Preface

Climate change is a major global challenge. However, some geographical regions are more affected than others. One of these regions is the African continent. Due to a combination of unfavorable socioeconomic and meteorological conditions, African countries are particularly vulnerable to climate change and its impacts. The IPCC Special Report "Global Warming by 1.5 °C" outlines the fact that maintaining global warming by 1.5 °C is possible, but also points out that a 2 °C increase could lead to crises in agriculture (rain-fed agriculture could decline by 50% in some African countries by 2020) and livestock, damage water supplies, and pose an additional threat to coastal areas.

The IPCC also predicts that wheat could disappear from Africa by 2080 and that maize – a staple food – may decline significantly in southern Africa. In addition, arid and semi-arid soils are likely to increase by up to 8%, which will have serious implications for livelihoods, poverty reduction, and meeting the UN Sustainable Development Goals. Pursuing appropriate adaptation strategies is therefore crucial to meet the current and future challenges posed by climate change.

Despite recent progress since the signing of the Paris Agreement in 2015 and the Katowice climate package in 2018, there is still much to be done to raise awareness on the relevance of climate issues for African nations. This process of awareness raising could be supported by specialized publications written by African experts (or by experts working in the region), based on the realities on the African continent, and comprehensively documenting and disseminating the many ideas, approaches, methods, and projects being implemented across Africa today.

Based on the need to address the above issues that the *African Handbook of Climate Change Adaptation* has been produced. It discusses current thinking and presents some of the main issues and challenges related to climate change in Africa, as well as evidences from a wide range of studies and projects that show how climate change adaptation is being – and can continue to be – successfully implemented in African countries. Thanks to its scope and wide range of topics related to climate change, this book is intended to become a flagship publication on the subject.

This handbook shares some of the latest research findings on climate change and its impacts in Africa. And apart from having provided senior African researchers and representatives from government and non-governmental organizations with a platform for the documentation and dissemination of their work, it provides an opportunity for young scholars from Africa to present their research and climate adaptation projects. Some special features of the publication are:

1. Over 100 scientific contributions written by African researchers and/or researchers based in Africa
2. All contributions have been peer reviewed by an international editorial team consisting of editors, associate editors, and reviewers
3. It represents all African regions and contexts, from North, East, and West Africa to Southern Africa.

The body of information and knowledge which characterizes the *African Handbook of Climate Change Adaptation* is of particular value to: early career and established researchers whose research and studies examine aspects related to climate change and climate change mitigation and adaptation in Africa; social institutions working on climate change and climate adaptation in Africa that need new information; nongovernmental organizations (NGOs); associations and companies, especially from the finance and insurance sectors; government institutions (ministries of the environment, planning committees, etc.); international and national aid organizations; and other actors in Africa whose activities are affected by climate change.

The handbook provides an overview of the impacts of climate change on the African continent and the methods currently being used to implement climate change adaptation. The experiences from the contributors will also be useful for international and regional experts working in the field of climate change and planning, as well as for all those interested in the linkages between climate change and climate adaptation. In order to support the training of a new generation of scientists, the *African Handbook of Climate Change Adaptation* will be especially used by young scientists (M.Sc. students, Ph.D. students, and postdoctoral students).

And, as importantly, the fact that this publication is available via open access means that it is free and can be read and used by all those interested on matters related to climate change adaptation in Africa, without any costs. Here, the editors would like to thank the assistance provided by the German Ministry for International Cooperation (BMZ), whose support has made this possible.

The editors would also like to thank the authors for their hard work, their patience during the peer-review process, and willingness to share their knowledge with a wide audience. Thanks are also due to the associate editors and reviewers for dedicating their time in the assessments of their manuscripts. Their support is greatly appreciated.

We hope that the *African Handbook of Climate Change Adaptation* will support the regional and global efforts to assist African nations handle the many challenges posed by a changing climate.

May 2021 The Editors

Acknowledgments

We acknowledge the support provided by the German Federal Ministry of Economic Cooperation and Development (Bundesministerium für wirtschaftliche Zusammenarbeit und Entwicklung), which has made it possible to produce the *African Handbook of Climate Change Adaptation* as an open access publication.

The editors also acknowledge the support provided by the International Climate Change Information and Research Progamme (ICCIRP) and the staff at the Research and Transfer Centre "Sustainable Development and Climate Change Management" at the Hamburg University of Applied Sciences for the assistance in the promotion and monitoring of the project, as well as in supporting the authors.

Contents

Volume 1

About the Editor-in-Chief

Walter Leal Filho holds the chairs of climate change management at the Hamburg University of Applied Sciences (Germany) and environment and technology at Manchester Metropolitan University (UK). He directs the Research and Transfer Centre "Sustainability Development and Climate Change Management."

His main research interests are in the fields of sustainable development and climate change, also including aspects of climate change and health. He has over 30 years' experience on climate change projects in Africa, having worked in many countries across the continent.

About the Editors

Nicholas Oguge is a professor of environmental policy at the Centre for Advanced Studies in Environmental Law and Policy (CASELAP), University of Nairobi, where he was a director for 6 years. He is a peer reviewer with NERC (UK) and a past member of the Scientific Review Committee (SRC) at the Socio-Environmental Synthesis Centre (SESYNC), University of Maryland, USA. Professor Oguge is also the founding president of the Ecological Society for Eastern Africa (ESEA) and editorial board member of the *African Journal of Ecology*. He is published widely and has expertise on a wide range of environmental issues. Professor Oguge was a coordinating lead author for the African region during the recent Global Assessments of Biodiversity and Ecosystem Services by IPBES. He has over 27 years of postdoctoral experience spanning academia, research, resource management, project management, and community outreach.

Desalegn Ayal is an associate professor of disaster risk management and sustainable development at the Center for Food Security Studies, College of Development Studies, Addis Ababa University. Desalegn holds a Ph. D. degree in geography. Desalegn serves as the deputy editor of the *International Journal of Climate Change Strategies and Management*. He has published more than 40 publications including books, book chapters, and refereed journal articles. He is East Africa vice president for Interconnections for Making Africa Great, Empowered, and Sustainable Initiative. He is a founder and director of Academics Stand Against Poverty (ASAP) Ethiopian Chapter. Desalegn has also presented papers on climate adaptation and related issues at many international and national conferences. His principal areas of research include climate change adaptation, climate resilience, climate change mitigation and related issues, indigenous weather forecasting, integrated natural resources rehabilitation and management, and livelihoods and food security nexus, among others. He thoroughly understands the link between natural and human-induced hazards with sustainable development, and works hard to familiarize with current tools of climate change impact assessment on livelihood and the wider environment. He has been actively involved in climate resilience and integrated natural resources rehabilitation and management research as well as development interventions to improve food security.

Lydia Adeleke is a senior lecturer and researcher with a Ph.D. in agricultural/resource economics (fisheries economist) at the Federal University of Technology, Akure (FUTA), Nigeria. As part of her doctoral studies, Adeleke was awarded a visiting scholar fellowship to the Fisheries Centre, University of British Columbia (UBC), Vancouver, Canada. She is a fellow of the African-German Network of Excellence in Science (AGNES) and a fellow of the African Women in Agriculture Research and Development (AWARD).

Her research focus is on global adaptation of the artisanal/small-scale fisherfolks to climate change in coastal areas. As an AWARD fellow, she ensures greener world for smallholders' farmers, especially women, through sustainable food production to increase income and living and health standards. As a social economist, she has been doing research on climate change adaptation since 2013, especially in the coastal zones, in order to promote their restoration, conservation, and sustainable use.

She successfully convened the hosting of the 3rd World Symposium on Climate Change Adaptation in Nigeria between 11 and 13 September 2019. The first of its kind in Africa, and The Federal University of Technology, Akure (FUTA), was the first University in Nigeria to host this world event.

Izael da Silva has a Ph.D. in power systems engineering from the University of Sao Paulo (Brazil). He is a professor at Strathmore University and the deputy vice chancellor – Research and Innovation. He started the Strathmore Energy Research Centre, SERC. The center does training, research, testing, and consultancy in energy. His topics of interest are: renewable energy, energy efficiency, energy policy, and sustainable environment. He was also instrumental in the setting up of a project sponsored by DFID and DANIDA and managed by the World Bank to set up the first Climate Innovation Centre (CIC) in the world. It is housed in Strathmore and serves SMEs financially and technically to solve challenges posed by the adverse impact of climate change either by mitigation or adaptation.

In 2013, he was honored by the Brazilian Government with the title of "Comendador da Ordem do Rio Branco" for his services towards education and poverty alleviation in Africa. Professor Da Silva is the first elected president and founding member of the Association of Energy Professionals (EA) and the current chairman of the KCIC board of directors.

W. Leal Filho et al. (eds.), *African Handbook of Climate Change Adaptation*,
https://doi.org/10.1007/978-3-030-45106-6_54

Abstract

Seaweed farming is an important alternative livelihood activity that has been heralded as a development success story. It has advanced women's empowerment and economic liberation in coastal communities in Zanzibar, despite recent declines in its production. Using data from 36 semistructured interviews, we explore the impacts of climate change on seaweed farming in Zanzibar and the coping and adaptation strategies available to farmers. Interviews reveal that climatic changes observed in Zanzibar are characterized by increased temperatures, increased winds, and irregular rainfall, and these changes have negatively affected coastal seaweed farming yields and quality. Combined with economic challenges, these environmental stressors are threatening the sustainability of seaweed farming and the wider development impacts that have been gained over the past decades. Establishing seaweed farms in deeper water, using new technologies, could be an adaptation method to overcome rising temperatures; however, there are significant socioeconomic barriers for this to happen. For example, women lack access to boats and the ability to swim. Adaptation options to the increasing impacts of climate change will be possible only with institutional support, significant investment, and through the empowerment of women and the participation local communities.

Keywords

Development · Climate variability · Coastal communities · Gender · Coping strategies

Introduction

The livelihoods of coastal communities are strongly linked to the health of the coastal and marine ecosystems on which they rely (Salafsky and Wollenberg 2000). These socioecological systems are vulnerable to sudden shocks and long-term change, including climate change, and communities often exhibit a high incidence of poverty that can be exacerbated by these shocks (Tobisson 2014; Ferrol-Schulte et al. 2015; Cohen et al. 2016). Alternative and diversification of livelihood activities are popular intervention options aimed at elevating the socio-economic status of coastal communities and reducing the pressure on marine resources (Sievanen et al. 2005). To be successful, however, these alternative livelihood activities must be resilient to fluctuations in ecological, economic, and social systems (Allison and Ellis 2001; Newman et al. 2020).

Seaweed farming is an alternative livelihood activity that has been promoted in many tropical developing countries (Crawford 2002; Sievanen et al. 2005) because of its low initial capital investment and short-farming cycle (Mshigeni 1973; Valderrama et al. 2015) which provides a fast return on investment (Valderrama et al. 2015). The positive socioeconomic impacts of seaweed farming have been documented in countries including the Philippines, Indonesia, Tanzania, and the Pacific Islands (Sievanen et al. 2005; Msuya 2006a; Namudu and Pickering 2006; Arnold 2008). However, these successes have also been contested (Bryceson 2002; Fröcklin et al. 2012) and seaweed farming is prone to environmental and economic boom-and-bust cycles (Valderrama et al. 2015). This raises questions about its resilience to ecological, economic, and social system fluctuations, particularly the impacts of climate change, and therefore about the sustainability of seaweed farming as an alternative livelihood activity (Allison and Ellis 2001).

Case Study of Zanzibar

Zanzibar is a semi-independent archipelago within the United Republic of Tanzania and its population rely heavily on a vulnerable marine resource base (Suckall et al. 2014). Seaweed farming was introduced in 1989 using the off-bottom method to farm *Kappaphycus alvarezii* (commercially known as *cottonii*) and *Eucheuma denticulatum (spinosum)* in the intertidal zone (Fig. 1) (Msuya 2011). This method involves tying algal fronds to ropes attached between wooden pegs driven into the sediment (Eklöf et al. 2012). Farming cycles are 4–10 weeks, depending on growth rates (Eklöf et al. 2012). Seaweed is dried on the ground over several days and sold to a company to be exported and processed into carrageenan (Fig. 1). Seaweed farming spread rapidly throughout Zanzibar and mainland Tanzania and yearly production increased from 800 tons (dry weight) per year in 1990 to about 11,000 t in 2002 (Eklöf et al. 2012). Farming employs 15,000–20,000 people in Zanzibar, of which 90% are women (Msuya 2006a; Fröcklin et al. 2012). In a traditionally conservative Muslim society, seaweed farming provides women with an opportunity to earn a regular cash income, negotiate household needs, and gain economic independence (Wallevik and Jiddawi 2001). It has been contended that seaweed farming has increased women's security at both the household and community level (Wallevik and Jiddawi 2001). However, despite initial successes, the industry in Zanzibar struggles to compete with global seaweed markets and there has been a production decline of 47% between 2002 and 2012 (Eklöf et al. 2012). The combination of low-sale price and seaweed die-offs, linked to climate change and overgrowth of fouling organisms such as epiphytes (Msuya et al. 2007; Msuya 2011; Eklöf et al. 2012), have caused many farmers to reduce their farm size or abandon the activity altogether (Bryceson 2002; Eklöf et al. 2005).

Adaptation initiatives aim to increase the value of seaweed and improve the livelihoods of the women who farm it. For example, the SeaPoWer project has introduced a new technology to farm *cottonii* (the more valuable species) in the

Fig. 1 (**a**) The seaweed farming cycle using the off-bottom method. (Adapted from Fröcklin et al. 2012). Background photo of seaweed farms in Paje, Zanzibar; (**b**) Fresh *Eucheuma denticulatum* (spinosum); (**c**) Two piles of seaweed drying on palm leaf matting outside Jambiani village. (All photos taken by the author)

deeper water (>8 m) using tubular nets and has provided a boat and other equipment to two groups of farmers (Brugere et al. 2019). Value addition training has been provided by academics and NGOs to enable women to process seaweed into more valuable products such as soap, shampoo, cookies, and juice (ZaSCI 2019). Some women have formed "clusters" to share costs of equipment and strengthen their business. Another example of an initiative is *The Seaweed Co.*, a business providing seaweed farm tours and products to tourists, where farmers are employed full time and receive a fixed salary. Adaptation initiatives may increase the sustainability of seaweed farming in Zanzibar; however, their accessibility, effectiveness, and resilience remain to be assessed.

Conceptual Framework

Sustainable livelihoods, adaptation, and gender equality are key concepts to be considered in relation to the unique socioecological system of seaweed farming in Zanzibar. A livelihood is understood in relation to natural, human, economic, and social capital and is considered sustainable if it can cope with present and future shocks and stresses, while not undermining natural resources (Scoones 1998; Serrat 2017; Quandt 2018). Considering the strong interrelations between environmental conditions and seaweed farming outcomes, attention needs to be paid to the implications of environmental change. Where previous literature has emphasized the challenges that environmental change can pose (Hassan and Othman 2019; Makame and Shackleton 2019) more attention needs to be paid to if, and how, people are responding. Therefore, this study adopts principles from the dynamic environmental sustainability of livelihoods (DESL) framework, which focuses on dynamic responses to change (Newman et al. 2020). Typically, those who are unable to cope, by making temporary adjustments, or to make long-term adaptations are vulnerable and unlikely to attain sustainable livelihoods (Scoones 1998). Responses to shocks and stresses include extensification, intensification, and diversification (Suckall et al. 2014). With regard to seaweed farming, these can be understood as increasing the geographical area where seaweed is farmed, increasing the time spent on the farm, and finally, taking on additional livelihood activities. Long-term adaptations are the actions of individuals, communities and governments undertaken for the purpose of improving or protecting livelihoods (Adger et al. 2005). The capacity to adapt is shaped by socio-institutional factors, including social identities and power relations, which include gender inequalities (Brown and Westaway 2011). The sensitivity of seaweed farming to environmental fluctuations and climate change make it particularly susceptible to shocks and stresses (Msuya and Porter 2014) and the unique nature of this female-dominated industry in the context of gender inequalities in Zanzibar, may impact farmers' ability to adapt. Assessing the viability of coping and long-term adaptation strategies is essential for understanding its future importance as an alternative livelihood activity. As such, we focus on adaptive strategies alongside barriers to adoption whilst critically reflecting on how such barriers might be overcome.

Aims and Objectives

This study aims to explore whether seaweed farmers in Zanzibar can adapt to climate change to ensure its continued sustainability as a livelihood diversification option. Firstly, we assess the environmental changes that are occurring in Zanzibar and farmers' perceptions of these changes. Secondly, we identify the challenges that women are facing, particularly in relation to climate change, and the effects these challenges have on production. Finally, we explore how farmers are responding to change, the adaptation strategies available and the barriers to adaptation. In doing so, findings from this work contribute to understanding the effectiveness of adaptation options and to developing recommendations for enhancing the sustainability of seaweed-related interventions.

Methods

Meetings took place with key NGOs and academics working with seaweed farming in Zanzibar to contextualize the project and gather additional background information, found in the supplementary information (S1: List of Academics and NGOs Contacted During Scoping Phase). Thirty-six semistructured interviews were carried out with seaweed farmers from five villages on Unguja, the largest island of the Zanzibar archipelago (Fig. 2, S2: Participant Profiles); participants were sought with the support of academics and NGOs working in Zanzibar. Thirty-four farmers were female, two were male and ages ranged between 23 and 70, with the average age of 45. Four different groups of farmers were selected to represent different types of seaweed farming options on the island (Table 1). Groups were identified during the scoping phase and a purposive sampling strategy was used to gain representation of the four identified groups of seaweed farmers. This number of participants was deemed an adequate sample size to permit case-orientated analysis while providing a new understanding of experience (Sandelowski 1995).

Interviews were semistructured to allow for supplementary information to be incorporated into the discussion. Interviews were carried out in participants' homes with the assistance of a translator and were recorded using a mobile phone if consent was given. The translator had an academic background in marine sciences and translated from Swahili to English. A meeting was held with the translator before interviews commenced to ensure that translation and interpretation of questions were accurate. Furthermore, to minimize misinterpretation, there was mutual consultation between the translator and the researcher throughout translation during interviews to fully unravel answers (Temple and Young 2004). Six pilot interviews were carried out and questions were adapted to make them clearer for participants and to make the challenges section less restrictive and allow participants to talk more openly and in depth about the challenges they were experiencing.

Questions were developed using themes that were based around the key aims and objectives (S3: Interview Questions Used as a Guideline for the Semi-structured Interviews). The first section gathered background information to gain understanding about whether farming contributes to financial stability in the household. The second section asked farmers to consider challenges, how these have changed over time and their coping strategies. Adaptation methods were considered by opening up conversation about deepwater farming and value addition (if applicable) and ways to make farming easier. The final question was very open-ended, allowing participants to freely add any information that they deemed important. Interviews lasted between 20 and 40 min. Participants received a small remuneration for their time according to local customs (4000 Tsh / US$ 1.5).

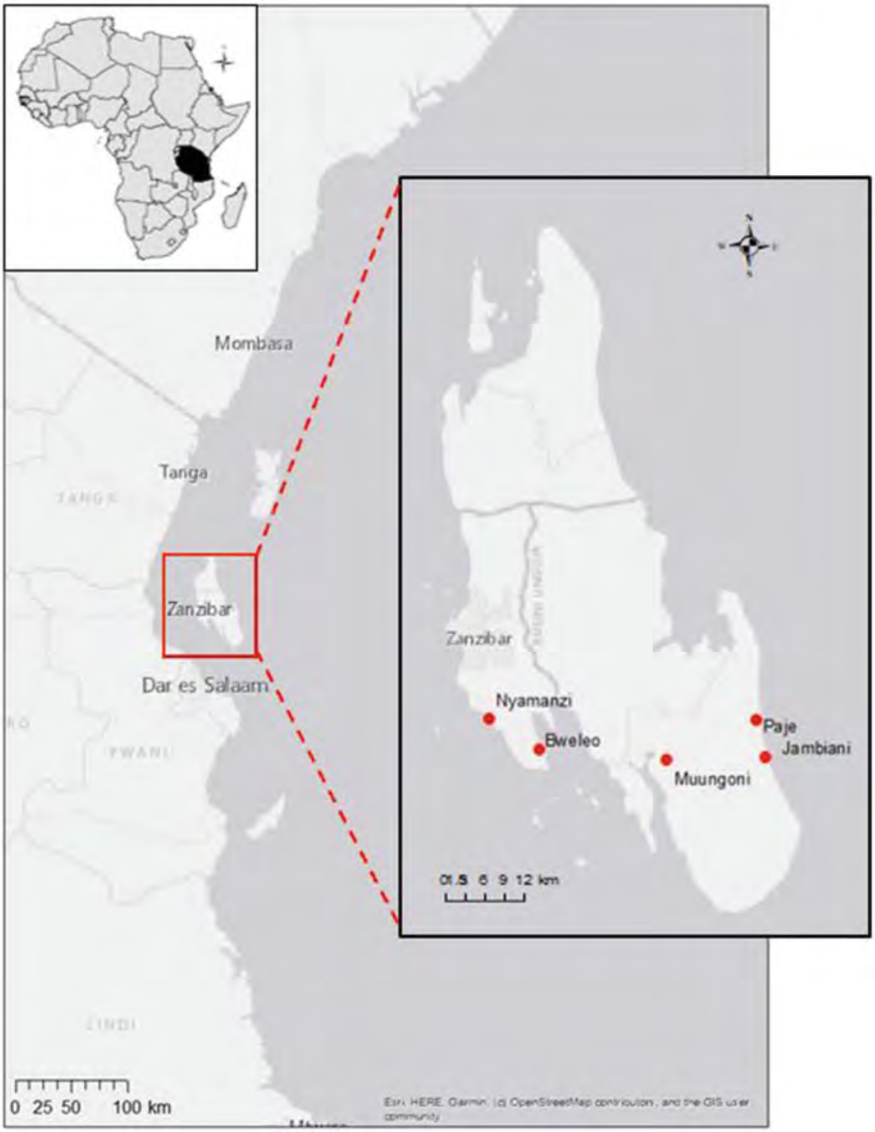

Fig. 2 Map of Zanzibar. Red dots indicate villages where participants were interviewed

Analysis

Interview notes were studied to identify key themes and concepts emerging from the data (Spencer et al. 2003). Thematic categories were based on the objectives but labeled using language from participants to ensure that analysis remained embedded in the data (Spencer et al. 2003). Interview scripts were then systematically coded

Table 1 Summary of the groups interviewed. (No. = number of participants)

Group	No.	Description	Method of farming	Value addition?
Independent Farmers	9	Farmers working alone, receiving no institutional support	Off-bottom	✗
Value addition	11	Farmers making value addition products, part of a "cluster"	Off-bottom	✓
Sea PoWer	10	Received equipment and training to farm in the deepwater using tubular nets	Off-bottom and deepwater	✗
Seaweed Co.	6	Employed 6 days per week, receive a wage. Business sells tours to tourists	Off-bottom	✓

under thematic categories using NVivo 12 (version 12.4.0) (S4: Coding Strategy Used to Analyses the Seaweed Farming Interview Data). Coded information about challenges was organized into a presence-absence data format (S5: Presence Absence Data for Challenges to the Off Bottom Method, S6: Presence Absence of Challenges for Deepwater and off Bottom Methods). Statistical analyses were carried out using R (version 3.6.0). Fisher's Exact tests were run to compare challenges across the deepwater farming ($n = 10$) and the off-bottom method ($n = 36$). Further analysis took place by examining recordings and full interview notes to capture detailed illustrative quotes. Quotes were selected to capture the breadth of challenges and emerging themes.

Results

Seaweed farming is often seen as one of the few options available for women to earn an income. With limited options for other employment, it is an important livelihood activity to alleviate poverty. Income from seaweed farming varied dramatically, ranging from 20,000 to 160,000 Tsh (US$ 9.00–69.00) per month. Farmers noted the considerably large differences in income when the harvest was "good" or "low." Challenges to seaweed farming are numerous and farmers indicated that farming has been affected by changes in climatic factors and nonclimatic stressors over the last 20 years. Climatic variables include increased sea temperatures, increased winds, and irregular rainfall (particularly impacting on the ability to dry the harvested seaweed). Other stressors include low market price and health repercussions, such as back pain and skin irritation. The more valuable species, *cottonii,* cannot be farmed in many areas in Zanzibar due to poor growth and die-offs driven by diseases, such as "ice–ice" disease. As a result of challenges, there has been a huge reduction in the number of farmers. For example, the number of farmers in Bweleo has been reduced from 200 to 60 (Seaweed farmer, VA, Bweleo, July 2019). This reduction in farmers echoes a decline in production across Zanzibar (Fig. 3).

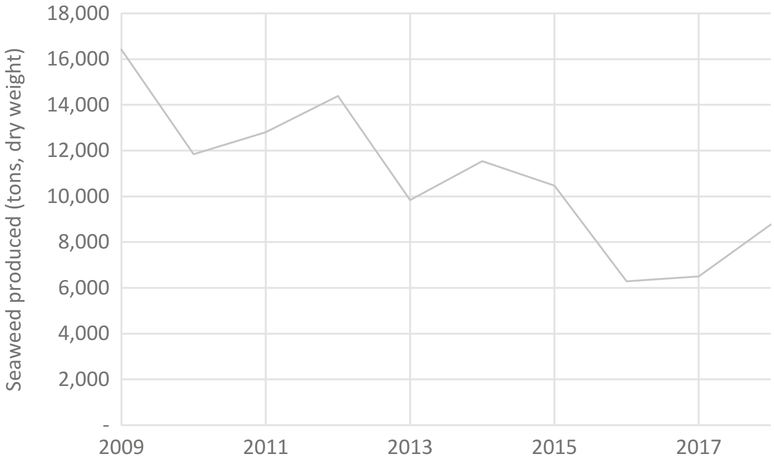

Fig. 3 Seaweed produced in Zanzibar 2009–2018. (Data acquired from Department of Fisheries Development (2019))

Meteorological Evidence

See Fig. 4**.**

Perceived Climatic Changes and Reported Impacts on Seaweed

Although some seaweed farmers did not observe climatic change or were unaware of why seaweed was not growing well, many were aware of changes and reported that stressors were having a big impact on seaweed farming, reducing yields. The more valuable species *cottonii* cannot be farmed anymore so farmers have to produce the lower value *spinosum*. Table 2 indicates the effects that climate stressors have on seaweed farming.

Adaptation Strategies and Constraints

Although some farmers could see no solution to the challenges they faced, there are some adaptation strategies to mitigate the effect of low market price and climatic stressors (Table 3). One coping strategy is to tend to farms more often, using "more energy" to farm. Value addition is an adaptation to the low sale price of seaweed because it can earn more money. However, it does not provide a solution to the problem of a low harvest.

> Due to the disease, we try to farm seaweed, but we harvest nothing. If we want to make value addition, we have to buy from other farmers. The solution is to get a boat to farm into the deep water. (Female seaweed farmer partaking in value addition, Bweleo, July 2019)

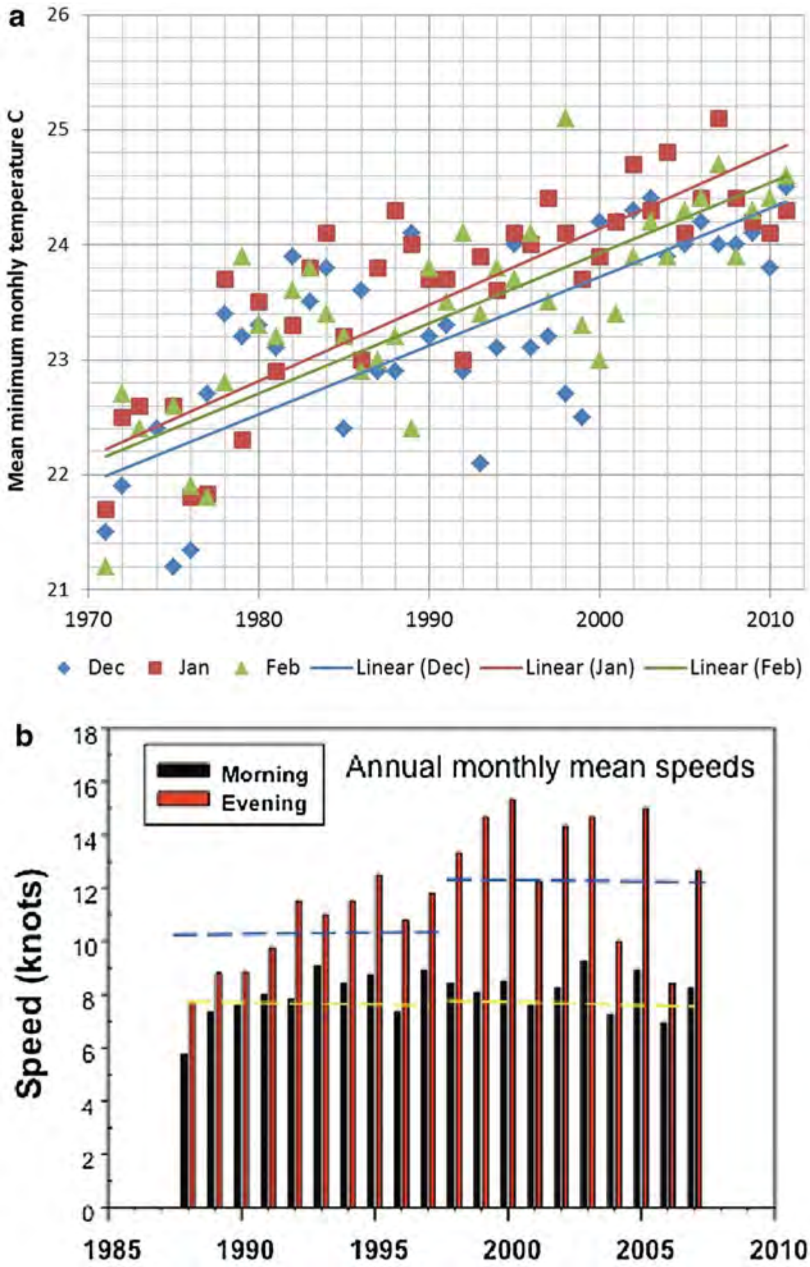

Fig. 4 (**a**) Mean monthly minimum temperature in January and February on Unguja show temperatures have increased strongly over the last 40 years. (Figure from Paul Watkiss, copyright permissions obtained); (**b**) Trends in annual monthly mean wind speeds for Unguja show that wind speeds have increased in recent decades. (Figure from Mahongo and Francis (2010), copyright permissions obtained)

Table 2 Effects of climatic stressors on seaweed farming as mentioned by participants

Stressor	Effects	% participants	Example
Increased sea temperatures	More disease – "ice–ice" disease which turns the seaweed white, causes it to rot	61%	*There is disease during the summer, the water got hot and boiled the seaweed* (Independent female farmer, Paje, July 2017) *It is getting worse because now the sun is very high and hot and so the disease is worse* (Female seaweed farmer partaking in value addition, Paje, July 2019)
Increased sea temperatures	Epiphytic algae, causes seaweed to rot	28%	*There is a type of seagrass that grows on the seaweed and causes it to rot. . . I wanted to cry because there was so much* (Female farmer employed at the seaweed business, Paje, July 2019)
Increased wind speed	Lower yields as seaweed breaks off the rope and farms get destroyed	50%	*Due to the changing of the weather, the seaweed that we plant gets ripped off by the wind. We plant a lot but when we go to harvest it there is not much there* (Independent female farmer, Bweleo, July 2017)
Changes in rainfall patterns	Lower yields as destroys the harvest if it gets wet whilst drying	19%	*During the rainfall we plant it but we don't harvest it because it is difficult to dry it* (Independent female farmer, Paje, July 2017)

Deepwater farming is a group activity that uses a new technology to farm in the deeper and cooler water. It requires the involvement of men to drive a boat and swim to place nets, although some swimming lessons have been provided to some women. SeaPoWer farmers believed that seaweed grows better in deeper water, particularly the more valuable species *cottonii* and it was believed that the new method addresses environmental challenges. A comparison of the off-bottom method and the deepwater method reveals that disease and seagrass infestation were significantly less of a challenge for farmers using the deepwater technology compared to the off-bottom method (Table 4). However, the deepwater method elevated alternative challenges including the presence of grazers (fish-eating the seaweed) and the need for training (Table 4). Farmers have placed fish traps at the bottom of the tubular nets in the deepwater to capture the herbivorous fish to sell. Interviews reveal that there are constraints to adaptation methods (Table 3). For example, independent farmers expressed a desire to partake in value addition but noted that they lacked training and equipment. Similarly, to farm in the deeper water using the tubular technology, farmers need to learn to swim and dive, and have access to a boat. Currently, farmers have to rely on men because boat skills are highly gendered activities that are

Table 3 Adaptation strategies to seaweed farming and associated constraints as mentioned by participants

Adaptation	% of participants	Constraint	Example
Tend to farms more often	19%	Takes more time and energy	*If there is extra wind, I spend more time because I need to check if the pegs and rope are ok* (Female seaweed farmer partaking in value addition, Paje, July 2019) *The main challenge is that I use more energy but get less money* (Female seaweed farmer partaking in value addition, Paje, July 2019)
Value Addition	50%	Seaweed will not grow	*Due to the disease, we try to farm seaweed but we harvest nothing. If we want to make value addition, we have to buy from other farmers* (Female seaweed farmer partaking in value addition, Bweleo, July 2019)
		Require training	*I would like to make products but I need education on how to do it* (Independent female farmer, Paje, July 2019)
		Require equipment	*I have had the training but I can't afford the equipment so I can't do it* (Female SeaPoWer farmer, Dimani, July 2019)
		Takes too much time	*I used to do it in a cluster but we stopped because of time* (Independent female farmer, Paje, July 2019)
Deepwater farming	39%	Ability to swim	*We would love to know how to swim so that we can participate in planting. We need training* (Female SeaPoWer farmer, Dimani, July 2019)
		Ability to dive	*Men should be engaged a lot more with seaweed farming. I think it is difficult for the women to dive. I don't think women will be able to dive* (Male SeaPoWer farmer, Dimani, July 2019)
		Training to drive the boat	*I want to learn to drive the boat myself and not rely on men* (Female SeaPoWer farmer, Muungoni, July 2019)
		Access to a boat	*If we had a boat we would be able to farm in the deeper water* (Independent female farmer, Bweleo, July 2019)
		Grazers	*The fish eat the seaweed. We put traps at the bottom but the fish still come* (Male SeaPoWer farmer, Dimani, July 2019)

Table 4 Comparison of the challenges mentioned by participants for seaweed farming using the off-bottom method and deepwater farming. ***P*** value represents the significance levels from fisher's exact test. * denotes significant results

Challenge	Off-bottom method	Deepwater	*P* value
Disease	64%	20%	$p = 0.028$*
Epiphytes	39%	0%	$p = 0.020$*
Winds	47%	40%	$p > 0.05$
Grazers	6%	50%	$p = 0.0031$*
Training	0%	60%	$p = 0.0000022$*

associated with fishing activity. However, there is strong consensus among the female participants that women would like training to be able to do these activities themselves. These constraints highlight clear socioeconomic barriers to adaptation options.

Discussion

Seaweed farming, using the off-bottom method, is susceptible to shocks and stresses and climatic changes are clearly having a big impact on seaweed farmers. Initial benefits associated with seaweed farming, such as increased household income and job opportunities, become less obvious as harvests are increasingly unreliable which leads to greater insecurity. Many farmers observed increases in wind speed and temperature, which is in alignment with meteorological data and other studies (Hassan and Othman 2019; Makame and Shackleton 2019). The presence of "ice–ice" disease, which causes a discoloration of the seaweed thali and affects the quality of seaweed, is linked to changes in light intensity and temperature (Largo et al. 1995). The more valuable species (*Cottonii)* is particularly sensitive to environmental fluctuations, and seaweed die-offs caused by "ice–ice" disease is a widespread issue and has been long documented in Zanzibar (Msuya et al. 2014; Msuya and Porter 2014). Moreover, the invasion of epiphytic algae, which causes the seaweed to rot (Critchley et al. 2004; Vairappan 2006), has also been linked to increased variability in water temperatures (Tsiresy et al. 2016). The emotional response of farmers during the interviews to this problem clearly indicates the effect it has on income and human capital because of the economic insecurity and emotional response it causes. The difficulty of high die-off rates and therefore low yields is compounded by irregular rainfall patterns, which cause post-harvest loss of yields if it rains during the drying process, and a low-sale price. The combination of environmental and economic challenges results in a very low income for farmers and therefore threatens the economic capital of farmers by reducing their ability to generate a stable income. Seaweed farming is clearly susceptible to economic and environmental shocks and stresses. Given that future projections estimate that temperatures will increase by 1.5–2 °C by the 2050s (Revolutionary Government of Zanzibar 2013), seaweed die-offs will be exacerbated and its sustainability is therefore questionable if adaptation is not achieved. Other challenges, such as poor health effects (Fröcklin et al. 2012), further impact sustainability by negatively affected human capital. The off-bottom method is negatively impacting human and economic capital and is becoming increasingly vulnerable to shocks and stresses. Therefore, it is important to understand indigenous perceptions about climate change and its impacts to assess the dynamic responses to changes and to determine suitable adaptation strategies to attain sustainable livelihoods.

There are a number of short-term and long-term adaptation strategies available to farmers. Intensification of farming (i.e., using “more energy” to tend to farms) is a short-term coping strategy in response to low production, high winds, and low sale price. Value addition is a form of long-term diversification, aiming to address the issue of a low sale price that farmers get as a result of their weak bargaining power with seaweed buyers. Interviews reveal that women clearly see the benefit of value addition through an increase in their income. Moreover, deepwater farming can be seen as either a form of extensification or a migration to a new production environment that successfully addresses many environmental challenges and farmers believe that they can earn more money by farming the more valuable species. Although there are still uncertainties regarding the outputs of these long-term adaptation strategies (value addition and deepwater farming), and further monitoring will be required to assess the impact that this has on the farmers’ household income, the attitudes of farmers engaging with these activities are positive. The farming innovations are also bringing about additional benefits such as greater social capital by empowering women producers and elevating women’s status in society (Brugere et al. 2020).

However, successful adaptation requires an enabling environment dependent on environmental, economic, social, and institutional factors and some strategies are more effective that others, particularly in relation to climate change. Although some long-term adaptation strategies are having positive impacts, there are a number of barriers to adaptation that warrant further attention, and adaptive strategies must be analyzed in the context of these barriers to assess their effectiveness. Given that climatic change is a major challenge for seaweed farmers that is likely to be exacerbated in the future, many adaptation strategies will not be adequate in ensuring the long-term sustainability of farming. For example, intensification of farming and value addition activities will not be resistant to climatic stressors because they do not address the inability to grow seaweed. Moreover, there are economic considerations that may inhibit farmers’ ability to adapt; unlike the off-bottom method, deepwater farming and value addition both require large initial investment to purchase equipment. If farmers do not have the financial capacity to make this initial investment, adaptation will not be possible unless enabled through institutional or NGO support (Wright et al. 2014).

Social factors will also either inhibit or enable adaptation. Deepwater farming and value addition both require substantial training and knowledge sharing. Many independent farmers interviewed were aware of adaptation methods but were unable to access them, highlighting the importance of social collaboration as a critical enabling environment to promote knowledge sharing for adaptation (Fu et al. 2011). Moreover, deeply engrained social practices and the complex nature of gender biases and power relations will be significant barriers to overcome for adaption methods. Labor-led intensification is characterized by an increased time burden, which disproportionately affects women due to their roles within the household and as child-carers (Wodon and Blackden 2006). Therefore, it is unlikely to be sustainable because of the impact on human and social capital by reducing time available for other roles that are typically dominated by women. The complex nature of gender biases and power relations also significantly affects deepwater farming, which currently entails the involvement of men. Gender power dynamics must be monitored to maintain (and promote) the positive impact to date of seaweed farming on women's security at the household and community level (Wallevik and Jiddawi 2001). Interviews revealed women want to learn to swim and drive the boat to reduce their dependency on men, highlighting a shift in traditional attitudes (Brugere et al. 2019; Brugere et al. 2020). Deepwater farming represents a shift in gender attitudes because it challenges the traditional belief that the deepwater is an area accessed by men due to women's limited mobility and role in society (Fröcklin et al. 2014). The government is promoting gender balance by increasing the number of female village leaders and females in government offices which shows a wider change in gendered roles. However, despite signs of attitude shifts, deeply engrained cultural practices and ways of thinking, held by both men and women, require repeated action, support, and perseverance over extensive periods of time to evolve (Brugere et al. 2019).

Lastly, government involvement will impact the success of adaptation methods by providing (or inhibiting) an institutional enabling environment. Policies and institutions play a major contributing role to the sustainability of coping and adaptation strategies (Osman-Elasha et al. 2006). Governance mechanisms aimed at adaptation can support coping strategies by providing training, technical support, and financial support (Jabeen et al. 2010). It is promising that there is government attention on seaweed farming in Zanzibar, highlighted by the recent appointment of National Seaweed Day to emphasize the importance of the activity and previous governmental attempts to increase the price of seaweed (Davis 2011). Moreover, there are currently plans to construct a processing plant on Pemba which is a large-scale value addition project (IPPmedia 2019). However, the government should be investing in technologies that will be resilient to climate change, not only promoting value addition activities which will be an ineffective coping strategy in the long-term.

Overall, short-term coping strategies are often ineffective and have resulted in many people ceasing to farm as seen by the reduction in farmer numbers in Bweleo and the reduction in production. Although long-term adaptation methods provide promising ways to increase the sustainability of seaweed farming by overcoming economic and environmental challenges, particularly those relating to climate change, there are significant socioeconomic barriers that need to be overcome. This will only be achieved through a supportive enabling environment with participation of local communities and institutional support (Sietz et al. 2011).

Future Study

Although 36 participants was deemed sufficient to enable thorough analysis due to the recurrence of themes during interviews, the study would benefit from incorporating the experiences of farmers on the other islands in Zanzibar, particularly Pemba where seaweed farming is a particularly important livelihood activity. More investigation is required into the potential cobenefit of using fish traps at deepwater farms to see if the catch of fish can outweigh the loss of seaweed yield. Moreover, there should be more research into drying techniques in order to reduce the post-harvest loss due to irregular rainfall, or the possibility of farmers selling seaweed fresh opposed to dried. Additionally, the complex issue of gender dynamics requires further study, particularly the possible shift in power as a result of extensification into deeper water, which could have major impacts on the long-term sustainability of seaweed farming as a way of empowering women.

Wider Implications

Seaweed farming is being promoted as an alternative livelihood activity in many tropical developing counties, including Zanzibar, Indonesia, and Philippines. However, it is important that alternative livelihood activities are resilient to ecological and social system fluctuations, particularly climate change (Allison and Ellis 2001). In order to maintain yields, efforts need to focus on seaweed farming adaptation strategies that will be resilient to climate change. Deepwater farming using the new tubular technology shows the most promising adaption method to environmental challenges. However, it requires significant investment and training to ensure its success. Interestingly, despite negative impacts of climate change on the growth of seaweed that have been reported in Zanzibar and elsewhere, seaweed aquaculture is gaining recognition as a climate-change mitigation strategy by its ability to act as a carbon sink (Duarte et al. 2017). Although it would be minor at this scale, it is worth exploring how climate change mitigation policies that provide economic compensation for the environmental benefits brought about by seaweed farming could help investment and could generate a new market for seaweed production (Duarte et al. 2017).

Conclusion

Seaweed farming is still heralded as a success story and is responsible for women's empowerment and economic liberation. However, climatic stressors such as increased sea temperatures, high winds, and variable rainfall reduce seaweed growth and quality. Given the current environmental and socio-economic challenges, seaweed farming provides an unreliable income. Despite the cultural importance as a livelihood activity, the future of seaweed farming is uncertain, particularly as the impacts around climate change are likely to increase. Individual short-term coping strategies, such as intensification of tending to seaweed farms are unlikely to be effective in the long-term. The sustainability of seaweed farming is reliant on long-term adaptation methods that will require adopting new technologies, overcoming significant socioeconomic barriers, and will demand substantial institutional support. It is important to support adaptation strategies that are codesigned with communities, and that use holistic approaches that embrace the technological, individual (social and economic), and institutional dimensions of climate change adaptation.

Questions

Background
How long have you been farming seaweed?
Why did you decide to start farming seaweed?
What do you think are the main benefits coming from seaweed farming?
What type of method do you use (shallow water/deepwater)?

– If you do both, why? If you changed from the traditional method to the new method, why?
– When did you start farming the new method?

What type of seaweed do you farm? *Cotonii* or *Spinosum?*
How much time do you spend farming seaweed in the traditional/deepwater method?
How many days a week do you spend farming?

Economic

Who do you sell the seaweed to?
How much money do you make from seaweed farming per month?
What is the price per unit (kg bag of dried seaweed) Are you able to negotiate the prices?
Which method earns more money? Which species earns more money?
Has the value of the seaweed you farm increased, decreased or stayed the same in the last 20 years?

How essential is seaweed farming to the income of the household?

Do you have any other sources of income other than seaweed farming?

What is the money from seaweed farming spent on?

Do you have a say on how the money from seaweed farming is spent?

What is the cost of the off bottom culture equipment per cycle of production?

If you have farmed using both methods, how do you think the deepwater technique compares with the traditional technique, in terms of

- Seaweed seedlings [more expensive, less expensive, the same]
- Equipment (ropes, pegs versus nets, strings, PVC tubes, boat, petrol...)
- Time/labour spent farming (more, less, the same)

What challenges are you facing? (Off bottom method)

Does the seaweed grow well?

Are these new/emerging challenges or have they always existed?

Are these challenges increasing/decreasing or staying the same?

Do the challenges vary across different seasons?

How do you respond to/cope with these challenges?

What would help to stop these problems?

Are you facing any health repercussions?

- Have these increased with exposure or stayed the same?
- How do you cope with or manage these health implications?

What does your family think of farming the new method/the old method?

- Does the time taken to farm seaweed affect your family?

Has there been any spatial conflict with other users of the ocean space? – eg does tourism or fisherman prevent you from farming?

- How do you manage this?

Is there anything that would make it easier for you?

Do you farm in the deepwater?

How much time do you spend on this?

What effect does this have on your income?

What are the challenges?

Do you do any value addition – making products?

How much time do you spend on making products? What equipment and/or inputs are you using?

How/where do you sell your products?

What products do you make?

Is there anything else that you would like to add or say?

Adaptation of Small-Scale Tea and Coffee Farmers in Kenya to Climate Change

2

Alice Nyawira Karuri

Contents

Abstract

The adverse effect of climate change on agriculture is well-documented and is a cause of concern for governments globally. In addition to concerns over food crop production, the economies of numerous developing countries rely heavily on cash crops. The coffee and tea sectors are key in Kenya's economy, contributing significantly to the gross domestic product, foreign exchange, and the direct or

indirect employment of millions. Farmers engaged in the production of coffee and tea are predominantly small-scale farmers, with the majority farming on less than five acres. Climate change poses a threat to the production of these two crops and by extension to the economy of Kenya and the livelihood of farmers and those employed in these sectors. This study identifies the challenges posed by climate change in the tea and coffee sectors, the adaptation and mitigation measures identified, and the scope of their implementation. The production, processing, and marketing of tea and coffee in Kenya differs widely in terms of the institutions and institutional arrangements in the two sectors. This study will therefore analyze the role played by institutions in both sectors and how this affects climate change adaptation and mitigation measures by small-scale farmers.

Introduction

Agriculture in Kenya

The agriculture sector is key to Kenya's economy. It accounts for 65% of the export earnings and provides the livelihood of more than 80% of the population. The sector employs more than 40% of the total population and about 70% of the rural population. In 2018, it contributed 34.2% of Kenya's gross domestic product (GDP) and an additional 27% through linkages to other sectors such as manufacturing, distribution, and services (Food and Agriculture Organization (FAO) 2020; Kenya National Bureau of Statistics (KNBS) 2019; Ministry of Agriculture, Livestock and Fisheries (MALF) 2020). The climate of Kenya varies from tropical along the coast to arid in the interior. The weather in Kenya is generally sunny year-round, with the main rainy seasons being from March to May and from November to December (International Coffee Organization (ICO) 2019a). The topography rises from the coastal plains to the eastern edge of the East African Plateau and the Great Rift Valley. The highest altitude is in the central region and temperatures of 15 °C compared to the coastal region with temperatures of 29 °C (UNDP 2020). The Agriculture in Kenya is 98% rain fed and highly sensitive to changes in temperature and rainfall. Studies indicate there will be a 20% decrease in rainfall by the year 2030 (Government of Kenya (GoK) 2015). Temperatures are projected to increase 1.2–2.2 °C by 2050 in addition to increase in frequency and intensity of heavy rainfall, increase in severity of dry spells and duration of heat waves, and 16–42 cm rise in sea level (United States Agency for International Development (USAID) 2018). Since the early 1960s, both minimum and maximum temperatures have been increasing. The minimum temperature has risen generally by 0.7–2.0 °C and the maximum by 0.2–1.3 °C. There has been increased variability of rainfall from year to year and during the year. Extreme weather occurrences such as droughts and floods have become frequent and intense, leading to crop failures.

The adverse impacts of climate change are compounded by human factors such as illegal encroachments and settlements, logging and livestock grazing, which exacerbate deforestation, land degradation, and desertification. Forest cover in Kenya, for instance, has fallen from 12% in the 1960s to less than 2% in 2010. Kenya has a landmass of about 582,350 km^2 with 17% being arable while 83% consists of arid and semiarid land (ASAL) (GoK 2010). The combination of deforestation to open up croplands, the extension of agriculture onto land with low potential, and the use of more basic farming techniques and technologies due to cost and capacity barriers make the current agricultural system unsustainable in the long term (Republic of Kenya 2018). This necessitates that farmers engage in activities to adapt to and mitigate climate change. Adaptation refers to actions that minimize negative impacts of climate change, including the social, environmental, and economic impacts while mitigation refers to activities that reduce, prevent, or remove greenhouse gas (GHG) emissions and therefore reduce climate change. These measures require that farmers engage in sustainable agriculture, which is defined as farming in a responsible manner while enhancing profitability, well-being of the people, and the environment for now and the future (Cameron 2017).

The MALF oversees agriculture in the country. The Agriculture and Food Authority (AFA) is a government agency under MALF and is responsible for the development, regulation, and promotion of scheduled crops (ICO 2019b). AFA is comprised of several directorates that are specific to particular crops and include the Tea Directorate and the Coffee Directorate. Tea, horticulture, and coffee are Kenya's main agricultural exports. Tea and coffee are, however, unique as they are predominantly grown by small-scale farmers. This necessitates the formation of farmer organizations to benefit from economies of scale and to navigate the labor and capital-intensive process from production at the farm to the sale of the finished products.

Climate Change Policies and Regulations in Kenya

Kenya recognizes the importance of climate change action and has policies and plans to enact adaptation and mitigation measures. These include the National Climate Change Response Strategy (NCCRS) of 2010, National Policy on Climate Finance (2015), the Climate Change Act of 2016, the National Climate Change Action Plan (NCCAP) 2018–2022, and the National Adaptation Plan 2015–2030. The Environmental Management and Coordination Act (EMCA) of 1999 is the framework law on environmental management and conservation. Under this Act, EMCA established various institutions including the National Environmental Management Authority (NEMA). NEMA is the principal instrument of government charged with the implementation of all policies relating to the environment, and to exercise general supervision and coordination over all matters relating to the environment (National Environmental Management Authority 2020).

The NCCRS is the main document that guides the Kenya government's climate change agenda. The main focus of the strategy is to ensure that adaptation and mitigation measures are integrated in all government planning, budgeting, and development objectives. It prioritizes agriculture as one of the vulnerable sectors of the economy. The NCCRS established that the institutions in place to govern climate change affairs were inadequate and recommended that a comprehensive climate change policy and related legislation be put in place. The Climate Change Act was subsequently passed in 2016 and provides for a regulatory framework for an enhanced response to climate change. The Climate Change Act pertains to all sectors of the economy and to the national and county level government in the 47 counties of Kenya. It aims to mainstream climate change responses into development planning, provide incentives and obligations for private sector contributions in achieving low carbon climate resilient development, promote low carbon technologies, facilitate climate change research, and enhance cooperative climate change governance between the national government and county governments.

The Act obligates the Cabinet Secretary responsible for climate change affairs to formulate a five-year NCCAP. In accordance with the Act, the NCCAP represents the national mechanism through which climate change will be addressed in Kenya, including the implementation of the Nationally Determined Contributions (NDCs). Kenya submitted its NDCs in 2016. The NCCAP 2018–2022 provides mechanisms for mainstreaming climate change into all sectors of the economy and in the County Integrated Development Plans (CIDPs). The initiatives undertaken through the NCCAP include the scale up of renewable energy technologies, clean energy solutions, improved water resource management, sustainable forest management and tree planting, climate smart agriculture, and agroforestry (GoK 2015). It prescribes measures and mechanisms for climate change adaptation and mitigation, and the review and recommendation of duties of public and private bodies on climate change. Climate change duties refer to the statutory obligations conferred on public and private entities to implement climate change actions consistent with the national goal of low carbon climate resilient development. NEMA monitors, investigates, and reports on compliance with the assigned climate change duties. The Act also provided for financial provisions through the Climate Change Fund, which is a financing mechanism for priority climate change actions and interventions (Republic of Kenya 2016). Kenya also has a Climate Smart Agriculture Strategy for 2017–2026, which has been used as a source of input for the development of NCCAP 2018–2022 (Republic of Kenya 2018).

Tea Sector in Kenya

Kenya is the third largest producer of black tea globally after China and India, and is the world's largest exporter of black tea, contributing over 20% of total world exports. The sector is therefore significant to the global and national economy. By 2012 the sector accounted for 17% of total export earnings and 4 % of the national GDP (FAO 2015). In 2018, tea earnings amounted to Ksh.127.7 billion (KNBS 2019). Tea is grown on 236,000 ha with smallholders cultivating 142,000 ha and estates 93,000 ha. Tea production in 2018 was 493,000MT with 272,500MT from smallholders and 220,500 from estates (KNBS 2019). The tea sector contributes to environmental conservation through improved water infiltration, reduced surface erosion rates, and enhanced carbon sequestration.

