty. The El Nino years showed better results with the least bias and RMSE. The seasonal mean RMSE in La Nina years was 2.24 compared to El Nino which has 1.84 (Table 2).

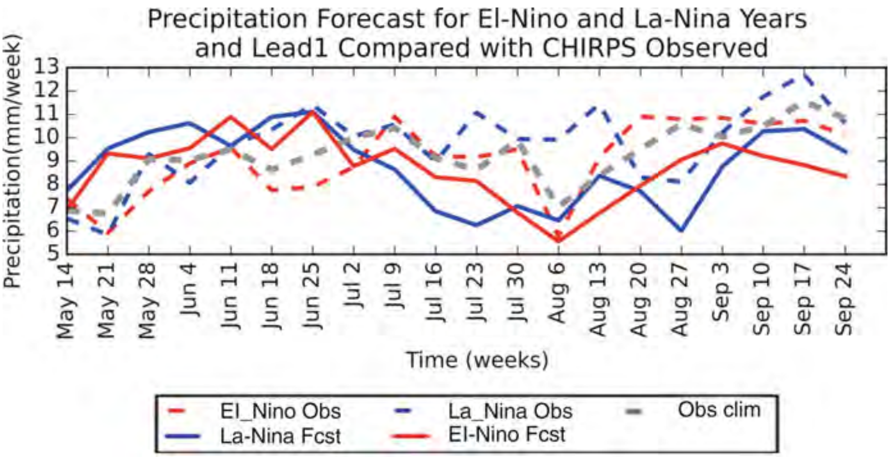

Fig. 5 Precipitation forecast and observation for El Nino and La Nina years for one week lead time compared with observed climatology (Source: Ugbah 2016)

Table 2 Comparing Lead1 scores for the climatological period, El Nino, and La Nina years

Scores of the ECMWF subseasonal weekly forecast over Southern Nigeria			
Period	1995–2015	El Nino years	La Nina years
BIAS	−0.69	−0.41	−0.97
RMSE	1.63	1.84	2.24

Weekly biases compared were positive during the first 7–8 weeks after which they became negative. This is to say that forecast for both El Nino and La Nina years was over predicted during the initial weeks and under-predicted thereafter. Another observation is that the forecast seem to follow the pattern of climatology rather than observation and was lower than the observed for a greater part of the season. The high bias and RMSE particularly in La Nina years shows that the model might be worst in La Nina years and more reliable in El Nino years as the El Nino forecast tends to agree more with the observation and climatology than forecast during La Nina years. All these still point to the model's inability to accurately simulate southern Nigeria precipitation and suggest that there is still a missing tele-connection between precipitation in the study area and ENSO that has not yet been properly resolved by the ECMWF model. This, however, does not imply that the model is bad, but requires fine-tuning to correct some of the biases observed in order to improve the quality of the forecast. Such biases could arise from the poor representation of the ENSO, MJO, and precipitation tele-connection within the study area. Another reason could be incorrect parameterization of convection and processes which modulate weather over Nigeria. This can also adjusted to give better results. The timing of ENSO events and the delay in the response of a particular region to an ENSO phase is also an important consideration in simulating the tele-connection between them (Joly and Voildoire 2009). This is because significant tele-connection is sometimes observed during the developing stage of ENSO or during its terminal stage (Joly and Voildoire 2009). All these, still remain a big challenge to many numerical modeling experts trying to simulate tele-connection between ENSO and the West African Monsoon (Joly and Voildoire 2009). The "August break" is well captured by the model forecast with strong agreement during the El Nino years than La Nina. However, the greatest noise is observed during this period (July–August). This again shows that the model can be improved.

Performance of the S2S Model Precipitation Forecast During Rainfall Peaks and Period of Little Dry Season

Should the ECMWF S2S model be able to properly simulate high rainfall amounts and pattern during periods of maximum rainfall within the season, then it will no doubt be a good tool in providing useful information for extreme rainfall disaster preparedness, prevention, and risk reduction. Fortunately, the model is able to properly simulate pattern of rainfall in the region and also identify periods of peak rainfall which mostly occurs in June and September as shown in Figs. 3, 4, and 5. The model is also able to depict the little dry season period which occurs between July and August. Such information is considered useful to planners. But unfortunately the model shows a low skill in simulating rainfall amount especially during the peak rainfall period and the little dry season. This is evident in the large biases observed between last week in June and mid-August at lead time of two, three, and four weeks. The biases and RMSE are however minimal at lead time of one week which is good for early warning purposes and disaster preparedness at least one week before the event happens. The skill is also found to be poor during La Nina years which are notable for high rainfall than El-Nino years in the region. This means that the model is not very skillful in simulating heavy precipitation amounts during heavy rainfall periods especially at lead times beyond one week. It is however still possible that some adjustment in the model by ECMWF to correct the observed biases could give better and reliable results which would make that ECMWF S2S forecast model a dependable tool for predicting extreme high/low rainfall and thus helpful in adapting and mitigating the effects of climate change in the study area.