Tea farming in Kenya is regulated by the Tea Act, Revised Edition 2012 [1960]. The Tea Directorate undertakes regulation and compliance of the tea industry, marketing and promotion of tea, the provision of technical and advisory services, and tea export guidelines. It facilitates research on all tea-related matters through the Tea Research Institute (TRI). All tea farmers are required to register with a factory as shareholders and to which they must supply the entirety of their production. Nearly all tea factories with small-scale farmer membership are shareholders in the Kenya Tea Development Agency (KTDA), a management company with several subsidiaries. Acreage per farmer varies from 0.25 to over 50 acres and most KTDA farmers grow on approximately half an acre of tea on average. Majority rely heavily on tea production for their livelihoods, which comprises over 60% of their total income. KTDA works directly with 611,000 farmers and indirectly impacts over four million people. A 2.5% management fee based on net price for services rendered is paid to KTDA Management Services and KTDA subsidiaries charge for their services separately. The government supports KTDA through guarantees for loans and support to extension services through the Ministry of Agriculture. The Kenya Tea Growers Association (KTGA) was established to promote the common interests of large-scale tea growers and is open to growers who maintain over 10 ha of tea. The large-scale tea sector, also referred to as tea plantation, includes both individual farmers and corporations, and accounts for about 40% of total tea production in Kenya (Kenya Tea Growers Association (KTGA) 2016). Challenges in the tea sector include declining prices, low yields, high production costs, low production diversification, low value addition, and a multiplicity of taxes and levies (Ngumo 2015).

The agro-climatic requirements of tea are temperatures ranging from 10 °C to 30 °C, ideally 0.5–10 degree slopes, elevations up to 2,000 m, acidic volcanic soils, well-distributed rainfall between the range of 1,200 and 1,400 mm annually, sufficient sunshine hours, and a mild climate. Tea in Kenya is grown in altitudes between 1,500 m and 2,700 m above sea level, receiving 1,200–1,400 mm of rainfall annually, which is spread throughout the year (FAO 2015). The agro-zones for tea production include the areas of Mount Kenya, Aberdare Range, Nyambene Hills, Mau Escarpment, Kericho Highlands, the hills of Nandi and Kisii, Mount Elgon, and Cherangani Hills (FAO 2015). Tea production in Kenya occurs all year round but the highest yields are in the rainy seasons in March–June and October–December. The tea supply is consistent throughout the year in both quantity and quality. Over 90% of tea from Kenya is handpicked, with only the top two leaves and a bud being picked for processing to ensure high quality. About 50 varieties of tea have been developed to suit the seven tea growing regions. The tea is grown without the use of agrochemicals as it is pest and disease free, and requires only fertilizer to replenish soil (TRFK 2010). Tea husbandry includes weeding, pruning, and fertilizer application. Pruning is ideally undertaken at the end of the peak-growing period, July to August, when the soil moisture is still adequate (East Africa Tea Trade Association 2020). The weather during this period is usually cold with light rains and enables pruning to occur without sun scorch.

Climate Change Challenges in the Tea Sector

Tea production is highly sensitive to changes in growing conditions. These conditions are expected to be impacted by climate change (Change 2015). Climate changes include inadequate rainfall, a larger soil water deficit, unpredictable rain patterns, and temperature rise (Ethical Trade Partnership (ETP) 2011). Climate change causes low productivity and poor quality in tea. Drought reduces the yields of tea while changes in the reliability and predictability of rainfall distribution and patterns have negative effects on tea yields and quality. Hailstorms and frost damage tea leaves and extreme temperatures suppress yields. High temperatures for example lead to decreased yields, reduced quality, high evaporation, reduced water content in the tea, dry weather pests, aggressive weed growth, weeds found in low country appearing in mid and up country poor bud break, bud scorch, stem and collar canker, wood root, leaf and bark desiccation. Excessive rain causes spread of fungal diseases, wet weather pests, and poor drainage in low-lying areas, heavy soil erosion that results in reduced water holding capacity, poor soil nutrients, and poor bud break and shoot development. Increase in extreme weather causes crop damage and failure due to events such as droughts, hail, storms, floods, frost, and landslides. Climate change also reduces productivity of subsistence crops which reduces food security (International Trade Center (ITC) 2014; Prematilake 2014). Due to climate change, the current areas of production are becoming unsuitable for tea production due to the risk of increasing temperature and increasing pests and diseases (ITC 2019; USAID 2018). A study by the International Center for Tropical Agriculture (CIAT) of climate change impacts on tea production in Kenya up to 2050, estimated that with increasing temperatures and rainfall, optimal areas for tea production will decrease, and production will have to shift to higher altitude areas, moving from around 1,500 m to 2,000 m above sea level (Ethical Tea Partnership 2011). A study by TRI indicates that in 2012, almost one-third of the harvest was lost (Omondi 2015). Incidences of severe and damaging frost that are attributed to climate change are becoming more common in Kenya. For example, the 2012 frost resulted in 30% tea crop loss in Nandi County (GoK 2015).

Adaptation and Mitigation Measures by Small-Scale Farmers in the Tea Sector

Tea planting is done through the planting of seedlings or more rarely, through the transplanting of a tree plant. Maturation of the tea seedling takes approximately 3 years, after which the tree plant continues production for decades. Adaptation to climate change can therefore not be carried out through adjusting the planting date. Adaptation measures can however be taken through adjusting the timing of tea husbandry activities such as pruning and fertilizer application, to climate change. Toward addressing issues on climate change, TRI is developing new technologies including environmental conservation efforts and development of improved tea varieties. TRI conducts research aimed at improving planting material, husbandry, yields, quality, and disease and pests control. It also provides advisory services to the growers on specific problems encountered in tea cultivation. The TRI has developed over 914 improved clones, of which 51 clones have been selected for consistent superiority in yield and quality. Thirteen of these clones yield between 5,000 and 8,000 kg of processed tea per hectare annually. These yield levels are some of the highest in the world and are three times the average yields of unimproved tea varieties. It has also developed a new tea clone – "Purple tea." According to the Kenya Agriculture and Livestock Research Organization (KALRO), the TRI began research on the "Purple Tea" cultivar over 25 years ago, and in 2011, the Tea Directorate began encouraging farmers to plant it. It is drought, frost, disease, and pest resistant. It has wide adaptability and is suitable for all designated tea-growing regions (KALRO 2020). Production of tea varieties such as purple tea, which is more resistant to climate variability than green tea, is a climate adaptation measure with the potential for higher income for tea farmers. Kimtai (2019) did a study aimed at establishing the rate of adoption of purple tea farming, determining the socioeconomic factors that hinders adoption and determining the role of purple tea farming for carbon sequestration. The purple variety had higher production than green tea and fetched higher prices. It was more resistant to drought, frost, hailstone, pests, and diseases. It was therefore highly rated for impacts of climate variability and change. Constraints to farming purple tea included availability of land, extension services were low particularly to farmers with the least acres of land (two acres), lack of training, poor access to credit, and limited market channels. The adoption of purple tea was however positively influenced by factors such as requiring little investment, higher income level, less risk on crop failure, and availability of labor.

Further adaption strategies include selection of the most suitable areas for tea growing, no expansion of new planting or replanting in low production areas, crop diversification in low production areas, efficient management of soil and water resources, catchment protection, riverbank protection, soil water conservation, crop insurance, use of drought tolerant cultivars, rainwater harvesting, and establishment of shade trees. Shade management particularly in the low and mid country reduces ambient temperature and prevents sun scorch. Other benefits of shade trees include carbon sequestration, improved net assimilation of tealeaf, reduced weed growth, additional organic matter from leaf litter and minimized wind damage, reduced frost, and reduced soil erosion (Ethical Tea Partnership 2011; Omondi 2015; Prematilake 2014). Tree planting also reduces frost and prevents soil erosion.

Several key partnerships enable the tea sector to adapt to and mitigate climate change. KTDA is involved in partnerships geared toward sustainable agriculture including climate change adaptation. One of its key partners has been Unilever, which is a multinational corporation with tea estates in Kenya and is also a major buyer of tea sold by KTDA. Unilever established a Sustainable Agriculture Programme in 1999. In 2007, it launched a partnership with the KTDA to enable Kenya's small-scale tea farmers acquire the certification standard set by the Sustainable Agriculture Network (SAN), which is a global coalition of environmental organizations. Factories and the KTDA trained farmers through Farmer Field Schools and Rainforest Alliance certification. Selected smallholder farmers are trained and they in turn instruct other farmers. Each lead farmer reaches an additional 300 farmers to ensure compliance with the SAN Standard required for Rainforest Alliance certification. KTDA in partnership with Unilever and IDH (the Dutch Sustainable Trade Initiative) has certified all the factories to the Sustainable Agriculture Network standards. Both farms and factories must meet the necessary requirements to receive Rainforest Alliance certification. By mid-2016, all of Kenya's smallholder tea farmers had met the Rainforest Alliance certification standards, and Unilever's Lipton brand was selling 100%-certified tea. Other major tea brands also began purchasing certified tea (Cameron 2017). The replicability, scale, and local leadership component of this system could serve as a model for developing participatory climate change adaptation plans (Moroge 2012). By March 2019, all 69 KTDA-managed tea factories were Rainforest Alliance certified and 21 tea factories were Fair Trade certified. Other certifications obtained by tea producers and factories included UTZ, Kosher, and Ethical Tea Partnership (ETP) (IISD (International Institute for Sustainable Development) 2019).

This success is attributed to several factors. Key among these is that Unilever, which has a large market share in Kenya, made the decision to purchase only tea that was Rainforest certified. Tea production is linked to global rather than domestic demand, with more than 95% of tea produced in Kenya is exported. Other factors include the strong regulation of the tea sector by the government including the registration and licensing of factories by the Tea Directorate. Kenya's tea industry is also highly concentrated both geographically and structurally with KTDA accounting for 60% of the market. KTDA's structure is highly integrated with strong links between farmers and factories (Cameron 2017). Unilever was also part of the development of the Cool Farm Tool, a calculator of GHG emissions that is freely available for use by farmers. In collaboration with the Kenyan government, it has been using it to quantify carbon within its plantations (Ellis et al. 2013).

The World Bank (WB) is also a key partner in climate adaptation in the tea sector. It announced during the March 2019 Nairobi Summit that an Emission Reduction Purchase Agreement (ERPA) would be signed between the Carbon Initiative for Development (Ci-Dev) trust fund, with WB acting as trustee, and KTDA Power Company Ltd. (KTDA Power). The contract aims to purchase carbon credits from small hydropower plants that provide power to 350,000 smallholder tea farmers and 39 of their regional tea factories in Kenya (Africa Times 2019). ETP, an alliance of tea packers working toward the sustainability of the tea sector, is another key partner. They started work in Kenya in 2010 and implemented a Climate Change Adaptation Program with GIZ, a German development agency. ETP utilized technology developed by its partners, such as Cafedirect Producers' Foundation, which developed a tool called WeFarm, an SMS platform for farmers (Budsock 2015). ETP also created a partnership with ITC and other nongovernmental organizations and founded a project to help farmers in climate change adaptation and mitigation. The program trains farmers and tea factory managers in carbon standards compliance, conservation and management of water, soil conservation, and use of biogas instead of wood. A partner factory, *Makomboki* Tea Factory that was using 2,000 cubic meters of wood per month as fuel for drying tea, changed to alternative energy sources. This included sawdust, rice husks, biomass, macadamia, and cashew nut shells and briquettes made from sawdust and rice husk. The new initiative saved more than 30,000 trees while lowering operational costs of that factory by 20% (Omondi 2015).

Multilateral partnerships are particularly effective in adaptation strategies. An example is the "Upscaling and Embedding Sustainability for Smallholder Tea Farmers," which is a collaborative initiative by KTDA Management Services (KTDA-MS), Unilever, and IDH – the Sustainable Trade Initiative. More than 85,000 (about 15% of 560,000 farmers) small-scale farmers had been trained by 2015 on Sustainable Agricultural Practices under a farmer field School (FFS) program (Cameron 2017). Another multilateral collaboration is between Germany, China, and the Food and Agriculture Organization (FAO), which was formed with the aim of promoting sustainable agricultural development and combating climate change in Kenya. This is through a project on carbon-neutral tea value chains. Germany through GIZ has been working with the KTDA, the Ethical Tea Partnership (ETP) among others in an integrated development partnership with the private sector to increase energy efficiency in all the factories to save GHG emissions and increase income of the farmers (Sino-German Center for Sustainable Development 2019). KTDA in 2015 signed a loan for Ksh.5.5 billion for the construction of seven small hydropower projects. The loan agreement was with the International Financial Corporation (IFC) which is a member of the World Bank, in partnership with other organizations including the Global Agriculture and Food Security Program (GAFSP) the French Development Institution (Proparco, the Netherlands Development Finance Company (FMO)). The expected reduction of reduce Kenya's carbon footprint from using hydropower is approximately 63,000 tons of carbon dioxide equivalent per year. On average, tea factories spend approximately Ksh. 30 million to Ksh. 65 million each per year on electricity (KTDA 2015). The hydropower plants have a total installed capacity of 16 megawatts and will provide captive power generation with the excess energy being sold to the state-owned power company. The farmers provided 35% equity on the loan via green leaf delivery, making it perhaps the first initiative in the world in which a farmer-owned institution is undertaking a renewable energy project of such a scale (IFC 2016).

KTDA Foundation, a nonprofit charity, also engages in environmental sustainability and climate change. Programs under climate change focus on promoting climate change mitigation, adaptation, and resilience building among smallholder tea farmers. In partnership with factories it has established over 31 indigenous, exotic, and fruit tree nurseries. Over 2.4 million trees have been planted in farms, major water catchment areas, and public forests. It is also undertaking an environmental conservation campaign for schools. Farmers are encouraged to adopt clean, renewable energy through promotion of and access to clean and renewable energy such as energy saving stoves, solar lighting products, and biomass. Adaptation measures include planting tea bushes along hill contours to reduce soil erosion. Seedlings from KTDA nurseries (commonly native species) are distributed throughout the local community for planting along farm boundaries, as buffers for waterways and forests, and to create small forest patches on farms. These native trees store carbon, stabilize the tea microclimate, and increase soil fertility. Planting native trees on steep slopes or degraded lands can also reduce vulnerability to heavy rains or prolonged droughts which creates resiliency to extreme weather. The KTDA is working to secure its own sources of sustainable fuel by acquiring land and encouraging its farmers to grow woodlots. Eucalyptus is commonly planted for fuelwood in the region. However, eucalyptus takes up large amounts of water, and KTDA and Rainforest Alliance are supporting farmers' efforts to replace eucalyptus in buffer zones with indigenous trees.

Although tea is on the "receiving end" of climate change, it also exacerbates it through deforestation. The common processing method of tea used in Kenya is the Cut Tear and Curl method, known as CTC. This involves the tea leaves going through a process of cutting, tearing, and curling, followed by oxidation and drying. The drying is often carried out using wood fuel due to the high price of electricity. Tea manufacturers are, however, gradually utilizing renewable energy alternatives such as electricity generation through micro-hydro plants to reduce energy costs and potentially generate further revenues by selling surplus electricity back to the national grid. Other mitigation measures include the use of biomass waste to power the water boiler systems. Gravity-powered ropeways are used by Finlay's, a multinational company, in some of its tea plantations. The KTDA also requires factories to acquire open land in order to plant seedlings and grow trees as a sustainable source of firewood. This saves money on the purchase of firewood or alternative fuels and could potentially generate revenues from carbon trading if the planted forests are managed sustainably. Varieties of tea other than Black CTC tea undergo a less emission-intensive process, as the wilting and CTC process are not required. Black CTC tea is manufactured by all 69 factories while only ten process black orthodox tea and four process other specialty tea.

Coffee Sector in Kenya

Kenyan coffee is grown on an estimated total area of 115,570 ha in 32 of 47 counties in the country. The sole type of coffee produced in the country is Arabica, which is planted during the rainy season from April to October with two harvest periods, April to June and October to December. Production is enabled by a combination of deep red volcanic soils, high altitude, rainfall, and moderate temperatures. The sole type of coffee grown in Kenya is Arabica. Coffee is grown in the high potential areas between 1,400 and 2,200 m above sea level, with temperature ranging from 15 °C to 24 °C, in red volcanic soils that are deep and well drained. Over 99% of Kenyan coffee is Arabica, whose main varieties are SL 28, SL 34, K7, Ruiru 11, Batian, and Blue Mountain (ICO 2019a). Coffee is an evergreen shrub and is therefore an important contributor to carbon sequestration, effective in stabilizing soils and permits the preservation of much of the original biodiversity in planted areas (ICO 2019b). The coffee sector contributes annually an average of US$230 million in foreign exchange earnings and is ranked as Kenya's fourth most important export, after horticulture, tourism, and tea. In 2018 coffee earnings amounted to Ksh. 14.8 billion. The value of coffee as a percentage of all export goods represented 5.5% in

2017, while its share of GDP was 0.22%. The coffee industry contributes an average of Ksh. 23 billion per year in foreign exchange earnings, ranking fourth after tourism, tea, and horticulture (ICO 2019a). Coffee is grown on 115,600 ha, 90,000 ha by smallholders and 25,000 ha by estates. Production was 41,400MT with 30,000MT from cooperatives and 11,000MT from estates (KNBS 2019). In 2017/18, the major importing countries of Kenyan coffee were Germany, the USA, Belgium, and the Republic of Korea, who imported about 58% of Kenya's coffee. Thirty-two of the 47 counties in Kenya are coffee producers (ICO 2019a).

Kenya has about 700,000 coffee farmers and about 99.63% have less than five acres. All coffee farmers with less than five acres are mandated to cooperative membership. There are between 500 coffee cooperatives (ICO 2019a) and 651 coffee cooperatives (KNBS 2019). Each coffee cooperative has factories where farmers deliver coffee berries for processing. At the factory, the coffee berries undergo pulping, which is a process of washing and drying, which results in "parchment." Parchment is then delivered to a coffee miller who further processes and grades the coffee, resulting in the "green" or "clean" coffee which is then sold by marketers at the Coffee Exchange through auctioning. Cooperatives also have the option of selling coffee directly to buyers without going through the auction. The Coffee Directorate is mandated to develop, promote, and regulate the coffee industry in Kenya. The Coffee Research Institute (CRI) conducts research in all areas of production, processing, and marketing of coffee. The global organization for coffee is the International Coffee Organization (ICO). It is comprised of member governments who represent 98% of world coffee production and 67% of world consumption. One of its objectives is to encourage members to develop a sustainable coffee sector in economic, social, and environmental terms (ICO 2019b).

Climate Change Challenges in the Coffee Sector

It is estimated that half the world's coffee-producing land will be unsuitable for coffee production by 2050 (Bunn et al. 2015; CIAT 2011). Other estimates indicate that the area unsuitable for production could be as high as 88% in Latin America (Worland 2018). Climate change caused by changing rainfall patterns and rising temperatures is affecting coffee production in several ways: directly through negative effects on the coffee plant and indirectly by altering the population dynamics and incidence of coffee pests and diseases (Jaramillo 2013). Rising temperatures will especially damage the Arabica bean, which accounts for about two-thirds of global coffee production, but whose production is limited to subtropical highlands in Brazil, Central America, and East Africa (Cameron 2017). This narrow region of the tropics is known as the coffee belt, and stretches from Central America to Sub-Saharan Africa to Asia (Worland, 2018). Rising temperatures will bring drought, increase the range of diseases, and kill large swaths of the insects that pollinate coffee plants (Worland 2018). Recent trends indicate that coffee growing is shifting from traditional optimal growing zones to higher altitudes. In traditional growing zones random flowering patterns and differences in berry growth stages has resulted in difficulties in disease and pest management, harvesting, and processing (Daily Nation 2012).

The effects of climate change in Kenya include unreliable and erratic rains with shorter seasons (ICO 2019b). Changing rainfall patterns affect the flowering of the coffee plants which impacts the whole production cycle. The altered flowering pattern with coffee berries at different stages of maturity poses a challenge in disease management, insect management, and harvesting (Ethical Tea Partnership 2011; Mugo 2016; Mwaura 2010). Extremely heavy rains lead to higher erosion levels, resulting in loss of soils, leaching of nutrients, and consequent soil infertility. On the other hand, the dynamics of incidence of coffee pests and their management are evolving rapidly due to changing climatic conditions. The changing environment is also posing challenges to patterns of cherry ripening and drying of parchment because of unpredictable rainfall patterns (ICO 2019b). Changing rainfall patterns cause uncertainty regarding the timing of fertilizer application and the drying of parchment. Most coffee growing zones in central Kenya, particularly Kiambu and Murang'a, are no longer suitable for the crop due to rising temperatures (Kamau 2017). Intermittent rainfall in the 2007/08 crop year caused a severe episode of Coffee Berry Disease that cut Kenyan output by 23% to 42,000 MT. This happened because farmers were not able to spray the crop on time (Mwaura 2010). Climate variability and its effects is however not a "new" problem, as evidenced by research shortly after Kenya's independence. This is illustrated by a 1969 journal article by Nutman and Roberts, titled "*Climatic conditions in relation to the spread of coffee berry disease since 1962 in the in the East Rift Districts of Kenya.*" (F.J. Nutman & F.M. Roberts 1969)

Adaptation and Mitigation Measures by Small-Scale Farmers in the Coffee Sector

The Coffee Directorate in collaboration with stakeholders provides capacity building to the counties' agricultural staff and other value chain players. The collaborating private agencies include Technoserve, Solidaridad, certification bodies such as UTZ, 4C, and Fairtrade, and management services providers. CRI develops technologies, releases new coffee varieties, and carries out research on disease and pest management, while the Ministry of Agriculture sets policy guidelines (ICO 2019b). The Coffee Research Foundation (currently CRI) started a program in 2012 to help farmers reverse the effects of global warming and boost coffee production. Farmer sensitization clinics were held and farmers were encouraged to plant indigenous trees to provide shade and to practice water harvesting (Daily Nation 2012). The CRI has made various recommendations on approaches toward environmentally sustainable coffee production systems. One approach is integrated farming, in which mulching, conservation agriculture, organic fertilizers, and use of bio-stimulants are recommended. Other measures include the use of suitable shade trees and the adjustment of spraying programs to cope with changing trends in the manifestation of coffee pests and diseases (ICO 2019a). Most Kenyan coffee is grown without shade, but shaded coffee is becoming increasingly popular in order to mitigate the effects of climate change, although quantifying the area under shade has not been done. Research is ongoing to determine the appropriate shade trees (ICO 2019a). Research shows that biodiverse shaded coffee is far more resilient and productive than coffee grown in monoculture. Shading coffee therefore improves the resilience of agro-ecosystems. Shade trees protect plants from microclimate variability, the effects of lower precipitation and reduced soil water availability, and reduce high solar radiation. It also improves soil fertility, protects coffee from insect pests, and provides economic benefits for farmers (Jaramillo 2013).

The need to develop disease-resistant coffee varieties was felt in early 1971 and breeding programs were initiated whose optimal outcome was the cultivar Ruiru 11 (Njoroge 1991). The CRI currently has developed two improved varieties of coffee – Ruiru11 and Batian. The improved varieties are resistant to Coffee Berry Disease and Leaf Rust Disease, thus lowering the use of agrochemicals and reducing production costs. The CRI estimated that the production cost of the traditional variety is four to five times more than Ruiru 11 and Batian. Over 300,000 farmers are estimated to have planted the new varieties (ICO 2019a). The traditional variety of coffee grown is SL-28. Other Arabica varieties include SL-34, K7, and Blue Mountain. A study of the coffee sector in Nyeri County showed that 50% of farmers in certified coffee cooperatives and 57% in the noncertified cooperatives had only the traditional SL variety of coffee on their farm. An additional 45% in the certified and 39 per in the noncertified had other varieties in addition to the SL (Okech 2019). It therefore means that less than 5% had the disease and drought resistant varieties exclusively on their farms. Incentives therefore need to be provided to encourage planting of new varieties, beyond the step of providing free seedlings.

The International Coffee Organization (ICO) has pilot projects in Africa and Latin America to address climate change by assisting coffee farmers use environmentally friendly technologies. These include building the capacity of institutions, improving access to credit and risk management mechanisms, reducing vulnerability to income volatility, and promoting gender equality. It also engages in long- and short-term adaptation strategies as well as mitigation strategies (ICO 2019b). Several organizations including private companies involved in coffee production and marketing have taken the lead in climate change adaptation and mitigation in the coffee sector. The World Coffee Research (WCR), a consortium supported by major coffee retailers, distributors, and exporters, has an $18 million coffee-monitoring program that covers 1,100 farms in 20 countries including Kenya. It conducts farmer training, provides technical assistance, and is testing coffee varieties and adaptive farming methods (Worland 2018). Since 2013 Starbucks has support centers in nine countries and a 10-year, $500 million investment fund that supports sustainability programs, including adaptation training for farmers and the testing of new coffee varieties (Worland 2018). Sangana Commodities Ltd and GIZ implemented a three-year project creating a link between coffee smallholders and carbon markets, and developing a verifiable and voluntary climate change module, which can be integrated into the existing 4C's standard (ETP 2011).

Sustainability standards in the coffee sector are geared toward sustainable agricultural practices, which include adaptation and mitigation measures. Certification in the coffee sector is, however, not as extensive as in the tea sector. In Nyeri County, which is a leading coffee producer, Fairtrade was the most common certification with at least 12 of the 23 cooperatives having received this certification. The earliest reported Fairtrade certification in the cooperatives was from 2006. At least seven cooperatives had obtained Rainforest Alliance certification and four had acquired 4C certification. Benefits of certification included payment of premiums and improved quality and quantity of coffee. Challenges included difficulty of maintaining certification as it was involving and expensive. This is illustrated by the example of an estimated Ksh. 400,000 for certification and renewal, with additional costs of up to Ksh. 1,000,000. Enforcing requirements as well as nonconformity to requirements was also costly. Certification organizations also did not source for markets and the cooperatives therefore used the conventional marketing channels, which were viewed as opaque (Okech 2019).

Recommendations and Conclusion

Tea and coffee are essential to farmers and other Kenyans as a source of livelihood, to the government as a contributor to GDP and foreign exchange and to the commodity chain players such as marketers and retailers. Tea and coffee also contribute significantly to climate change mitigation. Climate change, however, threatens to disrupt the production of these crops and by extension the economy of Kenya and the livelihoods of those who depend on it. Continued and increased uptake of climate adaptation and mitigation measures is critical for the sustainable farming of tea and coffee. Climate change can worsen the socioeconomic condition of farmers and conversely fragile socioeconomic conditions can exacerbate climate change. Various measures can be taken to increase the adaptive capacity of small-scale tea and coffee farmers.

Farmer Empowerment

Farmers are rational economic actors and farming has to be profitable for adaptation and mitigation measures to be implemented. Climate adaptation and mitigation activities such as uptake of improved crop varieties are carried out in view of perceived economic benefits and particularly for the most vulnerable, in view of immediate economic benefits. Activities such as the adaptation of improved crop varieties can be neglected due to small land size and the resultant “lost” while the new variety matures to the point of harvest. Other measures such as water harvesting may require capital expenditures whereby the capital is either unavailable or the returns to investment are deemed uneconomical. Interventions that deal with commodity chain weaknesses that reduce profitability are critical. Profitability of farming is the largest incentive to adopting sustainable agricultural practices. Increasing the adaptive capacity of tea farmers therefore requires farmers' economic empowerment. It is essential that stakeholders provide incentives for the implementation of measures whose returns are long-term or not tangible. This could include measures such as insurance for climate-related crop losses and a minimum guaranteed price per kilogram. Farmers also need to be politically empowered as decisions in farmer organizations are often made by elected representatives. Civic awareness is therefore an integral component of farmer empowerment. Social empowerment majorly revolves around gender. Men predominantly own land but women provide 60% of the labor on the farms and in the wet mills (ICO 2019b). Women therefore need to be major actors in activities involving climate change adaptation and mitigation. When they are not empowered, especially in terms of access to resources, various adaption and mitigation activities may not be implemented.

Strengthening of Institutions

The common features of the tea and coffee sector in Kenya is that both are cash crops, grown majorly for export and production is predominantly by small-scale farmers. Profitable production therefore requires that farmers organize so as to share costs. In the tea sector, the KTDA is the primary agency through which farmers produce process and market their tea. In the coffee sector, coffee cooperatives are the primary and mandated vehicle for production, marketing, and processing. However, there are coffee farmers with more than five acres who choose to remain in cooperatives due to economies of scale. Institutional capacity therefore has a large influence on farmers' activities, including those related to climate change adaption and mitigation. Lack of institutional capacity in farmer-owned organizations or institutions that support farmers can reduce productivity and profits and therefore constrain farmers' adaptive capacity. The average age of tea and coffee farmers is over 50 years and this further constrains the availability of alternative livelihoods. Unlike the tea sector where almost all small-scale tea farmers operate within the institutional structure of KTDA, coffee cooperatives are not homogeneous. For example, coffee payments for the 2017/18 year varied from Ksh. 9 to Ksh. 105/kg of coffee cherry (exchange rate in this period was approximately one USD to Ksh. 100–103). While there are climatic and soil-type differences, the differing payments were also within the same region. In Nyeri County, which is a leading coffee producer, the payment range was between Ksh. 12.75 and Ksh. 105. This points to institutional constraints at the cooperative level, although constraints occur across the coffee commodity chain. The challenges facing the coffee sector are well documented. Toward this end, a Coffee Taskforce was created to investigate the challenges and make recommendations for sectoral improvement. The tea sector has also encountered various institutional challenges. In January 2020, the president directed that the KTDA be restructured for the benefit of tea farmers (Cheruiyot 2020). The organizations that farmers engage in and the institutions within which they operate can either facilitate or constrain the activities of farmers, including those pertaining to climate change adaptation and mitigation.

Collaborations and Partnerships

Climate change adaptation and mitigation requires the long-term involvement of all actors in the commodity chain including the consumers. Stakeholder mapping is necessary, whereby a list of relevant groups, organizations, and people who can collaborate in climate change adaptation and mitigation can be invited to collaborate towards these measures. These stakeholders include the International Coffee Organization, the Tea and Coffee directorates, agricultural institutions and departments, producer organizations, certification organizations, technical support providers, financial institutions, and supply chain actors including processors, marketers, and retailers. Research, information, and best practices on sustainable agricultural practices and on measures to streamline the commodity chain can be enhanced and widely adopted through collaboration.

Certification

The 2017 SAN Standard aims to support farmers in advancing sustainable livelihoods, improving farm productivity, and becoming more resilient to climate change. Changes of note include climate-smart agricultural practices. These are built into the standard to help farmers address climate change risks. The effect of irregular rainfall, changing temperatures, and related increased pest and disease attacks can be reduced through soil conservation, water-use efficiency, and the conservation and restoration of natural ecosystems. The Standard is built on principles of sustainable farming including biodiversity conservation, improved livelihoods and human well-being, natural resource conservation, effective planning, and farm management systems (Rainforest Alliance 2019). The SAN Climate Module is an add-on for voluntary verification within the existing Sustainable Agriculture Network certification system. Farmers who achieve compliance with the module will be able to assess the risks posed by climate change to their farms and communities, analyze their practices to quantify and reduce GHG emissions, and increase the carbon levels stored on their farms through the restoration of degraded lands, reforestation, and improved soil conservation while also being able to better adapt to altered growing seasons and other conditions (Sustainable Agriculture Network 2011).

Fairtrade aims to help farmers become more resilient to climate change while giving consumers, retailers, and traders the opportunity to reduce their carbon footprint. Farmers can spend the Fairtrade Premium on climate change adaptation projects such as tree planting, irrigation, crop diversification, and clean energy. Farming communities can also benefit from access to carbon finance, which can be used in mitigation or adaptation activities (Fairtrade International 2015). While certification has numerous benefits, acquiring and maintaining of certification by coffee cooperatives and estates requires the collaboration and financial support of stakeholders.

Rainforest Alliance and Fairtrade are the major certification bodies in the coffee and tea sector in Kenya. Majority of the small-scale tea farmers in Kenya comply with the SAN Standard and have received Rainforest Alliance. This extensive certification can be largely attributed to the institutional arrangement of the tea sector. KTDA acts as the management agent for 69 factories, which comprise the vast majority of small-scale tea farmers in Kenya. In the coffee sector, however, more than 700,000 farmers are members of an estimated 500–650 coffee cooperatives. Certification depends on various factors including membership numbers, productivity levels, number of factories, cooperative leadership, and relationships with a multiplicity of commodity chain actors. While some cooperatives are certified by multiple certification bodies, others do not comply with any sustainability standard. Certification ensures the implementation of climate change adaptation and mitigation measures. Acquiring and complying with sustainability standards is therefore key for small-scale farmers.

3 Adaptive Capacity to Mitigate Climate Variability and Food Insecurity of Rural Communities Along River Tana Basin, Kenya

David Karienye and Joseph Macharia

Contents

Abstract

Climate variability is one of the leading natural threats and a root cause of food insecurity in the developing world, more so in Africa. It is a major impediment to the accomplishment of the global Sustainable Development Goals (SDGs), Vision 2030 and Big Four agenda in the Kenyan context. The rise in occurrence and brutality of extreme events resulting from variability of climate including prolonged flooding and drought has become more pronounced in the relatively

drier areas. This chapter presents a synthesis about rural communities in Garissa and Tana River Counties, Kenya. The key environmental conditions that face the rural communities in the two counties are prolonged drought and recurrent flooding events. The two conditions have resulted in various challenges facing the communities in these regions through low agricultural production (food and pastures), poor infrastructure, human displacement, and the resultant extreme poverty, overall food insecurity, and tough livelihoods. The problems have been exacerbated by lack of capacity by most of the community members to cushion themselves against these impacts. However, as the conditions continue to manifest themselves, the community members have also identified adaptive mechanisms that are best suited in the region including planting drought-resistant crop varieties, diversifying their livelihoods, embrace sustainable land use, and made efforts to plant trees. We, therefore, conclude that integrated information sharing including early warning alongside affordable and appropriate technologies and crop insurance could be an entry point in cushioning the local communities in the arid and semiarid lands (ASALs) against the extreme weather conditions experienced in the region.

Adaptive capacity · Africa · Climate variability · Food insecurity · Mitigation · Rural livelihoods

Introduction

Climate variability has been on the rise due to increased global atmospheric greenhouse gas emissions (GHG) comprising mainly of nitrous oxide, carbon dioxide, and methane (IPCC 2014). Carbon dioxide is the key GHG, while as much as methane and nitrous oxide are emitted in trivial quantities in reference to carbon dioxide, they play a significant role in global warming and their associated global effects. For example, N_2O, a potent gas with a high potential to deplete ozone layer, is over 265 more powerful while CH_4 is 28 more powerful in their global warming potential relative to carbon dioxide, over 100 years' time limit (IPCC 2014). These three main GHGs accounts more than 80% to the present global radiative imposing to enhanced global warming and consequently climate variability and its negative resultant effects (Myhre et al. 2013).

Climate variability characterizes one of the extreme economic, environmental, and social intimidations facing the earth presently (Nnadi et al. 2019). In emerging countries, climate variability has a substantial influence on the livelihoods and living situations of the rural communities. Sub-Saharan Africa (SSA) is a “vulnerability hot spot” of climate variability influences (Asfaw et al. 2018). SSA challenges on adaptation will raise considerably, even if the global emission gap is maintained lower than 2 °C due to limited adaptive capacity. The IPCC's Fourth Assessment (AR4) demonstrated that Africa's vulnerability to the effects of climate variability is relatively high due to low adaptive capacity and over-reliance on natural systems for their livelihoods (Mpandeli et al. 2019). Extreme occurrence of droughts is likely to become more rampant and severe in Africa (Schellnhuber et al. 2012). Consequently, climate variability is negatively affecting agricultural production, particularly in SSA where most countries rely heavily on rainfed agriculture as the mainstay of their economies (Abdul-Razak and Kruse 2017). Climate variability related to biophysical stressors is expected to worsen the existing vulnerabilities by dipping the crop yields (González-Orozco et al. 2020).

It is postulated that warming more than 3 °C worldwide will see almost all of the current crops such as maize, sorghum, and millet-cultivated regions in Africa becoming unfeasible for present cultivars. Water unavailability, lower feed quality which is inaccessible, and effects of disease and heat stress will negatively affect production in the livestock sector (Schaeffer et al. 2013). According to Huq et al. (2004), climate variability has a direct impact on how humans manage natural resources and which results in food insecurity. The risks associated with climate variability threaten the capacity of livelihoods to meet basic needs, such as food and water. These effects will be more intense in the arid and semiarid lands (ASALs) where the resources are already limited, vulnerable, and could, therefore, suffer the most.

To mitigate climate variability, community adaptive capacity must be pursued. According to Levina and Tirpak (2006), the term adaptive capacity has been defined differently by different authors. Different authors have explained the concept of adaptive capacity to simply mean the capacity of a natural system to positively respond to the impacts of climate variability. Policymaker also use the term adaptive capacity to refer to the ability of individual communities to respond and adjust their way of life based on the effects of climate variability and lead to adaptation. Therefore, whenever we use adaptive capacity, society and communities must come up with coping strategies especially when dealing with impacts of climate variability in order to minimize its adverse effects.

Communities living in SSA are facing climate variability in a very tough way due to their lack of capacity to respond. The influences include increasing temperatures, more inconsistent rainfall, and increasing incidence of floods and droughts (CARE and ALP 2013). These impacts have severe consequences especially among the rural poor whose livelihoods are directly pegged on the very vulnerable environment. These communities heavily depend on land resources for agricultural production and therefore the impacts of climate variability have a direct impact on their livelihoods. Crop yields will decline transversely in the landmass as ideal growing temperatures are surpassed and growing periods reduced. The areas and timing of cropping activities that were previously suitable for certain crop are anticipated to shift as home-grown climates varies.

In Kenya, the adverse effects of climate variability have also been witnessed particularly in the ASALs which forms ~80% of Kenyan land mass (582,646 km^2) (Macharia et al. 2020). The main effects of climate variability in Kenya have been demonstrated by prolonged and frequent droughts, floods, resurgence of diseases, pests, and environmental disasters. As a result, agricultural productivity is significantly reduced, resulting to increased food insecurity and threatened livelihoods which in most instances leads to human conflicts over scarce land and water resources (Enya et al. 2013). For instance, the *La* Nina occurring between 1999 and 2001 in SSA was the most prolonged and most severe ever, causing devastating effects especially on human livelihoods. The drought affected over four million people due to crop failure and the resultant reduced yields. Droughts have caused starvation, loss of life, and degradation of the environment as a result of deforestation.

Variability in climate poses major threats to environmental sustenance, commercial, and sustainable development in rural areas of the arid regions of Kenya. In particular, the ASAL region of Garissa and Tana River County has been experiencing severe prolonged drought and flooding despite having River Tana traversing the region. This has led to loss of vegetation cover, drying of water catchment areas, rivers, and seasonal streams. This is then followed by heavy lack of pastures and shortage of drinking water resulting to livestock deaths. Recently, in short rains of 2018/2019, Garissa and Tana River counties experienced floods which caused severe havoc resulting to over 50 fatalities, over 15,000 people displaced, and thousands of livestock killed as a result of bursting of River Tana's banks. In addition, extreme weather events such as flooding has spoiled or destroyed transport and communication networks and affected other nonagricultural portions of the food system badly. This has led the communities to seek alternative ways of meeting their livelihoods such as charcoal burning hence environmental degradation resulting to double tragedy from the loss of their only source of livelihood and land degradation. Against this backdrop, this study aimed to close the gap by identifying possible adaptive capacity of the vulnerable communities in the region for the purpose of coping mechanism. This study was conceived to explore the existing adaptive capacity which is sustainable and viable and which the communities would easily embrace to act as adoptive buffer towards the impacts of climate variability in Garissa and Tana River Counties.

Impacts of Climate Variability

Key among the impacts of climate variability includes the following.

(a) **Drought**

Drought is a major threat globally and more so in Africa due to low adaptation capacity resulting from limited resources. Drought results in decreased moisture emanating from inadequate and erratic rainfall and high extreme temperatures. As observed by Keya (1997), moisture storage is largely dependent on rainfall received prior to the onset of drought conditions and the permeability of the soil (micro edaphic conditions). Drought has led to loss of pasture for the livestock as well as wildlife, vegetation loss, and food insecurity. This threatens the source of livelihoods of local communities in the arid lands.

(b) **Loss of biodiversity**

Ecosystem varieties will hypothetically change rapidly as heating increases with reduced precipitation, and will result to biodiversity loss. Some species may be impotent to adapt to the varying climatic conditions (Schaeffer et al. 2013).

High temperatures and lack of precipitation affects distribution and abundance of fauna and flora species. Substantial shifts in climatic situations could result to loss of some standing biomes and the general aesthetic appeal of our environment (Williams et al. 2007). In some instances, the changes in climate may favor the growth of invasive plant species hindering the alien species such as *Prosopis Juliflora* “Mathenge” a common plant in the northern Kenya.

(c) **Food insecurity**

Extreme temperatures above the ideal may have harmful consequences on crop productivity (Wheeler et al. 2000). These changes have a significant effect on the facets of food security since they negatively affect food availability, access, and utilization resulting to unstable and unreliable food systems. Kenya may experience reduced yields with the changing climate (Herrero et al. 2010). Crop yields are drastically reducing in SSA as the optimal temperature increases altering cropping and seasonal calendars (Schaeffer et al. 2013). In Africa and to a large extent, the ASALs region of East African such as Sudan, Ethiopia, and Kenya have in the past experienced hostile climate change. This has hampered crop production leading to acute shortage of food, pastures, and fibers, hence food insecurity. According to Lobell et al. (2011), yields are likely to diminish by ~1% daily for maize crops if such high-temperature regimes are consistent similar with other crops such as cotton and soybeans (Schlenker and Roberts 2009). Similarly, livestock production will be severely affected through quality feed and water availability (Schaeffer et al. 2013).

(d) **Human health and diseases outbreak**

Water availability and increased rates of disease outbreak are transformed by climate change (Schaeffer et al. 2013). The impacts of climate variability will be felt through increased infectious diseases which are relatively high in SSA. Extreme weather events may lead to illness and mortality. The level of malfunction may also be on the rise up to between 35% and 80% due to a rise of between 1.2 °C and 1.9 °C (Lloyd et al. 2011). As reported by Patz et al. (2008), flooding results to disease outbreaks including diarrhea, cholera, trachoma, and conjunctivitis. Other diseases like malaria may shift and be felt to areas where they were not felt before due to changes in temperature suitability responsible for pathogen growth.

(e) **Water resources**

Change in the hydrological sequence due to climate variability has a direct impact on water timing and circulation (Goulden et al. 2009). With most of the countries in SSA facing challenges with provision and supply of clean usable water, climate change will exacerbate this and lead to more water shortages in the coming years (Schellnhuber et al. 2012). The resultant effect will be increased disease outbreaks due to poor sanitation, low agricultural production, food insecurity, and general influence on livelihoods. Rise in temperature due to global warming would lead to a complex rate of evapotranspiration leading to increased loss from water bodies (Ogolla et al. 1997).

(f) **Land degradation**

Population increase combined climate variability impedes good resource management leading to environmental degradation (UNEP 2002b). Climate variability is slowly encroaching and engulfing countries thus rendering their land unproductive due to variations in weather patterns and global warming. As human population grows further, the natural distribution of vegetation on earth will be altered. This leads to opening new land for agriculture and cultivation of marginal areas (UNEP 2002a). This has led to loss of natural habitats, reducing vegetation cover and exposing soils to wind and water erosion in many parts of Africa. Soil erosion has increased the rate of siltation in dams and rivers and at the same time reducing the productivity of the land.

Adaptive Capacity to Mitigate Climate Variability Impacts

Adaptive capacity calls for strategies to help the communities to adapt to these extreme events such as drought and flooding. Adaptation simply means adjustments made in the existing systems as a response mechanism toward countering the effects of climate variability by the communities and individuals involved. These adjustments are mainly meant to act as a buffer and to assure proper exploitation of the new opportunities that minimize harm and as they present themselves. Therefore understanding the adaptive capacity by farmers is crucial to effective adaptation planning since it assures continuous production crucial to effective planning and guarantees human survival (Chepkoech et al. 2020). With the projected increase in global temperature, likely to result to increase in global warming, it's thus inevitable for individuals and communities to find adaptive ways which guarantees their survival. Adaptive measures toward climate change are no longer regarded as second measured but should be taken as primary consideration especially by farmers. However, the adaptation capacity in most African countries is low mainly due to lack of capacity to invest in the recent technologies which have been studied and found to promote better survival and livelihoods. Majority of agriculture in SSA is rainfed with only a very small percentage of farmers with a capacity to carry out irrigation which makes it difficult to predict due to climate variability. Further, the challenges are associated with lack of reliable weather data to inform on policy, and therefore most of the countries lack early warning systems that can be used early enough to caution the governments of possible climate-related calamities.

Impacts and Adaptation Strategies to Climate Variability in Arid and Semiarid Lands: A Case of Garissa and Tana River Counties in Kenya

Rainfall and Temperature Impacts on Food Security

From a data synthesis on annual rainfall and temperature over a period of 20 years for Garissa and Tana River counties indicate that rainfall was characterized with extended dry season occurring between January and February. The long rainy season occurs between March and May (MAM) while prolonged dry season occurs from

Fig. 1 Reduced River Tana flow during the month of October. (Courtesy of D. Karienye)

mid-May to mid-October, while short rainy season begins in mid-October to end of December of each year. There are fewer days of more intense rainfall with the rains often starting late but intense which are described as "very unreliable" (that is seasonal failures are common).

Similarly, for temperatures, the highest temperature amounts were observed between February and March, which coincides with the same time when rainfall is lowest in the study area. Around September–October, the temperatures are also at highest. Temperature increase has an important impact on water availability, thus aggravating drought conditions. Decreases in rainfall have profound repercussions on river flows leading to declining river discharge (Fig. 1). The months that saw an increased rise in temperature also experienced drought. This can be explained by the high evapotranspiration making the vegetation deficient of moisture leading to crop and pasture failure.

However, in trying to escape the droughts, the few well-endowed farmers practiced drip irrigation and greenhouse farming as indicated in Fig. 2. This ensured a reduction in the impact of droughts. This low number of farmers adopting new farming mechanisms, and which is a shift from rainfed agricultural production can be explained by the high cost of the greenhouses' infrastructures. This represents an innovative technology in response to the changing weather patterns though the adoption rates remain relatively low due to high cost.

Community Perception on Climate Variability and Its Impacts

From the interaction with the community, majority of the households were extremely worried about climate variability and identified rainfall to be very unpredictable

Fig. 2 Farmers practicing greenhouses and drip irrigation. (Courtesy of D. Karienye)

Fig. 3 Land degradation through charcoal burning. (Courtesy of D. Karienye)

stating that there exists a consistently prolonged dry period every now and then. Nevertheless, farmers believe that temperatures have already increased and precipitation has declined or is unpredictable (Karienye et al. 2019).

The impact of climate variability has been felt mainly by reduced crop production, extreme cases of flooding, and land degradation as evident by charcoal burning (Fig. 3) and reduced biodiversity. The reduced precipitation coupled with flooding leads to crop failure which destroys the crops that are grown along River Tana. Floods have in the past been responsible for causing disruption in transport systems and displaced residents living in the low-land areas which are prone to flooding (CARE and ALP 2013).

Fig. 4 Community-based agro forestry programs. (Courtesy of J. Macharia)

Adaptations Strategies to Climate Variability in Arid and Semiarid Land

Based on their own experiences and from sharing information among themselves, most of the households in these ASALS of Kenya have identified several adaptive strategies to cushion them against the extreme conditions. The communities preferred livelihood diversification (business, cropping, and livestock) as an alternative livelihood option, sustainable use of the land including conservation agriculture, mulching, building trenches and ditches around the homesteads and watering crops using cans during dry spell. They have also adopted drought-tolerant and early maturing crop species, changing eating behaviors and afforestation (Fig. 4).

Conclusions

From our synthesis, the rainy seasons are no longer predictable thereby prohibiting any farming activities. The impacts of climate variability in the ASALs are mainly through extreme conditions of drought and flooding. The two conditions have resulted to various challenges facing the communities in these regions through low agricultural production (food and pastures), poor infrastructure, population displacement resulting to extreme poverty, overall food insecurity, and tough livelihoods. These challenges are exacerbated further by the inability of the majority of the communities to cushion themselves against the impacts of climate variability and this becomes a cyclic problem year in year out. The better-endowed community members have invested in greenhouses and drip irrigations to ensure continuous supply of food particularly for their domestic consumptions. However, efforts by the local communities have been identified where they have, through experience over time, resulted to planting drought-resistant crop varieties, diversified their livelihoods, embraced sustainable land use, and made efforts to plant trees. It's imperative to note that well-informed, adaptive, and forward-looking decision making is central to adaptive capacity of the host communities. In order for community to respond to expected changes and to participate in adaptive decision-making, they require precise information, knowledge and skills that enable them to actively address climate risks to their livelihoods. Therefore, adaptation energies must aim to ease access to information and the development of the skills and knowledge needed for accurate adaptation targeting. Institutions and agencies responsible for policy formulation should ensure an enabling atmosphere for local adaptation efforts.

Recommendations

In order to embrace the adaptive capacity as long-term practical solutions, the following are recommended:

- Monitoring daily weather patterns and improving scientific understanding of climate.
- The community needs to be trained on affordable and appropriate technologies such as sustainable agriculture.
- Promotion of climate-smart crops farming.
- Promotion of insurance services against the consequences of catastrophic weather events to mitigate against climate variability.
- Provision of early warning systems to the communities.
- There is a need to build community-based capacities in planning, coordination, and implementation of climate change adaptation activities and programs.
- Intensification of tree planting through community-owned nurseries, establish green zones, and invest in reforestation programs.

Abstract

Agricultural intensification worldwide is increasingly relying on a narrow range of crops such as rice, wheat, and maize. The reliability on this relatively small numbers of food diversities raises a very serious concern about the sustainability managing our nutrition today and in the future. We conducted a scoping review using online databases to identify various agricultural interventions that can be utilized for enhancement of underutilized root and tuber crops adaptability under the current observable effects of climate change. This is because reports of underutilized crops' adaptability to climate change continues to remain anecdotal with limited research capacity to support them. The results mooted a wide range of crop production techniques that can be utilized in production of root and tuber crops. They includes biofertilizers, tied ridging method, improved seed varieties, management of community seed banks, cropping systems, irrigation methods, exploiting abandoned lands, agroforestry practice, clean seed production technologies, and nutrient use efficiency. Based on the findings, each of these interventions plays different roles in management of the negative impacts brought up by climate change and thus they would be useful when adopted in combination since package adoption would enable farmers to benefit from the positive synergy of the selected interventions. The interventions are therefore recommended not only for sustainability but also for profitable production to meet feed, food, energy, and fiber needs and foster economic growth in the ever changing world. Therefore this chapter contributes immensely towards the development of innovative mechanisms for strengthening the resilience of root and tuber crop.

Keywords

Agricultural intensification · Sustainability · Adaptability

Introduction

The root and tuber crops are group of plants which yields tubers, starchy roots, corms, stems, and rhizomes. Okigbo (1989) defined while tuber crops as crops with edible carbohydrate-rich storage organs developing wholly or partly from underground stems while root crops as edible crops with energy-rich underground plant structures developing from modified roots. Major tropical root and tuber crops are: cassava (*Manihot esculenta*); potato (*Solanum spp*.); sweet potato (*Ipomea batata*); yam (*Dioscorea spp*.); aroids like elephant foot yam [*Amorphophallus paeoniifolius* (Dennst.) Nicolson]; taro [*Colocasia esculenta* (L.) Schott.], and tannia [*Xanthosoma sagittifolium* (L.) Schott.]. Additionally, there are minor tubers such as Chinese potato [*Plectranthus rotundifolius* (Poir.) J.K. Morton.]; yam bean [(*Pachyrhizus erosus* (L.) Urban], and arrowroot [*Maranta arundinacea* (L.)]. These crops are vegetatively propagated and plays major roles in food sector especially by managing the well-being of people in developing countries. According to FAO (2009), these crops are produced in approximately 53.93 million hectares globally and this produce about 736.747million tonnes annually.

In Sub-Saharan Africa (SSA), many people highly depend on root and tuber crops but not all as a contributory if not the primary source of their food and nutrition. This is also because of the role they play in food security, their ability to resist drought, as well as their capacity for commercial processing in Kenya. Actually they were ranked as the second most important food crop in 2019 by the ministry of agriculture after cereals (MoALF 2019). At the moment, the Kenya is producing 3.68 M MT of Irish potatoes, cassava, sweet potatoes, yam, and cocoyams. However, their yield is below average which is much way below country's potential. For instance Irish potatoes stands at 7MT per ha compared to the potential of 25 MT achieved under optimal husbandry practices (MoALF 2019).

Root and tuber crops are considered to be resilient because they are more adaptable to marginal areas. This areas are characterized by edaphic and climatic conditions that may not be favorable to the non-native materials. These crops are tolerant to poor soils and drought stress. They also grow very well on well-drained soils, with good organic matter, and especially those with loose and friable fertile clay loam or loam. Moreover, the optimal conditions for their growth are: annual rainfall ranging between 1000 and 2000 mm, temperature of 18–35 °C, and a soil pH ranging between 5 and 7.5. Nevertheless their planting differs from another case in point Coleus potato, tuberous rhizomes, or seed tubers are normally planted about 5 cm in depth on raised beds and are spaced at 15–20 cm while in Amora; they are planted at about 15 cm deep and a distance of 30–40 cm (Codd 1985).

These crops are also well known to serve as important components of subsistence farming system in their native areas and have played crucial, if not weighty roles income generation and in household food security of the rural areas. As food crops these crops are very rich in carbohydrates and on that account they play a paramount role as part of our daily diet, accounting for over 50% of the total staple food. In terms of energy requirements for global population, they contribute 3.9% energy that is sweet potato 1.5%, cassava 1.9%, yams and other root and tuber crops 0.3%. Along with this potatoes produce additional protein and dry matter per hectare than key cereals (Birch et al. 2012). Monneveux et al. (2013) also reported that potatoes have higher water generative capacity than cereals and are considered among the most energy productive crops, producing 5,600 kcal/m^3 of water, compared to 3860 in maize, 2300 in wheat, and 2000 in rice. Other root and tuber crops such as taro, yautia, and yam, also have notable energy values and inconsistent nutritional properties, including vitamin C, dietary fiber, and carotenoids (Asiedu and Sartie 2010). At the same time these crop plays a meaningful role as cash crops. They literally hold strong economic potential and can be financially rewarding to the agricultural economies. Finally these crops are progressively being used as a source of raw material for industrial use and for feeding the livestock. In comparison to other staple food crops, they provide comparatively huge amounts of nutrition and energy per unit area and time, they require less-intensive management systems even under risky environmental conditions. Consequently, these crops are very important in fighting famine caused by floods, droughts, civil strife, and other climatic catastrophe such as pests and diseases which seems to be unending in some countries.

Climate change is a menace posing extreme stress to the environment and also to the humans. Deschenes and Greenstone (2006) reported that it has an adverse effect on humans and their income-generating activities especially agriculture owing to its dependence on nature, largely temperature and precipitation. In addition climate change influences soil functions both directly and indirectly. The direct influence include soil process, namely, changes in organic matter and nutrient cycling and this is through adjusting temperature and moisture regimes or through increased soil erosion rates caused by increased frequency of intense rainfall occurrence. This causes severely effects on agriculture especially on the crops being grown. As a matter of fact, Africa is one of the riskiest continents to the ongoing climate variability causing robust negative economic impacts. This vulnerability is accentuated by development challenges specifically ecosystem degradation and endemic poverty which are supported by limited access to capital, infrastructure, markets, and technology (IPCC 2007).

Small-scale farmers in sub-Saharan Africa, who are the majority, have historically been confronted with high climate variability. Some of its negative effects on farm include decreased soil fertility and limited plant growth (Dhankher and Foyer 2018). Despite smallholder farming systems having proven to be resilient and being viable in risk-prone environments, climate change is likely to outpace their current coping capabilities (Morton 2007), if effective measures are not implemented. Specifically, low levels of income and technology, coupled with isolation from markets and lack of institutional support, are common characteristics of smallholder farming systems that make them particularly vulnerable to changes in external conditions (Morton 2007). This is worsened by the fact that food security and livelihood programs mostly stress on grain crops such as maize, rice, and wheat. In support of this, Atakos (2018) reported that only one or two studies have looked into the future potential of root tuber crops and their possible importance even with climate change. Our dependence on this relatively small number of food species therefore elevates serious concerns of feeding the whole world sustainably. In such context, investment in sustainable agricultural technologies and practices becomes crucial for adaption to sustain crop productivity to be able to feed the growing populations. In particular to able to reduce the negative effects of climate change on the agri-food system, Sombroek and Gommes (1997) proposed that populations and economic systems must be able adapt to future climatic conditions.

Since root and tuber crops play a great role as source of nutrition, and on the other hand, researchers are advocating for mitigation and adaptation as possible options to combat the adverse effects of climate change on agriculture, this chapter therefore focus on agricultural interventions that can enhance climate change adaptation of underutilized root and tuber crops.

Major Roots and Tuber Crops

Cassava

Cassava (*Manihot esculenta*) is a perennial woody shrub which grows as an annual crop. It is also referred as manioc, mandioca, or yuca, which is in the spurge family (Euphorbiaceae) (Hillocks et al. 2002). This crop is also known as the "king of tropical tuber crops" and has a significant position in the global agricultural economies. According Bennett (2015), the crop is ranked as the second most important food source in Africa with regard to calories consumed per capita. Cassava is native to South America (Allem 2002) but it is grown all over tropics and subtropics. It is largely produced in Brazil followed by Thailand, Nigeria, DR Congo, and Indonesia, even though about half of the global production is in Africa. The crop is grown in about forty African countries where it is recognized as an important food crop particularly in Nigeria, DR Congo, Ghana, Mozambique, Uganda, Cameroon, Madagascar, Angola, Côte d'Ivoire, Tanzania, Benin, and Kenya. FAO 2000 revealed that about 70% of Africa's cassava production is obtained in Nigeria, Tanzania, and DR. Congo.

It has been proposed that cassava could potentially be hardy to climate change than other staple crops (Jarvis et al. 2012). Likewise Nweke et al. (2002) revealed that cassava can grow well in marginal lands, and that it requires low farm inputs. The average cassava root yield is about 11.6 t/h worldwide (FAO 2018) which is exceedingly lower than its potential yield of 60 t/ha under better farming practices which was reported in some parts of Africa (Kintché et al. 2017). Even though FAOSTAT (2014) reported that world production of cassava storage roots improved tremendously from 176 to 277 million Mg between 2000 and 2013. Major limiting factors for cassava production are low soil fertility and pests and diseases.

Sweet Potatoes

Sweet potato (*Ipomoea batatas* (L.) Lam) is a herbaceous dicotyledonous plant belonging to Convolvulaceae family (Purseglove 1972). The plant has creeping, perennial vines and adventitious roots (Purseglove 1972). It is grown for its green leaves and storage roots which are very useful for human consumption, feeding animal, and to a certain extent, for industrial purpose (Woolfe 1992). For that reasons, according to Motsa et al. (2015), the crop plays a critical role for food security and income generation for many households. Consequently, the crop is extensively cultivated in tropical, subtropical, and frost-free temperate climatic areas of the world (Onwueme and Sinha 1991).

Sweet potato is ranked as the seventh most important food crop globally because it contributes majorly in terms of energy and nutrition (Marques 2015). The crop also matures at a very short time on marginal lands and play an important role in the economy of poor households (Nath et al. 2007). As stated by Ukom et al. (2009), the crop is important for its storage roots which can either be baked, cooked, fried, or roasted for human consumption. Its storage roots can also be processed into flour for baking bread, making noodles, as well as for alcohol production. In addition, the storage roots are very good source of vitamin A, vitamin C, vitamin B6, dietary fiber, manganese, copper, potassium, and iron (Baybutt et al. 2000). Even though the crop has a high storage root yield potential ranging between 20 and 50 t/ha (Kivuva et al. 2014), in Sub-Saharan Africa, this is yet to be realized since its production is still less than 10 t/ha (FAOSTAT 2017).

Yam

Yams (*Dioscorea spp*.) are tropical plants with large food reserve in their underground tubers and comprise of various species that originated from Southeast Asia, West Africa, East Africa, Brazil, and Guyana. The main species are *Dioscorea alata* (greater or water yam), *Dioscorea cayenensis* (yellow guinea yam), *Dioscorea esculenta* (lesser yam), and *Dioscorea rotundata* (white guinea yam) (Arnau et al. 2010), and this comprises both annual and perennial species. They cultivated all over the tropics and in some parts of subtropics and temperate areas. FAO (2000) reported that up to 95% of the world's production is realized in West Africa.

The tubers are very important and constitute stored wealth since they can be sold all-year-round by farmers because they can be stored for relatively longer period of time in comparison with other tropical fresh produce (Aidoo 2009). The tubers also provide a substantial amount of vitamins (vitamin B1 and C), potassium, and iron (Rudrappa 2013). Most essentially many of the yam species have high content of steroidal saponins which make them suitable for industrial use as corticosteroids precursors and anti-cancer bioactive compounds. Besides being staple food that is consumed by about 155 million people in the world, yams are grown as cash crop, as medicinal plant, and have high cultural value for the groups cultivating it (Coursey 1981).

Major hindrance for intensifying yam productivity is low soil fertility (both in terms of macro- and micronutrient deficiency) (O'Sullivan and Ernest 2007). This is because *Dioscorea spp*. are high-nutrient-demanding crops (Carsky et al. 2010). Therefore, yams still remains being categorized as orphan crop (Naylor et al. 2004).

Irish Potato

Irish potato (*Solanum tuberesum* L.) is indigenous to South America near the present border of Peru and Bolivia but not Ireland (Spooner et al. 2005). According to Robert and Cartwhight (2006), it belongs to the family solanaceae, and is named after Ireland country because it is associated with the Irish potato famine, also known as the Great Hunger. This was a historic famine caused by *Phytophthora infestans* which infected Irish potato crop. This crop plays a crucial role in the economy and is ranked number one non-grain food commodity (Rykaczewska 2013). Globally it is ranked third most important food crop in consumption after rice and wheat (Birch et al. 2012). It has a worldwide cultivation exceeding 19.34 million hectare in more than 158 countries, with an approximate yearly production of 364 million tons (FAOSTAT 2014). According to Tshisola (2014) in Africa, it is regarded as one of the most important food crops.

Practically the crop contains all the requisite dietary components such as protein, vitamins, carbohydrates, essential nutrients, and minerals (Sriom et al. 2017). Additionally it is a source income and employment opportunity in developing countries. Unfortunately, limiting factors to its production include short day lengths, low light intensities, high temperatures, and most importantly low soil fertility (Jones and Wendt 1994).

Cocoyams (Arrow Roots)

Cocoyam (*Colocasia esculenta* (L.) Schott.) is a member of Araceae family (Purseglove 1975) and is a subsistence and emergency food source globally (IFA 1992). It is an important starchy tuberous herbaceous perennial plant (Purseglove 1975). The crop has different varieties and commonly produced varieties are *Colocasia esculenta* (Taro) and *Xanthosoma sagittifolium* (Tannia). They also occur in all tropics and have been domesticated in most communities in Oceania, Africa, and Asia (Ramanatha et al. 2010).

The crop is cultivated for its edible cormels, corms, and leaves as well as other traditional uses (Pinto and Onwueme 2000). As food for consumption, it is essentially a source of calories obtained from underground corm and cormel (Davies et al. 2008). Their leaves which resemble spinach are nutritious and are source mineral and vitamin (Sefa-Dedeh and Kofi-Agyir 2002). Primarily, fresh cocoyam hold about 70–80% water, 20–75% carbohydrate, and 1.5–3.0% protein (Udo et al. 2005). It actually contains over 80% and 240% higher digestible crude protein than yam and cassava, respectively. Therefore this crop is high-ranking nutritionally than cassava and yam in terms of protein and other elements such as vitamin and mineral content. However, the crop still remains to be underexploited food resource (Onyeka 2014).

Root and Tuber Crop Production in Kenya

Ministry of agriculture, livestock, and fisheries of Kenya report indicate that roots and tuber crops production stagnated for a period of 3 years (2012 to 2015) with an average cultivated zone of about 240,000 ha, which gave a total production level of 3.3 million MT although these reduced to 2.4 MT in 2016 (MoALF 2019). This elicited the national government to draft a strategy (the national root and tuber crops development strategy 2019–2022) to help in upscaling their production. This was an initiative of the national government of Kenya, but it was being supported by other key stakeholders such as the European Union, and by organizations like Self Help Africa (Table 1).

Table 1 Production trends of roots and tuber crops in Kenya (2012–2016)

Commodity	Area (Ha)			Production (MT)				
Year	2012	2013	2014	2012	2013	2014	2015	2016
Irish potato	99,475	104,560	115,604	1,436,718	1,667,690	1,626,027	1,172,262	1,150,112
Sweet potato	66,971	58,509	61,067	859,549	729,645	763,643	1,232,332	697,324
Cassava	73,144	65,634	63,7265	930,922	935,089	858,461	709,926	571,845
Cocoyams	2,869	3,654	2,155	26,716	45,346	27,619	–	–
Yams	874	998	1210	10,143	13,569	20,028	–	–
Total	245,345	235,368	245,775	3,266,060	3,393,352	3,297,792	3,114,520	2,419,281

Source: MoALF 2019

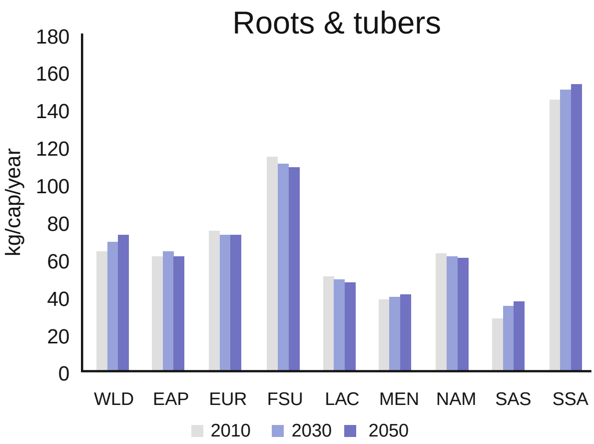

Fig. 1 Forecast sustained per capita demand for roots and tubers to 2050. (Source: Wiebe 2015). WLD = World; EAP = East Asia and Pacific; EUR = Europe; FSU = Former Soviet Union; LAC = Latin America and Caribbean; MEN = Middle East and North Africa; NAM = North America; SAS = South Asia; SSA = sub-Saharan Africa

In sub-Saharan African counties, there are noticeable cultural preferences for root and tuber crops, and using the Impact General Equilibrium Model, a 2015 analysis the International Food Policy Research Institute revealed that per capita consumption of these crops continues to rise (Fig. 1). Therefore, because of its low productivity brought by the effects of climate change and which cannot meet their demand, there is need to enhance their resilience to climate change using innovative ways.

Agricultural Interventions for Adaptation to Climate Change

Farmers, especially small-scale farmers, still use indigenous farming practices which lead up to ultimately low yields. This is coupled to farmer's nonadoption of better crop production strategies and lack of improved and high-yielding varieties. Moreover, these farmers on their own do have other alternatives that can help them bear and share loses or modifies threats. On the other hand, climate change adaptation should be built on sound and a working ecosystems, as it provides a variety of benefits and services on which agricultural production systems and rural livelihoods depend. Therefore, this calls for adoption of new technologies while producing these crop to help us throughout this challenging times. To this end, this chapter provide the suitable technologies available that can be exploited to increase root tuber crops adaptability to climate change. The technologies include:

Bio Fertilizers

By definition, bio fertilizers are products containing natural occurring microorganisms that are artificially multiplied for ameliorating soil fertility. Each and every type of crops grown in different agro-ecological zones can benefit from their use, since they are valuable to the environment. This is because they are enabling farmers to minimize the use of modern chemical fertilizers in crop production. In particular, they are designed to improve nutrient availability or reduce pest pressure. According to Malik et al. (2011), constant use of microbial-based bio-fertilizers enables microbial population to persist in the soil which helps in soil fertility conservation (Table 2).

Phosphate-Solubilizing Microorganisms (PSM): They are a group of beneficial microorganisms that capable of hydrolyzing inorganic and organic insoluble phosphorus compounds to soluble phosphorus form that can easily be absorbed by plants. They include various soil fungi and bacteria, and important species are *Pseudomonas, Bacillus, Penicillium,* and *Aspergillus.* Hikmatullah and K. Nugroho (1994) reported that their abilities of phosphate solubilization from organic materials differs due to their differences in their capacity to produce organic acids that play a key role in releasing phosphorus bound by aluminum, iron, and calcium ions. Specifically, this is because organic acids released by microorganisms are different in quantity and quality (Jha et al. 2013). Some of the organic acids released that are capable of freeing AI-P bond include Malic acid, malonic, tartaric, oxalic, and citric (Marbun et al. 2015). These organic acids decrease the soil pH in their locality to cause the dissolution of bound phosphates in soil. Khan et al. (2009) reported that 1 g of fertile soil can hold 10^1 to 10^{10} bacteria, and their live weight may exceed 2,000 kg ha^{-1}. Similarly Chen et al. (2006) outlined that among the whole microbial community in soil, phosphate solubilizing bacteria comprise 1–50% while phosphate solubilizing fungi comprise 0.1–0.5% of the total respective community. Therefore, microbial-based biofertilizers can be utilized to boost soil microbial population whenever they are low and when cultivating root and tuber crops. With high density of PSMs, it is expected that microbial phosphate solubilization can compete effectively with other microorganisms in the soil.

Phosphorus Mobilizing Fungi: This group comprise of the arbuscular mycorrhiza fungi (AM fungi) that belongs to the phylum Glomeromycota (Schüßler et al. 2001). The fungi form a mutualistic relationship with most terrestrial plants. In the association, the plants benefit through various ways such as water and essential

Table 2 Types of biofertilizers for root and tuber crops

Phosphorus-solubilizing microoganisms

nutrients uptake, and also by enhancing plant tolerance to biotic and abiotic stresses (Augé et al. 2015). This multifunctional ability and diversity of AM fungi has led to the development of mycorrhizal inoculants for use as biofertilizers in agriculture. Actually, most land plants are facultative symbionts such that they gain from AM fungi, yet they can also live without them, although at reasonable fitness cost. However, some plant species are obligate parasites on the fungus such that they are fully dependent on fungal nutrition (mycoheterotrophs) and have lost photosynthetic capacity (Graham et al. 2017).

Since mycorrhizal inoculations has been used for decades to stimulate plant growth for several crop, root and tuber crops which are highly mycorrhizal could also profit from the numerous services offered by this fungi not only in increasing their resilience to climate change but also their productivity. For instance, according to a report by Sieverding (1991) AM fungi inoculation of cassava increased its fresh roots weight by up to 5 t/ha.

Micronutrients Solubilizers: Such as Silicate solubilizing bacteria (SSB) are microorganisms that are able to degrade silicates and aluminum silicates in soil. These microorganisms such as Collimonas, Janthinobacterium, Proteobacteria, Aminobacter, Burkholderia, Dyella, and Frateuria are reported to solubilize the biotite which hold substantial amounts of silicate minerals (Uroz et al. 2009). During their metabolism, various organic acids are released which plays double roles in silicate weathering. These species supply hydrogen ions to the media which encourages hydrolysis. As well the organic acids let out such as oxalic acid, Keto acids, citric and hydroxyl carbolic acids form complexes with cations, which foster their removal and retention in the media in a dissolved state.

Since phosphorus and potassium are crucial macro elements for plant growth and development, P and K chemical fertilizers are regularly applied to replace the removed minerals in soil for yield optimization; SSB also plays an efficient role not only in solubilizing insoluble forms of silicates but also potassium and phosphates, hence this microorganisms when applied would increase the soil fertility, thereby enhancing root and tuber crops productivity.

Plant Growth Promoting Rhizobacteria (PGPR): Also referred as yield improving bacteria (YIB) are a group of bacteria that are known to increases plant growth and yield by-way-of several plant growth promoting substances as well as bio fertilizers. They are distinguished as free-living soil microorganisms colonizing plant roots and brings into play a beneficial effect on plant development and/or subdue plant pathogens. The microorganisms include; *Alcaligenes, Agrobacterium*, *Bacillus*, *Bradyrhizobium*, *Burkholderia*, *Enterobacter, Frankia, Klebsiella*, *Pseudomonas, Arthrobacter*, *Azospirillum, Azotobacter, Rhizobium,* and *Serratia*. The genera enclose most PGPR with well-known benefits on different crop species (Tailor and Joshi 2014).

There are numerous mechanisms through which the bacteria helps the plants including: inducement of increased nutrient uptake (termed Bio fertilizers), provision of nutrients by way of nitrogen fixation and phosphate solubilization, better plant growth promotion through the production of phytohormones (termed Bio stimulants), and the suppression of plant pathogens or the induction of systemic resistance to diseases (termed Bio protectants) (Vessey 2003). Also species of *Pseudomonas* and *Bacillus* produce plant growth regulators that stimulate crops to produce many fine roots which increases the surface area over which plant roots absorb water and nutrients.

Due to their multiple roles, research on these growth regulators has been rising and a number of experiments (both in vivo *and* in vitro) have been tested on different crops including root and tuber crops. For example, *Bacillus* and *Pseudomonas* sp. have been tried on potatoes and they have helped in improving phosphorus uptake, promoting indole acetic acid (IAA) production, and for biocontrol (Hunziker et al. 2015). Therefore, these microorganism can be very useful in fostering the growth and yield of root and tuber crops, with minor inputs of agrochemicals.

Organic Agriculture

Organic agriculture can be defined as a production system that sustains the health of soils, ecosystems, and people. This management system helps in mitigating climate change by diminishing the emissions of greenhouse gases and by sequestering carbon dioxide from the atmosphere. Organic agriculture is reported to be the most sustainable approach in food production. This is because it highly emphasizes on recycling practices and use of low external input for realization of high output. In addition, its principles dwell on increasing soil fertility, its diversity at all levels, and mitigating soil erosion.

Some management options of organic agriculture are generally considered to have both mitigation and adaptation benefits since they increase soil carbon. Ciais et al. (2013) stated that soil carbon provides a mitigation benefit by storing carbon taken out of the atmosphere by plants during photosynthesis. Soils with higher amounts of carbon are associated with greater water holding capacity, increased nutrient availability, and higher yield potentials, which could prove adaptive in a future climate (Stokes and Howden 2010). Organic agriculture practices are innovative way that can be used to increase these crops adaptability to climate change.

Soil Organic Matter Management

Soil organic matter (SOM) is a major measure of agricultural productivity and general soil health. Mean annual temperature and precipitation are major climatic drivers of SOM levels and dynamics. Long-term field trials and farm comparison show that organically managed soils have notably higher organic matter content. According to Foereid and Høgh-Jensen (2004), it was evaluated that under Northern European conditions, changing from conventional to organic agriculture resulted in enhanced SOM ranging from 100 to 400 kgha^{-1} yearly during the first 50 years. Therefore, after a hundred years of organic agriculture, it is estimated that a steady state of stable level of SOM would be realized.

Environmental Protection Agency estimated that composting 1 ton of organic matter gave a net storage of about 600 pounds of carbon dioxide (EPA 2006). Even though all kinds of agriculture poses the capability of sequestering carbon, essentially organic agriculture can sequestrate remarkably more carbon than conventional systems (Don 2007). This is because organic agriculture restrains the use of chemical fertilizer and pesticide and integrates use of cover crops especially from leguminous plants, and place in order increasing soil organic matter as the first step. Therefore, to sequester more carbon as possibly brought up by climate change, it is necessary to incorporate SOM management practices when producing root and tuber crops.

Mulching

Mulching is a traditional practice which involves the covering of soil surface with organic material which plays a vital role in soil and plant protection. Mulches are capable of changing the environment around the plants and control weed sand annual grasses, soil erosion and runoff, and soil-borne diseases. Besides, they decrease moisture evaporation, increase water absorption and retention, and boost root growth. Organic or natural mulches such as compost provide many favorable and fertilizer-like effects for root and tuber crops production by supplying abundant plant nutrients, during their decaying process.

Owing to climate change that has resulted in land slide, high temperature and flashfloods, mulching is necessary since several types of mulching practices have exhibited reduction in soil erosion by more than 90% compared to bare soil (Mostaghimi et al. 1994). Unger (1994) argued that mulches with low carbon to nitrogen ratio decompose rapidly providing nutrients for crop growth at a faster rate. Furthermore, studies in Latin America and Papua New Guinea revealed the benefits of mulching cassava and sweet potato plants for yield stabilization (Ossom et al. 2001). To support this, Coling (1997) reported that mulches of plastic film enhanced **dry matter** accumulation, plant height, leaf area index, and tuber yield of potatoes. Similarly Sarma et al. (1999) after planting potato cv. Kufrimegha on ridges and flat seedbeds in combination with mulches and earthing up, he confirmed that mulching with black plastic film resulted in enhanced tuber yield which was greater than the normal cultivating method. This is because plastic mulch literally conserved the soil moisture which helped in better crop growth and tuber yield. Similarly, mulching the soil has been positively correlated with plant species richness.

As a normal practice, root and tuber crops are usually cultivated on ridges where soil erosion and weeds can be a menace. Therefore, for their effective production mulching is important since it is a valuable practice that can be used to control weeds. This is because mulching prevents weed growth and development by blocking light from reaching the soil surface where their seeds lie. In root and tuber crops, mulching could assume an important function of lowering soil temperatures in addition to soil moisture conservation (Sangakkara et al. 2004).

Zero Tillage

Zero tillage which is also referred as direct drill or no till is an agricultural practice of cultivating crops or pasture without disturbing the soil surface through tillage. Its aim is to conserve soil and moisture through nondisturbance of the soil surface and also by ensuring that 30% or more of crop residues are conserved on the surface (Erenstein and Laxmi 2008). According to Fernández et al. (2010), the practice has been documented widely for its benefits including protecting the soil against erosion

Table 3 Area under zero tillage by continent

Continent	Area (ha)	Percentage of total (%)
South America	49,579,000	46.8
North America	40,074,000	37.8
Australia and New Zealand	17,162,000	11.5
Asia	2,530,000	2.3
Europe	1,150,000	1.1
Africa	368,000	0.3
World total	115,863,000	100

Source: Derpsch et al. (2010)

and managing soil structure. Also, this practice increases carbon sequestration and activities of the microorganisms (Helgason et al. 2010) (Table 3).

Studies show that practices that reduce soil disturbance and intensify cropping have the potential of increasing soil organic matter (SOM) and improving soil health. For instance, soil disturbance with tillage generally promotes loss of SOM by facilitating microbial degradation of SOM, promoting crop-residue-soil contact, and placing residues into more favorable subsurface moisture regimes as compared to surface placement under no-tillage (Halvorson et al. 2002). By adopting no till practices in root and tuber crops production, soil conservation would be improved greatly, water and wind erosion would be considerably reduced, while the crops would yield more since they would protect from pests and external environment.

Tie-Ridging

Tie-ridges are soil and moisture conservation structures that involves the construction of small basins that are rectangular shaped. This basins are formed within the furrow of cultivated fields mainly to enhance the storage of rain water and for allowing more time for water to percolate in the soil (Wiyo et al. 1999). Belachew and Abera (2010) reported that the stored water can accessed by plants for a longer period of time better than it can be used when there is run off. Ridging across slope is highly recommended in dry areas for soil and water conservation in crop production (Kumwenda 1999).

Mechanized ridging is achieved either by animal-drawn ridgers, as it is commonly practiced in African for cassava and other food crops production, or by tractor-mounted ridgers which is a major practice for cassava production in Asian countries (Suyamto and Howeler 2001). The purpose of mechanization is to reduce hard work and in the process increase the scale of production crops. Although when using tie-ridging the optimum height of the ridge depends on the soil type and the cultivar being grown.

Benefits of tie-riding reported include: increased number of roots per plant which is identified as a major contributory factor to the higher yields on ridges (Suyamto and Howeler 2001). In particular, ridging has been shown to increase sweet potato yields by 38% (Ennin et al. 2003) over mounding, mainly as a result of increased plant population density and better weed suppression on ridges. Shetto (1999) reported that many farmers find weeding of cassava to be easier on ridges than on mounds; it is also effective in soil erosion management and results in high yields. Ennin et al. (2009) recommended the cultivation of cassava, yams, and other tuber crops on tie-ridges for realization of economizing the available planting space and thus increase on the planting density. Ridging is also responsive to improved farming practices such as herbicide application, fertilization, and yam staking, and this is due to the regular spacing of crops obtained under the systems.

The concept behind creation of tie-ridges is to optimize water infiltration, improvement of soil-water management, enhancement of root growth and nutrient uptake, and enhancement of rooting depth which is also supported by FAO (2000). Therefore, tie-ridge would play a significant role in production of root and tuber crops.

Improved Seed Varieties

Unlike the other true seed crops, root and tuber crops are propagated vegetatively. The benefits of improved seed varieties for root and tuber crops can only be realized through breeding and addressing the challenges in their seed value chain. This can be achieved through having a functioning seed systems and directly linking of the systems as a key tool of addressing the issue of improved seeds. This can further be linked in addressing the issues of climate change.

To this effect, the International potato center (CIP) has fostered and expedited their breeding schemes that shortens the time it takes in developing and releasing new varieties of root and tuber crops actually from 8 to 4 years. To this effect, their breeders have released potato varieties that are tolerant to heat, salinity, and drought. Some of the varieties are Tacna and Unica which were developed and tested in Peru; Raniag variety in Philippines; and Kinga, Kiningi, and Meva developed in Africa (Atakos et al. 2018). Further variety Tacna was released in the Republic of China under the name Jizhangshu 8, and had covered 20,000 ha by 2008. Recently work has been going on to develop climate change resilient potatoes that have the characteristics of drought and salinity tolerance, and according to Atakos et al. (2018), variety Sarnav has been released in Central Asia (Uzbekistan and Tajikistan), while heat and salinity tolerant BARI Alu-72 has been released in Bangladesh. With minimal precipitation being realized ranging between 15% and 20% and new experiences in temperature increase of 2–3 °C due to the effects of climate change, these clones have shown a high degree of tolerance to these effects (CIP 2017). On that account, such efficient breeding practices that delivers improved seed varieties of root and tuber crops should be supported especially in the area of improving their resilient to climate change.

Management of Community Seed Banks

Community seed banks are entities that are governed locally and they are managed in an informal manner by institutions whose core function is to maintain seeds for local use (Development Fund 2011). Vernooy et al. (2014) reported that the community seed banks were founded by Rural Advancement Foundation International (RAFI) now known as ETC Group or Action Group on Erosion, Technology, and Concentration. The three key functions of the community seed banks are: (i) to conserve the plant genetic resources; (ii) to make the availability and accessibility of diverse seeds and planting materials according to farmers' needs and interests easier; and (iii) facilitating seed and food sovereignty (Vernooy et al. 2014). Community seed banks are globally located in Guatemala, India, Malaysia, Mexico, Nicaragua, Sri Lanka, USA, Honduras, Bhutan, Bolivia, Brazil, Canada, Bangladesh, China, Costa Rica, Nepal, Trinidad and Tobago, Rwanda, Uganda, Mali, Burundi, Norway, Zimbabwe, and South Africa. Recently it was launched in Kenya in Nyando in smallholder farmer areas by the Consortium of International Agricultural Research Centers (CGIAR) research program on climate change agriculture and food security (CCAFS) in sub-Saharan Africa which works in partnership with Bioversity International to establish community seed banks in Kenya, Tanzania, and Uganda. The idea behind is that when you take one seed you return two, if you take five, you return ten. This protocol aids in their sustainability. The idea of community is excellent; however, the existing community seed banks are focused on cereal crops neglecting the root tuber crops. Although the International Potato Center (CIP) researchers are promoting innovative ways that allows storage of seeds of root and tuber crops.

Specifically sweet potatoes farmers are encouraged to mass-produce their own vines during planting time. The system is known as Triple S (for storing vines in sand to make them sprout). It involves storing the vines in dry sand following harvest, and thereafter planting them in seedbeds 6–8 weeks before the rainy season, and watering them to produce enough vines to plant when the rains begin. The practice results in increased vines, earlier harvests, which provides food and income at a time. In addition in order to maintain disease free planting materials, the farmers in high virus pressure zones are advised to use net tunnels systems to protect against insects such as whiteflies and aphids which are known in spreading viruses. This practice is effective in suppressing the infection rate by sweet potato virus disease thus supporting the availability of clean planting materials. According to Atakos et al. (2018), such tunnels also have contributed in moisture retention by reducing the amount of water required for irrigation. The major benefits derived from community seed banks that can be exploited for production of root and tuber crop seeds are pest and disease reduction, increased production of seeds, and climate stress buffering.

Cropping Systems

Cropping systems plays important roles in crops adaptability to climate change since the practice encompasses on farm adaptation of improved farming technologies and in this case planting more than two crops with different maturity periods. This system has various advantages including: better utilization of the environment, greater food yield, increased return per unit area, and insurance against crop failure. Therefore, root and tuber crops which have great flexibility can be part of such a system. This is because they can be intercropped with plantation crop such as areca nut, coconuts, coffee, rubber, and fruit crops like mangos, bananas, and litchi as these crops are adapted to the same ecological conditions (Nayar and Suja 2004). In this system, the principal crop provides cash while root intercrops provide as high-energy secondary staple to the farm family and feeds for farm animals, behave as insurance crop against risk and natural calamities, ensure food security, enhance resource use efficiency, augment net income, and increase employment opportunities.

To support this, cultivation of root and tuber such as yam, cassava, sweet potatoes, and edible aroids in the interspaces of perennial plantations such as rubber, coffee, coconut, and banana is common in tropical countries. Crops such as elephant foot yam and yam grow as intercrops horticultural and planation crops. Also intercropping maize and yam is believed to be productive and compatible mainly because maize is a short season crop (3–4 months), while yams are long are long duration (7–12 months) crops. Sagoe (2006) also revealed that yams and cocoyams are usually cultivated in association with cocoa and furthermore new innovations propose use of cassava trees in cocoa production. Davis et al. (1986) reported that sweet potato are grown as intercrop and in rotation systems with crops like soybean, bean, sorghum, maize, and cassava. In India, cassava, yams, and edible aroids are intercropped with rubber plantations during their immature phase whereas in Malaysia cassava is grown as intercrop in Rubber estates (Leihner 1983). The cropping system also includes practices such as adjusting the planting dates, irrigation applications, and fertilizer application (Sagoe 2006). This examples suggests that when managed appropriately, cropping systems can enhance the adaptability of these crops to climate change especially when the right crops are chosen for the system.

Irrigation Method

Climate change causes in drought which is a major abiotic factor that limit crop production. On the other hand, global warming causes rainfall fluctuations increasing the risk of plant exposure to repeated drought (Miyashita et al. 2005). Other factors ever berating the drought situation include limited fresh water bodies which cause serious issues globally, particularly in arid and semiarid regions. These fresh water bodies are also decreasing due to population pressure, comping demands from the industries, low rainfall, agricultural and urban development. Furthermore drought is considered one of the major constraints for root and tuber crop production.

Root and tuber crops have much capacity in terms of their water use efficiency and nutrient use just like other food crops. Additionally, these crops have a unique growth characteristics and functionality. Therefore a suitable irrigation method must be selected while cultivating these crops such as: an irrigation method that releases the exact amount of water required, and time and method of water application. To this end, sprinkle and trickle irrigation methods therefore becomes the best option for these crops. This is because they save irrigation water by up 30% and 50%, respectively, as compared with surface irrigation (Al-Jamal et al. 2001). Amer (2011) revealed that in small-scale farming using gated pipes and double planting row beds, with partially wetted furrow irrigation, water saving is achieved just as in trickle irrigation. Even though partially wetted irrigation can be very useful especially because it decreases installation cost compared to trickle and sprinkle systems, in this case it is important to consider the right method for climate change adaptation. Considering this, trickle irrigation becomes the best method for theses crops under the prevailing climatic conditions since it conserves water, prevents nitrogen leaching, allows deep water percolation, and reduces soil erosion. Also it gives famers an opportunity to apply water at the right time.

Exploiting Abandoned Lands

In this chapter, land abandonment concept is used on a land where traditional or recently agricultural activities have stopped due to their marginal characteristics. Lands are classified as abandoned when their productivity level is situated close to the margin beyond which management expenses are not compensated by the profits obtained after harvesting. To this effect, cropland abandonment has become a common occurrence globally due to the improper agricultural practices being used.

To reclaim this types of lands and to increase the arable lands, alternative crop productions (in intensive form) should be used. This is because the remaining arable land is being lost to urban and industrial uses, deforestation, rural development, such as afforestation, and land fragmentation into smaller units. According to FAO (2011), many efforts to revamp land productivity have continued over the years since the abandoned lands represents a valuable resource for crop production. Such efforts are supported by the farmers desire to pass productive farmlands onto the future generation in just a good condition as when they inherited them (Greenland et al. 1998).

Root and tuber crops can therefore be very useful for use in reclaiming these abandoned lands. This is because of their agronomic advantage such that these crops are adapted to diverse soil, environmental conditions, and a variety of farming methods with minimum agricultural input. Also, variations in the growth pattern and adopting cultural practices make them specific in production systems. In addition, these crops are relatively easy to grow since they are highly adaptable in growing at a wide range of altitudes, on both flat and sloping lands, and on both sandy and clay soils where other crops are not well adapted. Finally, the variety to choose from for these crops is very high.

All these characteristics indicates that root and tuber crops have a comparative advantage for cultivation in marginal lands than other crops since they can be selected to resist stress conditions and in contributing to sustainable crop production with low input cost. Similarly, IPGRI (2000) reported that these crops contributes to the food crops diversity and hence exploits fully the abilities of agro-ecosystems. Under this scenario of large abandoned land, root and tuber crop can be produced effectively on these lands, and after years of their production, the lands can be returned for production of other agricultural crops production. In return this would lead to reduced clearing of additional forests and grassland for farming purposes.

Agroforestry Practice

Agroforestry is an interaction of agriculture and trees, including the agricultural use of trees. This encompass trees on farms and in agricultural landscapes; farming in forests and along forest margins and tree-crop production including coffee and cocoa. It ranges from traditional swidden agriculture to elaborate systems of fruits trees and vines in spatial complementarity. Examples of useful agroforestry trees include; *Acacia albida*, *Leucaena leucocephala*, Prosopis juliflora, *Acacia scorpioides*, and *Euphorbia spp*. Others include green manure crops such as Tephrosia *spp,* Desmodium *spp,* Dolichos *spp*, and Indogofera *spp.*

Some of the most promising agroforestry techniques for root and tuber crops include: (a) Scattered farm trees, this simply involves the increase in number of trees in the middle of crops and alongside the farm boundaries. The trees might have greater value than the crops they displace. Alternatively, the trees might actually increase the productivity of these crops by replenishing the soil and helping reduction of soil erosion. (b) Improved fallows, which involves fallows being enriched with fast-growing trees, vines, or shrubs. This is required by the fact that the fallow periods in many areas needs to be shortened considerably. (c) Buffer strips, which are areas of land maintained in permanent vegetation that helps control soil, air, and water quality. Root and tuber crops can therefore serve as buffers against soil erosion when planted along contour lines of slopes. In complicated systems, these root and tuber crops buffer strips can include other crop, such as grasses, trees, shrubs, and fodder legumes.

Clean Seed Production Technologies

Policy makers acknowledges that seed security is pivotal for global food security. This is because seeds serves as the primary farm input in crop production and is also a means for conveying agricultural innovations to the farmers. Forasmuch as seeds are among the main factors that impediment crop production, these seeds must therefore be in good quality by the time they are distributed to the farmers. Actually availability, accessibility, and use of quality seeds that are adapted are of essence in increasing agricultural productivity and improving farmers livelihoods.

For clean seed production of root and tuber crops, cases reviewed encouraged seed stakeholders to emerge as permanent seed producers (Bentley et al. 2018). This would enable clean seed to flow through the value chain constantly. Methods of clean seed production include:

(a) Commercial farms being contracted for one season, even though the method has demonstrated that it is labor intensive, it is susceptible to pests and diseases, and it is time consuming.

(b) Tissue culture, which is the growth of tissues of plants or animal in an artificial medium separate from the parent organism. This method is very important for plant propagation for example the use of this method in seed production has ensued in mass production of clean potato seeds within a short period of time. In support of this, Pruski (2001) revealed that the method is characterized by its flexibility in terms of the rapid multiplication of seedlings. This method has been adopted in several countries like Vietnam where it revolutionized production of potato seeds. The method is now well understood and has been used in propagation of several plant species across the globe.

(c) Aeroponic method: which is the process of cultivating plants in an air or mist environment without the use of soil or media. It is considered as one of the safest and ecological friendly method for producing natural and healthy crops. The multiplication of potatoes using this method of more advantage than other available systems. CIP (2018) reported that the method is ten times more successful than convectional techniques, hydroponics, and tissue cultures which takes much time and are more labor intensive. The method utilizes nutrient solution recirculation, thus water is not wasted and the available nutrients are used effectively. Therefore this system comparatively offers lower energy and water inputs per growing area. This system can therefore be utilized for rapid production of root and tuber crops seeds.

Nutrient Use Efficiency (NUE)

Nutrient use efficiency indicates the ability of crops to take up and utilize nutrients for yield. The concept entails three major processes in plants: uptake, assimilation, and utilization of nutrients. The nutrient uptake and fertilizer recommendation of important root and tuber crops are presented in Table 4. This is an indicator that root and tuber crops have a higher NUE. This is support by Nieto, C. O. (2016) who

Table 4 Nutrient uptake and fertilizer recommendation of important root and tuber crops

Crop	Tuber yield (t/ha)	Uptake (kg/ha)			Farmyard manure (t/ha)	Recommended dose (kg/ha)		
		N	P	K		N	P	K
Cassava	30	180	22	160	12.5	100	50	100
Sweet potato	14	34	6	47	5	50	25	50
Elephant foot yam	36	122	31	176	25	100	50	150
Yams	25	163	24	127	10	80	60	80
Taro	17	119	18	157	12.5	80	25	80
Tannia	20	125	37	187	25	80	50	150
Coleus	26	106	13	107	10	60	60	100
Arrow root	24	194	31	292	10	50	25	75

Source: Mohan Kumar et al. (2000)

reported that NUE of potatoes under low nitrogen input was higher than under high nitrogen input, and higher for late cultivars than for early cultivars.

Conclusion

There is an urgent need to broaden the food basket of the Sub-Saharan Africa by supporting root and tuber crops cultivation through boosting their capacity to adapt to climate change. Even though these crops have been neglected, there is evidence that the crops have greater adaptability to extreme climatic conditions and that they are more resilient to both biotic and abiotic stresses. Therefore, the suggested innovations and/or adaptation measures will help in enhancing their adaptability to climate change and also to enable them to produce more harvestable yields where major crops have failed.

Abstract

Small-scale farmers' limited adaptive capacity confronted with the adversities of climate change is a major call for concern considering that small-scale farms feed over half of the world's population. In this light, small-scale farmers' adaptive choices and adaptive capacity to climate change were assessed. Data were collected from primary and secondary sources using a mixed research approach. Findings revealed that extreme weather events have been recurrent and small-scale farmers perceived access to land, household income, and the planting of trees/shrubs on farms (agroforestry) as the main factors influencing their capacity to adapt to climate change. Agroforestry and monoculture practices were the main adaptive choices of small-scale farmers confronted with climate change. T-test and chi-square test statistics revealed a strong non-cause-effect relationship ($p < 0.001$) between small-scale farmers' capacity to adapt to climate change and different socio-economic, institutional, and environmental variables. Parameter estimates of the binomial logistic regression model indicated the existence of a strong direct cause-effect relationship ($p < 0.05$) between small-scale farmers' capacity to adapt to climate change and access to credit, household income, number of farms, access to information, and access to land, indicating that these variables enhance small-scale farmers' capacity to adapt to climate change. It is recommended that policy makers examine the adaptive choices and determinants of farmers' adaptive capacity unearthed in this chapter when formulating policies geared towards enhancing small-scale farmers' capacity to adapt to climate change.

Introduction

Background of the Study

The fight against climate change features prominently among the seventeen (17) United Nations Sustainable Development Goals (SDGs) – 2030 Agenda, demonstrating the desire of the global policy making community to tackle climate change, one of the foremost existential threats facing humanity today, head-on (IPCC 2018; Chanana-Nag and Aggarwal 2018; Niles and Salerno 2018). This comes in the wake of unprecedented levels of global warming caused mainly by increasing concentrations of carbon dioxide, methane, nitrous oxides, and other greenhouse gases (GHGs) in the atmosphere (Aggarwal et al. 2015; IPCC 2018). Anthropogenic activities especially excessive fossil fuel combustion, deforestation, and degradation of tropical forests have been singled out as the principal causes of the increasing emissions of greenhouse gases into the atmosphere (Biermann 2007; IPCC 2007; The Royal Society 2010; NAS and RS 2014). With the present climatic variations and changes, humanity has just two choices: adaptation and/or mitigation. With mitigation being a long-term option, adaptation becomes incumbent for different sectors of economic life especially the agricultural sector (Adger et al. 2007; Challinor and Wheeler 2008; Challinor 2009; World Bank 2013; FAO et al. 2018). With the most vulnerable actors in the agricultural sector being small-scale farmers, there is absolute necessity to promote measures that foster adaptation and enhance adaptive capacity to the adversities of climate change.

The FAO (2011) indicated that climate change will seriously threaten the livelihood of small-scale farmers. In 2016, studies demonstrated that small-scale farmers will be adversely affected by changes in climate patterns owing to their limited adaptive capacity (FAO 2016). Small-scale farmers' limited adaptive capacity when confronted with the adversities of climate change is a major call for concern considering that small-scale farmers – who in the majority are found in developing countries – contribute to the nourishment of over half of the world's population (FAO 2016). It is estimated that the developing world has roughly 500 million small-scale farms supporting about two billion people, and these small farms produce about 80% of the food consumed in Asia and sub-Saharan Africa (IFAD 2012). With the number of small-scale farms across the developing world rising (FAO 2010a, b; IPCC 2014; FAO et al. 2018), it becomes necessary to examine the capacity of small-scale farmers to adapt to climate change adversities and to examine the factors influencing the capacity of small-scale farmers to adapt to the negative effects of climate change.

Cameroon like other developing countries is dominated by food-based agricultural systems. These food-based farming systems owned in the majority by small-scale farmers (who constitute over 90% of the farming population) have been adversely affected by climate change (Molua 2006, 2008; Tingem et al. 2009; Azibo and Kimengsi 2015; Awazi 2018). Small-scale farmers' capacity to adapt to climate change could be enhanced if human, material, logistic, and financial resources are placed at their disposal (Molua 2008; Azibo et al. 2016; Innocent et al. 2016). From this perspective, this chapter sought to assess small-scale farmers' adaptive choices and the determinants of small-scale farmers' capacity to adapt to climate change, in the hope that the findings will go a long way to influence policy and alleviate the plight of small-scale farmers.

Review of Literature

Perceptions of Climate Change by Small-Scale Farmers in Africa

Africa's small-scale farmers are increasingly perceptive of climate change, although their perceptions vary on a country-by-country basis as shown by different studies carried out in Africa. In a study carried out by Belaineh et al. (2013) in the Doba District, West Hararghe, Ethiopia, it was found that all male-headed and female-headed households perceived the occurrence of climate change. Boissière et al. (2013) on the contrary, in a study carried out in Indonesia – the tropical forests of Papua – found that the local population's perceptions of adverse climatic variations and changes differed significantly across the studied villages. They concluded that these differences in perception of climate change could be due to the different agro-ecological conditions of the villages. Mtambanengwe et al. (2012) on their part found respondents unanimous that the total quantity of rainfall had declined. The findings of Mtambanengwe et al. (2012) corroborate those of De Wit (2006) and Anderson (2007) who revealed that Southern Africa is becoming increasingly drier, threatening agricultural sustainability, as rainfall distribution within the season fluctuates tremendously.

Maddison (2006), however, found that Zimbabwe's small-scale farmers' perception of climate change varied with respect to the number of years of experience in farming. According to Maddison, small-scale farmers with more than 20 years of experience in farming were more likely to notice significant changes in normal weather patterns compared to their less experienced counterparts. This is corroborated by Mtambanengwe et al. (2012) who also found that 3–4% of small-scale farmers who claimed not to have noticed any shift in climate in the two communities studied in Zimbabwe were young farmers or farmers mostly involved in off-farm activities.

In a study undertaken in South Africa, Benhin (2006) found that about 72% of farmers sampled were of the opinion that climate change has been occurring over the years, with delays in the timing of the rain, a drastic drop in the quantity of rain, and higher temperatures. The farmers' perceptions, however, varied slightly across the nine provinces in which the study was carried out. In the semiarid areas of Tanzania, Mary and Majule (2009) found that 63.8% of farmers sampled in Kamenyanga village and 73.8% of farmers sampled in Kintinku village perceived an increase in temperature. Farmers reported that the months of September to December were becoming extremely hot and the nights were generally becoming very cold. It was also found that most of the farmers sampled perceived a decrease in precipitation and changes in onset of rains as well as an increase in drought frequency in Kamenyanga and Kintinku districts, respectively. Most of the farmers stated that the onset of rainfall has changed because crops were usually planted in the months of October/November but lately crops are being planted in the months of December/January.

In a study undertaken in eleven (11) African countries, Maddison (2006) found that a large majority of farmers believed that precipitation is declining and temperature is on the rise. Majule et al. (2008) also reported similar findings. Tessema et al. (2013) in a study undertaken in the East Hararghe zone of Ethiopia found that farmers' perceptions differ with respect to changes in precipitation and temperature. A large majority (91.2%) of the farmers perceived a rise in temperature, whereas 3.5% and 5.3% of the farmers perceived a decrease in temperature and no change, respectively. Most of the farmers (90.3%) perceived a drop in the quantity of precipitation; meanwhile 2.6% and 6.2% of the farmers perceived an increase in the quantity of precipitation and no change, respectively. Only a small percentage (0.9%) of the farmers indicated that precipitation is variable rather than agreeing either on an increase or decrease in the quantity of rainfall.

In the same line of thought, studies undertaken across different parts of Africa have shown that small-scale farmers perceive climate change through variations in climate elements. Studies undertaken by Ishaya and Abaje (2008) in Kaduna state, Nigeria; Gbetibouo (2009) in the Limpopo Basin of South Africa; Mertz et al. (2009) in the Rural Sahel; Deressa et al. (2011) in the Nile Basin of Ethiopia; Nyanga et al. (2011) in Zambia; Nzeadibe et al. (2012) in the Niger Delta Region of Nigeria; Tambo and Abdoulaye (2012) in Nigeria; Yaro (2013) in Ghana; Juana et al. (2013) in sub-Saharan Africa (synthesis of empirical studies); Temesgen et al. (2014) in Ethiopia; Mulenga and Wineman (2014) in Zambia; and Aggarwal et al. (2015) in the Kullu District of the western Himalayan region all found that small-scale farmers were increasingly perceptive of climate change. Based on the findings of all these studies, a conclusion could be drawn to the effect that small-scale farmers' perceptions of climate change are quasi-unanimous across Africa.

Adverse Effects of Climate Change on Africa's Small-Scale Farmers

Africa's small-scale farmers are increasingly being affected by climate change. Scholarship indicates that climate change has mainly adverse effects on Africa's small-scale farming communities. In a study carried out in Kenya, Herrero et al. (2010) found that climate change adversely affected small-scale farmers through recurrent droughts. Mary and Majule (2009) carried out a study in Tanzania, revealing that the recurrence of extreme climate events (changing rainfall and temperature patterns) led to increased risk of crop failure owing to the washing away of seeds and crops, stunted growth, poor seed germination, and withering of crops. It was equally found that, in the case of livestock, variations in rainfall patterns (decreased rainfall–drought and increased rainfall–floods) led to a decrease in pasture and an increase in parasites and diseases. Similar findings have been reported by other studies carried out in Africa. Mortimore and Adams (2001), for example, found that the timing of the onset of the first rains and other intra-seasonal factors such as the effectiveness of the rains in each precipitation, and the distribution and length of the period of rain during the growing season, seriously affect crop-planting regimes as well as the effectiveness and success of farming. According to the IPCC (2007), changes in rainfall patterns and the quantity of rainfall affect soil moisture and the rate soil erosion, both prerequisites for crop growth and crop yields. All these negatively affect small-scale farmers.

In a study assessing the economic impact of climate change on agriculture in Cameroon, Molua and Lambi (2006) found that as temperature increases, and precipitation decreases, net revenue dropped across all the surveyed farms. The study equally revealed that an increase in temperature by 2.5 °C will lead to a drop in net revenues from agriculture in Cameroon by $0.5 billion. A 5 °C increase in temperature on its part will lead to a drop in net revenues by $1.7 billion. A 7% decrease in precipitation will lead to a drop in net revenues by $1.96 billion, and a 14% decrease in precipitation will lead to a drop in net revenues from crops by $3.8 billion. The study, however, found that increases in precipitation will lead to an increase in net revenues. Based on these findings, small-scale farmers in Cameroon will be adversely affected by climate change through a fall in farm revenue.

On their part, Tabi et al. (2012), in a study carried out in the Volta region of Ghana, found that climate change adversely affects rice farmers. These adverse effects were death of animals, loss of farming capital, heat stress, increase in social vices, shortage of water, slow development, and increased poverty and food insecurity. From these findings and those of other studies aforementioned, it could be said that climate change has mainly adverse or negative effects on small-scale farmers in Africa.

Drivers of Small-Scale Farmers' Vulnerability to Climate Change in Africa

In the face of climate change adversities, small-scale farmers in Africa are the most vulnerable actors involved in the agricultural sector (Rurinda 2014). Small-scale farmers' vulnerability to climate change adversities could be attributed to several factors. In a study carried out to examine the vulnerability of small-scale farming systems of Zimbabwe to climate change, Rurinda (2014) and Rurinda et al. (2014) found that the main causes or sources of vulnerability of small-scale farmers to climate change were lack of knowledge, lack of draught power, increased rainfall variability, lack of seed, lack of fertilizer, and declining soil fertility. Following Rurinda's findings, the single most important source or cause of small-scale farmers' vulnerability to climate change was increasing variability in rainfall.

In a study assessing rice farming in the Volta region of Ghana, Tabi et al. (2012) showed that the main sources or causes of rice farmers' vulnerability to climate change were low price of rice in the local market, difficult land tenure system, limited or no access to credit facilities, few farmers engaged in off-farm activities, poor soils, and lack of insurance in times of crop failure.

The CDCCP (2009), in a study undertaken in the Chiredzi district of Zimbabwe, found that the main causes of small-scale farmers' vulnerability to climate change were as follows: poor farming practices, high frequency of drought, inherent dryness, limited use of climate early warning systems, over-dependence on mono-cropping especially maize, high incidence of poverty, population pressure, skewed ownership and access to drylands' livelihood assets such as livestock and wildlife, lack of drought preparedness plans, limited alternative livelihood options outside agriculture, and low access to technology (irrigation, seed), markets, institutions, and infrastructure (poor roads, bridges, modern energy, dams and water conveyance).

These findings therefore demonstrate that small-scale farmers in Africa are highly vulnerable to the adverse effects of climate change.

Adaptation Options Implemented by Small-Scale Farmers in Africa Confronted with Climate Change

In Africa, small-scale farmers have adopted different adaptive options in order to improve their adaptive capacity confronted with climate change. Tabi et al. (2012) while assessing rice farming in the Volta region of Ghana found that rain-fed lowland rice farmers practiced different adaptive choices among which were the application of fertilizers, water management control practices, alternation of planting dates, herbicide use, and the use of high-yielding and disease-resistant varieties. On their part, Kuwornu et al. (2013) in a study carried out in northern Ghana found that small-scale farmers adopted both indigenous and introduced (modern) adaptive options to improve their adaptive capacity to climate change.

Molua and Lambi (2006), in a study undertaken in Cameroon, found that the main indigenous adaptation strategies implemented by small-scale farmers in the face of climate change were changing timing of farming operations, increasing planting space, undertaking traditional and religious ceremonies, change of crops, varying area cultivated, and cultivation of short season local varieties. The FAO (2006) found that the major indigenous adaptation strategies practiced by small-scale farmers were reducing food intake, change of crops, reducing personal expenditures, mortgaging land, homestead gardening, disposing of productive harvests, and re-sowing or re-planting.

Different authors have carried out studies across Africa with varying findings as far as indigenous adaptive choices implemented by small-scale farmers confronted with climate change adversities are concerned. For example, studies carried out by Hassan and Nhemachena (2008), the FAO (2008, 2009b), Gbetibouo (2009), and Deressa et al. (2010) showed that diversification of crops is a major indigenous strategy practiced by small-scale farmers confronted with climate change adversities. Studies carried out by Easterling et al. (2007), Boko et al. (2007), Gbetibouo (2009), the FAO (2009a, 2010c), and Deressa et al. (2010) showed that the integration of livestock to crop production is a key indigenous strategy practiced by small-scale farmers confronted with climate change. Studies undertaken by Molua and Lambi (2006), Easterling et al. (2007), Boko et al. (2007), Hassan and

Nhemachena (2008), Gbetibouo (2009), and the FAO (2009b) revealed that changing the timing of farm operations is one of the most important indigenous strategies adopted by small-scale farmers in the face of climate change. The FAO (2006, 2009b), Molua and Lambi (2006), and Gbetibouo (2009) found that changing of crops was a major adaptation strategy used by small-scale farmers to adapt to climate change. The FAO (2006) and Altieri and Koohafkan (2008) found that home gardening was a major indigenous strategy practiced by small-scale farmers confronted with climate change adversities.