Conclusion

Large negative biases and root mean square error which were observed to increase with lead times show that the model generally has a dry bias towards estimating precipitation over the area. The high biases and errors observed during La-Nina, than El-Nino years suggests that the model performs better during El-Nino years. Users should therefore be cautious of its use during La-Nina years. Re-calibrating the model output to reduce these biases is likely to produce better results. Seasonal mean Bias and RMSE which generally increased with increasing lead time during the season showed the best results in the one week lead time and the worst in four weeks lead time. This suggests that the forecast was better at shorter lead time. Seasonal mean ACC values which were generally less than 0.5 but with weekly values greater than 0.7 on certain start dates of the lead 1 and 2 forecast, and lower values for leads 3 and 4 confirm that the forecast is best at lead time of one and two weeks during specific periods in the season than at longer lead times. ECMWF should also consider making some adjustments in the model in aspects of parametization of ENSO tele-connection with rainfall over the study area to reduce the large biases observed during La Nina years. This is important because La Nina events bring more rains to the region than El Nino events and so the opportunity of more rains and water availability during La Nina years should be maximally exploited through use of good and reliable prediction tools that will provide accurate and reliable information needed for planning by farmers, environmentalist, disaster managers, water resource managers, and policy makers. The results also show that the S2S model precipitation forecast has a skill which is higher than persistence forecast at all the lead times of one to four weeks, thus negating the statement by Vitart (2014) that the long time range involved in subs-seasonal forecasting has made it difficult for it to beat Persistence forecast.

The observed large negative biases and RMSE at lead times of 2, 3, and 4 weeks suggest that the model is not yet very skillful in simulating precipitation amounts over southern Nigeria at longer time ranges; it is, however, very skillful in simulation precipitation amount, pattern, and periods of rainfall peaks/minima during the season at lead time of 1 week. This is evident in the very low biases and errors, thus confirming that the best results were observed for precipitation forecast made with a lead time of one week only. This means that S2S precipitation forecast can provide one week advance signals of periods of peak rainfall, little dry season and expected rainfall amount over southern Nigeriais. Such information is considered to be a good early warning and disaster preparedness tool. It could also be a useful tool for planning and decision making if provided at least one week before the event happens. Thus, a way of mitigating and adapting to the effects of climate variability and change is used. The ECMWF S2S can therefore be recommended for this purpose and for updating seasonal forecast on weekly basis in Nigeria for maximum Agricultural production and for disaster reduction since the skill is high at lead time of one week. It is therefore a good tool for monitoring of rainfall during the rainy season and could still yield better results at longer lead time if the model is further improved by ECMWF.

Future work will expand the scope to cover the entire Nigeria and also assess the skill of the individual ensemble members of the model instead of the average of the ensembles used in this study. Rain guage observation data will be considered for comparison with forecast. It is also good for work in the future to include determination of rainfall onset, cessation, and length of season using the S2S data instead of looking only at how the model can simulate rainfall amount and pattern as done in this study.

79 Agropastoralists' Climate Change Adaptation Strategy Modeling: Software and Coding Method Accuracies for Best-Worst Scaling Data

Zakou Amadou

Contents

Abstract

Investigating software and coding method accuracies are still a challenge when dealing with best-worst scaling data. Comparing various climate change policy estimates and their relative importance across different statistical packages has received little attention. In this chapter, we use best-worst scaling approach to determine agropastoralist preferences for 13 climate change adaptation policies across two popular statistical packages (R and SAS). While data were collected from 271 agropastoralists, mixed logit was used to analyze data. Results reveal that mean and standard deviation estimates for 13 climate change adaptation policies from R are higher and statistically significant than SAS estimates. Based on R estimates, prolific animal selection, vaccination, settlement, strategic

mobility, and strategic destocking are the most popular climate change adaptation policies, and more than two-third of respondents are in favor of these policies.