The FAO (2010a), Thorlakson (2011), Rao et al. (2011), Mbow et al. (2013), Bishaw et al. (2013), Mbow et al. (2014), Kabir et al. (2015) and Awazi and Tchamba (2019), found that agroforestry practices like scattered trees on croplands, improved fallows, home gardens, and cocoa, coffee, and banana agroforests were sustainable and climate-smart adaptive choices practiced by small-scale farmers across Africa in the face of climate change.

From the foregoing, small-scale farmers are adopting both indigenous and introduced adaptive measures to adapt to the adverse effects of climate change across Africa. However, very little has been done to assess the adaptive capacity of small-scale farmers in the face of climate change.

Determinants of Small-Scale Farmers' Choice of Adaptive Measures Confronted with Climate Change

Small-scale farmers' choice of adaptive measures confronted with climate change was influenced by several factors. Tabi et al. (2012), in a study carried out to assess the different adaptive choices of small-scale rice farmers in Ghana, found that the main variables influencing the different adaptive options of small-scale farmers were distance to farm and market, labor, advice from extension agents, gender, length of stay in rice farm, age, farm size, number of farms, credits, household size, and education. Deressa et al. (2008) and Atinkut and Mebrat (2016) on their part found that different infrastructural and institutional factors as well as household and farm characteristics influenced the adaptive choices of small-scale farmers confronted with adverse climatic changes. Through marginal analysis, Deressa et al. (2008), in a study carried out in the Nile Basin of Ethiopia, found that institutional factors (availability of information), social capital, household variables, agro-ecological features, and wealth attributes influenced small-scale farmers' adaptive choices confronted with climate change in the Nile Basin of Ethiopia.

Studies carried out by Maddison 2006 and Nhemachena and Hassan (2007) showed that the most common household attributes influencing small-scale farmers' adaptive capacity to climate change adversities were wealth, marital status, farming experience, age, education, and gender of the head of household; common farm attributes influencing small-scale farmers' adaptive choices to climate change included fertility, slope, and farm size; common institutional factors affecting adaptive choices of small-scale farmers to adverse climatic changes included credit accessibility and access to extension services; and the common infrastructural factor influencing small-scale farmers' adaptive capacity to climate change was distance to input and output markets. Across Africa, different studies have been carried out assessing the impact of climate change and factors affecting small-scale farmers' adaptive choices in crop, livestock, and mixed crop-livestock production systems confronted with climate change adversities (Maddison 2006; Hassan and Nhemachena 2008; Kurukulasuriya and Mendelsohn 2007). However, Zivanomoyo and Mukarati (2012) assessed the factors affecting small-scale farmers' choice of crop varieties confronted with climate change adversities. The study sought to examine how farmers' choice of different crop varieties contributed to improve their adaptive capacity to climate change. Findings revealed that the use of more disease-resistant and hybrid varieties contributed in a major way towards enhancing the adaptive capacity of small-scale farmers to climate change.

From the foregoing, the factors influencing the adaptive choices of small-scale farmers confronted with climate change adversities could be broadly classified into institutional, environmental, and socio-economic factors. Although the factors influencing the adaptive choices of small-scale farmers confronted with climate change have been examined by different studies across Africa, little has been done to assess the small-scale farmers' adaptive capacity to climate change.

Barriers to Adaptation for Small-Scale Farmers in Africa Confronted with Climate Change

In Africa, small-scale farmers have increasingly faced difficulties adapting to the adverse effects of climate change because of different factors. Tabi et al. (2012), in a study carried out on small-scale rice farmers in the Upper Volta region of Ghana, found that the main barriers to small-scale farmers' adoption of different adaptive options confronted with climate change were lack of equipment for quick and appropriate land preparation, lack of farm inputs, inadequate or no irrigation facilities, inadequate or no weather forecast, and limited access to credits. Deressa et al. (2008) in a study carried out in the Nile Basin of Ethiopia found that five major constraints affected small-scale farmers' adaptation choices to climate change. These barriers were shortage of land, shortage of labor, poor potential for irrigation, lack of money, and lack of information. The study however found that most of the constraints to small-scale farmers' adaptation to climate change could be largely attributed to poverty. Deressa et al. (2009, 2011), in studies undertaken in the Nile Basin of Ethiopia, equally demonstrated that poverty is a major barrier to small-scale farmers' adaptation to climate change, because lack of money makes it difficult for small-scale farmers to get the required resources and technologies that ease adaptation to climate change.

In a study carried out in the coastal regions of Bangladesh, Kabir et al. (2015) found that the main constraints to climate change adaptation for small-scale farmers were lack of information, lack of credit, unpredicted weather, shortage of land, shortage of farm inputs, and lack of water. Tessema et al. (2013), in a study carried out in the Eastern Hararghe Zone of Ethiopia, discovered that the major constraints to climate change adaptation for small-scale farmers were shortage of land, lack of seed, shortage of labor, limited market access, lack of money, lack of water, lack of fertilizer, lack of oxen, insecure land tenure, and lack of information. In different parts of Ethiopia, studies have shown that small-scale farmers face several difficulties in their drive to adapt to climate change (Maddison 2007; Deressa et al. 2009, 2011; Bryan et al. 2009; Mersha and Laerhoven 2016).

The aforementioned studies indicate that, small-scale farmers' inability to adapt to climate change is largely due to different barriers. However, limited work has been done to examine the adaptive capacity of small-scale farmers confronted with climate change and the barriers to small-scale farmers' capacity to adapt to climate change.

Effectiveness of Small-Scale Farmers' Adaptation Measures in Enhancing Adaptive Capacity to Climate Change

In Africa, the effectiveness of small-scale farmers' adaptive choices confronted with climate change varies tremendously. Kuwornu et al. (2013) carried out a study to assess the adaptive options of small-scale farmers confronted with climate change adversities and the effectiveness of these adaptive options. They found that among the different indigenous strategies used by small-scale farmers to adapt to the adversities of climate change, the strategies comprising of timing of rainfall and early or late planting were ranked by small-scale farmers in northern Ghana as the most effective strategy used in adapting to adverse climate change while soil-related strategies were ranked as the least effective indigenous strategy used by small-scale farmers. Kuwornu et al. (2013) equally found that among the introduced adaptation strategies (adaptation strategies introduced by research), soil and plant health strategies were ranked by small-scale farmers as the most effective introduced strategy enhancing adaptation to climate change, while non-adoption of any of the introduced strategies was quasi-unanimously ranked by small-scale farmers as the least effective way of adapting to the adverse effects of changing climatic conditions. Hadgu et al. (2015) in a study undertaken in the Tigray region of northern Ethiopia found that changing of crop variety/type was ranked by small-scale farmers as the most effective adaptation strategy to climate change while the "No" adaptation strategy was the least effective way to adapt to the adversities of changing climatic conditions.

The review of previous literature enabled the authors of this chapter to understand what had been done on the African continent in general and Cameroon in particular as far as small-scale farmers' adaptation and adaptive capacity to climate change were concerned. It equally afforded the authors the opportunity to identify some independent variables used in the chapter. However, it was found that while many authors had undertaken studies which revealed that small-scale farmers adopt different adaptive choices in the face of climate change, little had been done to examine small-scale farmers' adaptive capacity to climate change. This work was therefore initiated in a bid to fill the knowledge gap.

Description of Study Area and Methodology

Description of the Study Area

The study was carried out in the north-west region of Cameroon. The north-west region of Cameroon lies between longitude 9°30′E to 11°15′E and latitude 5°4′N to 7°15′N. The north-west region of Cameroon covers a total surface area of about 17,812 km^2 and hosts a population of over 1,840,500 inhabitants, which gives a population density of roughly 103 inhabitants/km^2 making it one of the most densely populated regions in Cameroon. The climate is tropical, and the vegetation is mostly made up of savannah grassland, interspersed with some forest patches. The topography is rolling and characterized by mountains like Mount Oku and plains like the Ndop and Mbaw plains.

Research Methods

Study Site Selection and Sampling Methods

The multiphase sampling procedure was employed. At the first phase, the area of study (the north-west region of Cameroon) was selected purposively owing to the presence of mainly small-scale farmers and the high levels of vulnerability of these small-scale farmers to climate change. At the second phase, ten villages were randomly selected from the different sub-districts found in the north-west region of Cameroon, taking into cognizance the agro-ecological, socio-economic, and environmental attributes of the different sub-districts. This was done with the help of agricultural extension agents working in the area. The third phase involved focus group discussions with small-scale farmers and key informant interviews with resource persons. This was done in order to get general information on the adaptive capacity of small-scale farmers and to triangulate this information with that gotten from small-scale farmers during household surveys. In the fourth and last phase, household surveys were conducted in the ten villages using the simple random sampling approach. With the use of semi-structured questionnaires, a total of 350 small-scale farmer household heads were sampled in the ten villages.

Data Sources and Collection

Both secondary and primary data were collected. Secondary data were collected primarily through the review of relevant literature from previous scientific studies as well as climate data from meteorological stations in the study area. Primary data were collected through a survey of 350 small-scale farmer household heads, complemented with focus group discussions, key informant interviews with resource persons, and overt observations.

Through the use of five-point Likert scale-style questions during household surveys, farmers were asked to rank their adaptive capacity to climate change based on their livelihood capital assets. These livelihood capital assets were natural, human, social, financial, and physical. These different capital assets constituted the independent variables of the study. It was on the basis of these capital assets that farmers ranked their adaptive capacity to climate change to be high, low, or no adaptive capacity.

Analysis of Data

Primary data collected on the field was coded and imputed into Microsoft Excel 2007 and SPSS 20.0 statistical packages for descriptive and inferential statistical analysis. Descriptive statistics computed were charts and percentage indices, while inferential statistics computed were t-test statistic, chi-square test, and logistic regression.

The independent samples t-test and chi-square (X^2) test statistics were used to identify the non-cause-effect relationship between small-scale farmers' capacity to adapt to climate change and independent variables.

The binary logistic (BNL) regression model on its part was used to examine the cause-effect relationship between small-scale farmers' capacity to adapt to climate change and independent variables. The binary logistic regression model predicts the log ODDS of having made one decision or the other. This model permits the analysis of decisions across two categories (Di Falcao et al. 2011; Awazi and Tchamba 2018).

Dependent and Independent Variables

Both dependent and independent variables were used. The dependent variable was adaptive capacity (binary, i.e., adaptive/not adaptive), while the independent or independent variables (different capital assets) were age of household head, household size, number of farms, income of household, educational level, gender of household head, practice of agroforestry, vulnerability to climate change, information accessibility, credit accessibility, land accessibility, and access to extension services. Because the dependent and independent variables were mainly qualitative in nature, the statistical analyses were done using non-parametric tests and the discrete regression model (binomial logistic regression).

Findings

Variations and Changes in Climate Elements

The analysis of over five decades of climate data revealed significant variations in climate parameters (Figs. 1, 2, and 3). In the past 58 years (1961–2018), temperature fluctuations were high, and most of the years experienced above mean temperature, implying that temperature is becoming higher than usual. Meanwhile the total

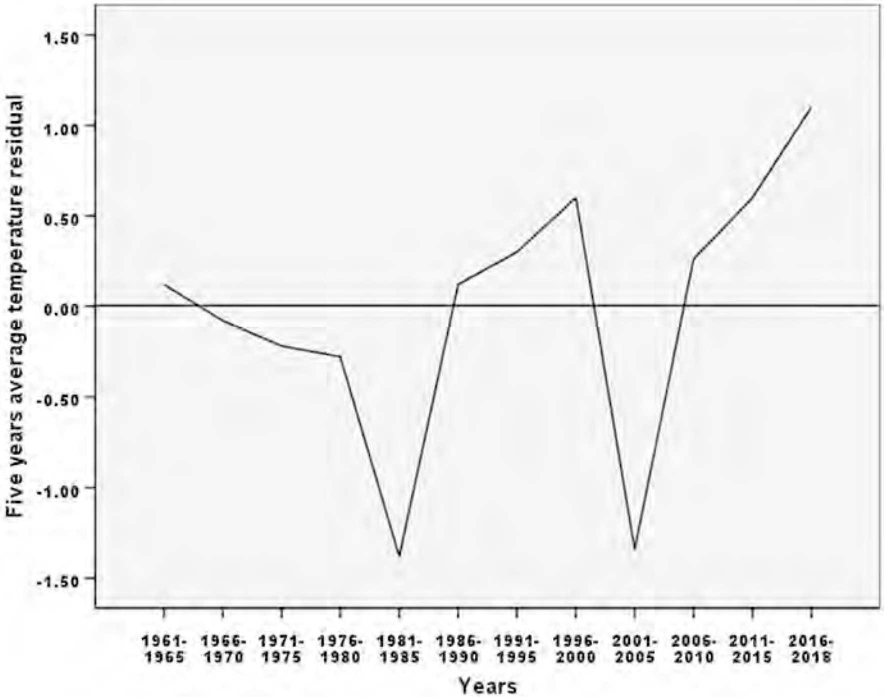

Fig. 1 Temperature variation 1961–2018

quantity of rainfall and number of rainy days equally experienced marked levels of fluctuation, with most of the years experiencing a decrease in amount of rainfall and fewer rainy days. This indicates that the amount of rainfall has been scanty while the number of rainy days has been erratic. These high levels of fluctuation in climate parameters within the past 58 years could therefore be seen as an indicator of climatic variations and changes.

In the face of climatic variations and changes, the relationship between the different climate parameters varied. Scatter plots indicated the existence of an insignificant negative correlation between rainfall and temperature, and rainy days and temperature. Meanwhile a relatively strong positive correlation was found to exist between rainfall and rainy days.

Adaptive Choices of Small-Scale Farmers Confronted with Climate Change Adversities

An analysis of small-scale farmers' adaptive choices confronted with climate change showed that a majority of the small-scale farmers (74%) were practicing agroforestry on their farm plots (Table 1). Among the agroforestry practices most patronized by

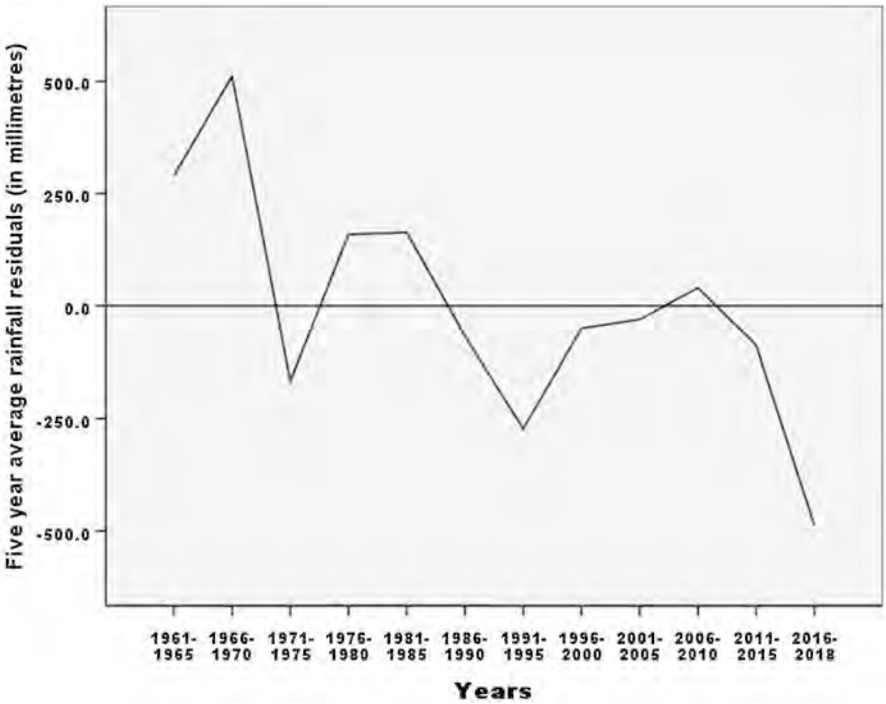

Fig. 2 Variation in rainfall 1961–2018

small-scale farmers confronted with adverse climatic variations and changes were home gardens with livestock (13%), home garden (11%), trees on croplands (11%), live fences/hedges (11%), and coffee-based agroforestry (9%) (Table 1).

Equally, some small-scale farmers confronted with adverse climatic variations and changes practiced monoculture (Table 1). The most common monoculture and mono-livestock practices of small-scale farmers confronted with adverse climatic variations and changes were market gardening monoculture (8%), cash crop monoculture (7%), and food crops monoculture (9%).

Farmer Perceived Factors Influencing Adaptive Capacity to Adverse Climatic Variations and Changes

Assessing small-scale farmers' adaptive capacity to adverse climatic variations and changes (Fig. 4), it was found that all the small-scale farmers perceived land accessibility (100%) and income of household (100%) as being the main factors influencing adaptive capacity to climate change.

Agroforestry (82%), accessibility to markets (77%), credit accessibility (72%), information accessibility (65%), and access to extension services (55%) were

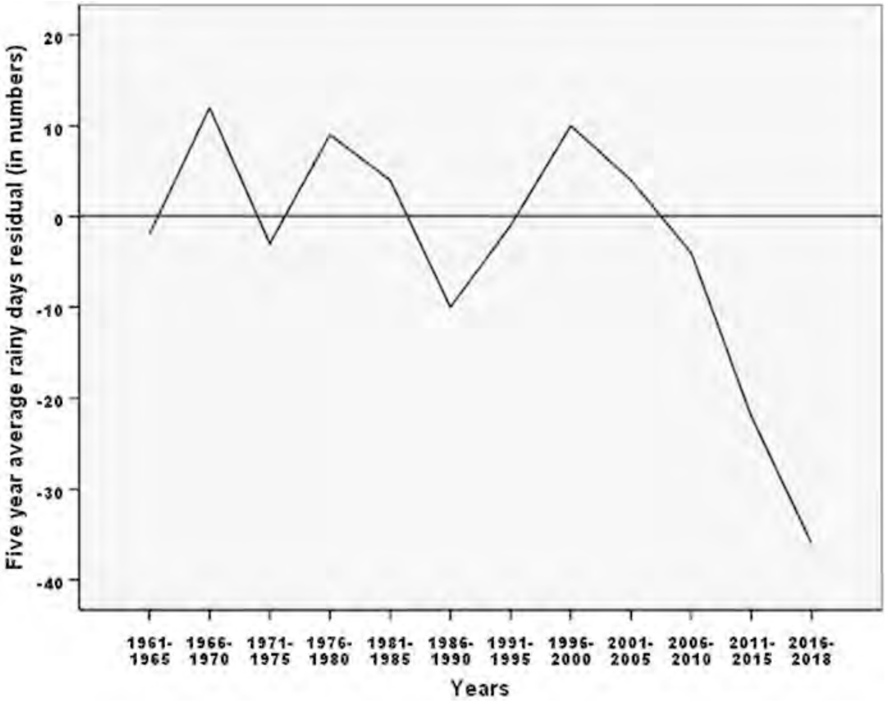

Fig. 3 Variation in rainy days 1961–2018

equally perceived by small-scale farmers as being among the key factors affecting adaptive capacity to climate change. Other least perceived factors influencing adaptive capacity to climate change were irrigation (31%) and others (14%) like road network and topography. However, it is worth mentioning that the main factors influencing small-scale farmers' adaptive capacity to climate change were land accessibility, income of household, agroforestry, accessibility to markets, credit accessibility, and information accessibility (Fig. 4).

Farmers' Capacity to Adapt to Climate Change

Concerning the adaptive capacity of small-scale farmers to climate change (Fig. 5), most small-scale farmers perceived that on the basis of their livelihood capital assets, they were not adaptive (58%).

Meanwhile 14%, 20%, and 4% of small-scale farmers perceived that, on the basis of their livelihood capital assets, they were adaptive, less adaptive, and much less adaptive, respectively, to climate change. Only 4% of small-scale farmers perceived that, on the basis of their livelihood capital assets, they were highly adaptive to climate change. From these perceptions, it was noticed that most small-scale farmers had a limited capacity to adapt to climate change (Fig. 5).

Factors Affecting Small-Scale Farmers' Adaptive Capacity to Climate Change

Non-Cause-Effect Relationship Between Small-Scale Farmers' Adaptive Capacity and Continuous Independent Variables

T-test statistics showed that there was a significant non-cause-effect relationship between small-scale farmers' adaptive capacity and four continuous independent variables (Table 2).

The continuous independent variables (number of farms ($t = 10.776$, $p < 0.001$), size of household ($t = 7.552$, $p < 0.001$), age of household head ($t = 8.224$, $p < 0.001$), and income of household ($t = 9.062$, $p < 0.001$)) all had a significant non-cause-effect relationship with small-scale farmers' adaptive capacity to climate change. This demonstrates that the number of farms owned, size of household, age of household head, and income of household play an important role in influencing the adaptive capacity of small-scale farmers confronted with climate change.

Non-Cause-Effect Relationship Between Small-Scale Farmers' Adaptive Capacity and Qualitative Independent Variables

Chi-square test statistics showed that there was a significant non-cause-effect relationship between small-scale farmers' adaptive capacity to climate change and seven (07) qualitative independent variables (Table 3).

The qualitative independent variables (level of education of household head ($X^2 = 123.10$, $p < 0.001$), gender of household head ($X^2 = 24.95$, $p < 0.001$), practice of agroforestry ($X^2 = 64.50$, $p < 0.001$), information accessibility ($X^2 = 44.70$, $p < 0.001$), credit accessibility ($X^2 = 90.88$, $p < 0.001$), land accessibility ($X^2 = 52.50$, $p < 0.001$), and access to agricultural extension services ($X^2 = 21.54$, $p < 0.001$)) all had a significant non-cause-effect relationship with small-scale farmers' adaptive capacity to climate change. This confirms that the level of education of household head, gender of household head, practice of agroforestry, access to information, access to credit, access to land, and access to

Table 3 Non-cause-effect relationship between small-scale farmers' adaptive capacity and qualitative independent variables

Binary Logistic Regression Model Predicting Small-Scale Farmers' Adaptive Capacity to Climatic Change from Independent Variables

The parameter estimates of the binary logistic regression model revealed that five main independent variables played a statistically significant role in influencing small-scale farmers' adaptive capacity to climate changes (Table 4).

From the parameter estimates of the binary logistic regression model, the number of farms ($\beta = 0.271, p < 0.05$), information accessibility ($\beta = 0.937, p < 0.1$), credit accessibility ($\beta = 1.596, p < 0.05$), income of household ($\beta = 1.821, p < 0.01$), and land accessibility ($\beta = 1.029$, $p < 0.05$) all had a significant direct cause-effect relationship with small-scale farmers' adaptive capacity to climate change. This implies that as the number of farms, information accessibility, credit accessibility, household income, and land accessibility increase, small-scale farmers' adaptive capacity to climate change also increases.

It is important to note that the parameter estimates of this model were valid looking at the likelihood ratio X^2, the number of cases correctly classified, and the Nagelkerke R^2. The likelihood ratio X^2 ($5, n = 350 = 145.835, p < 0.01$) indicated that the model was statistically significant and had a strong explanatory power. The model correctly classified up to 80% of the factors influencing small-scale farmers' adaptive capacity to climate change. Looking at the Nagelkerke R^2 (Pseudo R^2) of the model which stood at 0.648, it revealed that up to 64.8% of the changes in small-scale farmers' adaptive capacity to climate change could be explained by changes in the continuous and qualitative independent variables of the model. Hence, from the values of the likelihood ratio X^2, the number of cases correctly classified, and the Nagelkerke R^2, it could be said that the predictions of the model were very much

Discussion

Variations in Climate Elements

Extreme levels of variation in climate parameters (rainfall, temperature, and rainy days) have been recurrent in the north-west region of Cameroon in the past five decades which attests to climate variations and changes. Although other studies have shown the occurrence of climate variability in the north-west region of Cameroon (Innocent et al. 2016; Awazi 2018; Awazi and Tchamba 2018; Awazi et al. 2019), few studies in Cameroon have examined climatic variations using over five decades of climate data.

The chapter equally assessed the non-cause-effect and cause-effect relationship existing between climate parameters (temperature, rainy days, and rainfall) in the face of adverse climatic variations and changes. It was found that there is a very limited inverse relationship between rainfall and temperature as well as rainy days and temperature. Meanwhile a relatively strong direct relationship exists between rainfall and rainy days. This indicated that an interdependent relationship exists between rainfall and rainy days in the face of climate change. Studies carried out in other parts of the world by Chen and Wang (1995), Buishand and Brandsma (1999), Seleshi and Zanke (2004), Cong and Brady (2012), Berg et al. (2013), Olsson et al. (2015), Nkuna and Odiyo (2016), and Weng et al. (2017) have equally proven the existence of an interdependent relationship between climate parameters, although not in the context of climate change. By examining the relationship between climate parameters in the face of climate change, this chapter has filled a major knowledge gap.

Adaptive Choices of Small-Scale Farmers Confronted with Climate Change

It was found that most small-scale farmers practice agroforestry to enhance their adaptive capacity to climate change. Agroforestry practices therefore constitute a major adaptive choice for small-scale farmers. Most studies carried out in Africa (Easterling et al. 2007; Boko et al. 2007; Hassan and Nhemachena 2008; Gbetibouo 2009; FAO 2009b, 2010; Deressa et al. 2010) have merely shown that small-scale farmers adopt indigenous and non-indigenous adaptation strategies to combat the adversities of climate change. This chapter revealed that most small-scale farmers adopt agro-ecological farming practices like agroforestry to mitigate the adverse effects of climate change, thereby filling the knowledge gap.

Perceived Factors Affecting Farmers' Adaptive Capacity to Climate Change

Small-scale farmers perceived several factors influencing their adaptive capacity. Among these factors, land accessibility, income of household, and the practice of agroforestry were perceived by small-scale farmers as the most important factors affecting their adaptive capacity to climate change. As reported by other scientific studies, small-scale farmers usually perceive a combination of factors influencing their adaptation to climate variations and changes. Most studies have assessed the different adaptation choices practiced by small-scale farmers to enhance adaptive capacity to climate change (McCarthy et al. 2004; Gbetibouo and Ringler 2009; Folke et al. 2010; World Bank 2013), with very limited literature dwelling on the adaptive capacity of small-scale farmers confronted with climate change. By examining small-scale farmers' perceptions of their adaptive capacity to climate change, this chapter has filled the knowledge gap. Although some studies (Gordon 2009; Gbetibouo 2009; Thorlakson 2011) have used conceptual and theoretical approaches to assess adaptive capacity to climate change, this chapter by applying the inferential statistical approach to examine small-scale farmers' adaptive capacity to climate change adversities has filled a major knowledge gap.

Non-Cause-Effect and Cause-Effect Relationship Between Small-Scale Farmers' Adaptive Capacity to Climate Change and Independent/ Independent Variables

A non-cause-effect relationship was found to exist between small-scale farmers' adaptive capacity and independent variables (institutional, environmental, and socio-economic variables) like number of farms, household size, age of household head, income of household, level of education, gender, practice of agroforestry, information accessibility, credit accessibility, land accessibility, and access to extension services. Most studies undertaken across Africa and different parts of the world (McCarthy et al. 2004; Gbetibouo and Ringler 2009; Gordon 2009; Gbetibouo 2009; Folke et al. 2010; Thorlakson 2011; World Bank 2013; Awazi 2018; Awazi et al. 2019) mainly examined the non-cause-effect relationship existing between independent variables and small-scale farmers' adaptation choices to climate change. By unraveling the existence of a non-cause-effect relationship between adaptive capacity and different independent variables (institutional, environmental, and socio-economic variables), this chapter has therefore filled a knowledge gap.

A direct cause-effect relationship was found to exist between small-scale farmers' adaptive capacity and five main independent variables (credit accessibility, information accessibility, income of household, number of farms, and land accessibility). These five independent variables could therefore be considered as very important in enhancing small-scale farmers' adaptive capacity to climate change.

Thus, small-scale farmers with many farms are more adaptive to climate change which could be attributed to more yields obtained from these many farms which are consumed by the household and the excess sold to buy farm inputs. It could equally be that these farmers have more access to social and financial resources and/or better education which allows them to control more land and therefore enhanced adaptive capacity.

In the same light, small-scale farmers with better information accessibility are more adaptive to climate change than their counterparts with limited or no access which could be attributed to the fact that small-scale farmers with easy access to information are able to make plans into the future which helps them to adopt best practices.

Equally, small-scale farmers with more access to credit are more adaptive to climate change adversities than their fellow farmers with limited or no access to credit. This could be due to the fact that small-scale farmers with easy access to credit facilities are able to buy better farm inputs and can easily switch to best practices which act as a buffer to the adverse effects of climate change. Meanwhile small-scale farmers with little or no access to credit facilities are unable to buy good farm inputs and cannot switch to best practices on time which renders them weak and vulnerable in the face of climatic extremes.

Similarly, small-scale farmers with more access to land are better adaptive to climate change than their counterparts with limited or no land which can be attributed to the fact that land is an indispensable asset to any farmer, for it is the most important fixed asset, and without it, no farming activity can take place.

Some authors like Mccarthy et al. (2004), Gbetibouo (2009), Thorlakson (2011), and Awazi et al. (2019) have found the existence of cause-effect relationship between small-scale farmers' adaptation choices to climate change and different independent variables. Through the use of inferential statistics to examine the cause-effect relationship between adaptive capacity and different independent variables (institutional, socio-economic, and environmental factors), this chapter fills a major knowledge gap.

Conclusion and Policy Implications

Based on the findings of this chapter, it is clearly noticed that institutional, socio-economic, and environmental factors are key determinants of small-scale farmers' adaptive capacity to climate change. The existence of a statistically significant direct cause-effect relationship between small-scale farmers' adaptive capacity and independent variables such as credit accessibility, information accessibility, land accessibility, income of household, and number of farms is testament to the vital role these livelihood capital assets play towards enhancing small-scale farmers' adaptive capacity to climate change. Thus, it is recommended that policy makers seeking to alleviate the plight of vulnerable small-scale farmers take these determinants of small-scale farmers' adaptive capacity into consideration when formulating policies geared towards enhancing small-scale farmers' adaptive capacity to climate change.

Assessment of Farmers' Indigenous Technology Adoptions for Climate Change Adaptation in Nigeria

6

Idowu Ologeh, Francis Adesina, and Victor Sobanke

Contents

Abstract

Agriculture has shown a considerable capacity to adapt to climate change. Many adaptations occur autonomously without the need for conscious response by farmers and agricultural planners. However, it is likely that the rate and magnitude of climate change may exceed that of normal change in agriculture that specific technologies and management styles may need to be adopted to avoid the

most serious of effects. Thus areas likely to be most vulnerable to climate variability can be spared from its impacts through implementation of appropriate adaptation measures such as development of indigenous technologies.

Six hundred farmers from the six geopolitical zones of Nigeria were surveyed and they all possess different indigenous adaptation strategies ranging from swamp farming (Oyo State), application of neem seed (Kaduna State), soil erosion control (Enugu State), rainwater harvesting (Taraba State), land improvement (Cross River State) to farmland management (Benue State). They all have simple but profound technologies driving these schemes with much success. These indigenous adaptation techniques are majorly constrained by inadequate financial resources. Indigenous technology adoption is affordable with high revenue potential.

Introduction

Historically, agriculture has shown a considerable capacity to adapt to changing climatic conditions. If climate change is gradual, the adaptation may go widely unobserved and the adjustment process largely independent (Parry et al. 2004). In the field of climate change, vulnerability has been described as the degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes (Marrewijk 2011). Thus the need for climate change adaptation/mitigation measures to combat vulnerability. The major task of climate change adaptation and mitigation in agriculture is to produce more food efficiently and with clear reductions in greenhouse gas (GHG) releases from food manufacturing and marketing. “Adaptation” can be defined as societal or ecosystems efforts to prepare for or cope with future climate change. The coping methods can be defensive (i.e., being protective against adverse impacts of climate change), or adaptable (i.e., seizing the benefits of any advantageous effects of climate change) (USEPA 2014).

Nigeria along with other developing countries under UNFCCC is to focus on adaptation to make them able to cope with the new extremes in climatic regimes; they are also to concentrate on environmentally and economically sustainable development (Adesina and Odekunle 2011a). The argument is, the developing countries’ growth is being impaired by climate change effect and these countries produce only a small fraction of the GHG that is causing climate change. They also have fragile adaptive capability because their economies are still growing, thus they are highly vulnerable to the impacts of climate change.

Climate change adaptation is not novel; history has told how human societies whether by migration, improved crop varieties, or diversifying housing types have repeatedly proven strong capacities for adapting to different climates and environmental changes (Adger et al. 2007). However, the current rate of global climate change is unusually high compared to past changes that society has experienced and thus new innovations are necessary to combat the challenge. In this era that the world is getting increasingly interdependent, adverse effects of climate change on one community or economic sector can have aftermaths around the world (United States Global Change Research Programme – USGCRP 2009).

Adaptation is globally important because climate change will not become history soon. Many greenhouse gases linger in the atmosphere for 100 years or more after their emission and because of their long-lasting effects, they will continue to warm Earth in the twenty-first century, even if additional greenhouse gases emission were to stop today. Therefore, steps must be taken now to prepare for, and respond to, the impacts of climate change that are already occurring, and those that are projected to occur in the years ahead (USCGRP 2009).

There is need for continuous actions to mitigate climate because there are limits to the ability to adapt. Adaptation alone on long-term basis may not be sufficient to cope with all the projected impacts of climate change, thus it will need to be continuously coupled with actions to lower greenhouse gas emissions (IPCC 2007).

Adaptation is based on the level of socioeconomic development of a country; the resilience and adaptive capacity of a country is dependent on its level of development with respect to economy and political stability. To improve adaptation strategies, a clear understanding of local susceptibilities to climate change and critical thresholds must be established. Adaptation strategies should be adequately flexible in order to accommodate future possible changes in climatic parameters which may be responsible for quick review of plans; the plan should be reviewed periodically.

A myriad of possible adaptation strategies for agriculture are available; some of the most prominent in Nigeria are innovative indigenous technology options ranging from improved crop varieties, composting of organic waste, recycling and waste minimization, improved cultivation techniques, and cover cropping (Eze and Osahon 2015).

Reactive adaptations are those which occur after the impacts of climate change have been experienced, while anticipatory adaptations are proactive, undertaken before the impacts are fully felt. Planned adaptations are generally anticipatory, but can also be reactive (i.e., climate change effects are experienced). Farmers have access to various adaptations depending on their local environments and the specific farming system.

Some impact studies have suggested "adaptations" involving reductions and expansions of agricultural zones. This implies that some farmers would relocate, or others would completely change their type of farming while others would stop operations in some locations. Also, in other locations, there would be new farmers and some existing landowners would try new types of farming (Adesina and Odekunle 2011b). Although adaptations can be strategic at the farm level, the term "planned adaptation" is commonly used to describe actions taken by governments as a conscious policy response. Probable governments' planned adaptations include reinforcement of technological adaptations, such as crop development and early warning systems, promotion of land and water use options, changes in diversification or intensity of production aid, transformed financial support in established programs, and impromptu compensation.

Issue Description

Smallholder farmers were facing a lot of climate change-induced challenges on their farms of which flooding, pest and disease invasion, high temperature, and low crop yield are the most prominent. The Nigerian government has promoted various adaptation measures as its effort to curtail these challenges. These include provision of improved crop varieties, fertilizers, irrigation schemes, and geodata (Adefolalu 2007). Wisner et al. (2004) report that farmers' vulnerability is not determined by the nature and magnitude of climate change as such, but by the interplay of the societal capacity to adapt and/or recuperate from environmental change. The adaptation capacity and degree of exposure is connected to environmental changes and also to changes in societal aspects such as land use and cultural practices. Most studies on climate change and agriculture in Africa have concentrated on actual and projected impacts as well as farmers' coping/adaptation strategies (Adejuwon 2004). There has been little or no work in the area of local/indigenous adaptation technologies and their challenges or success. This chapter will therefore attempt, through a questionnaire survey, Focus Group Discussions, and review of relevant literature, to fill this gap.

The objective of this chapter is to assess indigenous technology adaptation options being used by smallholder farmers in Nigeria**.**

Research Techniques and Findings

The survey area is Nigeria; for ease of data collection, the major food-producing state of each geopolitical zone in the country is sampled for the survey. After relevant literature and National Bureau of Statistics consultation, the following six states were selected for the survey:

North-Central Zone – Benue State
North East Zone – Kaduna State
North-West Zone – Taraba State
South-East Zone – Enugu State
South-South Zone – Cross River
South-West Zone – Oyo State

It is very important to assess the various indigenous technology adaptations in use by smallholder farmers in Nigeria so as to know which can be fully developed for national adoption. To achieve this objective, 600 questionnaires were administered to smallholder farmers in the six states to survey their various indigenously designed adaptation options to climate change. The questionnaires were designed to collect information on farmers' biometric data, years of experience and skills, farm size, types of crops cultivated, educational level, experiences on climate change effects, and indigenous adaptation techniques. Secondary data was obtained from NBS and the Agricultural Development Agencies of each of the States. The retrieved questionnaires were imputed and analyzed using Microsoft Excel spreadsheet 2016 and the results are presented in frequencies and percentages.

A total of six hundred questionnaires were administered to smallholder farmers in the six states, and all were retrieved through the assistance of agricultural extension workers who administered them, the results are presented in Table 1.

In order to obtain realistic data, matured farmers are targeted, the average age is 53 years old. Majority (86%) of the farmers have more than 30 years of experience in farming with 60% of them owning more than one hectares of land. Female farm owners (42%) are mostly found in Southern Nigeria while men majorly own farmland in the north, and employ numerous women laborers. The most grown crops across Nigeria as detected in the data are cassava, maize, yam, rice, and vegetables.

Almost all the farmers (97%) complained of the various losses they have incurred due to devastation effects of climate change ranging from drought encroachment in the north to flooding in the south. The totality of the respondent farmers have poor knowledge of the scientific explanations behind climate change, but experience taught them that nature (weather) is no longer their friend and they have to devise strategies to make it work in their favor. Their understanding is that nature (or the gods) is fighting them through the massive attack of pests and diseases, flooding, erratic rainfall, high temperature, and low yield. As a result, they devise different techniques to adapt to climate change effects including sacrificing to the gods. These indigenous adaptation techniques vary from zone to zone, depending on the

Table 1 Socioeconomic characteristics of sampled smallholder farmers

prevalent climate change effect in the area. Swamp farming was devised in Oyo State, discovery, and application of neem seed to enhance soil fertility in Kaduna State, improved soil erosion control in Enugu State, rainwater harvesting in Taraba State, intentional cover cropping in Cross River State to farmland management (organic manure) in Benue State. They all have simple but profound technologies driving these schemes which will be discussed in details.

This finding harmonized with that of Eze and Osahon (2015) who listed adaptation strategies as improved crop varieties, composting of organic waste, recycling, and waste minimization, improved cultivation techniques, and cover cropping.

Devastating Effects of Climate Change on Smallholder Farmers

All the smallholder farmers surveyed have in their more than 30 years of experience suffered different adverse effects of climate change. The prominent effect in Northern Nigeria is erratic rainfall and unusual heat (heatwave). They are also faced with desert encroachment advancing into Nigeria from Niger republic and pest invasion. Their counterparts in the South are majorly faced with flooding, infertility, increase in temperature, and pest invasion. The major effect in North Central is the increase in temperature, soil infertility, and pest invasion.

The finding is in agreement with the work of Lybbert and Sumner (2010) that temperature increase is an indication of climate change, and also the work of Adegoke et al. (2014), who stated that weeds, pests, and fungi thrive under warmer temperatures, wetter climates, and increased carbon dioxide (CO_2) levels.

The different climate change effects being experienced in different zones in Nigeria dictate the corresponding indigenous adaptation techniques, and these are presented in Tables 2 and 3.

Indigenous Adaptation Techniques in Use in Nigeria

North-Central Zone – Benue State

Benue State is the food basket of Nigeria, the state is popular for large-scale food and fruit production including yam, cassava, sweet potato, beans, maize, millet, guinea corn, vegetables, soybeans, rice, and citrus. The smallholder farmers in Benue State are faced with climate change impacts such as soil infertility, increase in temperature, pests and diseases invasion, crop failure, and increased weed. To mitigate/adapt to these effects, the adaptation strategies common to smallholder farmers in the state are mixed cropping, growing pest/disease-resistant crop varieties, use of cover crops, and making bigger ridges.

The prominent indigenous adaptation practice in the state is local farmland management. The Benue farmers devised a farmland management practice to adapt to climate change. The practice entails conscious efforts to reduce temperature on farmlands and is very similar to organic agriculture. It is a complete management system with high organic matter content (mulching), soil cover (cover crops/tree

Table 2 Devastating effects of climate change on smallholder farmers

Variables	Benue	Cross river	Enugu	Kaduna	Oyo	Taraba

planting), and high soil fertility (crop rotation, organic manures, and legume planting) thus retaining nutrient and water, building more floods, drought, and land degradation resilient soils.

North West Zone – Kaduna State

Kaduna is a state in which 80% of the people are actively engaged in farming. They produce crops ranging from yam, maize, beans, guinea corn, millet, rice, and cassava. The prevalent climate change impacts in the state are drought, pests and diseases invasion, crop failure, land degradation, increase in temperature, flooding, access to water and soil infertility. The widely adopted adaptation practices are mixed farming, mixed cropping, growing drought-resistant crop varieties, growing pest-resistant crop varieties, crop rotation, irrigation, roof water harvesting, and making bigger ridges.

The unique indigenous adaptation method in use in the State is the application of neem seed for pest control (used as fumigant, pesticide), compost (used as fertilizer, manure), and soil fertility (used as soil conditioner and urea coating agent).

North-East Zone – Taraba State

Taraba State just as his North-West counterpart is 80% agrarian. They produce crops ranging from maize, millet, sorghum, rice, yam, cassava, and sweet potatoes. They experience climate change effects such as high rate of weeds, drought, decrease in soil moisture, increase in temperature, decrease in crop yields, and high rate of pests and disease incidence. The adaptation measures generally in use in the State are growing drought-resistant crop varieties, crop rotation, irrigation, integration of livestock farming system, changing crop varieties, mulching, and intercropping.

Table 3 General adaptation techniques in use in Nigeria

Variables	Benue	Cross river	Enugu	Kaduna	Oyo	Taraba
Mean max 5	Mean (M)	Mean (M)	Mean (M)	Mean (M)	Mean (M)	Mean (M)

Changing planting dates	3.1	3.1	3.0	3.3	3.2	3.5

Source: Fieldwork

The indigenous adaptation practice unique to Taraba State is rain harvesting. Access to water is an issue in the state and thus the need for irrigation. Rain harvesting is used to augment the water used for irrigation. The most common is roof water harvesting which is channeled into catchment tanks or concrete reservoirs.

South-East Zone – Enugu State

Enugu State has a diversified economy dominated by agriculture. Major crops produced in the State are yam, cassava, maize, rice, cowpea, sweet potatoes, and plantain. Their crop production is impaired by climate change effects such as increase in temperature, flood, soil erosion, pests and diseases invasion, and crop failure. Adaptation practices widely in use in the State include planting pest/disease-resistant crop varieties, use of pesticides/herbicides, construction of drainage systems, contour cropping, and diversification in crop planting.

Soil erosion is the major problem affecting smallholder farmers in Enugu State, and its volume was aggravated by the effects of climate change. Their key indigenous adaptation strategy is soil erosion control using stone and sandbags to divert erosion away from the farms, ridging, and use of wrapped weeds or grasses to cover planted heaps. Stems from previous harvests are also arranged or scattered on the soil in bands to reduce soil erosion. Tree planting on the borders of the farm also prevents soil erosion as the trees shield the farm from direct impact of rainfall.

South-South Zone – Cross River

Cross River State famously known for tourism and fishing is also fully involved in agriculture. The crops mainly cultivated in the State are cassava, yam, plantain, rice, and maize. Although it is a coastal state, they also have their share of climate change effects. They are affected by increased weeds, pests and diseases invasion, increase in temperature, crop failure, and flooding. They adapt by planting pest-resistant crop varieties, diversification of crops, planting cover crops, mulching, and construction of drainage systems.

Indigenous land improvement methods are the key indigenous adaptation practice in Cross River State. These methods include organic addition to the land (mulching, compost, and manure), cover tree planting, planting of legume crops (mixed cropping), and polyculture. Water harvesting from runoffs also helps to maintain soil moisture during dry season.

South-West Zone – Oyo State

Oyo State is an industrialized state with many educational institutions. It also enjoys diversified economy with agriculture as the major occupation. Smallholder farmers in Oyo State are faced with climate change effects like their counterparts in other states, this includes flooding, pests and diseases invasion, soil erosion, crop failure, and increased temperature. Their general adaptation methods are ridge construction, use of pesticides and pest-resistant crop variety, irrigation, crop substitution, and changing planting dates.

The major captivating indigenous adaptation method practiced by the smallholder farmers in Oyo State is swamp farming. There are lots of swamp areas in Oyo State, where smallholders resort to when there is prolonged delay in rainfall season. This initiative allows early and late farming as there is constant access to water. Some farmers in Oke Ogun area of the state channel their domestic wastewater to wet their vegetable farms all year round.

These findings are in agreement with that of Adger et al. (2007) that listed adaptation strategies as migration, improved crop varieties, or building different types of shelter, while Anríquez and Stamoulis (2007) list include changing the timing of operations, adoption of conservation tillage practices, and diversification in production systems, improvement of irrigation schemes, modification of farm support programs, and development of new plant varieties.

Constraints to the Development of Indigenous Adaptation Techniques in Nigeria

The various indigenous adaptation strategies assessed have developmental constraints. The major is inadequate financial resources; adaptation practices are cost-intensive and these smallholder farmers cannot afford elaborate adaptation strategies. Even the indigenous methods need funding to develop, e.g., the planting and processing of neem seed in Kaduna State and soil erosion control in Enugu State. Other constraints include inadequate farm labor due to express increase in rural-urban migration; poor extension services, insufficient drought-resistant varieties, and strict adherence to local varieties (see Table 4).

Indigenous Adaptation Techniques Contributing Factors

The results of the partial least squares (Ringle et al. 2005) are presented in Fig. 1, and showed the factor loadings for all observed variables, R^2 value of the unobserved endogenous (dependent) variable as well as regression coefficients between exogenous and endogenous unobserved variables. Nine (9) observed variables

Table 4 Constraints to the development of indigenous adaptation techniques in Nigeria

Variables	Benue	Cross river	Enugu	Kaduna	Oyo	Taraba
	Freq /%	Freq /%	Freq /%	Freq /%	Freq /%	Freq /%
Finance	93	92	88	95	91	86
Farm labor	34	62	57	37	48	33
Poor extension services	23	42	38	31	54	48
Insufficient drought-resistant varieties	76	84	63	67	66	52
Strict adherence to local varieties	62	33	28	56	14	51

Source: Fieldwork

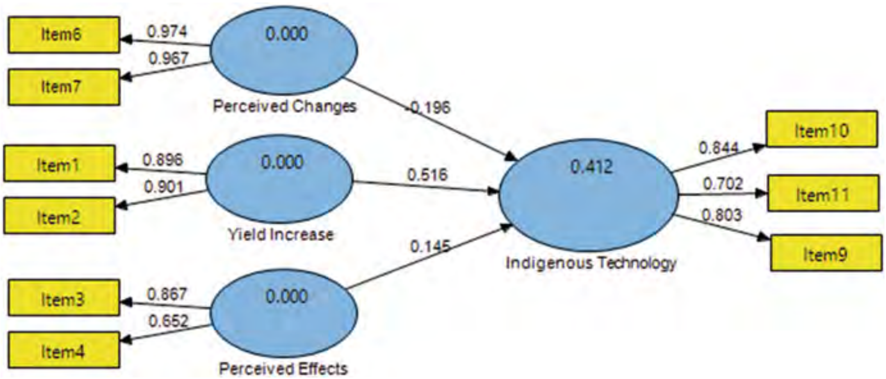

Fig. 1 Structural model of indigenous technology adoption

with high loadings were retained for further analysis, while items with low factor loadings were removed. The R^2 value of 0.412 indicates that about 41% variance observed in the choice of indigenous adaptation techniques employed by farmers can be explained by farmers' perceived effect of climate change, need for crop yield increase, and perception of changing weather.

Reliability and validity of unobserved variables is presented in Table 5. The results show that composite reliability (CR) which indicates the convergent validity in all the constructs is adequate and above 0.7 the minimum threshold (Hair et al. 2010). The average variance extracted (AVE) which is a more conservative method of measuring convergent validity than CR (Malhotra and Dash 2011) is also within the recommended threshold (>0.5). On the contrary, only the value of Cronbach's alpha for perceived effects was below the recommended threshold (0.7).

The results of the T-statistics showing the significant level of regression coefficients are presented in Table 6. This result showed that indigenous adaptation techniques by respondents is influenced by their perceived changes (2.703; $p < 0.05$) and yield increase (6.665; $p < 0.05$). The result suggest that respondent's choice of indigenous adaptation techniques depends on the aspect of perceived changes in climatic parameters as well as the usefulness of climatic information.

Table 5 Reliability and validity of unobserved variables

	AVE	Composite reliability	Cronbach's alpha	Communality	Redundancy
Indigenous technology	0.617	0.828	0.700	0.617	0.056
Perceived changes	0.942	0.970	0.938	0.942	
Perceived effects	0.589	0.737	0.317	0.589	
Yield increase	0.807	0.893	0.761	0.807	

Table 6 Path analysis

	Original sample (O)	Sample mean (M)	Standard deviation (STDEV)	Standard error (STERR)	T-statistics (|O/STERR|)
Perceived changes -> indigenous technology	−0.196	−0.198	0.072	0.072	2.703
Perceived effects -> indigenous technology	0.145	0.156	0.081	0.081	1.782
Yield increase -> indigenous technology	0.516	0.519	0.077	0.077	6.665

Conclusion

The chapter examined the various climate change effects affecting smallholder farmers across Nigeria. The general adaptation techniques adopted in each geopolitical zone of the nation were assessed as well as peculiar indigenous adaptation techniques initiated and in use in each zone. The constraints to the development of the indigenous adaptation techniques were also investigated. Going forward, these indigenous techniques need to be developed and commercialized; the state and federal government agricultural schemes and agencies can fund this project and support the efforts of the smallholder farmers. It is also essential for a functional link to be established between the farmers' indigenous innovation and the academia to foster research and development.

production. Food crop production under various climate change scenarios requires the use of improved technologies that are called climate smart agriculture to ensure increased productivity under adverse conditions of increased global temperatures, frequent and more intense storms, floods and drought stresses. This chapter summarizes available information on climate change and climate smart agriculture technologies. It is important to evaluate each climate change scenario and provide technologies that farmers, research scientists, and policy drivers can use to create the desired climate smart agriculture given the array of tools and resources available.

Introduction

Background

Climate describes the weather conditions of a region such as its temperature (hot, warm, or cold) which is due to amounts or intensity of sunshine, rainfall (dry or wetness) and its pattern, air pressure, humidity, cloudiness, and wind, throughout the year, averaged over a series of years. "Climate change" as a terminology was suggested by the World Meteorological Organization (WMO) in 1966 to represent climate variations over long periods of time often from decades to millennia, irrespective of the causative agents (Hulme 2017). The term has been widely accepted and has fast become a household name for climatic variations which are often not favorable for man's survival. Climate change has largely been associated with anthropogenic global warming; however, it is indeed larger and encompasses all vagaries in climatic conditions which occur over decades. Also human activities are estimated to have caused approximately 1.0 °C of global warming above pre-industrial levels, with a likely range of 0.8 °C to 1.2 °C. Global warming is likely to reach 1.5 °C between 2030 and 2052 if it continues to increase at the current rate (IPCC 2018). In today's world, the term climate change has evolved from being a technical jargon for describing vagaries in climatic pattern into a global issue agent which requires the intervention of man to prevent future disastrous outcomes being predicted.

It should be noted that this book chapter will cover very limited information on climate change as the objective is to guide the reader to appreciate the need for a response that adopts innovations to accelerate the development of climate smart agriculture technologies as mitigation efforts against climate change. With that understanding we shall proceed to attempt to cover the breadth of knowledge in a summary of what is known with regards to the expected impact of climate change on crop production and food security, an overview of climate smart agriculture technologies and what is possible given current trends in technology and innovation.

Even though mitigation and adaptation responses compete with each other due to potential negative trade-offs across spatial, temporal, institution (Smith and Olesen

2010), economic scales (Wilbanks and Sathaye 2007). While mitigation measures aim to reduce emissions on a global scale, adaptive measures are specific to micro-environments and address various local impacts of climate change. As a result of the interconnection between the environment and socio-economic risks, the agriculture sector offers opportunities for complementary actions through the implementation of ecosystem sensitive approaches known as the CSA. This new approach is to bridge the growing divide between the two discourses and foster long-term resilient development in the agriculture sector. CSA is defined by FAO as "agriculture that sustainably increases productivity, resilience (adaptation), reduces/removes GHG's (mitigation) and enhances achievement of national food security and development goals' (FAO 2010). Therefore, adaptation, mitigation, and food security are the three key pillars of CSA (Lipper et al. 2014).

Climate smart agriculture (CSA) is a way to achieve sustainable development as well as green economy goals. It intends towards food availability and takes part to conserve natural assets and is closely associated with perception of improved growth, as FAO develops it for crop yield (FAO 2011). There is a high need for climate smart agriculture because agricultural production systems are expected to produce food for a global population of about 9.1 billion people in 2050 and over 10 billion by the end of the century (UNFPA 2011). This, however, has necessitated the development of CSA strategies and policies at different levels of governance (Zougmore et al. 2016). Therefore, it is highly imperative to sustain livelihoods which are predominantly agrarian in these regions.

Climate Change and Food Security

Climate change has the potential to threaten food production and, consequently, food security especially in vulnerable regions. One major area where the impact of climate change is expected to be very significant in threatening the very existence of humanity is the estimated effect of climate change on agriculture. Agriculture is the major source of income and livelihood for an estimated 70% of the poor and vulnerable people who live in rural areas with limited resources oftentimes without access to basic technologies (World Bank 2016b). However, the production of food is being affected by climate change, it is therefore important to study the influence of this global climate change to meet the requirements of people and is estimated that by 2100, the world population will reach about 10 billion (Boogaard et al. 2014). The climate change and variability will adversely impact on food security and agriculture livelihoods of the poorest farmers, fisher folks and forest dwellers. Even though sub Saharan Africa contributes less than 5% of the global greenhouse gas (GHG) emissions, the region is vulnerable to the negative effects of climate change due to the fact that the region's development prospects are closely linked to the climate due to the great reliance on rainfall (Tol 2018). Added to other non-climatic stresses (poverty, inequality, and market shocks), the impact of climate change will make negatively impede the achievement of the Sustainable Development Goals (SDGs) on livelihoods, food security, poverty reduction, health, and access to clean water in vulnerable communities (IPCC 2014a). However, the use of climate change predictions based on theories and past data accrued over centuries is difficult to use in projecting the expected impact of changing climates on food security. Since the institution of climate change as a body or a field of study, many academic and scientific publications have emerged. The first scientific work by Katz, published in the first issue of the first journal on climate change titled "Climate Change" on the effect of climate change on food production clearly questioned the accuracy of any such predictions and warned that the predicted impacts at the time were estimates should be acknowledged as such. A direct quote from Katz follows: *"Attempts to assess the impact of a hypothetical climatic change on food production have relied on the use of statistical models which predict crop yields using various climatic variables. It is emphasized that the coefficients of these models are not* universal constants, but rather statistical estimates subject to several sources of error. Thus, any statement regarding the estimated impact of climatic change on food production must be qualified appropriately" (Katz 1977).

The aforementioned challenges have been addressed by leading investigators recently where climate change impact has been modelled based on quick country-level measurement of vulnerability to food insecurity under a range of climate change and adaptation investment scenarios (Richardson et al. 2018). The findings have been made accessible through their publication and an online interactive portal that is user friendly for policymakers (Met Office 2015). The interactive graphically displayed model predicts that food insecurity vulnerability is anticipated to worsen rapidly under all simulations of GHG emissions, and the re-distribution of vulnerable geographic regions remains very similar to present-day conditions where sub-Saharan Africa and South Asia remain the most severely affected. By the year 2050, an additional 2.4 billion people expected to be living in developing countries with much concentration in South Asia and sub-Saharan African, where agriculture is an important sector and major employment source, but currently more than 20% of the population is on average food insecure (Wheeler and von Braun 2013). About 75% of the global poor live in rural areas, and agriculture is their most important source of income (International Fund for Agricultural Development 2011). High levels of adaptation is seen to be able to decrease vulnerability across affected areas; however, the only scenario with the highest level of mitigation combined with high levels of adaptation shows appreciable levels of reduction in vulnerability compared to the present-day prevailing conditions (Smith and Olesen 2010). As agriculture is directly affected by climate change, adaptation strategies are becoming increasingly important issues for promoting development (Clements et al. 2011). Therefore, adaptation strategies in the context of climate change are all those practices that are employed by smallholder farmers to either get used to or minimize the effects of climate change and variability. According to the IPCC, adaptation is the process of adjustment to actual or expected climate and its effects that in human systems, adaptation seeks to moderate or avoid harm or exploit beneficial opportunities (IPCC 2014). The strategies for adapting to climate change and variability can be grouped into two; namely, autonomous and planned adaptation strategies. The autonomous adaptation strategies involve actions taken by non-state agencies such as farmers, communities, or organizations and/or firms in response to climatic shocks while planned adaptation involves actions taken by local, regional, and or national government to provide infrastructure and institutions to reduce the negative impact of climate change. However, the planned adaptation which measures or results from deliberate policy decisions and awareness from farm to global levels and are discussed in literature as key to reducing present and future vulnerability and climate impacts on livelihoods (IPCC 2014). However, there are limitations to planned adaptation measures under severe conditions. As a result, more systematic changes in adaptive capacity and resource allocation are being considered. So in this discussion we shall look at the various climate smart agriculture practices that can help mitigate the climate change effects on agriculture. Therefore, the effects of climate change can be solved by climate smart agriculture practices such as climate smart crop (breeding), improved pasture and animal rearing, amelioration of degraded lands, rehabilitation of polluted water bodies, and management of sustainable systems such as agroforestry, livestock management, and manure management. Also, the promotion of sustainable land management practices which are also part of CSA practices (Branca et al. 2011) have influenced paradigms shift from the traditional practices. Most of these technologies can help mitigate greenhouse gasses (GHG) emissions. Food security and improving food productivity can also reduce human vulnerability to climate impacts and the need for additional land conversion to agriculture, which represents almost as much as GHG emissions and those directly generated from agriculture activities (IPCC 2014), but food production and security measures may conflict with climate smart and conservation objectives, especially intensifying agriculture and producing more food for a growing population (Matocha et al. 2012).

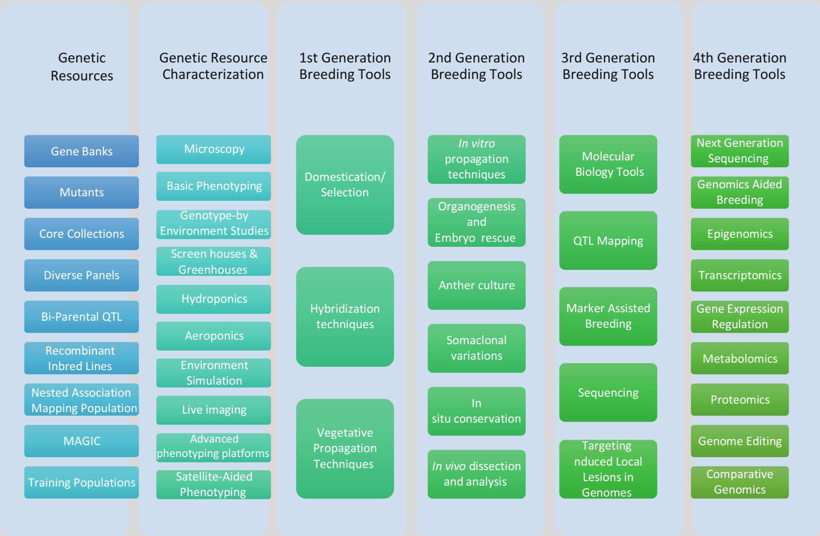
Climate Smart Agriculture Technologies

The climate smart agriculture technologies will focus on describing some of the approaches which include breeding (climate smart crop), efficient resource management, integrated renewable energy technologies for farming systems, resource conserving technologies, land use management, cropping season variation, efficient pest management, forecasting, and geographic information system (GIS) mapping.

Breeding and Climate Change

Agriculture was born about 13,000 years ago when man gradually transitioned from hunting and gathering lifestyle into domestication of wild plants and animals. Food production systems since the invention of Agriculture which remains heavily dependent on the availability of rainfall has been evolving progressively to match-up to the growing demands of the human population. It is noteworthy that the art of breeding which emerged through domestication which involved selecting plants and animals that were acceptable with good qualities for the consumption/utilization by man. Breeding which begun as selection has seen many advancements; notable are hybridization techniques, matting designs and schemes, genetics enhanced hybridization programs, tissue culture and mutagenesis aided systems, genetic engineering using recombinant DNA technologies, and Genomics- and other Omics-assisted breeding and the latest being genome editing. A summary of the resources and tools available for breeders in this day and age is presented in Box 1 below. As breeding has evolved based on man's knowledge and the development of tools to aid the development of new variants, climate and the rate of climate change has rapidly outpaced and outstripped the worlds production systems especially in areas of greatest vulnerability where new technologies remain inaccessible. The dry areas and flood prone areas are of the greatest concern where extreme weather conditions can prevail and persist for long periods disrupting the natural seasons and cycles of production that farmers are used to. These concerns can mostly be addressed if all tools available to breeders are widely accepted and utilized to aid in the development of climate smart crops that are designed to adapt to harsh and extreme weather conditions producing higher yields compared to currently available varieties that do poorly under such conditions.

Box 1 Array of Tools and Resources Available to Breeders



The myriad of available resources range from genetic resources available that are conserved in situ, ex situ, or in vitro; gene banks, core and representative collections not forgetting diverse panels in national, international, and regional research Centres as well as the Bi-parental, Recombinant Inbred Lines (RILs), Nested Association

Mapping, Multi-parent Advanced Generation Inter-cross (MAGIC) & Training populations in the hands of researchers and Scientists who originated and curated them. These genetic resources are sources of alleles of great agronomic importance required in the development of climate smart crops or animal breeds that can withstand and yield highly under changing climatic conditions. These are therefore the first range of arsenals of breeders in the fight against dwindling productivity under climate change conditions. The next in the array of tools are those that can be used to characterize, evaluate, detect, select, and then release these climate adaptable varieties to farmers and businesses for increasing productivity under prevailing circumstances. These tools have evolved from first generation to the current cutting edge fourth generation tools that are available for breeders to use in the development of new and improved varieties with better adaptation to the changing environmental conditions. The first-generation tools mainly encompass discoveries of basic principles of domestication/selection, the knowledge and use of pollination to make self and crosses as well as means of vegetative propagation such as grafting, corms, bulbs etc. Second generation array of tools are mainly based on advances in biology that allow for cell, tissue and organ culture which allow for more advanced technologies in the crop and animal improvement by breeders. Third and fourth generation tools such as represented in Box 1 that have been developed add speed and precision to the array of tools that are currently available for quick development of improved climate smart crops.

It is important to evaluate each climate change scenario and provide strategies breeders can use to create the desired climate smart crops given the array of tools and resources available. The various climate change scenarios, potential impact and climate smart breeding approaches are delineated in Table 1. For instance, climate change is greatly impacting agriculture currently in the tropics and other arid areas with erratic rainfalls that no longer follow the patterns or established seasons known to farmers that heavily depend on rain-fed crop production systems. This scenario has the potential impact of poor yields as a consequence of untimely start of the farming activities and crop failure. For adaptability to such scenarios, climate smart crops with adaptability to different types of droughts or erratic rains could be developed using a combination of tools and resources described in Box 1 and made available to farmers. Such climate smart crops are required in vulnerable areas threatened by climate change in order to avert the worsening food insecurity problem and ensure the achievement of sustainable development goals 1 (no poverty) and 2 (no hunger).

Efficient Resource Management

Another approach that can be of relevance in achieving the objectives of climate smart agriculture is efficient management of resources. This approach is an important part of CSA and the future environment. In the food production chain, from the farmer to the customer or final consumer, almost one third part of the food is lost due

Table 1 Climate change scenarios, potential impact, and climate smart breeding approaches

Climate change scenarios	Potential impact	Climate smart approaches
Erratic rainfall	Farmers plant too late or too early leading to yield losses	Climate smart crops with adaptability to different types of droughts or erratic rains.
Prolonged droughts in arid areas and New Droughts prone areas	Crop losses, Famine and loss of lives	Drought resistant crops that perform well under water limited conditions
Increased floods	Damage to crops and animals; loss of lives and property, displacement of people	Development of water loving crops as well as crops resistant to lodging
Intense rain and wind storms	Damage to crops and animals	None
Rise in sea levels	Increase in salt stress on crops, loss of arable lands to toxic levels of salts, low or no yields	Salt resistant or tolerant crops
Loss of soil cover	Soil erosion, loss of soil fertility, loss of microbes in the soil	Planting of trees and plants that will rehabilitate the soils. Introduction of bioengineered microbes that encourage soil health.
Increased global temperatures	Reduced yields, new pests and disease emergence and damage to crops and animals	Improved heat adaptable crops

to the improper management of resources (Hartter et al. 2017). On yearly basis, for instance, the total energy consumption in the global food losses are almost 38% of all the energies utilized by the food chain. Critical areas in the food chain processes which serve as good avenues for improving energy efficiency includes: transportation, conservation, processing, cooking, and consumption (FAO 2011). In Africa, a majority of wood removed is used for manufacturing household articles as well as cooking. However, cooking in stoves helps save energy thereby decreasing deforestation in the long run. For instance, this technique of managing resources and climate change projects has helped in supporting sustainable intensification through a number of initiatives including the establishment of an agriculture information and the decision support system and the preparation of soil management plans. Since this approach was adopted in 2014, climate smart agriculture was adopted on 2,946,000 hectares and has provided for a carbon sequestration potential of up to 9 million tons carbon dioxide annually, (https://www.worldbank.org/en/topic/climate-smart-agriculture). Additionally pastoralists are also enjoying some benefits from climate smart agriculture in the Sahel, Burkina Faso, Chad, Mali, Mauritania, Senegal, and Niger. The application of rangeland management is boosting productivity and resilience. This approach is also helping to reduce emissions.

Integrated Renewable Energy Technologies of Farming Systems

The Integrated Renewable Energy Technologies is the application of suitable energy technologies, tools, and different farming services which are relevant in creating the stable change to energy smart proficient food systems. These technologies are governed by conditions of nature. These technologies are very useful because in the long run there will be a reduction in GHG's emissions. For instance, mid-season aeration can be promoted through short term drainage. Some of the technologies in the energy smart food system are the windmills, solar panels, wind generators, photovoltaic lights, biogas, and conversion of hydrothermal tools, bio energy and water pumping machines, information and communication technological innovation, and other similar approaches (Bochtis et al. 2014; Basche 2015). This technology has been applied in Morocco through the Morocco inclusive project Green Growth project, through the supply of agrometeorological information and the facilitation of the resilience building technology such as direct seeders. The pumps used can be both fuel and electric water pumps which are mostly used on irrigation farming (deep well and submersible pumps). Stakeholders in the agricultural industry should appreciate this modern technological innovation due to the benefits of increasing the value of production in the farming business. Most times, these technologies are linked on the farm from an integrated food energy system as shown in Fig. 1 below.

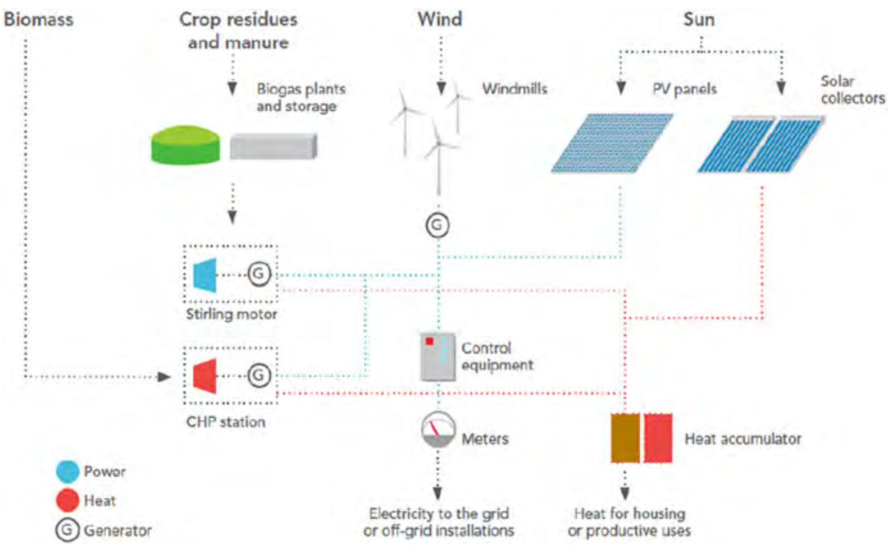


Fig. 1 Integrated renewable energy technologies for farming systems. (Source: Amin et al. 2016)

Resource Conserving Technologies (RCTs)

This technology consists of methods that enhance efficiency in the management of inputs. When these resource technologies are implemented, it comes with its own merits which includes low cost of productivity, limited use of fuel, labor, water, and early planting of crops which results in improved yields in the long run. For instance, the zero tillage system, which happens to be one of the resource conserving technologies, is a type of cultivation system in which the seeds are directly sowed into a virgin (uncultivated) soil. The zero-tillage system, however, involves the cultivation of crops into untilled soil by aeration of thin channels with adequate depth-width so as to attain suitable seed coverage. The soil remaining is left as if tillage has never been done on it before (Derpsch et al. 2010). In some parts of the globe, the zero tillage permits farmers to grow wheat very soon after the rice harvest. This allows the head of the crops to appear and the filling of the grains before the warm weather, pre-monsoon set off. Therefore, as the average temperature of the globe in certain parts rises, early planting will be more relevant for the production of wheat (Pathak 2009).

Land Use Management

Land use management involves the proper planning of land and its usage. The proper planning includes fixing the location of plants and livestock production, changing the concentration of the application of plant foods and bug sprays can reduce global warming on agricultural activities (Ahmad et al. 2014). Other land use practices involve shifting production out of marginal areas, changing the role of applying cartilage and pesticides. However, it must be noted that capital and labor can minimize the risks from Climate change on agriculture production. The farmers can regulate the duration of the growing season by changing the time at which the farming fields are sown. Other adaptation mechanisms can be in the form of changing the times of irrigation and use of fertilizer.

Figure 2 elucidates Cropland Expansion Potential for different continents.

Cropping Season Variation

The planting dates can be set to reduce the infertility that is caused by increasing temperatures; this may prevent the flowering period from meeting with the hot period (Arslan et al. 2015). The effects of the increased climatic variations which normally happens in both the semiarid and arid regions sometimes take advantage of the wet period by changing the planting times/dates. However, this approach is usually to avoid intense weather events in the growing season. This system of cultivation promotes the development of strong cultivars thereby leading to the production of different crops. The planting dates can be set to reduce the infertility that is caused by increasing temperature; this may prevent the flowering period from

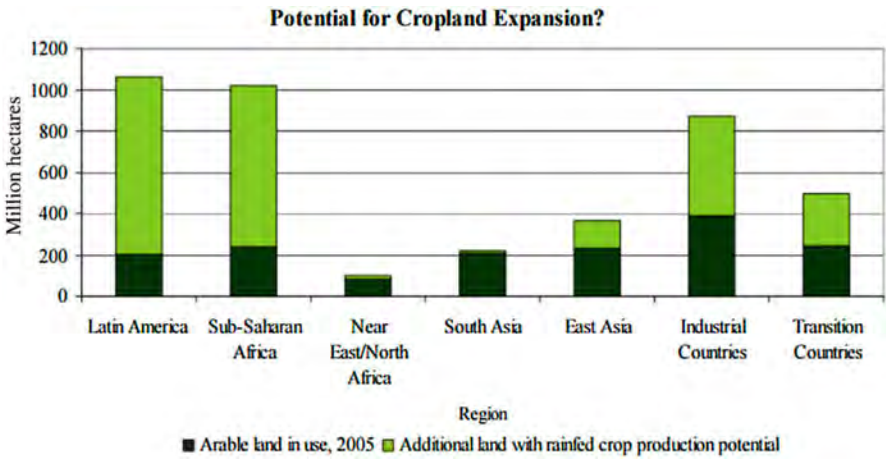

Fig. 2 Land use management. (Source: Burnisma 2009)

meeting with the hot period. The effects of the increased climatic variations which normally happens in both the semiarid and arid regions sometimes take advantage of the wet period by changing the planting times/dates. However, this approach is usually to avoid intense weather events in the growing season. This system of cultivation promotes the development of strong cultivars thereby leading to the production of different crops. The farmers will, therefore, need to ensure that they adopt the changing crop rotation system in the various hydrological cycles (Pathak et al. 2012).

Crop Relocation

This approach involves the grouping and sorting of the plants and the varieties with respect to its sensitivity to the weather condition of a place. Crop relocation helps the crops to perform well according to the sensitivity of the climate during the vegetative and productive stages (Shames et al. 2012). There are several factors which affect agricultural production as a result of climatic change. These include increase in temperature, carbon dioxide (Co_2) levels, and increase in drought and floods. These impacts vary across the various regions in the world as well as the different cultures. Other factors such as daylight, temperature, and humidity are very necessary for the vegetative and reproductive growth of the crops. Additionally the period for harvesting should be properly done so as to minimize losses during the period (Baba et al. 2017). However, it is therefore important to differentiate regions and crops that are highly susceptible to climate change. For instance, it is obvious that temperature increases affect the quality of many important crops. Some of these crops with respect to the discussion include basmati rice and tea.

Efficient Pest Management

The normal agriculture pest and insect management on farms poses a threat to the environment. The usage of chemicals to destroy and kill pests is very harmful for farmers and also living organisms in the soil. Even chemicals such as insecticide, herbicides for plant diseases have been banned by some governments of certain countries, as the situation exists now, there is no botanical or environmental friendly chemical available. Due to this, farmers still use the chemicals for controlling pests on their farms. So, basically this technique provides an opportunity to employ environmentally friendly measures for pest control. The difference in the climatic factors such as the fall and rise in temperature unpredictably influences pest and disease incidence thereby impacting on major crops.

Therefore, the change in climate will affect the relationship of pest and weed and the host populations. However, some of the adaptation strategies in this pest management approach includes;

(i) Improvement in different breeding types that are resistant to pest and disease.
(ii) Strong pest adaptation mechanism with more relevant control for both biological and cultural practices.
(iii) Adoption of techniques such as crop substitution with regards to places resistant to pest and hazards.

GIS Mapping

This approach is used in analysis and mapping. It is a system which is designed to capture, store, manipulate, analyze, manage, and present geographical data.

Fig. 3 Risk Assessment and mapping. (Source: Amin et al. 2016)

However, it helps in the estimation and computation of storm causes and flooding that is related to hot cyclones. The study in using GIS mapping considers factors such as property allocation, infrastructure facilities among other resources. The photograph and images (Fig. 3) were used in the experimentation of seashore due to rising sea levels and hot cyclones. The figure below shows risk which can be explained by the cumulative study of emerging threat and the existing patterns of vulnerability. The technique enables the creation of hazards and risk maps at many different possible scales or dimensions to show the threat allocation across different geographical spaces within the globe. Some of the geographical places can be site specific, municipal (administrative areas) and other natural landscapes in river basins, coastlines, and lakes. Figure 3 portrays Mapping and Risk Assessment.

Conclusion

Climate change is a great threat to agriculture and as such there is the need to tackle this adverse impact by adopting new innovative techniques in climate smart agriculture. This chapter has dealt with some of the climate smart agriculture techniques that can help reduce the impacts of climate change on agriculture and increase food crop production. To achieve food security and agriculture development goals, adaptation to climate change will be required to lower emission intensities per output. Thus improving food protection by moderate climate change, sustainable use of the natural resources, using all products more competently, have less inconsistency and greater constancy in their outputs. More fruitful and more flexible agriculture requires a paramount change in the usage of resources such as land, water, soil nutrients, and genetic resources management by climate smart agriculture approaches.

Sorghum Farmers' Climate Change Adaptation Strategies in the Semiarid Region of Cameroon

8

Salé Abou, Madi Ali, Anselme Wakponou, and Armel Sambo

Contents

Abstract

This chapter deals with the problem of sorghum farmers' adaptation to climate change in the semiarid region of Cameroon. Its general objective is to compare the various adaptation strategies' typologies and to characterize the sorghum farmers' adaptation strategies on the basis of the suitable one. The stratified

random sampling method was used to select the sites, which consist of twenty (20) villages, and the sample, which consists of six hundred (600) farm household heads. After conducting focus-groups in ten villages and interviews with resource persons, the primary data were collected using a semi-open survey questionnaire. It appears that the poor spatiotemporal distribution of rains and the drought constitute, respectively, the main climate hazard and the main water risk that farmers are dealing with; the farmers are vulnerable to climate change because the adaptation strategies used are mostly traditional, their adoption rates are very low, and the use of efficient adaptation strategies (irrigation, improved crop varieties) is almost unknown. The characterization of the adaptation strategies used shows that they are more complex than most authors who have established the typologies thought. It comes out that improving the resilience of these sorghum farmers absolutely requires the improvement of their basic socioeconomic conditions.

Semiarid region · Sorghum farmers · Climate change · Climate hazard · Water risk · Adaptation strategies

Introduction

Farmers in the semiarid regions of Africa, to which belongs the Diamaré division in the Far North Cameroon, are among the most vulnerable to water constraints caused by climate variability during the 1960s and 1970s. This vulnerability has its origin in their essentially rain-fed agriculture, their unfavorable socioeconomic characteristics, and their very fragile ecosystem.

According to Borton and Nicholds (1994), of all-natural hazards, droughts are the ones with the greatest economic impact, and affecting the greatest number of people. In the Diamaré division, as in the whole semiarid zone of Cameroon, water constraints, particularly droughts and floods, have had a negative impact on cereals' production, especially sorghums, which constitute the basic food of the population. According to L'hôte (2000), the period called "Drought in the Sahel" was an agronomic disaster for the entire region. Similarly, the results of the simulations carried out by Blanc (2012), compared to a reference without climate change, indicate that sorghum yields could decrease by around –47% to –7% by 2,100 in this region. Faced with this situation, a wide variety of adaptation strategies emanating from both farmers and agricultural research has been made available to sorghum farmers, but adoption rate remains low as everywhere else in the African semiarid zones (Yesuf et al. 2008; Leary Kulkarmi and Seipt 2007).

In order to better understand the main orientations of these various adaptation strategies, a variety of typologies has been previously established by some authors (Dingkuhn 2009; Nhemachena and Hassan 2007; Jouve 2010; then Fabre 2010); but a comparison between adaptation strategies on the basis of these typologies remains difficult because of the diversity of analysis' angles used by the authors. For this reason, it seems better to identify the main similarities and differences between the various typologies, and then to characterize the sorghum farmers' adaptation strategies on the basis of the most suitable typology. The sorghum farmers' adaptation strategies' characterization could allow researchers as well as policy-makers to better reorient research priorities and policies in order to improve farmers' resilience.

The Diamaré division located in the Far-North region of Cameroon (Fig. 1), between 10° and 11° North latitude (10°30′00″) and 14° and 15° East longitude (14° 30′00″), constituted the focus area. The climate is Sudano-Sahelian in its southern part and Sahelo-Sudanian in its northern part, all characterized by a long dry season (7–9 months), and a short rainy season. Agriculture (rainy season, dry season), animal husbandry, fishing, trade, and crafts are the main activities of these populations.

The information has been collected through directed interviews with some resource people (researchers, patriarchs, heads of technical services), and then focus groups and a survey questionnaire submitted to six hundred (600) household heads. The descriptive and inferential statistics (frequencies, percentages, Principal Component Analysis, Kaiser-Meyer-Olkin/KMO test) from the SPSS statistical software have been used to analyze the information gathered.

Socioeconomic Characteristics of the Sorghum Farmers

In general, agriculture and livestock are the main activities of the farmers, and the Diamaré division is one of the three divisions most exposed to food insecurity in the region. Priority is given to cereals in terms of land mobilization and work (CEDC 2010), and sorghum (rainy and dry seasons) constitute the staple food of the populations. This agriculture is essentially characterized by the practice of polyculture (93.80%) and self-consumption agriculture (79%), the small size of the sown areas (100%<10 ha, with areas varying between 0,5 ha and 1 ha for sorghum), the low quantity of agricultural inputs used (FAO 2009), the poor access to agricultural supervision (51.50%), and to credits (43.50%). Cotton and onion are the only export crops. In order to ensure their daily survival, these farmers multiply income-generating activities (65.50%), which reflects the inability of agricultural activities to meet their food needs, and therefore their high vulnerability. The household heads are mostly men, most of them aged between 35 and 54 years (FAO 2009), with an average age of 48 years in Diamaré. The average household size is around 9 people, and seems to be high compared to a regional average of 7 and a national average of 5.7. The school enrollment rate, which is 57%, is the lowest in the country, with 39.30% having reached primary, 17% secondary, and less than 1% (0.4%) higher education. Health and school infrastructures are among the least fortunate in the country.

Climate Hazards and Sorghum Farmers' Adaptation Strategies

Table 1 summarizes the climate hazards imposed by the climate change to the rainy and dry seasons' sorghum production.

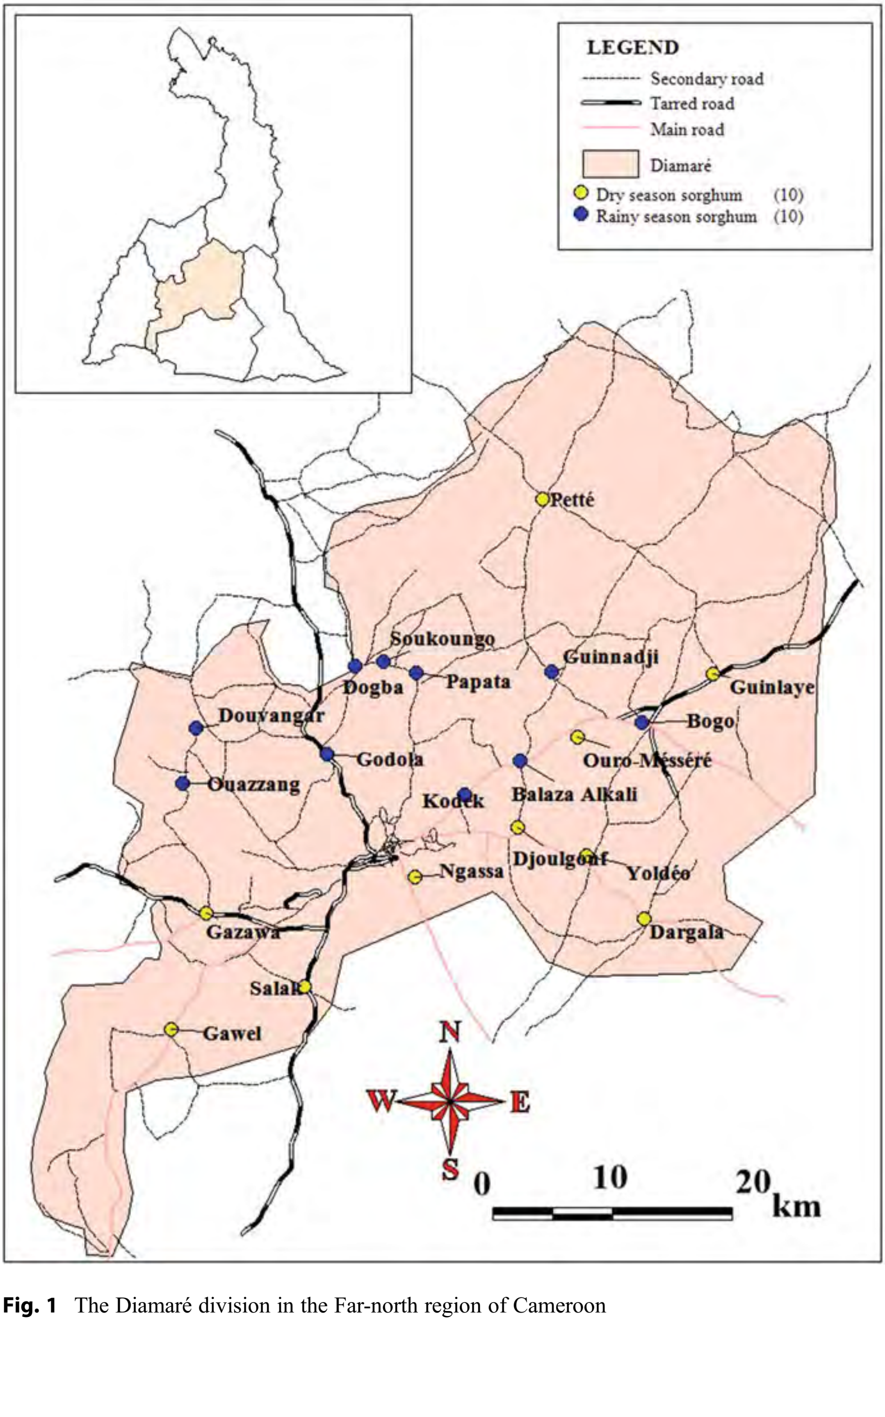

Fig. 1 The Diamaré division in the Far-north region of Cameroon

Table 1 Climate hazards perceived by rainy and dry seasons sorghums' farmers

Climate hazards	Rainy season sorghum		Dry season sorghum	
	Total	%	Total	%
Late or early arrival of rains	300	100	297	99
Early cessation of rains	300	100	293	97,67
Poor spatial rainfall distribution	299	99,67	299	99,67
More frequent and long dry spells	300	100	300	100
Flooding of crops	300	100	294	98
General decline in the total amount of rainfall	299	99,67	296	98,67
Rapid drying of water sources (ponds, rivers, lakes, wells)	–	–	300	100
Rapid drying and hardening of soils	–	–	292	97,33
Light rains at the beginning of the rainy season	–	–	297	99
Absence of heavy rains at the end of the rainy season	–	–	297	99
No haze during cold season	–	–	299	99,67

Most of the climate hazards listed relate to the poor spatiotemporal distribution of rains, while most of them are linked to drought, and not to excess water (floods); that means the poor spatiotemporal distribution of rains is the main climate hazard while drought is the main water risk limiting agricultural production both during the rainy and dry seasons in the area. This observation confirms the results obtained by Chédé (2012), Gnanglé et al. (2012), then Agossou et al. (2012).

Likewise, it emerges that all the three known forms of drought are represented here:

- Meteorological drought (late arrival of the rains, early start of the rains, dry spells, decrease in the amount of rains, light rains at the start of the rainy season, light rains at the end of the rainy season)
- Agricultural drought (rapid drying and hardening of soils)
- Hydrological drought (rapid drying up of ponds and rivers)

According to FAO and National Drought Mitigation Center (2008), when all of these three forms of drought rage somewhere, automatically, the socioeconomic drought which is their logical consequence, will also rage there; and that is noticeable through the socioeconomic characteristics of the sorghum farmers described in the previous paragraph.

One can also remark the high rate of climate hazards' perception by the farmers, which could reflect both the extent and the severity of these constraints, but also a good perception of the phenomena by farmers who control their physical environment. Indeed, Arodokoun (2011) considers that, in general, peasant communities which maintain close links with their environment have a perfect knowledge of the climate, its manifestations and the changes that have occurred. This situation could also be justified by the fact that according to Nhemachena and Hassan (2007), climate change has very negative effects on the poorest households which have the least capacity to adapt to changing climatic conditions.

It appears also that all the climate hazards affecting rain-fed sorghums also affect dry season sorghums; which reflects the strong dependence of dry season sorghum on meteoric water. On the other hand, the multiplicity of climate hazards affecting dry season sorghum can be explained by the diversity of the water resources (meteoric, surface, underground) essential to its production.

The adaptation strategies in use by sorghum farmers in the face of these climate hazards and water risks are summarized in Table 2.

The analysis of the nature of the adaptation strategies used by sorghum farmers in the face of climate hazards and water risks could lead to the following remarks:

- All the adaptation strategies used by sorghum farmers aim to compensate for either the poor distribution of rains, the droughts (meteorological, edaphic, hydrological, socioeconomic), or to both of the two types of constraints.
- An overwhelming majority of these adaptation strategies have been adopted to cope with meteorological drought, which is the main form of drought faced by sorghum farmers; it is followed by edaphic drought, then hydrological drought.

Table 2 Nature and frequency of adoption of the adaptation strategies used by sorghum farmers

Adaptation strategies	Rainy season sorghum		Dry season sorghum	
	Total	(%)	Total	(%)
Sowing early matured varieties	131	43,67	175	**58,33**
Sowing or transplanting early	178	**59,33**	139	**46,33**
Sowing of drought resistant crops varieties	178	**59,33**	194	**64,67**
Diversification of crops varieties	94	31,33	182	**60,67**
Changing of crops or crops' varieties	105	35	25	08,33
Labor of plots and mounding of plants	234	**78**	96	32
Temporary or permanent transfer of crops	170	**56,67**	30	10
Making of racks or bunds	103	34,33	203	**67,67**
Nursery organic or inorganic fertilizer input	271	**90,33**	82	27,33
Diversification of income-generating activities	195	65	141	47
Crops diversification	268	**89,33**	272	**90,67**
Multiplication of weeding	123	41	20	06,67
Sowing of molten seed holes or dried plants	166	**55,33**	05	01,67
Rocky bunds	05	01,67	–	–
Late transplanting	–	–	125	**41,67**
Deepening piles	–	–	129	43
Purchase or request of nurseries	–	–	104	34,67
Scaling of nurseries over the time	–	–	203	**67,67**
Organic or inorganic fertilization of nurseries	–	–	107	35,67
Cleaning and deepening of ponds	–	–	131	**60,33**
Water research over long distances	–	–	95	31,67
Fertilization of transplanting water	–	–	06	02

- Despite the identification of floods as another main water risk by sorghum farmers, no adaptation strategy has apparently been adopted by them to deal with it.
- The adaptation strategies used are traditional in their majority, and those recognized as efficient such as the irrigation or the use of improved crops' varieties are almost unused.
- Despite the traditional nature of the adaptation strategies used, their adoption rates by farmers are low in the majority of cases.

The synthesis of these preceding remarks conducts to the following conclusions:

- The poor spatiotemporal distribution of rains and the drought (especially meteorological), constitute, respectively, the main climate hazard and the main water risk faced by farmers in the area; this has been previously confirmed by several researchers including Batterbury and Mortimore (2013), then Mortimore and Adams (2000), who consider that all the Sahelian farmers' problems correspond to a group of "five (5) crises of the Sahelian orthodoxy," to which they are trying to provide solutions, the main one of which is represented by drought.
- Sorghum farmers in particular and farmers in general from the region are very vulnerable because they do not really adapt to but they simply cope with the climate change; this confirms the observation made by the IPCC (2014), Sissoko et al. (2010), OECD (2010), then Leary et al. (2007), according to whom Sahelian farmers do not adapt to but simply cope with climate change; these sorghum farmers' maladaptation (lack of adaptation) can be perceived or explained from the previous paragraph 1 through the practice of self-consumption agriculture, the small size of the sown areas, the low quantity of agricultural inputs used, the poor access to agricultural supervision and to credits, the multiplication of income-generating activities, and the weak school enrollment rate. Contrary to this result, authors like Jouve (2010) and Batterbury and Forsyth (1999) find that in fact Sahelian farmers adapt to climate change. This duality of contradictory observations could be justified either by the different use of the concept of adaptation, or by the difference in the results obtained in different contexts.

Sahelian Farmers Adaptation Strategies' Typologies

On the whole, the farmers' adaptation strategies in the dry regions (semiarid, arid) can be classified both on the basis of farmers' practices, which takes into account all the actions undertaken by them to ensure their survival, and on the basis of the agricultural research, which is only interested in crop management. According to these two angles of analysis, the typologies could be grouped into three main categories:

- The first category of typologies, proposed by Nhemachena and Hassan (2007), Jouve (2010), Ngigi (2009), Diarra (2008), Fabre (2010), then Batterbury and Mortimore (2013).
- The second category of typologies brings together those proposed by Batterbury and Forsyth (1999), then Ngigi (2009).
- The third category of typologies, which corresponds to that proposed by Dingkuhn (2009).

First Category of Typologies

The first category of typologies is that proposed by Nhemachena and Hassan (2007), Jouve (2010), Ngigi (2009), Diarra (2008), Fabre (2010), then Batterbury and Mortimore (2013). These typologies distinguish adaptation strategies which consist of facing risks from those focusing on avoiding risks.

In general, Nhemachena and Hassan (2007) estimate that there are roughly two types of adaptation strategies in agricultural production systems:

1. The strategies which are based on "confronting water risks," essentially based on increasing diversification which corresponds to the adoption of production activities tolerant to drought and/or resistant to thermal stress, as well as activities that relate to efficient management that value the quantity of water available and ambient temperatures among other factors.
2. The strategies which are based on "eviction of water risks," essentially based on crop management practices, and which consist in avoiding that the critical stages of plant growth do not coincide with bad climatic conditions such as inter-season droughts (modification of the crop cycle and modification of sowing and harvest dates).

Jouve (2010), Ngigi (2009), and Diarra (2008), based on the subjective assessment of risks and vulnerability, have grouped the farmers' adaptation strategies into three (3) categories:

1. The "pre-risk" or preventive management options (prevention strategies) or before risks, such as the choice between risk-tolerant varieties, investment in water management, and diversification of survival and agriculture, well before the arrival of the growing season.
2. The "intra-season" adjustment of crops and resources management options in response to constantly changing specific climatic shocks, also called "adaptive methods" or "mitigation strategies"; these are peasant innovations put in place to adapt to climate change and to make the best use of rainwater resources.
3. The "post-risk" management options or "palliative methods" or "adjustment strategies," which minimize the impacts of adverse climate shocks; they seek to mitigate the effects of climatic risks which particularly affect poor rural

populations; these methods, based on the establishment of insurance systems, aim to stabilize farmers' incomes and avoid their indebtedness and decapitalization during bad years; they are intended to alleviate the impact of the event when it happened.

The comparison between these two typologies indicates that they are identical: the strategies based on "confronting water risks" proposed by Nhemachena and Hassan (2007) correspond to the intra-season adjustment and post-risk" management options in the typology proposed by Jouve (2010), Ngigi (2009), and Diarra (2008), while "crowding out water risks" corresponds to "pre-risk" management options.

Batterbury and Mortimore (2013) estimate that the Sahelian farmers' adaptation strategies correspond to the five crises of Sahelian orthodoxy:

- The management of rainfall by farmers each year
- The integration of agriculture and animal husbandry
- The conservation management of biodiversity
- The intensive and sustainable soil management
- The diversification of livelihoods

Jouve (2010) and Fabre (2010), for their part, believe that sahelian farmers' adaptation strategies to climate variability can be split into three (3) groups:

- The choice of crops (species, varieties)
- The modification of practices (irrigation and drainage, polyculture, modification of the cropping calendar)
- The modification of sources of income (crafts, livestock, trade, etc.)

Reconciling the last two typologies also indicates that they are similar insofar as the management of rainfall, the integration of agriculture and animal husbandry, and the intensive and sustainable management of soil suggested by Batterbury and Mortimore (2013) corresponds to the modification of practices suggested by Jouve (2010) and Fabre (2010). Similarly, the conservation management of biodiversity corresponds to the choice of crops, while the diversification of livelihoods corresponds to the modification of sources of income.

Finally, the comparison between the two previous typologies and the two last ones indicates that they are in fact similar. The "increase in diversification" proposed by the first two typologies corresponds to the "modification of the sources of income and the practices" proposed by the two last ones, while the crop "management practices" correspond to the "choice of crops"; this amounts to saying that in terms of farmers' practices, the four typologies are identical.

The particularity of this first category of typologies is that they are based principally on the natural agro-pastoral resources (water, soils, crops, animals) spatiotemporal management.

Second Category of Typologies

The second category of typologies includes those proposed by Batterbury and Forsyth (1999), then Ngigi (2009). These typologies distinguish "adaptive processes" which are long and medium terms adaptation strategies, from "adaptive strategies" which are short term actions intended to ensure the survival of farmers.

Batterbury and Forsyth (1999) find that farmers' adaptation strategies can be divided into two categories:

- The "adaptive processes," which generally call for a spatial extension of activities outside the locality, in order to reduce the pressure on local resources; it is an appropriate strategy for communities in dry regions where diversification is the main response to drought or crop failure; adaptation processes are long-term transitions that change the configuration of relationships between a community and its resources; each transition has several components, and adoption and the form that transition takes depends on several factors of change, such as farmers' knowledge, the biophysical environment (especially precipitation and soil), and availability of the work force; for this reason, each transition will be relatively unique, thus reflecting the interactions between farmers, their institutions, their economic policy, and their environment.
- The "adaptive strategies" are short-term practices, adopted in response to sudden shocks or difficulties in accessing resources.

Ngigi (2009) differentiate adaptation strategies to climate change between:

- "Adaptation itself" or "adaptation strategies," which constitutes a change in response to changing climatic parameters and
- "Coping mechanisms" or "coping strategies," generally in the short term.

The comparison between these two typologies shows that they are also similar. "Adaptation itself" corresponds to "adaptive processes," while "coping strategies" correspond to "adaptive strategies."

This category of typologies is characterized by the fact that tries to differentiate the farmers' adaptation strategies, either on the long- and medium-terms use of agricultural or nonagricultural strategies to truly adapt climate change, or on the short-term use of agricultural or nonagricultural strategies to cope with climate change (without really adapting to it); in other words, it differentiates farmers' adaptation strategies based on whether they are genuinely adapting in the long- to medium-terms, or whether they are simply coping in a short-term with climate change to just ensure their survival.

Third Category of Typologies

The typology proposed by Dingkuhn (2009), corresponds to the third category, and groups adaptation strategies according to the agricultural research fields, into four very distinct types:

- Genetic adaptation (drought resistant varieties, early varieties)
- Agronomic adaptation (all the strategies linked to the management of crops, which are the most numerous)
- Geographic adaptation (temporary or permanent change in cultures)
- Temporal adaptation (early sowing, late sowing, staggering of nurseries)

The particularity of this category of typologies is that it is not interested in the climate hazards or risks that farmers are facing (first category of typologies), nor in the strength or weaknesses of the adaptation strategies in use (second category of typologies), but simply to the scientific field to which each of these adaptation strategies relates.

The comparison between all the previous typologies and the current one proposed by Dingkuhn (2009) indicates that one could very well transpose the genetic, agronomic, geographic, and temporal adaptations suggested by this typology in these ones; however, the socioeconomic adaptation taken into account by these typologies does not exist in the one proposed by Dingkuhn (2009), and this could be explained by the fact that this typology is essentially concerned with crop management and not with farmers practices in their whole.

After a careful analysis of the typologies' categories and the sorghum farmers' adaptation strategies, it appears that it is appropriate to characterize them on the basis of the first category of typologies because both (category of typologies, adaptation strategies) are oriented towards the agro-pastoral natural resources' management; on the other hand, while the second category of typologies requires the strategies to be monitored over time in order to assess their effectiveness, the third category is more descriptive and does not allow to grasp easily the real objectives targeted by sorghum farmers.

Characterization of Sorghum Farmers' Adaptation Strategies

The adaptation strategies were grouped according to crops, so first, the adequacy of the rainy season sorghum farmers' adaptation strategies has been tested using the KMO test. The results are listed in Table 3.

All the KMO values taken by the different adaptation strategies being greater than 0.49, all these strategies have been used in the test.

Table 3 Results of the KMO sample adequacy test applied to the rainy season sorghum farmers' adaptation strategies

Adaptation strategies	Codes	KMO values
Sowing early matured varieties	SEVARPRE	0.834
Sowing or transplanting early	SEMISSEC	0.743
Sowing of drought resistant crops varieties	SEMVARES	0.817
Diversification of crops varieties	DIVARCUL	0.896
Change of crops or crops varieties	CHASPVA	0.671
Labor of plots and mounding of plants	LABBUTPL	0.815
Temporary or permanent transfer of crops	MUTEDECU	0.858
Making of racks	CONFCAS	0.925
Organic fertilizer input	FUMORGA	0.849
Diversification of income-generating activities	DIVACGER	0.854
Crops' diversification	DIVERCUL	0.850
Multiplication of weeding	MULTSARC	0.867
Sowing of molten seed holes or dried plants	RESREPIQ	0.845

The eigenvalues of the various factors from the PCA results reveal the existence of two (2) main factors, which explain 53.64% (>49%) of the total variation of the adaptation strategies, in accordance with the KMO rule (Fig. 2 and Table 4).

Loading these adaptation strategies according to the two main factors gave the results mentioned in Table 5.

Factor 1 brings together the adaptation strategies "sowing of early matured varieties," "diversification of crop varieties," "change of crops or crop varieties," "labor of plots and mounding of plants," "temporary or permanent transfer of crops," "organic or mineral fertilizer input," and "sowing of melted seed holes or dried plants." This factor can be called "Adaptation to climate hazards through efficient management of natural resources (soil, water, crops)." This factor can be interpreted as the decision-making by farmers to continue to carry out agricultural activities despite the risks, and corresponds in fact to the adaptation strategy by "**confronting climate hazards and water risks**" suggested by the first category of typologies.

Factor 2 groups together the adaptation strategies "sowing or transplanting early," "sowing of drought resistant crops varieties," "making of racks," "diversification of income-generating activities," "crop diversification," and "multiplication of weeding." This factor brings together adaptation strategies whose main objective is to avoid water risks.
It therefore corresponds to all the activities carried out by farmers with the aim of minimizing climate hazards and water risks and their impacts; and for that, it corresponds well to the adaptation strategy by "**eviction or minimization a priori of climate hazards and water risks**" suggested by the first category of typologies.

It finally emerges from this analysis that all the rainy season sorghum farmers' adaptation strategies correspond very well to the typology proposed by the first category of typologies' authors, namely adaptation by "**confronting water risks**" and adaptation by "**a priori eviction or minimization of water risks**".

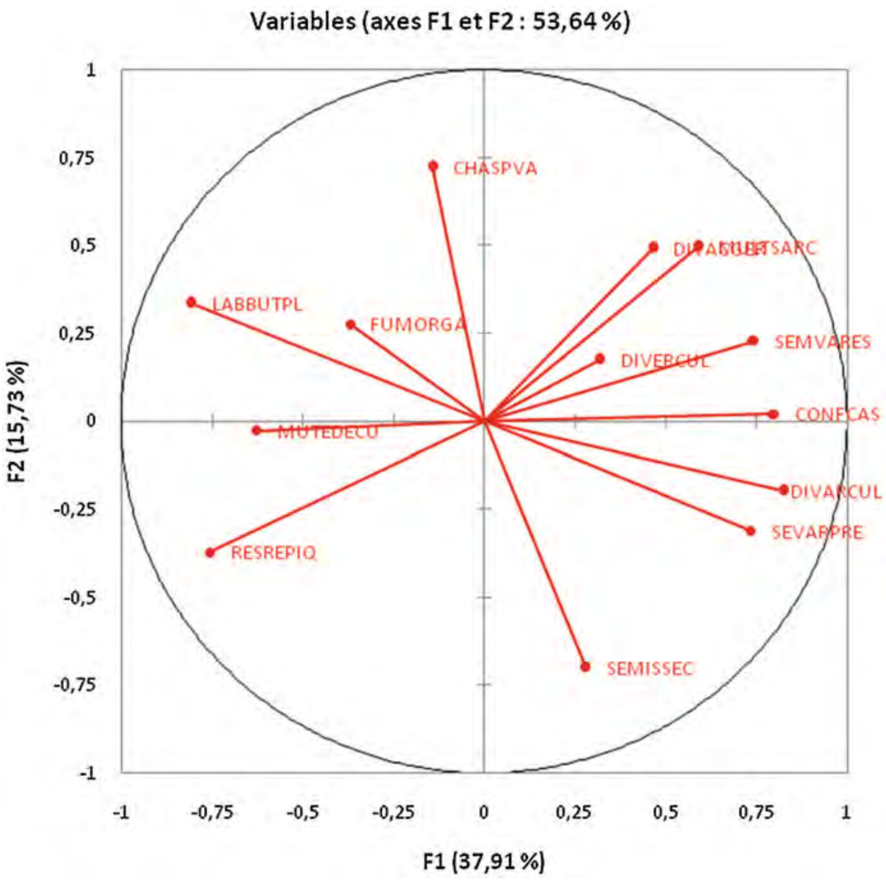

Fig. 2 Percentage explanations of variables by factors F1 and F2

Table 4 Variability explained by factor

Factors	Variation	%	Cumulative %
F1	4.928	37.908	37.908
F2	2.045	15.731	**53.64**

The test of the adequacy of the dry season sorghum farmers' adaptation strategies using the KMO test gave the results mentioned in Table 6.

All the KMO values taken by the adaptation strategies are greater than 0.49, except that of the "late transplanting" strategy, which will not be used in the KMO test.

The eigenvalues of the different factors from the PCA results reveal the existence of five (5) main factors, which explain 53.612% (>49%) of the total variation of the adaptation strategies, in accordance with the KMO rule. (Fig. 3 and Table 7).

Loading the adaptation strategies of the dry season sorghum farmers according to the five (5) main factors gave the results mentioned in Table 8.

Table 5 Results of the loading of the rainy season sorghum farmers' adaptation strategies by factor

Adaptation strategies	Factor 1	Factor 2

Scaling of nurseries over the time	−0.357	**0.438**	−0.386	−0.007	0.084
Organic or mineral fertilization of nurseries	−0.215	0.253	0.262	**0.418**	0.245
Cleaning and deepening of ponds	−0.337	**0.477**	−0.359	−0.023	−0.038
Water research over long distances	−0.251	**0.471**	0.049	0.389	0.143
Fertilization of transplanting water	0.026	**0.657**	0.498	−0.401	−0.016

long distances", and "fertilization of transplanting water". This factor brings together all the adaptation strategies aimed at the sustainable management of water resources, and can be called "**Adaptation to water risks by efficient management of water resources**".

Factor 3 contains the "crops organic or inorganic fertilizer input" strategy. It brings together strategies aimed at sustainable soil management, and can be called "**Adaptation to water risks through efficient soil management**".

Factor 4 groups together the strategies "change of crops or crop varieties", "crops diversification", "purchase or request of nurseries", and "organic or mineral fertilization of nurseries". It brings together strategies aimed at the sustainable management of crops, and can be called "**Adaptation to water risks through sustainable management of crops**".

Factor 5 groups together the strategies "sowing or transplanting early" and "temporary or permanent transfer of crops", which aim to avoid water risks, and can be called "**Adaptation by a priori eviction of water risks**".

Analysis of all the five factors reveals that factors 1 and 5 correspond to the farmers' adaptation to climate change by "**eviction or a priori minimization of water risks**", while factors 2, 3, and 4 correspond to their adaptation by "**confronting water risks**"; and therefore, it could be said that the dry season sorghum farmers' adaptation strategies corresponds very well to the typology proposed by the authors of the first category of typologies, namely, adaptation by "confrontation with the water risks" and adaptation by "a priori eviction or minimization of the water risks."

That said, depending on the results of the characterization of the sorghum farmers' adaptation strategies using PCA and KMO test, their whole adaptation process can be explained through a set of two actions:

1. The agro-pastoral natural resources management by "confrontation with the climate hazards and water risks" or by "eviction of the climate hazards and water risks".
2. The intense spatiotemporal diversification of the practices (agro-pastoral natural resources management, income generating activities).

Finally, it can be said that the characterization of the sorghum farmers' adaptation strategies shows that they are more complex than most authors who have established the typologies thought, because of the spatiotemporal diversification of the practices.