Keywords

Climate change adaptation policies · Best-worst scaling · Agropastoralists · Mixed logit models

Introduction

A myriad of climate change adaptation policies have been proposed to improve farmers and herdsmen's resilience building capacity, diversify their income and food, and increase their welfare in a changing climate. Several computation methods have been used to analyze discrete choice and best-worst datasets. While conditional logit, multinomial logit have been widely used in the academic literature, the usage of mixed logit (ML) models has been exploded because it is capable to relax (IIA) and can approximate any random utility model (McFadden and Train 2000).

A recent research has studied mixed logit models: accuracy and software choice by comparing ML across three popular packages, namely, SAS, NLOGIT-LIMDEP, and a user-written add-in module for STATA. Results indicate that the data generating process used was not well suited to evaluate the accuracy of software packages and further research is needed to determine which software is the most accurate (Chang and Lusk 2011).

Another challenge is to determine the climate change adaptation policy, and there are few studies geared at computing welfare effects of individual climate change policy. In addition, determining the relative importance of several climate change policy options can be challenging though they may have the same objective towards resilience building. For instance, prolific animal selection and changing herd composition both aim at reducing herd size and thereby enhancing agropastoralists' resilience build capacity. A third challenge facing researcher is to write an algorithm capable of solving real-life problem.

This chapter contributes to fill a knowledge gap by eliciting agropastoralists preference for alternative climate change policies and also enriching literature related to climate change and choice modeling. While data collected from choice experiment and best-worst have been well-documented, coding methods and algorithm development vary considerably from one statistical package to another.

Background on BWS

Climate change is increasingly becoming recognized as a global threat and concerted effort such as new climate change adaptation strategies should be undertaken both at local, national, and regional and global levels.

While various government climate change adaptation policies have been proposed to reinforce vulnerable farmers' resilience capacity, little is relatively known about farmers indigenous knowledge related to climate change adaptation strategies. However, not all climate change policies have had expected results on farmers' welfare, and previous studies have indicated that combined government and farmers adaptation strategies are more welfare enhancing (Tabbo et al. 2016).

Climate Change Policy Identification and Survey Design

Based on previous research and interview with agropastoralists, 13 climate change adaptation policies have been identified and included in this study. To determine the relative importance that agropastoralists place on these policies, a BWS experiment was designed (Marley and Louvriere 2005). A balanced incomplete block design (BIBD) developed by Louviere et al. (2015) has been used to determine allocation of the 13 policies for each BW question. The resulted design contains 13 BWS questions, each having four policy options. The BIBD is the most widely used design in the BWS literature because it is not only a balanced design but also an orthogonal design (Flynn and Marley 2014). Furthermore, the policies were selected to reflect the main issues and challenges recently discussed in climate change adaptation choice as compared to the food choice literature documented by Lusk and McCluskey (2018).

For each BWS question, respondent was asked to select his best and his worst climate change adaptation policies. Figure 1 listed below reports an example of the best-worst questions used in the study.

The coding method used for R is based on position for each pair of best-worst question. The value for the position can be ranged from 1 to 4. For SAS, best options will be assigned 1, worst options (-1), and 0 for non-chosen options. This shows that a scale difference may exist between the two coding methods (Table 1).

Data Analysis

The BWS approach assumes that respondents simultaneously make repeated choices by choosing the best and worst items in a given set and thereby maximizing the difference (Flynn and Marley 2014). By denoting J as number of items in each BWS

Best	Endogenous Strategies	Worst
□	Strategic mobility	□
□	Transhumance	□
□	Settlement	□
□	Income generating income	□

Fig. 1 Please select your best and worst endogenous strategies

Table 1 Climate change adaptation policy and description

Climate change policy	Description
Mutual assistance	Helping agropastoralist to rebuild his herd by donating a gift
Settlement	Combining farming and animal rearing
Strategic mobility	Mobility orientated towards researching forage and water
Strategic destocking	Reducing herd size to accommodate shortage of forage and drought
Prolific animal selection	Keeping animals capable of yielding higher meat and milk products
Sheep and cattle fattening	Increasing sheep and cattle weight by feeding on high concentrate
Vaccination	Treating animal from infectious diseases and producing safe products
Transhumance	Unidirectional movement of the herd in searching of H_2o and forage
Emergency destocking	Reducing herd size as result of disease's outbreak
Water and soil conservation activities	Aims at increasing food and forage production
Changing herd composition	Keeping only animals that have developed strong resilience
Income generating activities	Undertaking various activities capable of boosting revenue
Forage cultivation	Selecting and growing forage to meet its increasing demand

question (4 climate change adaptation policies), then J (J−1) best-worst pairs of best-worst choices are possible.