Conclusion

At the end of this chapter, we could draw the following conclusions:

- The poor spatiotemporal distribution of rains and the drought respectively constitute the main climate hazard and the main water risk faced by sorghum farmers in particular, and farmers in general in the semi-arid region of Cameroon.
- The sorghum farmers are highly vulnerable to climate change, and that could be perceived through the coexistence of all the three forms of drought (meteorological, agricultural, hydrological), the permanent food insecurity, the mostly traditional adaptation strategies used and their very low adoption rates, the underuse or absence of efficient adaptation strategies (irrigation, improved crop varieties), and their socioeconomic characteristics (the practice of self-consumption agriculture, the small size of the sown areas, the low quantity of agricultural inputs used, the poor access to agricultural extension and to credits, the multiplication of income-generating activities, and the weak school enrollment rate).
- The characterization of the adaptation strategies used shows that they are more complex than most authors who have established the typologies thought because the whole adaptation process used by sorghum farmers can be explained through a set of two actions: the agro-pastoral natural resources management by "confrontation with the climate hazards and water risks" or by "eviction of the climate hazards and water risks"; and the intense spatiotemporal diversification of the

practices (agro-pastoral natural resources management, income generating activities).
- Insofar, as the farmers are very vulnerable to the climate change, it seems given their poor socioeconomic conditions that a real improvement in their resilience depends absolutely on a real and deep improvement of these socioeconomic conditions.

Attaining Food Security in the Wake of Climatic Risks: Lessons from the Delta State of Nigeria

9

Eromose E. Ebhuoma

Contents

Abstract

Climate variability and change have undermined the poor rural households' ability in sub-Saharan Africa (SSA) to engage in food production effectively – which comprises their primary source of livelihood – partly because it is predominantly rain-fed. Notwithstanding, the rural poor are not docile victims to climatic risks. They actively seek innovative ways to utilize their bundle of assets to reduce the negative effects of climatic risks to ensure household food security. Bundle of assets comprise the financial, human, physical, social, and natural assets owned by, or easily accessible to, an individual. Drawing on primary data obtained qualitatively in the Delta State of Nigeria, this chapter analyzes

how Indigenous farmers utilize their bundle of assets to grow their food in the face of a rapidly changing climate. The results indicate that human and social assets played crucial roles in facilitating household food security. Also, social assets facilitated the procurement of other assets necessary to ensure continuity in food production, albeit farmers continue to live under the global poverty line. This chapter critically discusses the implications of these findings in relation to the attainment of both the first and second Sustainable Development Goals (no poverty and zero hunger) by 2030 in the Delta State.

Introduction

Climate variability and change have adversely affected various sectors of the global economy including health (Ebhuoma and Gebreslasie 2016), transportation (Jaroszweski et al. 2010), and tourism (Fitchett et al. 2017). However, no sector has been severely affected like agriculture, especially in the developing world (Intergovernmental Panel on Climate Change (IPCC) 2014). This is primary because the agricultural practices embarked upon by poor rural households are extensively dependent on rainfall (Conway and Schipper 2011). Consequently, the slightest deviation of weather patterns from the normal can subject most of the rural poor in developing countries to excruciating poverty and misery due to their inability to obtain their livelihood from food production (IPCC 2014). Furthermore, the vulnerability of the rural poor to climatic risks is exacerbated by weak institutions and agricultural policies, deficiency of social safety nets, inability to purchase farm insurance, and low levels of education (Perez et al. 2015).

In Nigeria, for example, agriculture contributes about 20% to its gross domestic product (GDP), making it next in line to the country's mainstay after crude oil (National Bureau of Statistics (NBS) 2014). In the last two decades, however, climate variability and change have wreaked havoc in various farming communities, especially in the Delta State where 90% of rural households are actively engaged in food production (Ifeanyi-obi et al. 2012). Climatic risks have become a huge cause for concern among the rural poor due to growing uncertainty regarding anticipated food productivity and outputs (Mavhura et al. 2013; Nelson et al. 2014). Despite the increased climatic risks that the rural poor in the Delta State and other parts of sub-Saharan Africa (SSA) are besieged by, they are not docile victims to these threats.

The poor, as Moser (2011) argue, are actively and consistently seeking innovative ways to utilize, modify, and adapt their bundle of assets or capital to reduce the negative effects of climatic risks on their livelihood. Bundle of assets comprises the financial, human, physical, social, and natural assets (Table 1) owned by or easily accessible to an individual. The focus on assets is crucial to facilitating the

Table 1 Definition of bundle of assets

Asset or capital	Definition
Physical	This includes equipment, infrastructures such as road networks, and other productive resources owned by individuals, households, communities, or the country itself
Financial	This refers to financial resources available and easily accessible to individuals, which includes loan, access to credits and savings in a bank or any other financial institutions
Human	This refers to the level of education, skills, health status, and nutrition of individuals. Labor is closely associated with human capital investments. Health statuses of individuals impact either positively or negatively on their ability to work, while skill and level of education is crucial because it influences individuals return from labor
Social	This refers to the norms, rules, obligations, mutuality, and trust embedded in social relations, social structures, and societies' institutional disposition
Natural	This refers to the atmosphere, land, minerals, forests, water, and wetlands. For the rural poor, land is an essential asset.

Sources: Bebbington (1999); Moser and Satterthwaite (2008); Moser (2011)

identification of entry points to inject tailored policy interventions that are necessary to build and fortify the adaptive capacity and resilience of the rural poor (Moser 2011; Moser and Stein 2011). As documented by Moser (2011), individuals are not docile victims but possess resources that they can draw upon in times of crisis. Thus, identifying and strengthening these resources is crucial for the poor to be able to hold their own in times of crisis such as climate variability and change by deploying their available resources to ensure food security.

In the wake of a rapidly changing climate, the injection of tailored policy interventions is desperately needed to scale up food production in SSA and facilitate the actualization of Sustainable Development Goals (SDGs) 1 and 2 (no poverty and zero hunger) by 2030. Against this background, this chapter analyzes the ways in which Indigenous farmers in Igbide, Uzere, and Olomoro communities in the Delta State of Nigeria utilize their bundle of assets to grow their food in the face of a rapidly changing climate. Indigenous, in this context, refers to people that possess a peculiar culture and knowledge distinct to their community that have been examined with real-life scenarios (Ebhuoma 2020).

Research Methodology

The chapter is based on primary data obtained in Olomoro, Igbide, and Uzere communities situated in *Isoko* south local government area (ISLGA) of the Delta State in Nigeria (Fig. 1). The mean annual rainfall in the Delta State is between 2500 to 3000 mm (Adejuwon 2011). Both Igbide and Uzere are low-lying, while Olomoro comprises both high- and low-lying areas. Due to annual heavy rainfall events, the low-lying farmlands are submerged from June to the last week in October.

Fig. 1 Map of the study areas. (Source: Cartographic Unit, Wits University, South Africa (2016))

Omohode's (2012) documentation, following the 2012 flood disaster that severely affected most States in Nigeria, influenced the choice of these communities. He highlighted that most low-lying communities in ISLGA were completely submerged, making the area resemble emergency oceans when viewed from a distance. Thus, unpacking the ways in which Indigenous farmers in these communities engage with their bundle of assets will provide valuable insights regarding how vulnerable people grow their food in the face of climatic risks.

The communities are homogeneous in nature. For instance, *Isoko*, an Indigenous language, is the local dialect spoken. Also, small-scale farming is the major economic driver of these three communities, with the women at the helm of the practice. While some men assist their wives to produce food, they are mostly involved in fishing. In terms of food production, cassava and groundnut are the predominant staples cultivated annually. Cassava makes up approximately 65% of the total caloric intake in each community. Other cultivated crops include cocoyam, potato, pepper, and plantain. With the exception of cassava which requires a minimum of 6 months to reach maturity, the other crops can be harvested 3 months after planting.

Focus group discussions (FGDs) and semi-structured interviews were used to obtain primary data. Thirty-five FGDs and four one-to-one, semi-structured interviews (two in Olomoro, one in Igbide and Uzere) were conducted between June and October 2015. Of the 35 focus groups, 24 were made up of female respondents; five comprised male respondents, while six were made of both male and female respondents. Respondents in each FGD varied between 3 and 12 respondents aged between 20 and 85.

Respondents were identified using purposive sampling based on age, gender, those who have been farming in the study areas for a minimum of 10 years, those whose household assets and livelihoods were severely affected by the 2012 flood disaster, and those that grow their food on low-lying farmlands. Key informants who have lived in each community for over 40 years and an agricultural extension worker facilitated the recruitment of eligible respondents. Primary data retrieved were analyzed using the thematic analysis technique.

Findings

Livelihood Vulnerability to Climatic Risks

Respondents pinpointed heavy rainfall events – which resulted in seasonal flooding of low-lying farmlands annually – as the worst weather conditions that undermined effective food production through farmers' inability to maximize their natural capital. In this regard, a respondent from Uzere, in his 80s, stated:

> We are constrained to practice seasonal planting due to flooding which must occur on our farmland annually. Consequently, we must harvest all our cultivated cassava before our farmland gets inundated. This usually worsens food insecurity in times of poor harvest. . .. This is the advantage farmers in neighboring communities who cultivate on high ground have over us. They do not lack *garri* (processed cassava) throughout the year.

Seasonal flooding restricts farming for 8 months annually, which has implications for the amount of food farmers are able to produce annually. The second weather conditions that adversely impacted food production are rising temperatures, especially between February and April. On the one hand, respondents aged 40 years and below revealed that the weather has become warmer in the last decade. On the other hand, the elderly respondents (50 years and above) argued that the rise in temperature began in the early 1980s. Both groups unanimously acknowledged that in the last 5 years, temperatures between February and April have become abnormally high in the afternoons. This has undermined their ability to work effectively on their farmlands. From the respondents' viewpoint, the adverse effects of the rising temperature are evident in groundnut production as they now harvest empty pods more frequently than in previous times. A respondent from Igbide, in her 50s, asserted:

> The sunlight during the months of February and March is really terrible and planting during those months is very difficult. Groundnut is the crop that is seriously affected because it is does not require intense sunlight for optimal productivity.

Approximately two-thirds of the respondents stated that the change in weather conditions is due to God's making and supernatural forces. When probed about the role of humans in contributing to climate change, most debunked the claim. To concretize this viewpoint, female respondents in a FGD in Igbide unanimously agreed that *the change in weather, humans have nothing to do with it; it is solely the making of God*. However, the youths attributed the vagaries of weather to the increased rate of deforestation carried out by farmers to obtain firewood. Also, few elderly respondents revealed that the rising temperatures are due to continuous gas flaring activities by Shell's crude oil exploration activities for over 40 years. These three communities have about 62 oil wells that Shell drilled oil from before selling all its oil wells in these communities to the Integrated Data Services Limited (IDSL), a subsidiary of Nigerian national petroleum corporation (NNPC), in 2014. In this light, a male respondent from Uzere, in his 50s, commented:

> This community is particularly known for farming. But since the early 1980s, the quality of both cassava and groundnut produced has reduced significantly. This is due to Shell's oil exploration activities. Most of the youths now engage in off-farm activities because farming can no longer foot their bills.

Most elderly respondents attributed the poor starch content of the *garri* (processed cassava) they produce to crude oil exploration activities. They lamented that the oil exploration had compromised their soil's nutrients, which in turn has affected the nutritional value of the *garri* produced, especially when compared to the produce harvested in the 1980s. However, only a few respondents highlighted farmers' inability to engage in bush fallowing, due to increased demand for land stemming from sporadic population growth, as an added factor that has facilitated the reduction in quality of food produced.

Assets and Food Production Nexus

Due to the annual seasonal floods, farmers employ their human capital to produce cassava on their low-lying farmland through an Indigenous strategy referred to as *elelame* (follow the water). The other cultivated crops – cocoyam, potato, pepper, and plantain – are produced using the early rains, which usually begins between February and March and last till the end of May. The water strategy commences as soon as the floodwater starts to recede the farmland, usually in November. The farmers' plant their cassava stems on the part of the soil that is visible and moist. They replicate this process until the floodwaters have completely dried up from their farmland. The planting process usually ends between the second and third week in December.

The following year, between June and August, when the rain is heavy and continues to fall consistently, they start harvesting their produce. The decision regarding where to commence harvesting is hinged on their human capital informed by their Indigenous knowledge, as they know the precise portion of their farmland that will be submerged at the earliest. Thus, they do not harvest all their farm produce simultaneously. The crop closest to where the inundation will commence are harvested first. The reason for not harvesting all the produce at the same time is because the longer cassava remains in the soil, the bulkier they get. Also, labor shortage is another factor that contributes to adopting this harvesting strategy. Thereafter, usually within a week, they would return – pending on the consistency of rainfall – to their farmland to employ a similar process to harvest the other produce. After harvesting all their produce, they preserve the cassava stems on their inundated farmland by constructing temporary structures to use them for food production in the next planting season (Fig. 2).

To ensure they have *garri* to eat all year round, they utilize their human capital to process the harvested cassava as well as store it properly. Respondents explained that after the necessary procedures have been implemented, which entail peeling, soaking the cassava in water for several hours, drying the soaked tubers and blending into powdered form, it is fried with little palm oil to an overly dried state. After cooling down, the *garri* is preserved in airtight sack bags. Thereafter, a wooden structure is constructed and the sack bags placed on top of it. The fundamental reason for suspending the sack bags from the ground is to prevent the *garri* from going bad through mold formation.

Fig. 2 Indigenous technique used to preserve cassava stem on low-lying farmland. (Photograph: John Ayiko (2015))

It is noteworthy to mention that some farmers rent farmland, a natural capital, to grow their food. Because most farmers lack financial capital during the planting season, social capital plays a vital role in this regard only for trustworthy individuals. As a respondent from Uzere, in her 40s, highlighted:

> Most farmers lack finances during the planting season. Consequently, only trustworthy individuals are privileged to get farm plots leased to them without having to pay the agreed sum upfront. Often times, they pay the landowners after harvesting and traded some of the produce.

Also, some farmers – due to a shortage of household labor and lack of capacity to hire laborers – drew on their social capital to acquire human capital to facilitate the harvesting of farm produce before the occurrence of the seasonal flooding. Specifically, some farmers depend on neighbors, relatives, and friends to accelerate the harvesting process to avert the possibility of some of the produced cassava from decaying. Furthermore, social capital catalyzed the procurement of financial capital. This is particularly useful as most farmers have been unable to benefit from several loan schemes afforded by the Delta State government against the backdrop of the farm loans being disbursed consistently for over 10 years (United Nations Development Program (UNDP) 2014). Some highlighted that they only hear of farm loans after the application process had closed, a state of affairs which was largely attributed to nepotism.

Although microfinance banks (MFB) in the Delta State have been given directives to provide the rural poor with farm loans, the inability to provide collateral matching the value of the loan sought after or a guarantor with valuable assets has hampered farmers' ability to secure such loans. As respondents in a female-only FGD in Olomoro bemoaned:

> Loans exist that could reduce some of the challenges we undergo as farmers, but due to the fact that there is nobody to stand as a guarantor [lack of social capital], they have not been able to harness such opportunities.

Since farmers' annual earnings from food production (between 137 USD to 219 USD) are inadequate to secure their livelihood objectives, they utilize their social capital to temper the financial drought. This is achieved by some community members coming together to form a small group where the prior agreed monetary contributions are made weekly to a trustworthy individual. At the end of each month, the total sum is given to a group member, hinged on prearrangement. This scheme, referred to as *Osusu*, is useful in ensuring that farmers can purchase items necessary for food production.

Households Still Living Below the Global Poverty Line

Despite farmers' skillful utilization of their meager bundle of assets at their disposal to ensure continuity in food production, the majority still live under the global poverty line of less than $US 1.90 a day (Livingston et al. 2011). A fundamental reason for this is due to the low financial gains made from the sale of *garri* underpinned by its inferior quality when compared with those produced in neighboring communities' void of oil exploration activities. Thus, they are "forced" to market their produce at a much-reduced price.

Another factor that impeded farmers from transcending living above the global poverty line is due to the exorbitant interest rate money is borrowed from unregulated bodies such as informal meeting groups and money lenders. Respondents highlighted that not knowing influential people, underpinned by lack of social capital, to act as guarantors to co-sign the credit agreement to access farm loans from MFB is a pull factor toward securing loans from unregulated sources. As some respondents explain, this is prevalent during the planting season as farmers often run out of money having addressed other pressing issues such as paying for both children's tuition fees and levies attached to social responsibility. Thus, farmers are left with no feasible alternative but to obtain loans from "financial predators" as their requirements are less demanding. While the loan obtained enables farmers to produce their food, it proved counterproductive in terms of evading the poverty maze. For example, if a farmer borrows 50 USD for 6 months, the farmer is required to refund the loan with a whopping 40% interest. This is testament to the fact that the drive to become food secure pushes farmers to do anything within their powers to achieve the objective, regardless of the long-term consequences.

The financial predators are well knowledgeable on the importance of farm loans in ensuring household food security. As a result, they are unwilling to water down their terms and conditions. In this regard, a farmer from Igbide, in his 50s, explained:

> Without loans, some farmers cannot grow food. After these farmers secure loan from non-government bodies, grow their food and sold some of the produce to refund the loan, most of the time, they are left with little or nothing for the next planting season. The only choice they have is to go back to secure loans from the group that lend them money previously. This is the survival tactic of some farmers in this community.

In fact, the inability to access loan is a catalyst that has made some farmers to engage in off-farm activities. Another factor that compromised effective food production was the lack of physical capital, especially for farmers with access to large hectares of land enough to engage in commercial farming. For example, farmers' inability to access farm machinery dampened their fight to transcend the boundaries of a subsistence farmer. A male respondent in Uzere stated that while the Delta State government usually provides farm equipment for farmers, "it never gets to them." Instead, the equipment is "always hijacked" by influential politicians and close associates of key politicians in the Delta State. In addition, the unavailability of rice milling machines has prevented farmers from producing rice. Few elderly respondents (50 years and above) in Igbide revealed:

> In the 1960s, they were actively involved in rice production because of the swampy nature of their farmlands, and rice milling machines provided by the government. But since the 1970s till date, no provision has been made to provide rice milling machines for farmers. As a result, rice cultivation has been abandoned.

Finally, the farmers lamented bitterly that despite the enormous contributions their communities have made to the nation's foreign revenue for over four decades, their communities have remained shockingly underdeveloped. The lack of good road networks within each community, for example, erodes the financial capital of some farmers, albeit insidiously. To illustrate, during the rainy seasons, it can be challenging for motorists to navigate their way through their community due to countless potholes. This makes accessibility to markets where they have to sell some of their farm produce an exasperating venture.

Discussion

The adverse effects of climatic risks are palpable in Igbide, Uzere, and Olomoro communities in the Delta State of Nigeria. They have manifested in the form of heavy rainfall events (Ifeanyi-obi et al. 2012), which leads to seasonal flooding of low-lying farmlands, and rising temperatures (Ike and Ezeafulukwe 2015). While these climatic variables have undermined food production, oil exploration activities have aggravated farmers' woes. By significantly degrading soil's nutrients, oil exploration activities have adversely compromised the quality of food produced. This assertion is corroborated by research findings that have also emerged from the Delta State (Ererobe 2009; Elum et al. 2016). Nonetheless, the findings can be disaggregated into two key points.

First, farmers' perception of climate change is underpinned by religious framing. Similar findings have been recorded in Botswana (Spear et al. 2019), Mali (Bell 2014), Nigeria (Jellason et al. 2020), South Africa (Okem and Bracking 2019), and Zimbabwe (Moyo et al. 2012), respectively. Attributing the cause of climate change to oil exploration activities, God and other supernatural forces as well as disentangling their lifestyle activity – deforestation – as a contributing factor seems the logical way for people to continue with the state of affairs without any ill feelings. Accepting how their lifestyle choices may be contributing to climate change, no matter how insignificant it may seem in comparison to gas flaring, for example, will doubtlessly require behavioral changes. In contrast to studies that show that people highly vulnerable to climate change may be more willing to adopt behavioral changes (Akerlof et al. 2013; Azadi et al. 2019), this may not be feasible for farmers in the Delta State due to their quest to obtain their livelihood by any means necessary.

For instance, to rely on kerosene or gas-fueled stoves for cooking may have substantial financial implications in comparison to firewood. In this light, therefore, the need to sensitize farmers on how their actions are contributing to climate change, including the possible future implications for household food security, is essential. This is primarily because rural households in SSA are expected to be adversely affected by the impacts of future climate change (IPCC 2014). Also, it is necessary to involve religious clergies as key stakeholders in the discourse around climate change mitigation as their beliefs and values have the potential to influence the behaviors of their congregation.

Second, farmers have carved out unique strategies to maximize their meager asset portfolios to produce food despite the increasing threats from climatic risks. The systematic ways in which farmers utilize their human capital to grow food on their low-lying farmlands indicate that farmers are not helpless victims to climatic risks. This is corroborated by findings in Bangladesh (Al Mamun and Al Pavel 2014), Botswana (Motsumi et al. 2012), and Zimbabwe (Mavhura et al. 2013). With the right support and interventions such as providing easy access to loans, machinery, and good road networks, the likelihood that farmers will successfully transcend living above the global poverty line is extremely high. As several studies show (Kochar 1997; Akoijam 2012; Ibrahim and Aliero 2012; Assogba et al. 2017), easy access to government loans remain a major challenge for rural farmers in developing countries. It is documented that the flourishing of exploitative money lenders is due to low priority given to rural credit (Akoijam 2012). Thus, to ensure farmers access farm loans, robust broadcasting of any program through mediums utilized by households to receive vital information are crucial. Otherwise, the persistent dependence on financial predators will continue to flourish, to the detriment of farmers in the Delta State achieving the first SDG.

It should be emphasized that the skillful utilization of social capital to acquire human capital (assistance with cassava harvesting), financial capital (*Osusu*), and natural capital (not paying the rental before cultivating on farmland) indicates that climate adaptation interventions that may cause fragmentation of households should be avoided. For example, suppose the government wants to provide farmlands on higher grounds to farmers to ensure they can produce food all year round. In that case, farmers in the same community should be given land close to one another. This is crucial for the strengthening of social capital, which is essential to facilitating household food security and ensuring that the country is on the trajectory toward achieving the first (no poverty) and second (zero hunger) SDGs by 2030. As Joshi and Aoki (2014) argue, strong social networks influence household's ability to recover from a disaster.

Final Remarks

Climatic risks are making life difficult for the farmers cultivating on the low-lying farmlands in Olomoro, Uzere, and Igbide communities. In responding to these threats, Indigenous farmers skillfully employ their limited bundle of assets to continue producing their food. Specifically, this chapter illustrated how human capital plays a pivotal role in ensuring the production of cassava in the low-lying farmlands, which experiences seasonal flooding annually, through an Indigenous strategy referred to as elelame (follow the water). Also, social capital is a crucial asset in farmers' portfolio through its ability to facilitating the procurement of financial capital through a local scheme called Osusu. Further, it enabled the acquisition of natural capital by allowing trustworthy individuals to renting farmlands and only paying the fee after harvesting and selling some of the produce. Since social capital is overwhelmingly fundamental to the achievement of food security, any scheme meant to assist farmers to adapt more effectively to climatic risks to produce more food must ensure it creates an avenue for strengthening ties among farmers.

This chapter also finds that despite farmers' ability to attain household food security every year, they still live below the global poverty line. A key factor fuelling this state of affairs is primarily due to the inaccessibility of government loans. Consequently, financially strapped farmers are constrained to secure loans from unregulated sources. While it provides a leeway to continue in food production, it is counterproductive due to the high-interest rates attached to the loans. Perhaps, easing the loan acquisition process from MFB may successfully combat this menace. Otherwise, farmers will be unable to weave their way out of poverty. To conclude, until interventions are geared toward ensuring the protection, strengthening, and making the acquisition of assets that play a fundamental role in food production, chances of successfully achieving the first and second SDGs will be slim.

Abstract

Climate change and variability is already reducing agricultural productivity and opportunities for employment, pushing up food prices and affecting food availability and production of formerly adapted crop types. Such is the case in cotton production in Zimbabwe, where it was the only viable commercial crop in marginal areas. As a form of adaptation, there is need for African farmers to have a range of agricultural techniques as coping strategies and tactics to enable sustainable production of crops and deal with extreme events. Such techniques include water conservation and introduction of new adapted crop genetics to cope with the new environment. The emerging trends in climate change will force farmers to adopt new crops and varieties and forms of agricultural production technologies. The objective of this study is to determine the contribution of combining in-field water harvesting and early maturing cotton varieties in curbing drought in cotton in semiarid Zimbabwe. The results show that both water harvesting in form of planting basins significantly ($P < 0.05$) increased boll number and branch number of cotton across all varieties. The varieties M577 and M567 out-performed the conventional varieties in early growth, branch number, and boll number. Tied contour ridges gave a significantly ($P < 0.05$) higher moisture content in 0–5 cm and the 6–10 cm depth compared to conventional tillage. The new varieties displayed early phenological development. Despite the existence of rainfall gaps, the in-field water harvesting techniques captured enough moisture and prevented moisture losses through runoff which resulted successful flowering and fruiting in the short varieties compared to conventional tillage on conventional varieties. In this regard, water harvesting and early maturing varieties offer considerable hope for increasing crop production in arid and semiarid areas of Zimbabwe.

Introduction

Africa is regarded as having climates that are among the most viable in the world on seasonal and decadal time scales (UNFCCC 2007). Floods and droughts can occur in the same area within months from each other. Of the total additional people at risk of hunger due to climate change, although already larger proportion, Africa may account for the majority by the 2080s (Fischer et al. 2002). The increase in inerratic rainfall seasons characterized by unpredictable length of seasons, high temperatures alternating floods and dry spells, and variable rainfall amounts presents new

Table 1 Agro-ecological regions and potential land use for Zimbabwe

Agro-ecological zone	Area (ha)	Area as % of country	Characteristic weather	Recommended land use
I	703,400	1.8	High rainfall (>900 mm per annum), with some precipitation throughout the year. Low temperatures	Fruits, tea, coffee macadamia nuts, intensive livestock production
II	5,861,400	15.1	Moderately high (750–1000 mm per annum) rainfall confined to summer. Severe dry spells are rare	Intensive crop and/or livestock production
III	7,287,700	19.5	Infrequent heavy rainfall leads to moderate annual recording of about 650–800 mm. Fairly severe mid-season dry spells	Marginal for maize, tobacco, and cotton production, livestock production
IV	14,782,300	36.7	Fairly low total rainfall (450–650 mm per annum). Periodic seasonal droughts, severe dry spells during rainy season	Drought resistant crops such as sorghum and pearl millet, livestock production
V	10,441,100	26.8	Low and erratic rainfall (<450 mm per annum, <650 mm in the Zambezi valley, and <600 mm in the Sabi-Limpopo Valleys). Prolonged midterm dry spells	Too dry for successful crop production without irrigation. Marginal millet, sorghum, extensive beef ranching, game ranching

challenges to the majority of the farmers in the absence of appropriate response strategy (Zimbabwe climate change response strategy, 2017). In the 2018–2019 cropping season below normal and highly erratic and patchy rainfall was recorded for the first half of the season and most crops were stressed with most being completely written off because of prolonged dryness (FEWS Net 2019).

In Zimbabwe, over 70% of Zimbabwe's employment is directly or indirectly accounted for by agriculture. The national agricultural production largely relies on rain-fed agriculture which is one of the most vulnerable sectors to climate change and variability. Adaptation to climate change will entail adjustments and changes at every level from community to national level. Communities must build their resilience including adapting appropriate technologies while making the most of traditionally and locally generated technologies and diversifying their livelihoods to cope with the current and future stresses (Fischer et al. 2002).

Zimbabwe is generally characterized by low rainfall and more than 50% of its land area falls under region IV and V which receive rainfall lower that 650 mm per season (Table 1).

Maize planted late will not give good yields, thus making maize production a less viable activity under climate change conditions. In the low-lying areas of southern

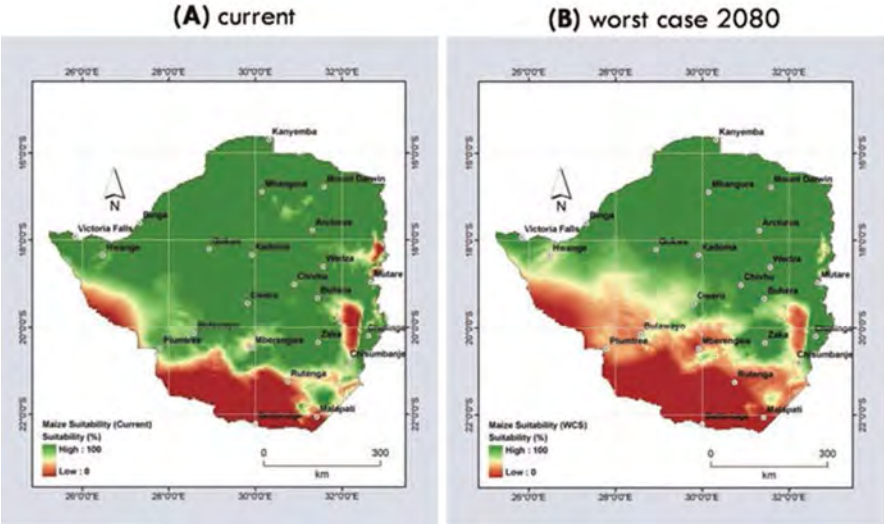

Fig. 1 A comparison of the maize production zones under the current and worst case scenario for the year 2080. (Source: Zimbabwe's Second Communication to the United Nations framework convention on climate change (UNFCCC))

Zimbabwe, for example, it is probable that climate change will turn the region into a non-maize-producing area, as exemplified by reduced maize production in Masvingo (Fig. 1). The projections are that by 2080 the area suitable for maize production in the south-western and central provinces of Zimbabwe will have decreased (Fig. 1).

This area, which represents 42% of the communal area, will become even more marginal for maize production. Based on site results, seasons could be 25% shorter than now.

Communities living in natural regions IV and V (which make up about 64% of the land area) are at the mercy of climatic extremes, with few livelihood options (Brazier 2015). They tend to be the most vulnerable to poverty. These regions are already feeling the impacts of climate change and will be the hardest hit in the future. Climate change will exacerbate hardship and poverty among the people of Zimbabwe. Women, children, and the disabled, especially those living in rural areas, will be the worst affected. The causes of rural poverty relate to the adverse climate and environmental conditions that disrupt agriculture, the main livelihood activity in areas where most people live. Women, children, the elderly and the disabled have been identified in several studies as being the most vulnerable to shocks. Zimbabwe's agricultural systems are already insecure as they depend mainly on seasonal rainfall. In addition, ruinous land use practices in the form of poor soil and water management, reduced biodiversity, and poor choice of crops to plant have led to degradation of the resource based on which agriculture depends. Climate change will hasten the degradation and exacerbate food insecurity, which is already

Table 2 The impacts, sectorial vulnerabilities, and adaptive capacity to climate change

Impacts	Sectorial vulnerability	Adaptive capacity
Warning by 1.5 °C	Agricultural production severely compromised	Rainwater harvesting
Drier subtropical regions	Uncertainty on what and when to plant	Improved varieties that fit into the current seasons
Decrease in annual rainfall	Yields from rain-fed production can be halved	
Extreme events: increase in frequency and intensity of storms and droughts and floods	Net revenue could fall by 90% by 2100	

Adapted and modified from Christensen et al. (2007)

prevalent in Zimbabwe. There are likely to be shifts in the start and end of the rainy season, and the onset of the rains may be delayed by between 4 and 6 weeks. This will mean changes in planting and harvesting dates, the length of the growing season, and the types of crops that farmers are forced to adopt.

Climate change affects crop production in the following ways (Table 2).

Characteristics of Cotton Growing Areas in Zimbabwe

The farms are generally small, often held under traditional tenure and are located in marginal areas which are risk prone (FAO 2012). Their challenge is to improve production of cotton under climate change. The investments in farming are low and their ability to adapt is very low. The inventions in this sector have to low cost so that adaptation levels are high hence the introduction of tied ridges and use of imported varieties for sustainable cotton production. Varieties purchase will be done by everybody prior to the onset of the season. Tied ridges are not an expensive technology to introduce to the farmers as long as they understand the merits.

Crop Genetic Diversity and Climate Change

The emerging changes in climate will force farmers to adopt new varieties and crop types and forms of agricultural production technologies that can respond to new and changing stress factors. The areas that are currently the most food insecure will be worst affected and will have the greatest need for new crop varieties that are tolerant to drought high temperatures flooding salinity and other environmental extremes (FAO 2015). Diverse crop species, varieties, and cultivation practices allow crops to be grown across a wide range of environments. Sometimes better adapted varieties will need to be brought in from outside.

Traits that contribute to phenotypic plasticity (ability to cope with a wide range of environmental conditions) may be increasingly important. Such is the case with cotton in Zimbabwe where the traditional varieties were complimented by imports of new cotton seed varieties from India.

Genetic resources could contribute greatly to efforts to cope with climate change. It is likely that climate change will necessitate more international exchanges of genetic resources as countries seek to obtain well-adapted crops. There is likely going to be a greater interdependence on the use of genetic resources and that underscores the importance of international cooperation (FAO 2015).

Food-insecure people in the developing world such as Zimbabwe especially women and indigenous people are among the most vulnerable groups and usually the hardest hit. In the case of cotton, the varieties used in Zimbabwe were not of a match to the current environmental characteristics. Zimbabwe farmers continued to cultivate the varieties although they were poorly adapted to the environment. The Cotton Company of Zimbabwe imported hybrid varieties from India with the objective of improving productivity and helping farmers to cope with environmental adversities.

Status of Cotton

Cotton is the second most important cash crop in Zimbabwe and is grown by thousands of smallholder farmers on average plot sizes of about 1 ha in the summer growing season (Global Agricultural Information Network 2017). The crop is strategic for poverty alleviation and is of major significance to food security for smallholder farmers in marginal areas due to its contribution to incomes and employment (Mujeyi 2013). The crop supports over one million people in marginal areas of Zimbabwe including farmers their families, farm workers, and industrial workers (Buka 2017; Mujeyi 2013). Most cotton growers have limited opportunities as these are in semiarid areas and cotton production is the only viable option.

However, cotton production has been on the decrease in terms of the number of farmers producing the crop (Fig. 2).

In some yeas the government intervened in cotton production through free cotton inputs. Generally the trend from the number of cotton farmers to yield per hectare (Figs. 2 and 3) points to the fact that cotton production is in the decrease. This might be partly due to the low prices on the international market. The low levels of production might be partly due to old varieties which are poorly adapted to the current environmental trends as dictated by climate change. There have been no new cotton varieties over the past 25 years in Zimbabwe. This implies that the recent climate shifts experienced in most parts of the world has not been factored in Zimbabwe cotton breeding program. The government of Zimbabwe prohibited the use of genetically modified seed which might have improved cotton yields.

Climate change has brought greater uncertainty and exposure to multiple climate stress. The lives of millions of people in semiarid Zimbabwe who depended on

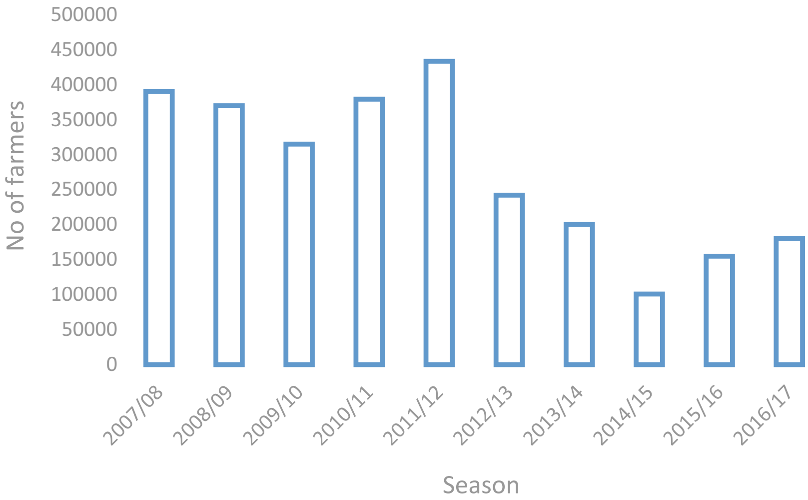

Fig. 2 Number of farmers cultivating cotton from 2007/08 season to 2016/17 season in Zimbabwe

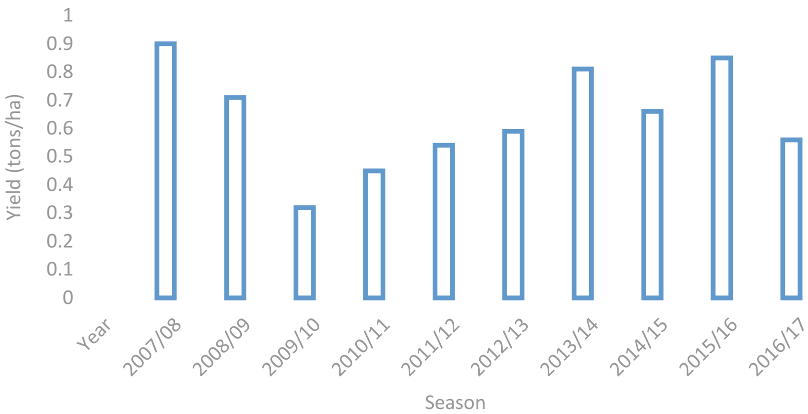

Fig. 3 Average yield of cotton (t/ha) from 2007/08 to 2016/17

cotton for their livelihood are highly vulnerable to climate change. The local farmers have traditionally managed harsh environment by growing moisture stress-tolerant cotton. In order to improve the effectiveness of crop production in these marginal rainfall regions, cultural practices which conserve water availability to the crop are essential (Mupangwa et al. 2006).

Investing in agricultural production methods to boost farmers' resilience against weather shocks is a key strategy to reduce negative impacts. The cotton growing areas of Zimbabwe are generally rain fed and are characterized by rainfall patterns which are highly variable in amount and distribution. This has been exacerbated by climate change. According to McHugh et al. (2007), the main limitation for increasing crop yields in rain-fed farming systems is crop water stress caused by inefficient use of rainwater. Rockstrom and Falkenmark (2000) reported that inefficient use of rainwater is often a consequence of poor rainfall partitioning resulting in low root-zone soil moisture or poor plant uptake of available moisture. Making rainfall available and its effective storage and efficient use are therefore important adaptive mechanisms and major determinants in cotton production under climate change. According to Nyamadzawo et al. (2013), climate change models have projected a decrease in rainfall in southern Africa and research has already shown the same. Therefore, the focus should be on upgrading rain-fed smallholder farming in tropical environments characterized by frequent droughts and mid-season dry spells. According to Ibraimo and Munguambe (2007), there is need for more efficient capture and use of scarce water resources in arid and semiarid areas. The optimization of rainfall management through water harvesting in sustainable and integrated production system can contribute to improve small scale farming households by upgrading rain-fed agricultural production. Research has documented substantial increases that are obtained through soil water conservation and efficient use of it by the crop, and, subsequently, the yield increases.

In-Field Moisture Harvesting

Tied Ridges

The effect of the ridges was generally higher in drier periods and more when the ridge ends were tied. Belay et al. (1998) reported that in wetter seasons, open-end ridges gave higher yields which show how important it is that soil and land management practices include means to safely dispose water from the field, should the rain exceed the retention of the soil. UNEP (1997) also confirmed that rain water harvesting involves the use of methods that increase the amount of water stored in the soil profile by trapping or holding the rain where it falls and it involves small movements of rainwater in order to concentrate it where it is required.

Planting Basins

In Zimbabwe, planting basins are structures that are dug from July through October in the same positions annually and whose recommended dimensions are 15 cm length by 15 cm width and 15 cm depth (Mupangwa et al. 2006; Twomlow and Hove 2007). These basins are spaced at 90 cm by 60 cm. The basins benefit, particularly, poorer farmers with no access to draught power as they will not have delayed planting as they wait to borrow draught power from their neighbors (Mazvimavi and Twomlow 2007).

Mulch Ripping

Ox-drawn rip lines are made from attachments fitted on the plough frame and were developed to open furrows for moisture capture. They also break superficially compacted layers (Mandumbu 2011). Mapfumo et al. (2002) explained that mulch ripping makes use of the soil on the surface to protect the soil underneath, making soil disturbance limited to the planting zones, and ripping is done to a depth of 23 cm. In Zimbabwe, rip lines that are being promoted go to a depth of 23 cm.

Cotton Production Under Climate Change

Drought-tolerant cotton and in-field water harvesting are promising technologies to minimize the impacts of drought (Katengeza et al. 2019). The farmers in Zambezi valley in Zimbabwe have traditionally used two cotton varieties. Although these have over the years sufficed, they are currently failing due to recent trends on climate change. The low cotton genetic diversity and its use in traditional risk management may affect the resilience of farmers especially recently due to existing stresses which have made the environment more unpredictable (Meldrum et al. 2017). According to Thomas et al. (2015) the importance of crop genetic diversity or resilience and adaptation of farm systems to climate change is highlighted in many studies.

Recently, the cotton companies have promoted subsoiling and tied contours as in-field water harvesting techniques to cushion farmers against the adverse effects of climate change (Chaniwa et al. 2020). In situ water harvesting involves small movements of rainwater as surface runoff, in order to concentrate water where it is wanted most (Ibraimo and Munguambe 2007). Therefore the objectives of this study are to determine the effects of two tillage systems (conventional and tied ridges) on the performance of six cotton genotypes in semiarid northern Zimbabwe.

Effects of Water Harvesting on Soil Moisture Content

The results showed that tied rides had a significantly higher ($P < 0.05$) moisture content in the 0–5 and 6–10 cm depth compared to conventional system, while there were no significant differences between the two tillage systems at 11–15 cm (Fig. 4).

The results indicated that tied ridges had significantly higher percentage of moisture content at 0–5 and 6–10 but not at 11–15 cm. Higher moisture content at 0–5 cm illustrates the effectiveness of tied contours in moisture conservation on top soil horizons. The 2018–2019 season was a drought year in Zimbabwe, so the effects of the tillage method on moisture was apparent. These results are in tandem with Mupangwa et al. (2006) and Nyamadzawo et al. (2013) who reported the efficiency of tied ridges in capturing moisture and concentrating it on the root zone. Usually shallower depths are first ones to dry, hence the ability of the tied ridges to retain moisture makes the crop grow better compared to those in conventional plots; as the season was characterized by short duration, high-intensity rainfall, this might have

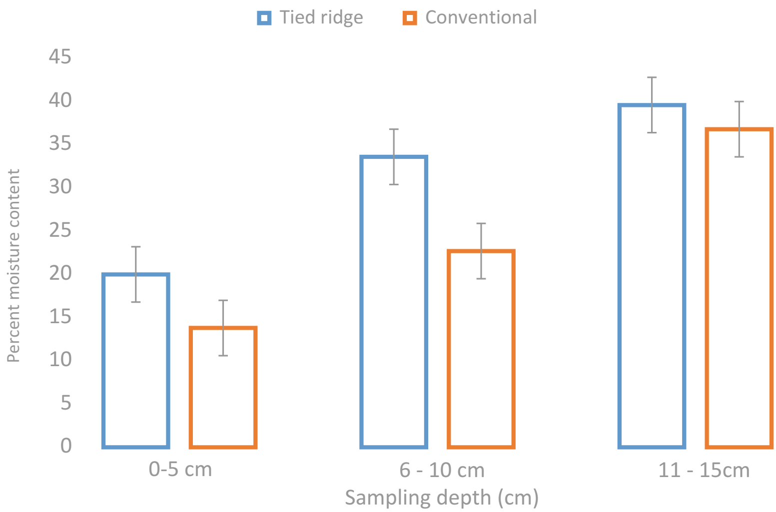

Fig. 4 Effects of tillage system on percentage moisture content at three sampling depths

resulted in moisture loss through runoff as rainfall intensity exceeded the infiltration capacity of the soil.

This means that the use of tied ridges as moisture conservation techniques was advantageous in the cotton as plants grown in tied ridges could still absorb moisture from the top horizons while those in conventional tillage could not. Higher moisture content will be followed by higher water use efficiency and subsequently higher yields. Promoting such a technology in the communities located in marginally drier areas would increase productivity of the cotton plants and help farmers cope with dryness caused by climate change.

Tied ridges increase the amount of water in the soil profile by trapping or holding the rainfall. These structures reduce runoff from the fields and enhance infiltration. This leads to higher amounts of stored moisture. Water harvesting is currently being rejuvenated in the marginal areas as an adaptive mechanism to climate change. High-intensity rainfall causes moisture to be lost through runoff. Research done by Nyamadzawo et al. (2012) found moisture losses as much as 50% being lost to runoff from cultivated fields. Due to the erratic nature of the rainfall such losses may never be recovered.

Soil water content near field capacity allows for best combinations of sufficient air space for oxygen diffusion, greatest amounts of nutrients in soluble forms, greatest cross-sectional areas for diffusion of ions and mass flow of water, and most favorable conditions for root extension.

The days to flowering varied significantly due to the effects of cotton genotypes. The results indicated that the genotypes M579 and M 577 had significantly fewer days to flowering compared to QM301 and CRIM 51 which are the Zimbabwe varieties (Fig. 5).

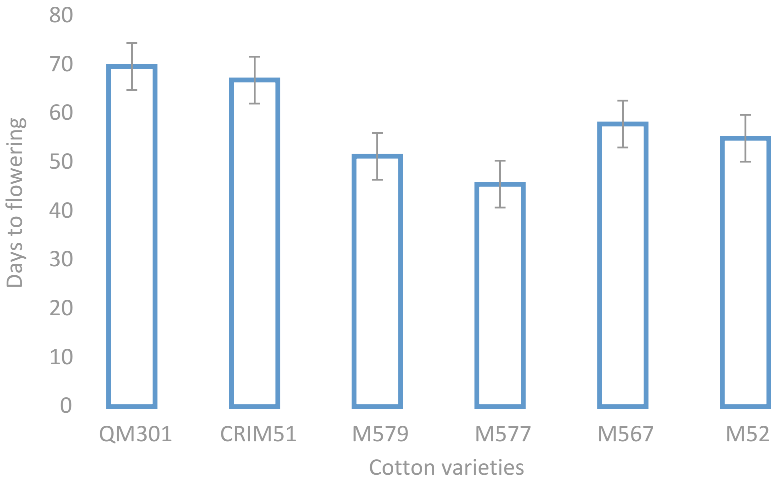

Fig. 5 The effect of cotton varieties on days to flowering

It was observed that M579 and M577 flowered the earliest compared to the rest of the varieties (Fig. 2). The variety M577 had the highest number of productive branches (Fig. 2). This according to Kooyers (2015) illustrates drought escape. Drought escape occurs when plants develop rapidly and reproduce when the environment becomes severe. Usually a variety that develops early escapes drought due to the shortened life cycle. The early flowering varieties represent a response when the plant's genetic resources are sourced to assist farmers to adapt to the changed climate. FAO (2015) reported that the biggest challenge for future food or commerce is to find a good match between the crops and the production environment as the effects of climate change increase. The two varieties are therefore suited to the changed conditions of semiarid Zimbabwe. These genotypes were obtained from India. Singh (2017) reported that one of the breeding strategies to mitigate the effect of climate change is to improve adaptation through increased access to a number of varieties at the local level with different growth durations to escape or to avoid predictable occurrences of stress at critical periods. This reduces the vulnerability of local farmers to the effects of climate change extremes.

The cotton variety M577 had the biggest cotton branch number compared to the rest of the varieties. The locally bred varieties showed lower branch numbers compared to the imported one (Fig. 6).

Branch number was also significantly ($P < 0.05$) affected by moisture conservation method. Tied ridges had significantly higher branch number compared to conventional tillage (Fig. 6).

The hybrids showed potential for use in environments with low water availability. Obtaining hybrids with good grain yield in environments with water restriction and a significant increase in water-limited environments has been an aim of many breeding

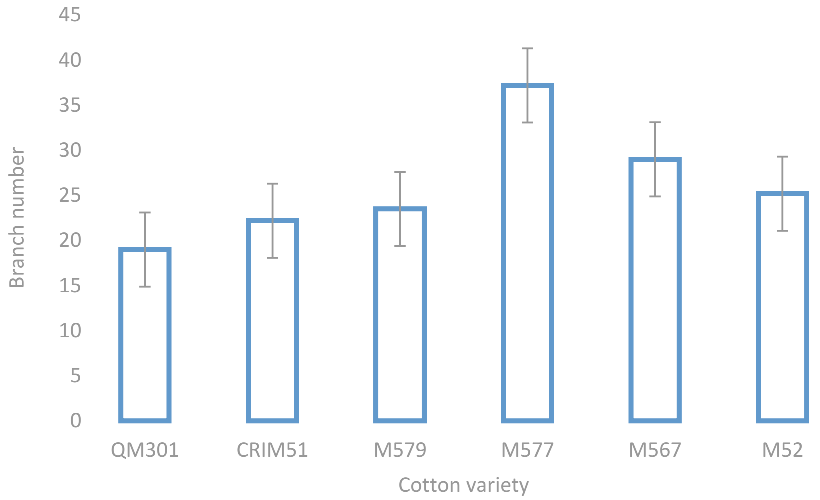

Fig. 6 The effect of cotton varieties on branch number

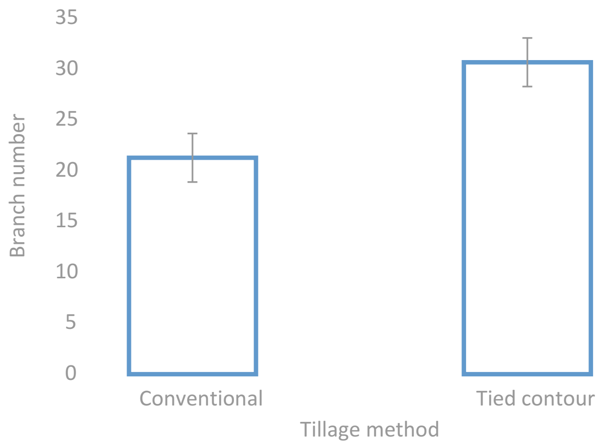
Fig. 7 Effect of tillage method on cotton branch number



programs. Varieties with lower yield reduction in stressful environment mean stability of production which is desirable.

A combination of high bearing branch number and few days to flowering is key in selecting crop varieties suited to climate change. One major characteristic of the seasons is erratic rainfall which begins early and terminates prematurely. Other seasons have delayed start and end prematurely. Generally, most seasons are not long enough to allow most varieties from germination until it reaches maturity. The varieties M577 and M567 suit such an environment as it can escape droughts through early phenological development. Quicker production of flowering branches also indicates tolerance to drought. Therefore, introduction of varieties to small-scale farmers in Zimbabwe is for farmers' adaptation to climate change.

For flower number the M577, M579, and M567 had the highest number of flowers. Flower number represents reproductive capacity. The same trend was observed on boll number. Higher flower numbers were observed on tied ridges compared to conventional system (Fig. 7). This showed that the varieties respond to tied ridges compared to conventional. As cotton is grown by small-scale farmers in high-risk environments, the results illustrate the suitability of these three varieties to the northern Zimbabwe environment. Adopting the three varieties to the Zimbabwean conditions illustrate Nhemachena et al. (2016)'s assertion that new crop varieties will be needed to cope with climate change. Areas with shortened seasons result in low yield potential, affecting agricultural productivity. Local breeding efforts may be slow to match the changing environments, hence the importation of genotypes that suit the environment. The new environment is forcing farmers to abandon some varieties or even abandon the crop especially if the varieties cannot withstand the new conditions.

The tied ridges gave a significantly higher branch number compared to conventional system (Fig. 5). This illustrates the suitability of the moisture conservation to maintain cotton production in arid areas which are vulnerable to climate change. Tied ridges tended to concentrate moisture on the few areas and that makes more moisture available for the crop.

The varieties M579 and M577 were the most suited to the climate of northern Zimbabwe as they performed much better that the traditional varieties which farmers have been using. Also making tied ridges improve water retention properties of the soil and leads to greater water use efficiency. Therefore adoption of tied ridges and the two varieties has potential to be an adaptive strategy that has potential to resuscitate an industry that was facing extinction due to climate change. Bringing new varieties and introducing water harvesting has been key in alleviating the effects of climate change on cotton production. The current conventional cotton varieties had failed to cope with climate change effects of reduced moisture availability. Other characteristics noted on the new varieties were very early development and increased branch number. These new varieties are better able to withstand the current adversities and keep marginalized farmers in production. The number of bolls noted per branch and on branches is all yield parameters which are critical for cotton productivity.

The cotton parameters noted above contribute to phenotypic plasticity which is the ability to cope with a wide range of environmental conditions. According to Kooyers (2015), drought escape may be optimal for annual plants in environments with shorter growing periods that are ended by sever terminal drought while drought avoidance may be optimal where if the growing season is punctuated by transient droughts.

Abstract

Understanding the factors influencing the perception of climate change can help improve policies for strengthening the adaptive capacity of pastoralists with regard to climate change. Despite this importance, few studies have focused on this issue,

especially among cattle farmers. In order to attempt filling this gap, this study analyzed the determinants of the perception of climate change by cattle farmers distributed in the dry and sub-humid tropical zones of Benin as well as the current adaptation strategies developed by these farmers. For this purpose, surveys were carried out through group discussions and an individual questionnaire administered to 360 cattle farmers in the two climatic zones. The data collected related to the sociodemographic characteristics of cattle farmers and their perception of climate change and adaptation strategies. A binary logit model has identified the factors that influence cattle farmers' perceptions of climate change. The results of the study showed that cattle farmers perceive a drop in rain (at least 77%), an increase in temperature (at least 80%), and violent winds (at least 60%). Breeding experience, level of education of the farmer, household size, membership of a breeders' organization, and cattle herd size determine these perceptions. Four major groups of adaptation strategies have been developed by farmers to cope with climate change. These are production adjustment strategies, activity diversification strategies, livestock management strategies, and selection strategies. The political implication of this study is that government and development partners should integrate these factors into projects and programs related to climate change.

Introduction

Climate change is currently an increasingly visible threat to the viability of the rural population of sub-Saharan Africa, where communities depend mainly on the exploitation of natural resources (Kaboré et al. 2019; Adimassu and Kessler 2016). Livestock rearing is one of the main economic activities on which the poorest people in sub-Saharan Africa depend as a source of food and income. Despite its importance, livestock is currently threatened by climate change (Apata et al. 2009; Deressa et al. 2009) because of its high dependence on natural resources specifically fodder and water (Idrissou et al. 2019; IUCN 2010). The impacts of climate change in the livestock sector are felt in the production and quality of forage crops (Polley et al. 2013; Chapman et al. 2012), water availability, animal growth, milk production, reproduction, and disease (Henry et al. 2012). Faced with this situation, the challenge for the scientific community is to produce knowledge enabling farmers to anticipate the effects of climate change on their system and to develop methods and tools to adapt to it (Sautier 2013). To achieve this, it is necessary to understand how pastoralists perceive climate change (Deressa et al. 2011), as this influences the way they manage climate-related risks and opportunities, as well as the strategies put in place to adapt (Mamba 2016). In developing countries, numerous studies have dealt with the perception and adaptation strategies of pastoralists in the face of climate change (Idrissou et al. 2020; Sanou et al. 2018; Ayanlade et al. 2017). In Benin, for example, several studies show that pastoralists perceive climate change through the drop in rain, irregular rainfall, and late start and early end of the rainy season (Idrissou et al. 2020; Dossa et al. 2017; Zakari et al. 2015). Pastoralists in Burkina Faso have unanimously discerned some changes in precipitation and temperature (Sanfo et al. 2015). They saw a decrease in annual precipitation, an increase in the intensity of precipitation, and the frequency of flooding. In Kenya, pastoralists have reported changes in the amount and distribution of precipitation, fog, temperature, and wind over the past 20 to 30 years (Cuni-Sanchez et al. 2019). To cope with the harmful effects of climate change, pastoralists in developing countries have developed several strategies such as herd mobility, storage of crop residues, and integration of livestock rearing with crop farming, among others (Idrissou et al. 2019).

These studies, although they allow apprehending the perceptions and adaptation strategies of cattle farmers, are still insufficient. Indeed, information on the factors that determine the perceptions of pastoralists has not often been analyzed. Knowledge of this aspect is important for science and will allow better targeting of policies to support the adaptation of pastoralists to climate change in developing countries.

Benin, a small country in West Africa, has three climatic zones, the most vulnerable to climate change being the dry and sub-humid tropical zones (Gnanglè et al. 2011; MEHU 2011). It is in these most vulnerable areas that more than 85% of the country's cattle farms are concentrated (Alkoiret et al. 2011). These cattle farms will be severely affected by the effects of climate change, resulting in reduced productivity (Nardone et al. 2010). Pastoralists in these zones are thus exposed to risks of food insecurity and increasing poverty. A study analyzing the perception and adaptation strategies of pastoralists in these areas in the face of climate change is timely as it can help improve policies aimed at supporting these pastoralists to adapt sustainably to climate change (Folefack and Tenikue 2015; Mabe et al. 2014). The aims of this study are therefore to (i) analyze the determinants of the perception of climate change by cattle farmers in the dry and sub-humid tropical zones of Benin and (ii) identify the current adaptation strategies developed by these farmers.

Material and Methods

Study Areas

This study was carried out in two of the three climatic zones of Benin (located 6° and 12° 50′N and 1° and 3° 40′ E). These are the dry tropical zone between 9° 45′ and 12° 25′ N and the sub-humid tropical zone located between 7° 30′ and 9° 45′ N (Fig. 1). The choice of these zones is based on the fact that climate forecasts indicate that they are the most vulnerable to rainfall deficit and high sunshine (Gnanglè et al. 2011; MEHU 2011), yet more than 85% of the Beninese cattle herd is concentrated in these zones (Alkoiret et al. 2011).

In each zone, two (2) municipalities were chosen based on the large number of cattle farmers and preliminary interviews with technicians from the "Agences Territoriales pour le Développement Agricole" (ATDA). Thus, the municipalities

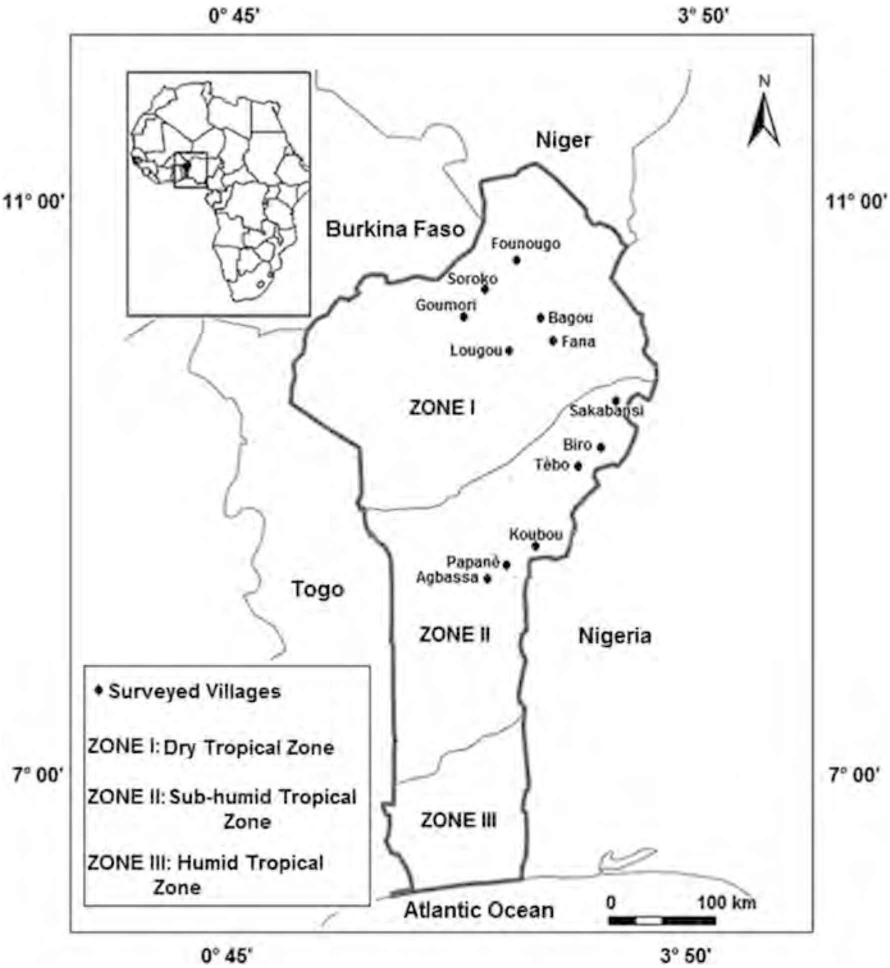

Fig. 1 Location of the villages surveyed in Benin

of Tchaourou and Nikki were selected in the sub-humid tropical zone and those of Gogounou and Banikoara in the dry tropical zone. Within each municipality, three villages have been selected (Fig. 1). In the dry tropical zone, which includes the municipalities of Gogounou and Banikoara, the mean annual rainfall is often less than 1000 mm, and the relative humidity varies from 18 to 99% (highest in August). The temperature varies from 24 °C to 31 °C. The soils in this zone are hydromorphic, well-drained soils, and lithosols. The vegetation of this zone is mainly composed of savannas with trees of smaller size. The sub-humid tropical zone, made up of the municipalities of Tchaourou and Nikki, is characterized by unimodal precipitation, from May to October, and lasts about 113 days with an annual mean rainfall varying between 900 and 1110 mm. The annual temperature ranges from 25 °C to 29 °C and the relative humidity from 31% to 98%. Soils in this zone are ferruginous with variable fertility. The vegetation of the sub-humid tropical zone is characterized by a mosaic of woodland, dry dense forests, tree and shrub savannas, and gallery forests.

Data Collection

Data collection was carried out from November 2018 to April 2019 in two stages that include the exploratory study and in-depth interviews.

Exploratory Study

During this phase, interviews were carried out with technicians from the ATDA in order to identify the villages and cattle farmers to be surveyed. On the basis of the defined criteria, with the local technicians, the villages of Koubou, Papanè, and Agbassa were identified in the municipality of Tchaourou; the villages Tèbo, Biro, and Sakabansi in the municipality of Nikki; the villages of Bagou, Fana, and Lougou in the municipality of Gogounou; and finally those of Founougo, Goumori, and Soroko in the municipality of Banikoara (Fig. 1).

After identifying the villages, focus groups of staff varying from 6 to 15 people were carried out (one focus group per village). During the focus groups, the questions were open and made it possible to record the maximum of responses on the perceptions and adaptation strategies of cattle farmers. At the end of these focus groups, a list of climatic parameters cited by cattle farmers was drawn up. These climatic parameters have been broken down into different indicators of their manifestations as cited by farmers. A global synthesis was made to constitute the content of the questionnaire for in-depth interviews.

The interviews carried out during the exploratory study made it possible to randomly select 30 cattle farmers per village to whom questions were addressed individually for the continuation of the study. Thus, a total of 360 cattle farmers were surveyed during this study. The criteria for choosing cattle farmers were having cattle breeding as their main activity and being at least 50 years old. The choice of breeding as the main activity to discriminate the respondents is justified by the fact that several studies focus on agro-pastoralists and generalize the results obtained both to agro-pastoralists and to pastoralists. However, these socio-professional categories face different socioeconomic problems (Zampaligré et al. 2014). The age barrier (50 years) is explained by the fact that climate change is very slow and elderly people are needed to have reliable historical information (Kaboré et al. 2019; Bambara et al. 2016).

In-Depth Interviews

The in-depth interview consisted of collecting data through semi-structured interviews with the 360 cattle farmers identified during the exploratory study. For data collection, local investigators were recruited and trained. The training of local investigators was undertaken for a week and piloted before the start of interviews with cattle farmers. The aim of the training was to minimize bias and errors in data collection. The interviewers used to conduct the interviews with the cattle farmers were selected from each study village and understood the local language of the village. The data were collected using a questionnaire. A first series of questions related to the sociodemographic characteristics of the cattle farmers (sex, age, breeding experience, ethnic group, household size, number of agricultural assets, level of education, contact with agricultural extension services, membership of a breeders' organization, etc.) and a second series of questions concerned the perception of climate change indicators as well as the adaptation strategies developed. The questions posed to farmers on their perception of climate change are consistent with the indices of the Expert Team on Climate Change Detection Monitoring and Indices (ETCCDMI) (Zhang and Yang 2004). Climate change indicators are meteorological parameters whose evolution over time reflects climate change. These indicators are total annual precipitation, rainfall intensity, daily maximum, and minimum temperatures. Other parameters were also taken into account including "rainless days" or pockets of drought, vortex, and strong winds (Bambara et al. 2016; Salack et al. 2012).

Statistical Analysis

The data from the surveys were processed using the Statistical Package for Social Sciences (SPSS) version 17. Frequencies of responses were reported and compared with chi-square ($\chi 2$) test. The quantitative variables describing the cattle farmers surveyed were presented as means $\pm$ standard deviations and compared between climatic zones using the Mann-Whitney U nonparametric test (McDonald 2009).

The determinants that influence cattle farmers' perception of climate change have been analyzed by binary logistic regression (Kaboré et al. 2019; Uddin et al. 2017). The equation of the binary model is as follows:

$$Yi = Xi\,\beta + \varepsilon i \tag{1}$$

where Yi is the variable which takes the value 1 if the farmer perceives a climate change indicator and 0 if he does not perceive it; Xi is the set of explanatory variables indicating the factors that influence the cattle farmers' perception of climate change; and εi is the standard error.

Before estimating the logistic regression model, the explanatory variables were checked to determine the existence of multi-colinearity, using the contingency coefficient test (Uddin et al. 2017). A collinearity was observed between the breeding experience and age; between the number of agricultural assets and household size; and between membership of a breeders' organization and contact with extension services. Consequently, age, number of agricultural assets, and contact with extension services were omitted from the logistic regression model after the multi-colinearity test. The explanatory variables used for the regressions are sex, breeding experience, ethnic group, level of education, location (climatic zone), membership to a breeders' organization, household size, and herd size.

Results and Discussion

Sociodemographic Characteristics of the Cattle Farmers Surveyed

The sociodemographic characteristics of the cattle farmers surveyed are summarized in Table 1. The majority of the cattle farmers surveyed are of the Fulani sociocultural group (80.83%) and of the male sex (92.5%). They are relatively old (56.43 ± 5.88 years) and have an average experience of 30 years in cattle breeding. Cattle farmers in the sub-humid tropical zone were older and more experienced ($p < 0.05$) than those in the dry tropical zone. Very few cattle farmers have been educated (5%). The household size of the cattle farmers surveyed was on average 11 people, and the cattle herd size was on average 64 heads. A large number of cattle farmers are members of an organization (90.92%) and are also in contact with agricultural extension services (66.21%). It is specified that the number of cattle farmers in contact with agricultural extension services in the dry tropical zone is significantly high ($p < 0.05$) compared to that of the sub-humid tropical zone. This could be explained by the fact that historically the dry zone is an area purely dedicated to animal husbandry, which leads technicians leaving agricultural college and university to settle more in this zone. Additionally, the first livestock extension structures were created in the dry zone.

Cattle Farmers' Perception of Climate Change Indicators

Seventy-seven percent (77%) of cattle farmers in the sub-humid tropical zone and 82% in the dry tropical zone perceived a decrease in rainfall (Fig. 2a). The indicator "high intensity of rainfall" was perceived by 78% of the cattle farmers of the dry tropical zone against 52% of the cattle farmers of the sub-humid tropical zone. In the both zones, indicators of change in precipitation such as the duration of the drought pocket, the late onset, and the early cessation of the rains were perceived by more than 80% of the farmers interviewed. At least 50% of the farmers in both zones perceived an irregularity in the rains. These indicators of change in precipitation perceived by pastoralists could be explained by the fact that these indicators remain the most visible in the observation of rainfall pejoration in Africa (Bambara et al.

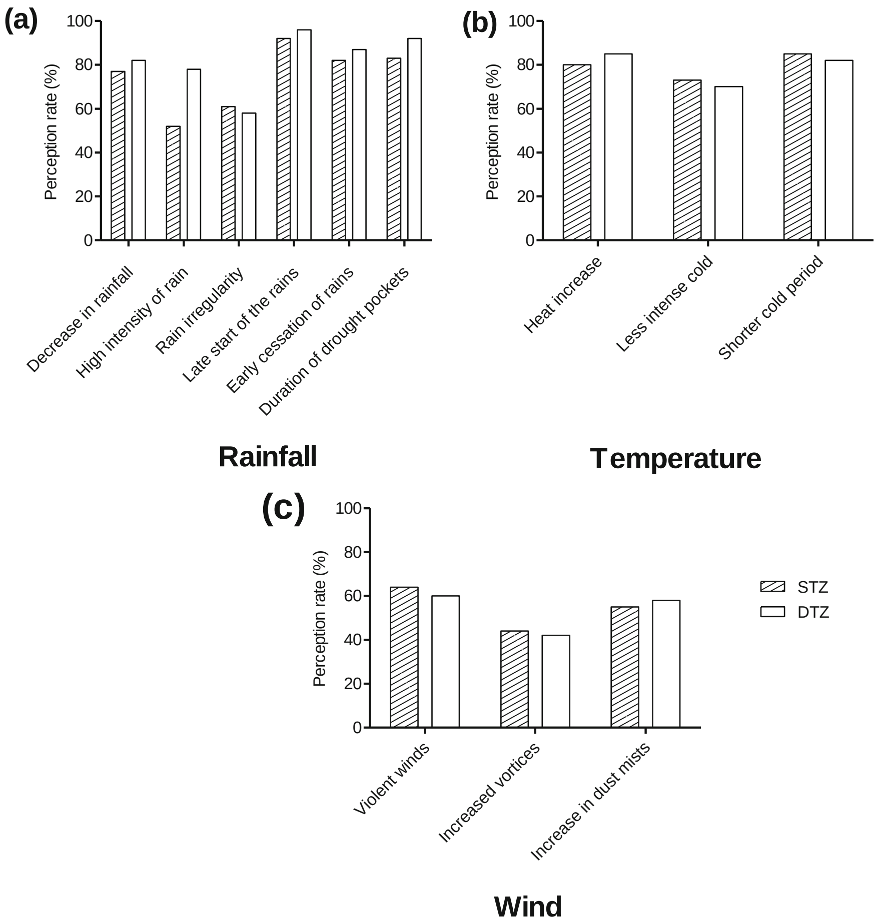

Fig. 2 Perception of indicators of changes in rainfall (**a**) in temperature (**b**) and wind (**c**) by cattle farmers in the dry (white) and sub-humid (black) tropical zones of Benin

2013). These results therefore confirm the work of several authors in Africa (Cuni-Sanchez et al. 2019; Opiyo et al. 2016).

The majority (at least 80%) of cattle farmers in the both zones recognize that the heat is getting stronger (Fig. 2b). These results reflect an increase in maximum and minimum daily temperatures observed throughout the year. Farmers also indicated that the cold season is warming up (70% and 73% of the cattle farmers in the dry and sub-humid tropical zones respectively) and tends to become shorter (82% in the dry zone and 85% in the sub-humid zone). As the temperature is a direct feeling, the farmers can easily see its increase through warmer days and nights. In addition, high temperatures cause animals to seek more shade and water (Idrissou et al. 2020). This behavior of animals observed by farmers could also explain their perception of the increase in temperature.

According to 60% of cattle farmers in the dry tropical zone and 64% of the farmers in the sub-humid tropical zone, the winds have become more and more violent (Fig. 2c). The increase in vortices was reported by at least 40% of cattle farmers in the both zones. In addition, more than 50% of the cattle farmers in the two zones perceived an increase in dust mists. Strong winds cause material damage such as destruction of roofs, erosion of cultivable land, uprooting of trees, etc. This damage noted by farmers could explain their perception. Similar perceptions have been reported by several authors in other parts of Africa (Limantol et al. 2016; Opiyo et al. 2016).

Determinants of Cattle Farmers' Perception of Climate Change

The analysis of binary logistic regression performed to determine the factors that influence the farmers' perception of the change in precipitation and temperature is summarized in Table 2. The variable "Breeding Experience" positively affects perceptions of reduced rainfall and late onset and early cessation of rains. This result indicates that farmers with longer years of cattle breeding experience were more likely to perceive climate change. In addition, experienced farmers observe changes over time and compare them to current climatic conditions, allowing them to quickly perceive climate change. This result is similar to those obtained by several authors (Sanogo et al. 2017; Uddin et al. 2017).

The level of education of the cattle farmers positively influences the perception of the late onset of the rains at the threshold of 10% (Table 2). The most educated farmers are more interested in calendar dates or the start of school holidays, which generally coincide with the start of winter (Kaboré et al. 2019). The less educated do not really make the difference between an early or late season.

Membership of a breeders' organization influences cattle farmers' perception of reduced rains and late onset and early cessation of rains. Breeders' organizations benefit from training from development partners through non-governmental organizations (NGOs), agricultural development projects, and programs. Through these different structures, cattle farmers are made aware of climate change as well as the present and future consequences on their livelihood. In addition to these sources of

learning are the relationships that cattle farmers have with each other which serve as channels for sharing experiences.

Household size positively influenced the cattle farmers' perception of the increased heat. This finding indicates that with increasing household size, the likelihood that cattle farmers perceive climate change increases. Milk represents an essential constituent of the food ration of Fulani cattle farmers and also generates income for their households (Alkoiret et al. 2010). Climate change is causing a decrease in the milk production of animals (Henry et al. 2012). Large households are therefore no longer able to meet the milk demand of their large families. This is why cattle farmers can more easily detect climate change (Kosmowski et al. 2016).

Cattle herd size has also influenced cattle farmers' perception of the increase in heat, the decrease in rainfall, and the late onset and the early cessation of rains. This means that farmers with large numbers of cattle perceive climate change better than those with small numbers due to the high demand for water and forage. This result is similar to that obtained among Turkana cattle farmers in northwestern Kenya (Opiyo et al. 2016).

Cattle Farmers' Adaptation Strategies to Climate Change

To adapt to climate change, cattle farmers in the dry and sub-humid tropical zones of Benin have developed several strategies (Table 3). These strategies can be grouped

Table 3 Adaptation strategies of cattle farmers in the dry and sub-humid tropical zones of Benin in the face of climate change

Adaptation strategies			Climatic zones			
Strategy group	Type of strategy	Total	DTZ	STZ	X^2	p-Value
Production adjustment strategies	Forage cropping	31.1	10[a]	52.2[b]	72.9	<0.0001
	Storage of crop residues	76.1	82.2[a]	70[b]	6.7	0.009
	Making hay	18.9	19.4[a]	18.3[a]	0.01	0.89
	Night grazing	14.4	13.9[a]	15[a]	0.02	0.88
	Use concentrated feed	72.8	77.8[a]	67.8[b]	4.05	0.04
Activities diversification strategies	Integration livestock-crop	83.9	95[a]	72.8[b]	31.2	<0.0001
	Fattening	15.3	11.1[a]	19.4[a]	3.68	0.051
	Off-farm activities	25.6	15[a]	36.1[b]	19.9	<0.0001
Livestock management strategies	Herds destocking	70	77.8[a]	62.2[b]	9.6	0.001
	Livestock diversification	58.9	92.8[a]	25[b]	167.9	<0.0001
	Pastoral mobility	96.1	100[a]	92.2[b]	12.5	0.0003
Selection strategies	Breeding local breeds	2.3	19.4[a]	21.1[a]	0.06	0.79
	Cross between local breed and breed adapted to heat	25.3	31.7[a]	18.9[b]	7.1	0.007

DTZ dry tropical zone, *STZ* sub-humid tropical zone

[a, b]The values of the same line indexed by different letters are significantly different at the 5% threshold

into four major groups of strategies, namely, production adjustment strategies, activities diversification strategies, livestock management strategies, and selection strategies. This classification is similar to that developed by Calvosa et al. (2010).

The production adjustment strategies consist of the storage of crop residues, use of concentrated feed, forage cropping, making hay, and night grazing. The adoption rates for the storage of crop residues (82.2%) and the use of feed concentrates (72.8%) were significantly higher ($p < 0.05$) in the dry tropical zone than in the sub-humid tropical zone. Conversely, forage cropping (52.2%) was more adopted ($p < 0.0001$) by cattle farmers in the sub-humid tropical zone. Indeed, the rainfall and the number of rainy days recorded in the sub-humid zone being higher than that obtained in the dry zone could favor the forage cropping in this zone. Also, as the climatic conditions are not conducive to the forage cropping in the dry zone, this leads cattle farmers in this zone to resort to other strategies such as the use of feed concentrates and the storage of crop residues to feed the animals.

Integration of livestock rearing and crop cultivation, fattening, and off-farm activities are the types of strategies contained in the activities under the diversification strategies category. The practice of fattening did not vary significantly ($p > 0.05$) from one climatic zone to another. On the other hand, the integration livestock and crop was more adopted ($p < 0.0001$) in the dry zone than in the sub-humid zone. This result means that pastoralists have moved to agro-pastoralism. Indeed, milk was the staple food for Fulani cattle farmers (Alkoiret et al. 2010), but with the fall in milk production due to climate change, the consumption of cereals has increased. To obtain these cereals, cattle farmers exchanged milk for these products with farmers. But today, given the decrease in crop yield and the strong demand due to the demographic surge, cereals are inaccessible because their prices have increased, making the exchange of products difficult. This may be the reason why cattle farmers integrate livestock and crop because they are convinced that livestock cannot be their only source of food. This result is similar to those obtained in Burkina Faso by Sanfo et al. (2015). Off-farm activities were more practiced by cattle farmers in the sub-humid tropical zone ($p < 0.0001$) than those in the dry zone. This could be explained by the fact that the sub-humid tropical zone is an area which abounds in urban centers of a commercial nature, which could facilitate trade. Thus, income from off-farm activities can be used by cattle farmers to increase the level of investment in inputs such as labor, feed concentrates, and veterinary products.

Herd destocking, livestock diversification, and pastoral mobility, all of which are livestock management strategies, were adopted more in the dry zone ($p \leq 0.001$) than in the sub-humid zone. Indeed, the insufficiency of forage due to the precariousness of the rains pushes the cattle farmers having a large number of cattle to practice the transhumance to reduce the risk of mortality (Kiema et al. 2013). In addition, other cattle farmers are forced to reduce the size of their herd (Kima et al. 2015; Oyekale 2014). Livestock diversification through the introduction of small ruminants into the breeding constitutes a real advantage for the farmers because of their low food needs, their larger feeding areas, and their higher reproduction rates (IUCN 2010).

Breeding local breeds adapted to local climatic conditions, and the crossing between local breeds and heat-resistant breeds were the two selection strategies implemented by the cattle farmers in both zones. The adoption rates for the first strategy were not significantly different ($p < 0.05$) in the two study zones. On the other hand, crossbreeding between local breeds and heat-resistant breeds as an adaptation strategy was more adopted in the dry zone ($p = 0.007$) than in the sub-humid zone. This could be explained by the fact that the dry zone is a pre-Sahelian zone where there is a high temperature, therefore requiring the breeding of heat-resistant animals.

Conclusion

The manifestations of climate change are perceived by cattle farmers in the dry and sub-humid tropical zones of Benin. The changes in rainfall are felt through signs such as reduced rainfall and late start and early end of the rainy seasons. Changes in temperature and wind were felt through increased heat and violent winds. This study showed that the sociodemographic characteristics of cattle farmers such as the level of education and membership of an organization influence local perceptions of climate change.

Adaptation strategies implemented by cattle farmers can be grouped into four main groups. These are production adjustment strategies, activities diversification strategies, livestock management strategies, and selection strategies. These current developed strategies allow farmers to take advantage of their livelihood.

Based on the results of this study, there is a need to strengthen the adaptive capacities of farmers in both zones through their access to education and training on adaptation to climate change within breeders' organizations. These help to improve their perception of this phenomenon and help them to better develop adaptation strategies. Climate information is needed to enable them to increase production to achieve food security. In addition, endogenous climate change indicators should be further promoted, as they allow farmers to predict the course of the rainy season and guide them better in implementing their adaptation strategies to climate change.

Contents

Abstract

Climate change is a major development challenge affecting developing countries that rely on rain-fed agricultural production for food and income. Smallholder farmers in these countries are using multiple adaptation practices to manage the effects of climate change. This chapter examines household and community-level factors that influence smallholder farmers' level of adaptation to climate change in the Hwedza District in Zimbabwe. Data for this study were collected from 400 randomly selected smallholder farmers, using a structured questionnaire, focus group discussions, and key informant interviews. The study used a multilevel modeling approach to examine the factors that influence smallholder farmers' level of adaptation to climate change. Results from the study show that smallholder farmers' level of adaptation to climate change is conditioned by access to extension services, access to remittances, family labor, household education

(household level factors), and linking capital (community-level factor). This chapter therefore concludes that smallholder farmers that have higher levels of adaptation to climate change are those that are well linked to external organizations and have access to agricultural extension services. The chapter recommends that adaptation to climate change can be enhanced by improving access to agricultural extension services and promoting linkages with external organizations that provide information on agricultural adaptation practices.

Introduction and Background

Climate change is a major development challenge facing developing countries particularly those in Southern Africa (Ali and Erenstein 2017; IPCC 2014). These countries are battling to address multiple stressors that include a high incidence of poverty, chronic food insecurity, malnutrition, HIV, lack of disaster preparedness, political upheavals, and macroeconomic instability (Adego et al. 2018). In this region, rain-fed agriculture which accounts for 95% of agricultural production provides livelihoods to over 70% of the population (Zamasiya and Nyikahadzoi 2018; Asfaw et al. 2016). Overreliance on climate-sensitive agricultural systems exacerbates the vulnerability of countries in Southern Africa such as Zimbabwe (Rurinda et al. 2013). Rainfall is the major determinant of agricultural production. Reports show that the mean annual rainfall has already declined by over 5% and forecasted to further decrease by 10%. The IPCC's 2018 report notes that with business as usual approach to greenhouse emissions, temperatures will increase by over 1.5 °C. The consequences of such an increase will be catastrophic to resource-constrained smallholder farmers in Southern Africa particularly those with low adaptive capacity. This development will plunge developing countries into dire food insecurity and chronic malnutrition. These conditions require that smallholder farmers who are the major food producers adapt to climate change (Abid et al. 2015; Mabe et al. 2012). Adaptation, in this case, is the use of farming practices that can reduce the impact of climate change on smallholder farmers' food security.

Scholars observe that adaptation reduces the impacts of climate change on food security systems (Adego et al. 2018; Shisanya and Mafongoya 2016; Di Falco et al. 2011). Some of the adaptation practices that smallholder farmers are to manage the impacts of climate change include crop diversification, drought-tolerant varieties, income diversification, staggering of planting dates, crop mixing, and soil and water conservation (Adego et al. 2018; Shisanya and Mafongoya 2016; Nyikahadzoi et al. 2017). Studies show that some smallholder farmers use more than one adaptation practices. In such circumstances, such smallholder farmers are likely to have better food security than those that use solitary adaptation practices. Although adaptation is a viable response to climate change, smallholder farmers face challenges in implementing the adaptation practices. These challenges include lack of access to climate information, lack of access to agricultural credit, lack of access to an extension to adequately prepare for seasons, lack of knowledge on adaptation practices, and lack of labor resources (Nyikahadzoi et al. 2017; Salau et al. 2012; Di Falco et al. 2011). Since adaptation differs by contexts, some of the adaptation practices may not be applicable in other regions.

There are very limited studies (Ali and Erenstein 2017; Below et al. 2012) on drivers of the level of adaptation to climate change by smallholders. While the limited studies that are there provide important insights on determinants of the level of adaptation among smallholder farmers, their major challenge is that they used simplistic modeling techniques. These techniques do not recognize the nesting of data in groups and may, therefore, lead to biased results and poor policy targeting. This chapter recognizes that since farmers are nested in villages and villages are nested in wards, the actions of individual smallholder farmers are a function of household socioeconomic level and community-level variables. This is because smallholder farmers live in an open environment in which they interact among themselves, interact with people from other wards, and interact with external organizations. The levels of interaction vary from village to village, and this necessitates the use of multilevel modeling techniques (Frankenberger et al. 2013). The chapter proposes the use of the hierarchical linear modeling technique to examine the drivers of the level of adaptation to climate change among smallholders' farmers in the Hwedza District of Zimbabwe. This model addresses the weaknesses of confounding that are inherent in models used in previous studies.

In some of the studies on drivers of the level of adaptation to climate change, social capital was used as an explanatory variable. The definition used for social capital is restricted to farmer-farmer interactions at a local level such as within a village. This definition does not capture vertical interactions between communities and organizations that are external to the community. In this study, a deliberate attempt is made to distinguish between social capitals. The chapter adopts the categorization of social capital proposed by Aldrich (2012) and Frankenberger et al. (2013) which provides a clear distinction between bonding capital, bridging capital and linking capital. In this study, our concern is on linking social capital. It refers to the linkages between communities and organizations that are external to it. Scholars argue that communities that have better resilience are those that have higher linking social capital compared to bonding capital (Aldrich 2012; Taruvinga et al. 2017). This chapter measures linking capital as a village-level variable and use it as a level 2 covariate in the hierarchical linear regression model.

Given the inevitability of climate change, adequately preparing for this eventuality requires policymakers to understand the drivers of the level of current adaptation practices to climate change by smallholders. The purpose of this chapter is to improve policymakers' understanding of the determinants of smallholder farmers' level of adaptation to climate change. The issue of determinants of the level of adaptation to climate change among smallholder farmers is poorly understood and measured. In this study, the level of adaptation to climate change is the number of strategies that are used by a smallholder farmer in response to climate change. This chapter, therefore, seeks to provide empirical evidence on what drives the level of adaptation. This information is critical for identifying and setting policy targets for enhancing adaptation. Without that, it is difficult for policymakers to enhance current and future adaptation by smallholder farmers.

Data Gathering and Analytical Framework

This study was conducted in Hwedza District in Mashonaland East Province of Zimbabwe is a "climate hotspot." Zimbabwe is divided into five agro-ecological regions known as natural regions (NR). This classification is based on the soil quality, rainfall regime, and vegetation distribution. The quality of the land resource declines from natural region (NR) I through to NR V. Hwedza District is located in natural region II with an annual rainfall of 650–800 mm and a mean temperature of 29 °C (Rurinda et al. 2013). The predominant soil type is coarse sandy soils derived from granitic rocks (Rurinda et al. 2014). Average household farm sizes range between 2 and 5 ha per household (Rurinda et al. 2014). Hwedza District is a communal area dominated by subsistence maize production for food security. The subsistence farmers also grow groundnuts, finger millet, and cowpeas on small plots (Zamasiya et al. 2018). Crop production is complemented with livestock rearing mostly cattle, goats, and indigenous chickens. During poor cropping seasons, smallholder farmers in the district rely on non-timber forest products for food (Woittiez et al. 2013) and food aid from nongovernmental organizations (NGO). Due to climate change, the onset and distribution of rainfall in the Hwedza District are now very unpredictable. The district experiences frequent midseason droughts with good rainfall years increasingly becoming fewer over the past 20 years (Rurinda et al. 2014). Smallholder farmers in this district use different farming practices to manage the effects of climate change. These practices include crop diversification, staggering of planting dates, soil and water conservation practices, drought-tolerant varieties, integrated soil fertility management, and crop mixing (Zamasiya et al. 2017). Public and private research organizations and nongovernmental organizations were promoting a basket of ex ante climate adaptation practices to improve smallholder farmers' preparedness to droughts and increased rainfall variability.

The study used a multistage sampling technique to select the study site and the survey respondents. The target population in this study are smallholder farmers practicing crop and/or livestock farming in Hwedza District in Zimbabwe. In stage one, purposive sampling was used to select the Hwedza District in Mashonaland East Province of Zimbabwe. This study site was selected on the basis that it has a high agro-ecological potential and has experienced an increase in extreme climatic events since the year 2000. In stage two, random sampling was used to select Ushe and Dendenyore wards from a total of 22 wards in the district. In stage 3, simple random sampling was used to select 10 villages per ward. Dendenyore ward has 30 villages, and the Ushe ward has 22 villages. In the last stage, the study used simple random sampling to select 20 households in each village. In total, 400 smallholder farmers were interviewed during the survey in February 2015.

Quantitative and qualitative data used in this study was solicited from smallholder farmers using a structured questionnaire, focus group discussions (FGDs) and key informant interviews. The structured questionnaire collected data on demographic information, strategies used by smallholder farmers to respond to climate change, access to extension, remittances, and challenges experienced by farmers in adapting to climate change. The key informant interviews were conducted with ward level agricultural extension officers (AEOs) and district level extension officers. In total, eight AEOs participated in the key informant interviews. The study also collected data from knowledgeable smallholder farmers. A total of six farmers participated in the key informant interviews. Knowledgeable farmers are smallholders who have at least 30 years of conducting farming activities in the Hwedza district. Purposive sampling was used to select participants for the key informant interviews. Focus group discussions were conducted with smallholder farmers in each village. Each FGD had 12 smallholder farmers (6 males and 6 females). The purpose of FGDs in each village was to get an average rating of the village's perception of the level of linking the capital, the farming practices used by smallholder farmers, and the challenges that they are experiencing in adapting.

Quantitative data analysis was done in STATA Version 15. This study used a multilevel modeling technique that is known as the hierarchical linear modeling (HLM) to establish the determinants of farmers' level of adaptation to climate change. An HLM technique is a random coefficient modeling approach that can be used to analyze data that is nested within groups (Huta 2014). Such models are used to examine how individual-level relationships vary as a function of group characteristics (Hox et al. 2018). The HLM estimation procedures are capable of analyzing nested data (Huta 2014). The results from this analysis are presented in tables as coefficients. This study used a level 2 HLM approach comprising household-level variables for individual farmers and group level variables. Qualitative data collected from interviews and focus group discussions and observations were analyzed thematically.

Multilevel Estimation of Determinants of Level of Adaptation

This chapter presents the results from the determinants of the level of adaptation to climate change among smallholder farmers in Zimbabwe.

The first stage is to run the random effects model. The purpose of doing this is to understand the portion of variance that is due to cross-village interactions compared to individual household interactions. This model can be written as follows:

Random Effects

Results in Table 1 show that there are 400 level 1 units (number of observations) in the analysis and 20 level 2 units (number of villages/groups). The cluster size varies from 14 to 28 with a mean cluster size of 20. The log-likelihood ratio is −797, 1447. The grand mean across the villages is 1.5066 with a standard error of 0.1640. The z

Table 2 Estimation results for a random intercept model

Adaptation (Adj)	Coef.	Std. Err.	z	P > z	[95% Conf.	Interval]
Visitextn	1.1785	0.2022	5.8300	0.0000***	0.7822	1.5748
FamilyRemit	0.7180	0.2262	3.1700	0.0020***	0.2747	1.1612
Farmlabor	0.1669	0.0433	3.8500	0.0000***	0.0819	0.2518
Hheducation	0.0533	0.0316	1.6900	0.0920*	−0.0087	0.1152
_cons	0.3953	0.2588	1.5300	0.1270	−0.1119	0.9025
Random effects parameters		**Estimate**	**Std. Err.**	**[95% Conf. Interval]**		
village: Identity						
var(_cons)		0.2390	0.1193	0.0898	0.6360	
var(Residual)		2.6064	0.1892	2.2608	3.0049	

Wald chi2(4) =59.92; Prob > chi2 = 0.0000; LR test versus linear model: chibar2(01) = 13.61 Prob ≥ chibar2 = 0.0001

statistic is 9.1900, and the p-value is 0.000. The reported LR test statistic is 22.5800 with a p-value of 0.000; we, therefore, reject the null hypothesis that tao is equal to zero. It, therefore, means that there is intervillage variation in the adaptation by smallholder farmers. Based on the output, the interclass correlation is 11.57%. This means that 11.57% of the variation in adaptation among smallholder farmers in Hwedza district is due to differences across villages and 88.43% is due to individual differences across farmers.

The random intercept model involves the addition of level 1 covariates to the model, but it assumes fixed effects. In this stage, the intercept is allowed to vary across villages to accommodate intervillage variations. The model can be expressed as follows:

Table 2 shows the estimation results of the random intercept model. The results show that all the independent variables have positive effects on adaptation. They are all statistically significant with Visitextn (p <1%), FamilyRemit (p <1%), Farmlabor (p <1%), and Hheducation (p <10%). The Wald test shows that W = 59.92 and p-value =0.0000. Comparing the fit of the random intercept model and the LR = 13.61 and a p-value of 0.0001. Therefore, the null hypothesis that the intercept is the same across all villages is rejected.

Hierarchical Linear Regression Model with Random Intercept and Level 2 Covariates

This model seeks to account for the variation in intercepts across villages. This is done by adding a level two covariate.

Table 3 shows the results of the hierarchical linear regression model with random incept and a village-level covariate. The results show that Level 1 covariates are all significant. The level 2 covariate (linking social capital) is also very significant ($p < 1\%$). The Wald test statistic $W = 100.55$ has a p-value of 0.000. The results show that the second level variable linking social capital improves the level of adaptation for smallholder farmers.

This chapter presents the discussion from the study. The discussion is based on theoretical and empirical evidence to recommend how government and organizations external to the community can help in improving adaptation to climate change by smallholder farmers. Based on this study, the variables that can be influenced to promote adaptation are access to agricultural extension services, access to remittances, family labor, level of education, and linking social capital.

The coefficient of access to agricultural extension services ($p < 1\%$) is statistically significant and positively influences smallholder farmers' level of adaptation to climate change. Extension officers play a pivotal role in the dissemination of agricultural adaptation technologies (Zamasiya and Nyikahadzoi 2018; Zamasiya et al. 2014). Through field-based demonstrations and awareness meetings, extension officers help in disseminating information to smallholder farmers on adaptation practices that they can use to manage the impacts of climate change on food security (Zamasiya et al. 2017; Ali and Erenstein 2017). Smallholder farmers who have access to AEOs are more likely to know different adaptation practices. As such they are more likely to have higher levels of adaptation to climate change than their counterparts. However, key informants highlighted that the major challenge facing AEOs is Zimbabwe is lack of motorcycles for improving mobility and contact with

Table 3 Estimation results for HLM with random intercept and level 2 covariates

LOA	Coef.	Std. Err.	Z	P > z	[95% Conf. Interval]	
Extension	1.0950	0.1995	5.4900	0.0000	0.7040	1.4859
FamilyRemit	0.6645	0.2234	2.9700	0.0030	0.2267	1.1022
Farmlabor	0.1574	0.0428	3.6700	0.0000	0.0735	0.2414
Hheducation	0.0554	0.0312	1.7800	0.0760	−0.0057	0.1165

_cons	−0.4074	0.2734	−1.4900	0.1360	−0.9433	0.1286
Random effects parameters		Estimate	Std. Err.	[95% Conf. Interval]		
village: Identity						
var(_cons)		0.0216	0.0493	0.0002	1.8808	
var(Residual)		2.6050	0.1890	2.2597	3.0031	

Wald chi2(5) = 100.55; Prob > chi2 = 0.0000; LR test versus linear model: chibar2(01) = 0.23 Prob ≥ chibar2 = 0.3150 smallholder farmers. The wards in Hwedza District are so big that it becomes difficult for the AEOs to effectively contact farmers if they are not motorized. Other AEOs highlighted that they have motorcycles but have no access to fuel. This, therefore, makes it difficult for them to dispatch their roles efficiently. During FGDs, smallholder farmers highlighted that the challenge with AEOs is that climate change is a new phenomenon to them. They were advising farmers based on their lived realities. These results corroborate with the findings of Zamasiya et al. (2018), and Ali and Erenstein (2017).

Results show that the coefficient of access to remittances ($p < 1\%$) is very statistically significant and positively improves a smallholder farmer's level of adaptation to climate change. Remittances improve the number of financial resources that are available to a household (Nyikahadzoi et al. 2013) for purposes of financing transaction costs associated with adaptation to climate change. These costs could include the cost of improved seed, inorganic fertilizers, and herbicides. Zamasiya et al. (2018) note that smallholder farmers with access to remittances are more likely to adapt than their counterparts. They further highlight that some smallholder farmers rely on disposing of small livestock to finance adaptation costs. This is the case in economies such as Zimbabwe where most smallholder farmers have no access to formal banking systems (Nyikahadzoi et al. 2012). With improved access to financial resources, it is more likely that the smallholder farmers will improve their levels of adaptation. During FGDs, smallholder farmers highlighted that their major challenge is lack of agricultural credit. They mentioned that the lack of access to financial resources limited their ability to implement several adaptation practices. For instance, some farmers highlighted that they lacked financial resources to purchase improved seeds, inorganic fertilizers, and herbicides, and this made it difficult to implement several adaptation practices. Some of the smallholder farmers ended up planting recycled maize seeds. Key informants highlighted that when smallholder farmers used recycled seed, they used the wrong seed rate for maize crop. The key informants also highlighted that in most cases, agro-dealers sell only one variety of maize seeds. The smallholder farmers just end up buying the available seed. These results corroborate with the findings of Ali and Erenstein (2017).

Study findings show that the coefficient of family labor positive and statistically significant ($p < 1\%$) influences a smallholder farmer's level of adaptation to climate change. Labor is a major constraint to adaptation among smallholder farmers (Deressa et al. 2010). The family offers technical and manual skills that are crucial for executing agronomic practices on time. Smallholder farming households that have large pools of labor can spread labor resources across different adaptation practices. Such households can utilize labor-intensive practices such as crop diversification and soil and water conservation practices (Zamasiya et al. 2018). As such, households with higher labor resources are more likely to have higher levels of adaptation than their counterparts. These results corroborate with the findings of Ali and Erenstein (2017).

Research findings show that the coefficient of level of education ($p < 10\%$) is marginally statistically significant and positively influences a smallholder farmers' level of adaptation to climate change. Zamasiya et al. (2018) note that education improves a smallholder farmer's ability to receive, decode, and use the information on adaptation practices. These results suggest that smallholder farmers who are educated are more likely to be aware of climate change, the adaptation practices that they can use, and the benefits of adaptation. It is therefore likely that such smallholder farmers are more likely to have higher levels of adaptation to climate change than their counterparts. During FGDs, it was observed that most educated smallholder farmers were aware of adaptation practices and were proactively seeking more information on the practices from extension officers. Key informants highlighted that educated farmers were willing to experiment with new adaptation practices than uneducated smallholder farmers. Key informants highlighted that the lack of education among smallholder farmers is a major constraint to adaptation. Results corroborate with the findings of Below et al. (2012) and Ali and Erenstein (2017).

Study findings show that the coefficient of linking capital (p <1%) is very statistically significant and positively influences the level of adaptation to climate change. Linking social capital is an important driver of the level of adaptation to§ climate change by smallholder farmers. As observed by Aldrich (2012), linking capital improves adaptation through the provision of information that is otherwise unavailable. Through vertical relations with organizations external to the community, linking social capital improves access to information that is very important for enhancing adaptation to climate change (Taruvinga et al. 2017; Babaei et al. 2012). Information that communities may access through linking social capital includes improved varieties, yield robustness of such varieties, baskets of adaptation technologies, research results, and opportunities for exchange visits. In the study site, the communities are linked to research institutions that conduct farmer-managed and researcher-managed experiments. The smallholder farmers participate in field days where they get to interact with staff from organizations that play a key role in the agricultural value chain. Through these platforms, smallholder farmers have access to valuable agronomic information that they use for enhancing their adaptation to climate change. During FGDs, smallholder farmers highlighted that external organizations played a pivotal role in the dissemination of information on adaptation practices. The smallholder farmers noted that they were now aware of new crop varieties, their performance under different management regimes, and had acquired invaluable knowledge on different adaptation practices. Key informants highlighted that financial resources were scarce for the Agritex Department. As such, access to linking capital is associated with higher levels of adaptation to climate change.

This chapter sought to understand the determinants of the level of adaptation among smallholder farmers in Southern Africa using the example of the Hwedza district in Zimbabwe. The study used the multilevel modeling approach. Results show that level of education, access to agricultural extension, family labor, and access to remittances positively influence the level of adaptation. At a community level, adaptation is influenced by access to linking social capital. We, therefore, conclude that smallholder farmers that have a high level of adaptation to climate change are those that are well linked to external organizations and have access to extension services and financial resources.

Promote Learning Through Linkages with Public and Private Extension Services

Based on the results from this study, the chapter recommends that to improve smallholder farmers' level of adaptation to climate change, there is a need to enhance access to agricultural extension services and NGOs or research organizations. Because the mobility of extension staff is a recurrent problem in most areas, the public extension should establish linkages with other extension service providers in their area such as NGOs and private companies so that they can combine their programs. This will ease the mobility challenges. Further, government can also boost extension service delivery through timely recruitment, periodic training of the agents, and provision of adequate logistical support. The role of organizations that are external to the smallholder farming communities cannot be underestimated. These institutions provide a feedback loop between grassroots and policymakers. They gather critical information on climate change technologies and disseminate it to smallholder farmers. For instance, NGOs and research organizations have pioneered agricultural technologies and trainings that have since been incorporated into the public extension system. To promote development of linking capital, policymakers need to adopt participatory and inclusive decision-making processes in their work with communities, encourage smallholder farmers to work in groups, promote look and learn tours to other communities to challenge, inspire, and educate communities. This will improve access to critical information on agricultural technologies that are useful for enhancing smallholder adaptation to climate change.

Acknowledgments The authors would like to thank the International Foundation for Science who provided funding for this research through Grant No. S/5158-1.

Economic Analysis of Climate-Smart Agriculture Technologies in Maize Production in Smallholder Farming Systems

13

Angeline Mujeyi and Maxwell Mudhara

Contents

Abstract

Smallholder farmers who grow the staple maize crop rely mainly on rain-fed agricultural production, and yields are estimated to have decreased by over 50% largely due to climate change. Climate-smart agriculture (CSA) technologies, as adaptive strategies, are thus increasingly being promoted to overcome problems of declining agricultural productivity and reduced technical efficiency. This study analyzed profitability and profit efficiency in maize (Zea mays) production as a result of CSA technology adoption using cost-benefit analysis and stochastic profit frontier model. The study used data from a

W. Leal Filho et al. (eds.), *African Handbook of Climate Change Adaptation*,
https://doi.org/10.1007/978-3-030-45106-6_17

cross-sectional household survey of 386 households drawn from 4 districts in Mashonaland *East* province located in the northeastern part of *Zimbabwe*. Results from the cost-benefit analysis reveal that maize performs best under CSA technologies. The profit inefficiency model shows that extension contact, number of local traders, and adoption of CSA had significant negative coefficients indicating that as these variables increase, profit efficiency among maize-growing farmers increases. This implies that profit inefficiency in maize production can be reduced significantly with improvement in extension contact, access to farm gate/local markets, and adoption of CSA. The findings call for development practitioners to incorporate market linkages that bring buyers closer to the farmers, support for extension to be able to have frequent contacts with farmers, and promotion of CSA adoption.

Introduction

Maize (*Zea mays* L.) is the most important cereal crop in sub-Saharan Africa and is the world's most widely grown cereal crop as well as essential food source for millions of the world's poor (Abate et al. 2017). In sub-Saharan Africa, maize is a staple food for an estimated 50% of the population and an important source of carbohydrate, protein, iron, vitamins (A, B, E, and K), and minerals (magnesium, potassium, and phosphorus) and is grown on an estimated 100 million hectares throughout the developing world (Nsikak-Abasi and Okon 2013; Siyuan et al. 2018). In 2018, Zimbabwe got approximately 730,437 tonnes of maize, and the average yield was 613.1 Kg per hectare pointing to some technical inefficiencies. The average yield is lower as compared to the world average of 5923.7 Kg tonnes/ha and 2040.2 Kg/ha for Africa in the same year (FAOSTAT 2020). The smallholder farmers rely mainly on rain-fed production and in addition are often constrained by multiple constraints such as reduced soil fertility; limited income to access inputs such as fertilizers, improved seed, herbicides, and pesticides; unavailability of lucrative output markets; high cost of inputs; and reduced yield due to climate variability (Poole 2017; Rurinda et al. 2014). Researchers and development practitioners have reported reductions in agricultural yield due to extreme weather (UNCCS 2019). These unpredictable seasons have become a major constraint in smallholder crop and livestock production farming systems, and as such, the use of climate-smart agriculture (CSA) technologies becomes essential as a solution. Climate-smart agriculture technologies are innovations that sustainably increase agricultural productivity, help households to adapt and be resilient to climate change, and contribute to the reduction of greenhouse gas emissions (Steward et al. 2018).

Adaptation strategies for households can either be reactive (Shongwe et al. 2014), i.e., soil fertility maintenance through the use of animal manure and inorganic fertilizers, rotations, and intercropping in order to address problems linked to observed climate change impacts, or proactive CSA technologies such as use of new drought-tolerant varieties, use of early maturing varieties, and policy measures such as insurance policy. Zimbabwe has participated in interventions and alliances promoting CSA such as the DFID-funded Vuna (2015–2018) and the Africa Development Bank's Africa Climate-Smart Agriculture (ACSA) (2018–2025) (Thierfelder et al. 2017; Rosenstock et al. 2019). The Government of Zimbabwe (GoZ) has developed policies and interventions to lessen the impacts of climate change on agriculture. These policies include a child-friendly climate policy which targets education in schools on climate change issues, the climate-smart agriculture policy which promotes adoption of CSA by farmers, and the national climate policy which is targeting putting legal structures to guide businesses on becoming greener (GOZ 2018). Government and nongovernmental organizations have introduced a range of CSA in Zimbabwe which include conservation agriculture, drought-tolerant maize and legume varieties, cereal-legume intercropping and rotation systems, and improved fodder crops among others (Mujeyi 2018). Assuming economic rationality, smallholder farmers who rely on agriculture for livelihoods would adopt technologies that reduce costs of production while increasing benefits from greater incomes through improved yields. Smallholder farmers are heterogeneous, and as such, they adopt different combinations of CSA to address varying constraints that they face. These different technology bundles have different profitability levels because of the different input requirements associated with them as well as their potential impact on productivity.

The need to upscale CSA as adaptation mechanisms in order to improve or maintain high productivity levels in smallholder farming communities can effectively be achieved if profitability of these technologies and factors that enhance efficiency are properly understood. This study therefore aims to:

1. Estimate profitability and compare benefit-cost ratio (BCR) of maize production in smallholder farming communities across CSA technology bundles
2. Investigate the determinants of profit efficiency and identify the determinants thereof

The aim of this study is to contribute to the literature on CSA in Zimbabwe by analyzing profitability of current CSA technology bundles in maize production and technical inefficiency. Furthermore, using stochastic frontier model, the chapter aims to identify determinants of efficiency. The results will provide a better understanding of costs and benefits that would make it possible to design more economically efficient policies and programs to promote CSA technology adoption. Economic evaluations can provide critical information to those making decisions about the allocation of limited agriculture input resources across enterprises. The chapter provides empirical evidence from actual farmer behavior in uncontrolled environment, thus adding to studies from on-farm and on-station trials.

CSA in Crop-Livestock Farming Systems

This study particularly chose to do analysis for maize (*Zea mays*) as it is the most important crop in smallholder farming systems in the four districts. Maize is the staple crop in Zimbabwe to 98% of the 12.7 million people in the country, and it provides 40–50% of the calories (Kassie et al. 2017). Average maize yield has dropped from a highest (after independence) of 2163.7 Kg/ha in 1985 to 667.8 Kg/ha in 2017 (FAOSTAT 2020). Maize productivity has been negatively affected by infertile soils, inadequate water due to drought, and erratic rainfall patterns caused by climate change as well as incidence of pests and diseases. Various CSA technologies have been used in maize production in an effort to boost yields. One such technology is conservation agriculture (CA) which consists of three key principles, namely, minimum tillage, permanent soil cover (mulching with crop residues or cover crop), and crop diversification (either temporal diversification, i.e., rotation, or spatial diversification, i.e., intercropping). CA offers benefits of increased yields when properly followed. Crop rotation and intercropping improve soil fertility through the nitrogen fixing characteristics of legumes. Large increases in maize yields in maize-groundnut rotations have been reported by CIMMYT researchers in Zimbabwe from long-term trials in smallholder farming systems (Waddington et al. 2007). Cereal-legume rotations also have benefits of reducing build-up of pests and diseases. Minimum soil disturbance reduces the rate and amount of soil erosion. Soil cover leads to reduced runoff, reduced soil erosion, increased water infiltration, and reduced evaporation of soil moisture (Michler et al. 2019; Steward et al. 2018; Thierfelder et al. 2017). Drought-tolerant maize (DTM) varieties have been promoted by organizations such as CIMMYT, and these are input-responsive, stress-tolerant, and high-yielding in comparison to traditionally grown commercial hybrids (Mujeyi and Mujeyi 2018).

Methodology

Study Area and Data Collection

This study uses data collected from a cross-sectional household survey using a structured interview in communities that were exposed to CSA technologies and data from key informant interviews with stakeholders who were involved in technology dissemination. Multistage sampling method was used to select the 386 respondents from maize-growing communities in 8 wards located in 4 districts, i.e., Goromonzi, Murehwa, Uzumba Maramba Pfungwe, and Mutoko. The economies of the four districts are integrated crop-livestock farming systems that rely on rain-fed production. Maize is the main cereal staple crop, while groundnut is the leading legume crop. The main livestock kept by the farmers are cattle and goats.

Livestock rely mainly on pastures for feed. Integration of the crop and livestock enterprises helps farmers to maximize resource uses. Stover from the field crops are used to feed livestock, while dung from the livestock is used to improve soil fertility through its use as manure.

Murehwa district falls under agro-ecological region IIB which is characterized by moderately high rainfall (700 mm annually) and moderate temperatures for crop production. This district has predominantly sandy loamy soils. The majority of Motoko's communal area is in natural region IV which is characterized by subtropical climate with cool dry winter and hot rainy summers (650 to 700 mm rainfall annually). The soils are shallow to moderately deep, yellowish red, coarse-grained loamy sands. Goromonzi is located in natural region II which also gets moderately high rainfall. Uzumba Maramba Pfungwe (UMP) has two natural regions (natural regions II to V), but wards were selected from natural region V.

Two wards that have been exposed to CSA technologies were chosen from each district. Households were randomly selected from one randomly selected village in each ward. Sample households were distributed within the wards according to the ward sizes (proportionate sampling). The farm households were interviewed by trained enumerators during the 2017/2018 crop season.

Data Analysis

The study employed descriptive statistics and inferential statistics. It explored the economic assessment of CSA technologies through a cost-benefit analysis (CBA) and a stochastic profit frontier model. This study precisely probed farmers to state which CSA technologies they had used for various crops in one season and the inputs that were used and grain harvested after such an investment. Information from this economic analysis is important for price setting of commodities by government watchdogs, researchers working to improve the technologies, farmers using them, and donors and governments who fund research and development work.

Economic Analysis of CSA

Farmers use different technologies as adaptation strategies, and their decisions on which technology to adopt under what area depend on the cost-effectiveness (Shongwe et al. 2014). Cost-benefit analysis thus plays an important role of farmers' decisions with regard to input costs, e.g., fertilizer, labor, seed, pesticide, etc., and was used in the economic analysis. Other researchers have used CBA in analyzing CSA technologies (Papendiek et al. 2016; Sain et al. 2017). Cost-benefit analysis (CBA) compares inputs and outputs for a technology in monetary terms (Shongwe et al. 2014). CBA for this study focuses on the quantitative evaluation of CSA technologies on the maize crop. All benefits and costs are estimated in monetary terms, and through calculating net benefits, the most economic efficient CSA are identified. Benefits from maize include grain and stover used to feed livestock. The net benefits are calculated as follows:

$$NB = \Sigma\,(Bt - Ct) \tag{1}$$

$$NB = \Sigma Bt - \Sigma Ct \tag{2}$$

where:

NB represents the net benefits.

ΣBt = total benefits in year t.

ΣCt = total variable costs (TVC) in year t.

Bt is the combination of revenue from quantity of grain output and stover benefits.

$$\begin{aligned} \Sigma Bt &= \text{Total Revenue} \\ &= \Sigma\,(\text{Grain Output (Kg)} * \text{Unit grain prices (\$/Kg)} \\ &\quad + (\text{Stover Output (Kg)} * \text{Unit stover prices}) \end{aligned} \tag{3}$$

Average local market prices obtained by the farmers were used to compute returns. The farm gate price of the output is the value (price) farmers receive or can receive for their harvested crops. Total variable input costs refer to the sum of all variable input costs and vary from one CSA technology to another.

$$\begin{aligned} TVC &= \Sigma Ct \\ &= P_{landprep}Q_{landprepr} + P_{basalfertiliser}Q_{basalfertiliser} \\ &\quad + P_{topdressingfertiliser}Q_{topdressingfertiliser} + P_{seed}Q_{seed} + P_{labor}Q_{labor} + \ldots \\ &\quad + P_nQ_n \end{aligned} \tag{4}$$

The benefit-to-cost ratio (BCR) which is a financial ratio that is used to determine whether the amount of money made through a project will be greater than the costs incurred in executing was also computed as follows:

$$BCR = (\text{Benefit}/\text{Costs}) \tag{5}$$

For each CSA technology, the total costs incurred when using that strategy and benefits were used to compute the net benefit for that particular adaptation strategy.

Return on Investment

Return on investment values help link the value of technologies to users. The return on investment (ROI) value is more powerful than the benefit-cost ratio because the ROI value shows the net return for a \$100 investment.

$$ROI = (\text{Net Benefit}/TVC) * 100 \tag{6}$$

The Stochastic Profit Frontier Model

The stochastic frontier models have been used extensively even in agriculture, to model input-output relationships and to measure the technical efficiency (Greene 2010). These were first proposed in the context of production function estimation to account for the effect of technical inefficiency (Wang 2008; Dziwornu and Sarpong 2014). The analytical method has been used to compare the performance of farmers under different technological regimes. For example, the method has been used to examine the impact of technology adoption on output and technical efficiency of rice farmers or even beef farmers under various production systems (Omhile et al. 2016; Villano and Fleming 2006). In this study, the stochastic profit frontier model is used to compare inefficiency of farmers using CSA versus those who are not using any CSA technology. The model captures inefficiencies associated with different endowments as well as input and output prices. The model is specified as follows:

$$y = \beta' x + \varepsilon_i \tag{7}$$

where y is the observed outcome in this case maize profitability estimated by the gross margin (goal attainment), x is the logarithm of costs of that input, coefficient β are parameters estimated, and ε_i is the error term. The error structure is specified as follows:

$$\varepsilon_i == v_j - u_j \tag{8}$$

where v_j is the random error term and u_j is the inefficiency effects of farm j.

Uj is independently distributed with mean μ_1 and variance $\sigma^2{}_u$.

Thus, the stochastic model is:

$$y = \beta' x + v_j - u_j, \tag{9}$$

$\beta' x$ + v is the optimal, frontier goal (e.g., maximal production output or minimum cost) pursued by the individual, $\beta' x$ is the deterministic part of the frontier, and v ~ N [0,σv^2] is the stochastic part. v_j is the stochastic error term, and u_j is a one-sided error representing the technical inefficiency of firm j. Both v_j and u_j are assumed to be independently and identically distributed.

Inefficiency model is modelled using farm-specific, market-specific, and household characteristics and can therefore be estimated as follows:

$$U_j = \alpha + \alpha_i Z_i + \varepsilon i \tag{10}$$

$$U_j = \alpha + \alpha_1 Z_{1+} \alpha_2 Z \alpha_{2+} \alpha_3 Z_3 + \ldots \alpha_n Z_n + \varepsilon_i \tag{11}$$

where U_j is technical inefficiency of the jth farm.

Z_1 to Z_n are the determinants and ε_i is the disturbance term and the coefficients $\propto$ are parameters estimated. Stochastic frontier models allow to analyze technical inefficiency in the framework of production functions. Production units such as households are assumed to produce according to a common technology and reach the frontier when they produce the maximum possible output for a given set of inputs. Inefficiencies can be due to structural problems or market imperfections and other factors which cause countries to produce below their maximum attainable output. The stochastic frontier model decomposes growth of the output variable into changes in input use, changes in technology, and changes in efficiency. All parameters in the stochastic frontier and the technical inefficiency effects model are simultaneously calculated by a single-stage maximum likelihood estimation procedure using sfcross command in Stata (Karakaplan 2017). Table 1 gives a summary of all the variables thus used in the stochastic frontier model.

Results and Discussion

Profitability across CSA technology bundles was estimated using cost-benefit analysis, and the stochastic profit frontier model was estimated to see if CSA adoption has a significant effect on technical inefficiency. Tables 2, 3, and 4 show the results of the analysis with subsequent discussions.

CSA Adaptation Strategies Employed by Households in Maize Production

Maize production is negatively affected by climate change, and as such, adoption of CSA technologies is key to increasing yields. Table 2 shows the CSA technologies currently being used by the farmers.

The results show that farmers use various CSA technologies in maize production, with crop rotation being the highest in Mutoko followed by Murehwa (66% and 54.6%, respectively). Minimum tillage and DT maize are highest in Mutoko (48% and 36%, respectively). Few farmers (less than 10%) are not using any CSA technologies in maize production. This highlights the importance of CSA in the smallholder farming communities. Adoption of CSA such as intercropping, rotation, minimum tillage, DT maize, manure use, and mulching was significantly different across the study districts. Overall, CSA technology use is still low with less than 50% of households adopting CSA across all the districts except for rotation which is adopted by more than 50% of households in Murehwa and Mutoko districts. Farmers highlighted during FGDs that manure use had become low as there was an outbreak of theileriosis which led to most households being left with no cattle, which are the major source of manure. Manure from small ruminants and poultry is prioritized for use in horticulture gardens. Farmers also cited that technologies such as minimum tillage promoted by NGOs particularly basin making with hoes were strenuous in as much as they could be done bit by bit in the dry season for farmers with fencing. This was not so for the majority with unfenced fields who therefore needed to do it at the onset of the season. This has led to farmers shunning basins in favor of even hiring in

animal-based tillage services. Minimum tillage could be achieved using animal-drawn rippers and direct seeders, but farmers highlighted that there has been an outbreak of January diseases which saw farmers losing cattle and draft power was the hardest hit. Mulching and intercropping under maize also recorded the least frequencies. Farmers highlighted that mulching was difficult to come by given that stover was used to feed livestock. The study further identified CSA technology combinations in maize production using principal component analysis-clustering. Four distinctive clusters were identified, i.e., Technology Cluster 1 (dominantly minimum tillage with lower use of rotation, DT maize, manure, and intercrop), Technology Cluster 2 (dominantly rotation use with lower use of intercrop and very low DT, manure, and minimum tillage), Technology Cluster 3 (higher use of mulch, manure, and DT maize, average use of minimum tillage and rotation, and less intercrop), and Technology Cluster 4 (conventional).

Economic Analysis of Maize

Economic analysis was performed to estimate the net return and benefit-cost ratio in various CSA technology bundles. A comparison of costs and returns from various CSA technology combinations in maize production is presented in Table 3.

The results show that the farmers who used CSA had higher gross margin ranging from $259 (return on investment of 69%) with a BCR of 1.69 under higher CSA use to \$161.30 (return on investment of 42%) and a BCR of 1.42 under low CSA use compared to a negative gross margin under sole conventional practices (−\$63.59) with a BCR of 0.9 but negative ROI of close to 10%. This indicates that farmers get at least more than \$40 for every \$1 spent in maize production using CSA technologies. The difference in profitability is mainly maybe a result of yield differences of conventional system versus CSA. These findings are consistent with the findings of Sain et al. (2017) who found that the incorporation of the CSA practices increased maize yields by 20% or more in comparison to existing farm management systems and Ali and Erenstein (2017) who found that yields differed according to production system and technology used.

Estimated Stochastic Frontier Profit Function

The analysis was done using the sfcross Stata commands for the estimation of parametric stochastic frontier (SF) models using cross-sectional data (Bell and Bellotti 2014; Newton et al. 2014). Table 3 shows the maximum likelihood estimates for parameters of the stochastic frontier model. Almost all inputs have positive correlation with maize profitability except for fertilizer, herbicide, and labor costs that have negative effects on maize output variable.

Table 4 shows the determinants of technical inefficiency in maize production. Inefficiency is the dependent variable in the technical inefficiency model, and as such, variables with a negative (positive) coefficient sign will have a positive (negative) impact on technical efficiency. The analysis found that frequency of extension contact had a negative and significant effect on inefficiency. This implies that farmers with high frequency of extension contact are more technically efficient. Extension officers impart skills to farmers through one-on-one visits, training workshops, advisory services, and promotional events like exchange visits and field days. Farmers can thus learn about new technologies when they are in constant contact with extension, and thus they end up becoming more efficient farmers. This finding is in line with those of Dziwornu and Sarpong (2014), Welch et al. (2016), and Abdulai et al. (2018).

They are also in line with findings from Mango et al. (2015) who found a negative and statistically significant relationship between technical efficiency and extension contact in smallholder farming systems of Zimbabwe following the fast track land reform program. Another researcher, Konja et al. (2019), also found positive impact of extension contact on technical efficiency in certified groundnut seed production in Northern Ghana.

Correspondingly, the coefficient for number of locally available traders was negative and significant. This means that farmers who have access to farm gate traders are technically efficient. Maize farmers in most rural areas are constrained when it comes to capital and hence have difficulties to access distant markets. Therefore, if traders come to buy locally, this acts as an incentive for them to produce that crop knowing there is going to be a guaranteed market with potential to lower transaction costs. Furthermore, the coefficient of CSA adoption was negative and significant. This means that farmers using CSA technologies are more efficient.

The stochastic frontier results showed that fertilizer and other costs have negative and significant effect on the inefficiency of maize profitability. The negative signs of the variables indicate that as these variables increase, the profit inefficiency of maize producers decreases. This means a unit increase in costs of the basal dressing fertilizer (DFERT) and top dressing (ANFERT) will lead to 166.68% and 40.02% increases in profitability, respectively. Basal and top dressing fertilizer applications are very critical for maize profitability, and the increase in use as proxied by costs will result in increased profitability. Total livestock units (TLU) and farming experience had significant positive coefficients implying that as the farmer's TLU/head size and farming experience increase, the profit inefficiency of the farmers also increases. This contradicts prior expectation and might be explained by the fact that experienced farmers are older and unwilling to invest in any new technologies that come around.

Conclusions and Recommendations

The most economic adaptation strategy in the face of climate change would be adoption of CSA technologies as evidenced by positive gross margins and higher returns on investment when compared to the conventional way of farming. This is further supported by the positive effect of CSA adoption on technical efficiency. Farmers should however note that not all adaptation strategies are economical; thus, record-keeping of costs and income for regular computation of costs and benefits is crucial. Farmers can then choose technologies that give higher benefits or those that use less inputs given that most of the farmers are financially constrained. Based on variables that significantly influenced profit efficiency, the study makes three recommendations.

Government should continue putting resources towards supporting mobility of extension staff for continued extension to farmer contact and giving them adequate resource (information materials) so that they continue delivering key information on yield enhancing CSA technologies.

Policies to promote inorganic fertilizer use in order to boost soil fertility remain critical. Government should therefore strengthen the capacity of rural agro dealers to sell fertilizers locally at reasonable prices.

Policies to promote farm gate buying or market centers within wards should also be put in place as they have the potential to increase efficiency if farmers are aware of such a guaranteed market with very low transaction costs.

Declaration This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Data Availability The household dataset can be obtained through permission from UKZN.

Declaration of Competing Interest The authors certify that they have no affiliations with or involvement in any organization or entity with any financial interest (such as honoraria; educational grants; participation in speakers' bureaus; membership, employment, consultancies, stock ownership, or other equity interest; and expert testimony or patent-licensing arrangements) or non-financial interest (such as personal or professional relationships, affiliations, knowledge, or beliefs) in the subject matter or materials discussed in this manuscript.

Acknowledgment The authors wish to appreciate the Ministry of Agriculture officials and Rural District Administrators for granting the permission to do data collection in the sampled districts.

Role of Cassava and Sweetpotato in Mitigating Drought in Semi-Arid Makueni County in Kenya

14

C. M. Githunguri and E. N. Njiru

Contents

Abstract

Cassava and sweetpotato are major factors in food security across sub-Saharan Africa. Though cassava and sweetpotato varieties that are early maturing and resistant to diseases have been developed, many farmers still grow local varieties. Cassava and sweetpotato cultivars that mature between 6 and 12 and 3 and 4 months after planting, respectively, are available. The objective of the synthesis was to obtain a general overview of cassava and sweetpotato production in Matiliku subcounty of Makueni County in semi-arid eastern Kenya before the establishment of a seed system for them. Participatory rural appraisal and focused group discussions with key stakeholders in Makueni County on the current status

of these crops provided very useful information. It was observed that there are a few early cassava and sweetpotato adopters, meaning a lot of effort in communicating the need to commercialize them needs to be made. Even though the farmers had sufficient experience in growing them at subsistence level, they were searching for cultivars that combine both nutritional and food security. There is a need to engage more extension service providers in order to campaign on their adoption. There is a need to carryout training and awareness creation on their role in food security and wealth creation.

Cassava · Food security · Kenya · Makueni · Sweetpotato

Introduction

Cassava and sweetpotato produce starchy tuberous roots. Cassava and sweetpotato may be sweet or bitter depending on the variety. The crops are resistant to drought and are mainly propagated through stem cuttings or vines. Cassava and sweetpotato can adapt to diverse climatic conditions, survive long dry spells, and can be harvested and stored on a flexible time schedule, all of which qualifies cassava and sweetpotato as food security crops and technologies that respond well to climate change. Cassava and sweetpotato tuberous roots are rich in carbohydrates and are a staple food for many Africans. They are also used to manufacture alcohol. The leaves are richer in protein and minerals than the tuberous roots both qualitatively and quantitatively and are used both as vegetable and fodder. Cassava and sweetpotato have high potential if people are sensitized to their usefulness and nutritive value. Currently, women and children usually grow cassava and sweetpotato as food security crops. However, the scenario changes when the two crops are grown for commercial purposes with men playing a prominent role (Nweke et al. 2002).

Thirty-centimeter (30) stem cassava cuttings are planted upright, slanting, or buried horizontally. Sweetpotato is propagated also from 30 cm vines, about 2/3 s of which are inserted in the ground. Both crops have a great yield potential of 20–50 t/ha of root dry weight in the tropics. This yield potential has yet to be exploited as farmers are producing an average of less than 10 t/ha. Cassava and sweetpotato provide 8% or more of the minimum calories requirements of some 750 million people in the tropics, making it one of the most important energy sources in the human diet. Cassava and sweetpotato have great potential as industrial starch production crops and hence provide employment at the production, marketing, and sales levels. Given that the demand for food and feed remains unsatisfied and the time pressure to meet the challenge is increasing rapidly, cassava and sweetpotato can help alleviate this problem.

Cassava and sweetpotato produce about 10 times more carbohydrates than most cereals per unit area and are ideal for production in marginal and drought prone areas, which comprise about 75% of Kenya (Githunguri et al. 1998; Githunguri

2002; Nweke et al. 2002). Despite their great potential as a food security and income generation crops among rural poor in marginal lands, their utilization remain low. The potential to increase cassava and sweetpotato utilization is enormous with increased recipe range (Githunguri 1995). The International Institute of Tropical Agriculture (IITA) has officially recognized cassava as a new cash commodity and a vital food in Africa. The Common Fund for Commodities has recognized cassava as an internationally tradable commodity. The Intergovernmental Group on Grains has adopted cassava as a commodity. Cassava and sweetpotato can accelerate development and improve livelihoods of Kenyan rural communities as has been demonstrated in Vietnam and Thailand. Adoption of improved cassava production, processing, and marketing technologies earns these countries about one million US$ per annum. This model is being pursued by initiatives in Africa such as the NEPAD Pan African Cassava Initiative, Sub-Saharan Africa Challenge Program, and the South African Root Crops Research Network and East African Root Crops Research Network.

Cassava and sweetpotato are major factors in food security across sub-Saharan Africa. In Kenya, cassava is grown in over 90,000 ha with an annual production of about 540,000 tons. Cassava (*Mahihot esculenta* Crantz.) is a relatively neglected tropical root crop in East and southern Africa (Githunguri 1995; Githunguri et al. 2017a, b, c). It is grown widely in East Africa in areas below 1500 m above sea level (Acland 1985). Cassava production in Kenya is concentrated in three main regions: Coastal, Central, and Western region. Western and Coastal regions are the main cassava producing areas, producing over 80% of the recorded cassava output in the country (Githunguri et al. 2017a). Though cassava is considered to be a food security crop in the sub-Saharan Africa, its production in Kenya is low compared to other crops like maize, beans, and sorghum. Its consumption is low especially in the central region of Kenya where it is considered a poor man's crop and is usually consumed during periods of food scarcity. Despite its high production in the coastal and western regions of Kenya, utilization is limited to human consumption. In order to promote production, which has been decreasing in recent years, there is a need to explore and identify other uses of cassava.

According to FAO (1990), Africa produces about 42% of the total tropical world production of cassava and contributes significantly to food security across sub-Saharan Africa. Githunguri et al. (1998) and Nweke et al. (2002) noted that cassava could grow well in marginal lands, requires low inputs, and is tolerant to pests and drought. Cassava is grown in over 90,000 ha with an annual production of about 540,000 t in Kenya and could remain in the ground for 7–24 months after planting and then harvested thereafter (Githunguri et al. 2017a). Utilization of cassava remains low in Kenya because the fresh root tubers are limited to roasting and boiling for consumption only despite its great potential as a food security and income generating crop (Githunguri 1995; Githunguri et al. 2017a). However, it should be noted that cassava is widely used in Kenya by almost all communities despite the fact that there is still a lot of room for expansion on its use especially by industrialists who have yet to fully utilize cassava in food and stock feed manufacture. The Home Economics Department of the Ministry of Agriculture and other organizations have a wide range of options in developing cassava recipes acceptable to a larger community (Githunguri 1995; Githunguri et al. 2017a). In Kenya, cassava is the second most important food root crop after *Solanum* potato. However, due to its small production base, it is ranked 36th out of 50 in KALROs 1991 priority setting exercise (KALRO 1995; Githunguri 1995; Githunguri et al. 2017a). There is a slow but steady increase in cassava production because its consumption has a direct effect on demand.

Variability studies by Rai et al. (1986) on cassava showed that phenotypic variance was higher than genotypic variance for all characteristics, which included plant height, tuberous root girth, length, and weight. Later rain-fed trials involving several cassava cultivars showed significant genotype by environment (g $\times$ e) interaction for yield (Naskar et al. 1989). Selection for a slightly higher than optimal leaf area index, and hence greater biomass, can lead to stable cassava yields across both favorable and stress environments. Further, according to Nartey (1981) and Githunguri et al. (2014), the harvested cassava yields depend on the distribution of dry matter between the useful and other parts of the plant, which may be affected by the sink capacity of the useful parts to accept photosynthates, as well as the capacity of the leaves to supply it. In sub-Saharan Africa, most boil and eat fresh cassava consumers prefer roots with high dry matter contents, which are boiled and consumed as vegetable (Nartey 1981; Githunguri et al. 2014). It is important to note that Dixon et al. (1994) had reported negative correlation between root dry matter content and root cyanogenic potential which is important when selecting cassava varieties targeting fresh tuberous root consumers. According to IITA (1990b) and Githunguri et al. (2016), useful yields of the cassava crop depend on its total biomass and its distribution among useful parts. As such, since the total light intercepted strongly depends on leaf area, the best yielding cassava is one that establishes adequate and efficient photosynthetic surface sufficiently early in the cropping season, maintains it at least over the duration of the moisture cycle, and partitions dry matter into yield (Cock 1985); IITA 1990a). Other studies (IITA 1990b) have shown that best root yields are obtained at a leaf area index of 3.5, with general reduction in yield as the leaf area indices increase.

African farmers usually grow cassava under field conditions where one or more of the resources are limiting. However, it should be noted that most of the research works carried out are under optimum management conditions (Githunguri et al. 2006). Importance of cassava as an industrial crop is increasing rapidly in several countries within the tropics and especially sub-Saharan Africa (Ayinde et al. 2004; Azogu et al. 2004; EFDI-Technoserve 2005; Ezedinma et al. 2005; Githunguri 1995; Onyango et al. 2006). According to several studies (Githunguri 2002; Odongo 2008; Tivana and Bvochora 2005), safety of cassava products is important and could be affected by agro-ecological zones and genotypes. According to Ekanayake et al. (1997a) and Ekanayake et al. (1997b), a cassava plant possesses several physiological parameters and processes that confer to it the ability to produce modest yield under a range of both abiotic and biotic stresses. Some of these parameters include heliotropism, leaf drooping, long fibrous roots, loss of leaves, high water use efficiency, and large source potential, and sink capacity (Ekanayake 1998; Githunguri 2002). Other studies have shown that the cassava value chain has three main components: field production, processing, and marketing (Githunguri et al. 2017a, b, c). Though cassava varieties that are early maturing and resistant to diseases have been developed, many farmers in the cassava growing regions (coastal, central, and western) still grow local varieties (Githunguri et al. 1998, 2006, 2007a; Githunguri 2002). In addition, early maturing, high yielding, disease, and pest tolerant cassava cultivars developed through participatory breeding by the Kenya Agricultural and Livestock Research Organization (KALRO) are available to farmers (Githunguri et al. 2006, 2007a).

Sweetpotato is an important staple food in the East African region after banana and maize. It has high potential for livestock feed and industrial use as well (Onwueme 1978). Generally, small-scale farmers using traditional farming systems on marginal soils produce most of the sweetpotatoes and cassava. According to Onwueme (1978), yields of sweetpotato and cassava vary with cultivar, disease resistance, and location and production practices. Constraints to sweetpotato production in Kenya include the sweetpotato weevil, lack of adequate disease and pest-free planting materials, poor cultural practices, lack of appropriate storage and processing technologies, and poor market infrastructure (Lusweti et al. 1997; Githunguri et al. 2003). Although some trade occurs, there is minimal official record of international trade in sweetpotato. Kenya mainly meets her consumption needs almost exclusively through internal production. Thus, sweetpotatoes like cassava are consumed locally and hence traded in a closed economy. This suggests that prices are mainly dependent on local forces of supply and demand. Due to lack of external market, the aggregate demand for sweetpotato within Kenya is assumed to equal supply (Odendo et al. 2001). One of the major constraints towards cassava and sweetpotato production and commercialization is their low and slow multiplication ratio due to their being vegetatively propagated. This constraint is further compounded when their production is carried out in the arid and semi-arid areas where their multiplication can only be effectively and commercially multiplied under irrigation and high inputs. Most local cassava and sweetpotato cultivars are low yielding and are late maturing. Though cassava and sweetpotato varieties that are early maturing and resistant to diseases have been developed, many farmers still grow local varieties. KALRO has sweetpotato cultivars that mature between 3 and 4 months and cassava cultivars that produce appreciable yields between 6 and 12 months after planting. As such, the specific objective of this synopsis was to obtain a general overview of cassava and sweetpotato production in Matiliku Division Makueni District in semi-arid eastern Kenya before the establishment of a seed system for the two crops.

Farmer Interviews

Participatory rural appraisal (PRA) and Focused Group Discussions with farmers, local leaders, extension staff, and other stakeholders were conducted at Matiliku Division in Makueni District. The PRA involving 51 farmers was conducted at a farm with an elevation of 1043 m above sea level located on Latitude S: 011.867812 and Longitude E: 042.78234. Using a semi-structured questionnaire, farmers were interviewed individually whereby an overview on cassava and sweetpotato production in Matiliku was obtained. The data was subjected to descriptive analysis methods while charts were generated using Microsoft Excel application. The results were used to inform decisions on their training and cassava and sweetpotato production requirements.

Survey Observations and Synthesis in a Semi-Arid Area in Kenya

Figure 1 shows about 35.3% of the farmers put 0.25 acres under cassava cultivation while 13.7% have a few stands and 33.3% do not grow cassava at all. About 11.8% of the respondents put in cassava on land ranging from 0.5 to 1.5 acres and this category could be the early adopters.

The number of years under cassava production ranged between 1 and 40 years with only a few (7.7%) farmers indicating to have been growing cassava for a period above 40 years (Fig. 2). The majority of farmers, about 41.1%, have grown cassava

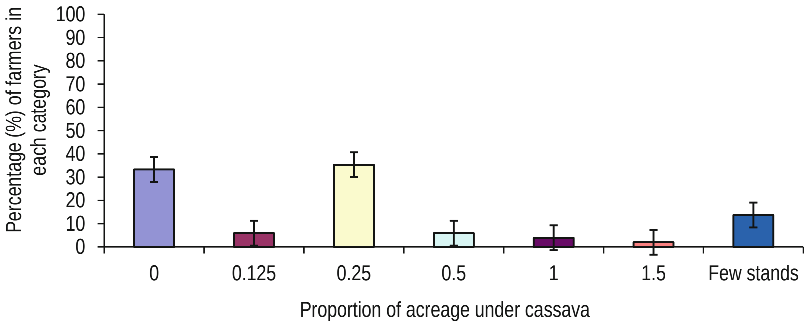

Fig. 1 Proportion of acreage under cassava production in Matiliku Division, Nzaui District, Makueni County. Vertical bars represent the standard error between means ($P = 0.05$)

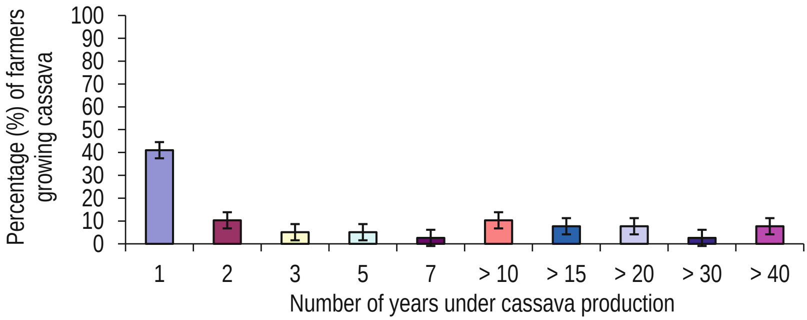

Fig. 2 Number of years under cassava production and proportion of farmers growing cassava in Matiliku Division, Makueni (Nzaui) District. Vertical bars represent the standard error between means ($P = 0.05$)

for only 1 year while the rest had cassava-growing experience ranging between 2 and 30 years in proportions ranging between 5.1 and 10.3%. These results suggest that cassava is grown as a subsistence crop and a lot needs to be done if it is going to be commercialized in Matiliku.

According to Table 1 the majority of farmers, about 40.5%, were growing a local cassava cultivar whose name seemed to be unknown while 31.0% were growing a cultivar whose origin was uncertain. Among the known local cultivars, Kitwa was being grown by 7.1% of the respondents. A similar percentage (7.1%) of respondents were growing the improved “Mucericeri” cultivar obtained from KALRO and FIPs Africa. Other minor cultivars included 990,005, “Kiisungu,” and “Nyawo.” These results suggest that even though KALRO and some significant service providers have started distributing improved cultivars, a lot still needs to be done if cassava is going to play its rightful role in supplying the much needed calories.

Table 2 shows that the most significant methods of utilization include boiling and eating cassava for breakfast and chewing raw as a snack. About 10.1% of respondents mix cassava with maize and beans (“githeri”) while 17.7% grow cassava for

Mix with meat to make a stew	1.3
Peel, chip and mix with sorghum or maize	1.3
Process cakes	1.3
Sell in the market	17.7

sale in the local market. Only 5.1% of the respondents indicated they have not utilized cassava in any way. The results indicate that there is very little processing of cassava taking place in Matiliku suggesting that there is need to carryout training and awareness creation on the role of cassava in food security and wealth creation.

Results in Table 3 show that KALRO (35.9%) has been largely responsible in the introduction of cassava as a viable technology in this area. 25.6% of the respondents were not certain about the origin of their cultivars, whereas 20.5% obtained them from the local market. It seems 20.5% of the respondents purchased cassava cuttings from the market, which is a positive sign on the viability of cassava being taken up as a commercial venture. There is need to increase the number of extension service providers in the area.

Figure 3 shows that the majority of respondents comprising 52.5%, 30%, and 10% grow sweetpotatoes on 0.25, 0.125 acres of land and only a few stands, respectively. The rest 7.5% grow sweetpotatoes on pieces of land ranging from 0.5 to 2 acres who seem to comprise the group of early adopters. These results suggest that sweetpotato is also grown as a subsistence crop. Serious efforts need to be put in place in order to move sweetpotato from subsistence level to commercialization in Matiliku.

Table 3 Origin of cassava cultivars cited and proportion of farmers growing them in Matiliku Division, Makueni (Nzaui) District

Origin of cassava cultivars cited	Percentage (%) of farmers growing them
Farmers	7.7
FIPs Africa	7.7
Inherited from parents	2.6
KALRO	35.9
Local market	20.5
Unknown	25.6

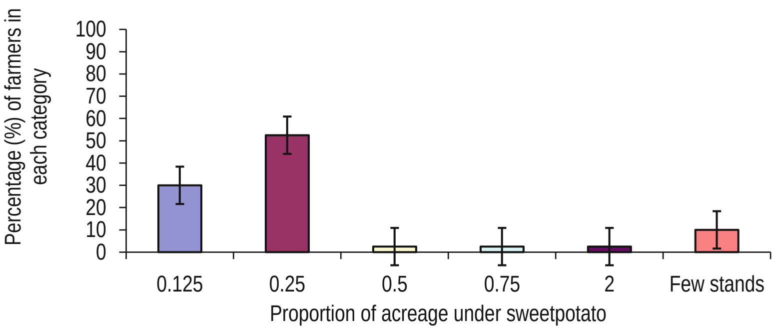

Fig. 3 Proportion of acreage under sweetpotato production in Matiliku Division, Makueni (Nzaui) District

Figure 4 shows that majority of the respondents, about 60%, have mainly grown sweetpotatoes for the last 3 years. The rest 40% have mainly grown sweetpotato for a period ranging from 4 to 30 years. This suggests that the concerted efforts that have been put in place by KALRO and its partners in extension service providers during the last 4 years have paid divided and all that is needed is to sustain the efforts.

The results in Table 4 show that 21.2% of the respondents were growing a local cultivar of an unknown origin while 16.7% of the farmers were growing an unknown improved cultivar presumably obtained from KALRO or other extension service providers. Sallyboro, an improved orange-fleshed sweetpotato cultivar, and "Mwezi moja," a drought tolerant local cultivar, were the only cultivars being grown by an appreciable number of respondents, 15.2% and 10.6%, respectively. The rest of the

SPK004	3.0
Unknown	4.5
Unknown improved	16.7

13 cultivars were thinly spread among the respondents with proportions ranging between 1.5% and 7.6%. The multiplicity of cultivars suggests that the farmers have accepted sweetpotato as an important part of their food security technologies and it seems they have been searching for a suitable cultivar. It seems a combination of Sallyboro and “Mwezi moja” have the qualities the farmers have been looking for: namely, food and nutrition security. There is a lot of potential to commercialize sweetpotato production in Matiliku if a sustainable seed system is established.

According to Table 5, the most popular method of utilization of sweetpotato is boiling and taken for breakfast. The sweetpotato is also a tradable commodity with 26.5% of respondents selling them in the local market. About 6% of the late adopters had not utilized sweetpotato at all. A few farmers were feeding sweetpotato vines to livestock while there was very little processing. In the area of utilization, there is a lot of room for training and improvement. However, farmers here like in the major sweetpotato producing areas in Western and Central Kenya could target the huge fresh market in Nairobi and other major urban centers.

Table 6 shows the origin of sweetpotatoes is mainly from KALRO (35.8%), neighboring farmers (34.0), and FIPs Africa (20.8). It seems KALRO and FIPs Africa have made major inroads in addition to the farmers being receptive and a willing congregation.

Table 5 Method of utilization of sweetpotato and proportion of farmers involved in Matiliku Division, Makueni (Nzaui) District

Method of utilization	Percentage (%) of farmers utilizing them
Boil for breakfast	42.2
Boil for lunch	1.2
Chew raw	8.4
Feed vines to livestock	3.6
Have not utilized	6.0
Process into cakes	3.6
Roast	7.2
Sell in the market	26.5
Sell vines	1.2

Table 6 Origin of sweetpotato cultivars cited and proportion of farmers growing them in Matiliku Division, Makueni (Nzaui) District

Origin of sweetpotato cultivars cited	Number of times cited by (respondents) farmers	Percentage (%) of farmers growing them
Farmers	18	34.0
FIPs Africa.	11	20.8
KALRO	19	35.8
Local market	1	1.9
Unknown	4	7.5

Table 7 Education level, occupation, and main mode of communication by farmers involved in cassava and sweetpotato production in Matiliku Division, Makueni (Nzaui) District

Education level	Occupation	Telephone	Percentage (%) of farmers within the main categories
Postsecondary	Farmer	Cellphone	8
Postsecondary	Farmer/service provider	Cellphone	2
Primary	Farmer	Cellphone	34
Primary	Farmer	Cellphone/ email	2
Primary	Farmer	None	6
Primary	Farmer/ shopkeeper	Cellphone	2
Secondary	Farmer	Cellphone	36
Secondary	Farmer	Cellphone/ email	2
Secondary	Farmer	None	2
Secondary	Farmer/ shopkeeper	Cellphone	6

Results in Table 7 show that the majority, over 70%, of cassava and sweetpotato farmers had attained at least the Primary Level of education with more than half of them having a secondary level of education. At least 2% of the farmers had an email address. The results suggest that the majority of the farmers were educated and had already started embracing modern technology meaning it will be easy to convince them to adopt the new cultivars.

Cassava: Postanalysis

Cassava production and its optimized food, nutritional, and industrial positioning as a climate smart crop faces challenges including diseases, late maturing varieties, pests and lack of climate smart adaptable varieties, low yields, weak seed systems, insufficient value addition, limited market linkages, and insufficient mapping of gendered roles in production and marketing. Limited availability of clean planting materials has resulted in few agro producers growing improved varieties, hence reduced root yield and quality. The majority of cassava famers (93%) in Kenya use planting materials from their own or neighbor's fields (Githunguri et al. 2014), hence a continued build-up of diseases and pests (Githunguri and Njaimwe 2013a, b, c, d; Githunguri 1983a, b). Unfortunately, the perception of cassava as a poor peoples' food has impacted negatively on national efforts to promote cassava as a viable, commercially marketable product which has confined it to subsistence production, rudimentary processing, and limited consumption (Githunguri et al. 2017a). There is need to address and change this negative attitude towards cassava through advocacy and change in policy. The minimal processing techniques are usually tedious, time-consuming, low yielding resulting in products with unpredictable qualities and hence rarely stocked in markets. We believe that adjustments of locally available processing technologies accompanied by an aggressive vigorous promotion and marketing campaign will significantly raise the profile of climate smart crops like cassava and thus contribute to the improvement of food security, incomes, and community resilience.

Cassava (Manihot esculenta Crantz) is the fifth most important food crop in the world (Githunguri 2002). It produces more energy per unit area compared to most cereals (Githunguri et al. 2015; Githunguri and Amata 2015). The crop is drought tolerant and produces under marginally fertile soils where other crops fail (Githunguri et al. 2014); hence, it is the most resilient to climate change among all major African crops (Jarvis et al. 2012). Cassava is grown by smallholder agro producers in western, coastal, and eastern Kenya. Considering that about 75% of Kenya is arid or semi-arid and the majority of small-scale farmers in cassava growing areas are women, increased cassava production and consumption will contribute greatly towards poverty alleviation, food security, women empowerment, and wealth creation of the nation (Githunguri et al. 2007). In 2017 the country produced 1,112,000 tonnes from 90,394 ha, translating to 12 t/ha which is lower compared to 16 to 24 t/ha in China, Indonesia, and Thailand (FAO, IFAD, UNICEF, WFP and WHO 2017) and the crop potential of 90 t/ha (Cock et al. 1979). Lamu and Kisumu are among the major cassava producing counties in Kenya and the crop contributes 6% of the total household incomes (MOALF 2018). Production is dominated by low-yielding varieties that are susceptible to pests and diseases under poor crop and pest management practices. Major diseases are cassava mosaic (CMD) and cassava brown streak (CBSD) disease which cause yield losses of up to 100% with CBSD causing necrosis which renders roots unfit for food, feed, and industrial purposes (Monger et al. 2010). Pests such as cassava mealybugs (CMB) and cassava green mites (CGM) affect production particularly during the dry periods. Kenya Agricultural and Livestock Research Organization (KALRO) has identified improved varieties such as MM95/0183, Midgyera, and Katune (990005) and that are high yielding, early maturing, and tolerant to pests and diseases. Therefore, validating and upscaling improved varieties and good agronomic, pest and disease management technologies will contribute to increased productivity. Wide adoption of improved varieties will be enhanced if planting materials are bulked in close proximity to production areas to reduce transportation costs. Lack of an efficient seed delivery system has resulted in limited availability and accessibility of clean planting materials, resulting in 93% of the agro producers in Kenya using infected planting materials (Amata et al. 2012; Ekanayake and Githunguri 2000). This causes a buildup of pests and diseases further contributing to low productivity of clonally propagated crops (Githunguri et al. 1992). There is a need to have a system compliant with national regulations to avail high quality planting materials to agro producers, to address losses attributed to these pests and diseases. Use of tissue culture and three node technology to mass propagate disease free planting materials and bulk at three levels – primary (NARS, breeders' seed), secondary (Government, NGOs and other private Institutions), and tertiary (village seed entrepreneurs) – could be beneficial in availing clean materials to agro producers. Cassava utilization in the target counties is limited to boiling, deep frying, roasting, and blending cassava with maize, millet, or sorghum flour to make porridge or "ugali" (Githunguri 1995). In Nigeria, the crop is processed into feeds and food products like garri. Cassava can replace 10–30% of maize in food and feeds, 60–70% in confectionery products, and up to 60% of barley in beer making, hence can relieve the demand for and importation of wheat and save on foreign exchange. This potential has been recognized and the Ministry of Agriculture in Kenya is enacting a law to enforce blending of maize and wheat with cassava flour. Production of high quality flour is a requirement for blending and hence improved processing technologies that will ensure safety of products will be validated and up-scaled. In addition, new products will be introduced to entrepreneurs who will be linked to markets to create employment and increase income generation.

Sweetpotato: Postanalysis

Sweetpotatoes are important in the economy of poor households and are a major source of subsistence and cash income to farmers in agroclimatically disadvantaged regions and even in high potential areas of Kenya. Constraints to sweetpotato production in Kenya include the sweetpotato weevil, sweetpotato virus complex, lack of adequate disease and pest free planting materials, poor cultural practices, lack of appropriate storage and processing technologies, and poor market infrastructure. Effective control of major biotic and abiotic stresses on sweetpotatoes through selection and breeding of clones' resistance and/or tolerant to them plus the availability of clean planting material will boost food availability significantly in arid and semi-arid lands through the establishment of sweetpotato based industries in sweetpotato growing areas. The objectives of the Root and Tuber Crops Programme in the Kenya Agricultural and Livestock Research Organization (KALRO) are to develop sweetpotato varieties that are widely adapted to diverse agro-ecological zones. The varieties should also be high yielding, early bulking, and drought resistant/tolerant, resistant to major biotic and abiotic stresses and have good root quality and especially high in ß-carotene content (orange fleshed sweetpotatoes). The Kenya Agricultural and Livestock Research Organization has recognized the importance of involving farmers in their selection and breeding research programs.

Sweetpotato produces starchy tuberous roots. The crop is resistant to drought and is mainly propagated through vines. Sweetpotato can adapt to diverse climatic conditions, survive long dry spells and can be harvested and stored on a flexible time schedule, all of which qualifies it as a food security crop. Sweetpotato tuberous roots are rich in carbohydrates and are a staple food for many Africans. They are also used to manufacture alcohol. The leaves are richer in protein and minerals than the tuberous roots both qualitatively and quantitatively and are used both as vegetable and fodder. Sweetpotato has high potential if people are sensitized to their usefulness and nutritive value.

Sweetpotato is propagated also from 30 cm vines about 2/3 s of which are inserted in the ground. Both crops have a great yield potential of 20–50 t/ha of root dry weight in the tropics. This yield potential has yet to be exploited as farmers are producing an average of less than 10 t/ha (Nweke et al. 1994). Sweetpotato provides 8% or more of the minimum calories requirements of some 750 million people in the tropics, making it one of the most important energy sources in the human diet. Sweetpotato has great potential as an industrial starch production crop and hence provide employment at the production, marketing, and sales levels. Given that the demand for food and feed remains unsatisfied and the time pressure to meet the challenge is increasing rapidly, sweetpotato can help alleviate this problem.

Sweetpotatoes have the potential to contribute towards increased and sustainable food security, poverty alleviation, and wealth and employment creation. As such, the Kenyan government needs to have challenges and opportunities addressed along the sweetpotato value chain. Kenya's Economic Recovery Strategy of 2003 focuses on creating employment and wealth in the various subsectors including agriculture which contributes about 30% to the gross domestic product and provides about 70% of employment opportunities annually (MoA 2005). The vision of the government Strategy for Revitalizing Agriculture and Kenya Vision 2030 (National Economic and Social Council of Kenya (NESC) 2007) is to make the sector profitable, commercially oriented, and competitive (MoA 2005). Value addition and efficiency in production, processing, and marketing of high quality competitive sweetpotato products in Kenya and beyond will be used to enhance household incomes, employment, and food and nutrition security.

Despite its great potential as a food security and income generation crop among rural poor in marginal lands, its utilization remains low. However, its utilization can be increased with an enhanced number of recipes. Sweetpotato can accelerate development and improve livelihoods of Kenyan rural communities as has been demonstrated in China. Studies indicate sweetpotato seed, flour, crisps, starch, livestock feeds, and ethanol as the six best bet sweetpotato technologies. However, there is need to focus on sweetpotato seed. Several small-scale sweetpotato-based technologies have been initiated in a number of countries and similar models can work for Kenya (Onyango et al. 2006). What is lacking is an effective technology transfer mechanism that makes it possible for sweetpotato farmers and processors in Kenya to test, select, and adopt or adapt the best options. There is need to train farmers and processors on good sweetpotato field production and manufacturing practices and facilitate their access to microcredit and market avenues to catalyze sufficient investment in the sweetpotato industry.

A successful commercial sweetpotato seed industry could lead to increased sweetpotato field production which could in turn lead to processing of products and better markets for sweetpotato products leading to increased incomes to the rural community thus leading to a reduction in poverty levels among them. This could also lead to increased utilization of quality sweetpotato products and enhanced food security as proposed by the ERS and the SRA. Quality sweetpotato products have the potential of greatly contributing to improved health of the rural populations and enhance nutritional security among small scale farmers.

With successful interventions, there will be need for policy makers to create policy instruments to absorb surplus sweetpotato, which will create incentives for local producers. Making it mandatory for processors to use a certain percentage of sweetpotato, flour in making livestock feeds could achieve this. This would promote use of sweetpotato in addressing rural food security, industrialization, employment creation, rural urban migration, and rural youth occupation.

The sweetpotato value chain has three main components: field production, processing, and marketing. We will build strong ties with both public and private institutions engaged in research, extension, and social development in order to accomplish this linkage by the end of project. Though sweetpotato varieties that are early maturing and resistant to diseases have been developed, many farmers in the sweetpotato growing regions still grow local varieties. Many local sweetpotato cultivars take more than 6 months to mature, whereas the Kenya Agricultural and Livestock Research Organization has sweetpotato cultivars that mature between 3 and 4 months. Intensive multiplication and dissemination of the newly bred early maturing high yielding disease and pest tolerant cultivars will result in increased sweetpotato production and ensure a source of food and income for the rural households. Early maturing, high yielding disease, and pest tolerant sweetpotato cultivars developed through participatory breeding at various Kenya Agricultural and Livestock Research Organization Centres are available.

Conclusions

There are a few early cassava and sweetpotato adopters, meaning cassava and sweetpotato are still being grown as a subsistence crop and a lot needs to be done if they are going to be commercialized in Matiliku. The farmers had sufficient experience in growing the two crops albeit at subsistence level. The farmers seemed to be searching for cultivars that combined both nutritional and food security. There is need to engage more extension service providers than there are currently in order to hasten the adoption of new cultivars. There is very little processing of these crops taking place in Matiliku suggesting that there is need to carryout training and awareness creation on their role in food security and wealth creation. Sallyboro, an improved orange-fleshed sweetpotato cultivar, and “Mwezi moja,” a drought tolerant local cultivar have been accepted by the farmers. There is a lot of potential to commercialize cassava and sweetpotato production in Matiliku if a sustainable seed system is established. Cassava and sweetpotato are tradable commodities in Matiliku. Farmers could target the huge fresh market in Nairobi and other major urban centers. Majority of the farmers are educated and could easily adopt new technologies.

Abstract

Food security is a major public health priority in Cameroon, amidst climate change and sea level rise (CC/SLR), vis-à-vis the ever-increasing population growth with associated challenges. CC/SLR, singly or combine, is well known to have severe impacts on agricultural productivity, food security, socioeconomic activities and ecosystem (environment, plant and animal) health systems in coastal areas. They contribute to natural disasters including erosion, flooding, inundation of coastal lowlands, and saltwater intrusion, altogether reducing agricultural productivity. Additionally, these disasters provoke adverse animal, human, and environmental health implications; reduction in tourism; and potential close of some socioeconomic activities that constitute secondary (after agriculture), or main source of livelihood/income for many coastal indigents. Although there are inadequate reports on the impacts of CC/SLR, preliminary reports point to negative effects on crop production and socioeconomic activities in coastal Cameroon. This chapter highlights the susceptibility of coastal Cameroon agriculture and socioeconomic activities to CC/SLR. Furthermore, it has propose agricultural (CC/SLR and non-climatic) and educational intervention socioeconomic strategies for the mitigation and adaptation to CC/SLR and for sustainable agricultural productivity in coastal Cameroon. The proposed strategies may provide a small contribution toward a wider multi-stakeholder pool of strategies and which, when applied, may enhance food security in coastal Cameroon amidst CC/SLR and promote socioeconomic and touristic activities while reducing negative implications on animal, plant, human, and environmental health.

Keywords

Agriculture · Climate change · Sea level rise · Food security · Ecosystem health

Introduction

Food security is a major concern in feeding the world's estimated 9.8 billion people by 2050 (Worldometer 2020). The demand for food by 2050 will increase by an estimated 60%. This will be associated with broader economic and societal issues. Thus, there is increasing need for sustainable agriculture (Breene 2016; Abia et al. 2016; Center for Development Research (ZEF), Forum for Agricultural Research in Africa (FARA), Institute of Agricultural Research for Development (IRAD) 2017) toward sustainable food supply. Food security exists when all people, at all times, have physical and economic access to sufficient safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life (Food and Agriculture Organization (FAO) 2010). In addition, food security has three dimensions. These include (i) availability of food (which consist of three elements related to production, allocation, and exchange); (ii) access to food (that is connected with affordability, e.g., income and wealth, provision, and preferences); and (iii) utilization of food (focusing on the essential elements that are associated with dietetic and social values as well as food safety issues). Additionally, it is vital to ensure that the available and accessible food is safe. Furthermore, food waste should be minimized as much as possible (zero food waste concept. According to the Codex Alimentarius Commission (CAC 2003), food safety is the assurance that food will not cause harm to the consumer when it is prepared and/or eaten according to its intended use.

Food security is generally affected by several factors. Climate change remains one of the most devastating factors. Notwithstanding, both climatic and non-climatic factors, singly and collectively, hinder agricultural productivity. These factors include increase in temperature, fluctuation in rainfall (periods and amounts) and population growth, and sea level rise. Their effects on coastal agricultural productivity and sustainability may be a concern (Schiermeier 2018). They may provoke inundation, soil erosion, and saltwater intrusion (Gopalakrishnan et al. 2019).

In Cameroon, agriculture and food associated sectors provides employment to an estimated 75% of the adult-working population (mainly small-scale peasant farmers (NIS 2010), contributing 30% to the gross domestic product (GDP) and account for approximately half of total earnings from exports (DSCN 2002). The sustainability of the agricultural sector in Cameroon is essential (Abia et al. 2016) and sustaining the food sector (ZEF, FARA, IRAD 2017). However, there is inadequate focus on the limitations to the country's coastal agricultural productivity. Coastal Cameroon's agricultural productivity is likely already and may continue to experience adverse impacts of climate change and sea level rise (CC/SLR) especially in terms of area of inundation, soil erosion, flooding, salinity intrusion, and reduction in crop production. This may have serious repercussions on farmers, food security and safety, as well as on the ecosystem (plant, animal and human) health. An early awareness and preparation toward helping coastal farmers cope with CC/SLR is relevant. This chapter highlights the vulnerabilities of coastal Cameroon's agricultural productivity and ecosystem health to CC/SLR induced hazards, with proposed mitigation strategies.

Highlights of Coastal Cameroon

The coastal lowlands of Cameroon is located between the Atlantic Ocean and the western highlands in the northeast and the south Cameroon plateau in the southeast and covers 402 km of coastline. The coastal Cameroon spans 15–150 km inland from the Gulf of Guinea with an average elevation of 90 m. The coastal zone of Cameroon has three sedimentary basins (Campo Kribi, Douala, and Rio-del Rey). These are known to be potentially rich in hydrocarbons and are currently being exploited by petroleum companies. The northern part of the coast (including Idenau, Debundscha, Batoke, Bota, and Down Beach) is characterized by a small population size and very few industries and suffering impacts from the volcanic eruptions of Mount Cameroon. For example, during eruption, lava flows obstruct road networks, destroying crops, and induce rise in ocean water thereby killing fishes and other marine ecosystems. The coastal zone harbors the coldest place in Cameroon, Debundscha, which is at the foot of the Mount Cameroon, which experience the highest rainfall (annual average: 11,000 mm). The coastal region is characterized by equatorial climate with less dry (~3 months) and wet (~9 months) seasons alternating. The coastal line has high humidity mainly associated with the Guinea monsoon winds. The center of the coast, i.e., Douala, has an estuarine system of river Wouri and is the part with highest human/anthropogenic activities. Additionally, the central coast has the highest coastal population size and is home to approximately 60% of Cameroon's industries (Alemagi et al. 2006). It harbors the countries important industrial and environmental interests (Onguéné et al. 2015). The southern coast area (Kribi) harbors the smallest coastal population size and has few industries. The characteristics of coastal Cameroon have been presented variedly e.g., based on water, salt, and nutrient budget of the two estuaries (Gabche and Smith 2002) and based on characteristics of coastal vulnerability to climate change (Leal Filho et al. 2018).

Coastal Zones and Risk Factors of Agricultural Productivity

Coastal areas are likely to be more vulnerable to climate change than inland areas because, in addition to changes in flooding, temperature, and precipitation, coastal lowlands are frequently affected by sea level rise (SLR) and sea wave heights. Increasing Greenhouse Gas (GHG) emissions may raise the average atmospheric temperature by 1.1 °C to 6.4 °C over the next century, with possible thermal expansion of the oceans, rapid melting of ice sheets, and consequently SLR (Intergovernmental Panel on Climate Change (IPCC) 2007a). On the average, the global SLR stood at the rate of 1.8 mm per year from 1961 to 1993 and at the rate of about 3.1 mm per year from 1993 to 2003 (IPCC 2007b). Even if GHG emissions were stabilized soon, thermal expansion and deglaciation would continue to trigger SLR for many decades. Furthermore, the continuous growth of GHG emissions and associated global warming could well promote SLR of 1–3 m in this century, and unexpectedly rapid breakup of the Greenland and West Antarctic ice sheets might produce a 5 m SLR (Church et al. 2001) and may rise to 7.5 m by 2020 (Bamber et al. 2019). Altogether, the IPCC Third Assessment Report of 2001 projected a global average SLR of between 20 and 70 cm between 1990 and 2100 using the full range of IPCC GHG scenarios and a range of climate models (IPCC 2001). Recently, SLR projection until 2030 was reported in the "Special IPCC Report on the Ocean and