By following this approach, our data were analyzed using random utility framework which is well rooted in microeconomics (McFadden 1974), whereby a given respondent n derives from the selected best-worst pairs in each BWS question t is the difference in utility between the j best and k worst policies.

This can be mathematically expressed:

$$U_{njt} = \mu_{jt} - \mu_{kt} + \varepsilon_{njt} \tag{1}$$

where μ is the vector of estimated importance parameters of the best and worst climate change policies (j and k respectively) relative to some policy normalized to zero for identification.

The probability that respondents choose item j as best and k as worst out of J items in BWS question t is the probability that the difference in utility of the chosen items (U_{njt} and U_{nkt}) is greater than all other J (J−1)−1 possible differences within each BWS question (Lusk and Briggeman 2009). While several econometric methods can be used to model this behavior, mixed logit is the most widely used estimation procedure, because it is flexible and can approximate any random utility model (Train 2009).

The mixed logit model and the probability that an individual n chooses j as best and k as worst can be mathematically written as follows:

$$P_{nj} = \int \mu \prod_{t=1}^{T} \frac{e^{\left[\mu_{njt} - \mu_{nkt}\right]}}{\sum_{l=1}^{J} \sum_{m=1}^{J} e^{\left[\mu_{nlt} - \mu_{nmt}\right] - J}} f(\mu_n) d\mu_n \tag{2}$$

where $f(\mu_n)$ is the density of the importance parameters μ_n.

The share of preferences for each climate change adaptation policy can be expressed as follows:

$$\varphi_j = \frac{e^{\mu_j}}{\sum_{k=1}^{j} e^{\mu_k}} \tag{3}$$

where φ_j is the share of preference for a given climate change adaptation policy.

Results

Data were collected via well-structured questionnaire delivered to a sample of 271 respondents. Summary statistics and variable definitions are reported in Table 2. Most of the respondents have an average of 40 years and about 76% of respondents were male and 84% of the respondents were married. About 75% of respondents were uneducated, and about 52% and 27% of our sample have an annual income below 90,000 FCFA and between 90,0000 and 180,000 FCFA, respectively. In addition, average household size was 8 persons with an average of 16 and 24 respectively for large animal and small animal. About 87% of respondents strongly believe that climate change and environment are correlated.

Table 3 reports estimates from mixed logit models for both R and SAS software. Coefficients reflect the importance of each 12 climate change adaptation polices to forage cultivation, which was normalized to zero for identification purpose. Results show that based on R software estimation, strategic mobility followed by mutual assistance, settlement, strategic destocking, prolific animal selection, sheep and cattle fattening, vaccination, transhumance, emergency destocking, water and soil

Run time	11 m:22 s	7 m:43 s	

Numbers in parentheses are standard errors, * denotes mean importance of the policy which is statistically different from forage cultivation, Sd stands for standard deviations conservation activities, and changing herd composition are the most climate change adaptation policies with a significant difference to forage cultivation. Standard deviation estimates for 12 climate change adaptation policies obtained from R software were statistically and highly significant, implying that heterogeneity is a pattern when analyzing climate policies within the population. Table 2 also reports SAS software estimates. Results reveal that settlement followed by emergency destocking, prolific animal selection, water and soil conservation activities, strategic mobility, transhumance, and mutual assistance are the most important climate change adaptation polices relative to forage cultivation. Results also suggest that standard deviation estimates for settlement, emergency destocking, prolific animal selection, water and soil conservation activities, strategic mobility, transhumance, mutual assistance, sheep and cattle fattening, and changing herd composition are statistically significant, revealing that these estimates do vary in the population and thereby confirming heterogeneity pattern. Heterogeneity pattern when analyzing data in R is higher than heterogeneity pattern with SAS.

Table 3 also shows that R and SAS generated different mean estimates. For instance, the mean estimates for strategic mobility were 0.887 and 0.264 respectively for R and SAS. Similarly, the mean estimates for mutual assistance were 0.587 and 0.172 respectively for R and SAS. The mean estimates for settlement were 0.582 and 0.571 respectively for R and SAS. The mean estimates generated by R are all statistically significant. Similarly, the standard error estimates for strategic mobility, mutual assistance are higher for R than SAS, while standard error estimates for settlement and prolific animal selection are higher for SAS than R. This implies that estimates of standard errors considerably diverge across R and SAS. The standard deviation estimates are generally higher and significant for R than SAS; implying heterogeneity pattern is highly significant for R than SAS. Consequently, R software accurately predicted heterogeneity pattern than SAS.
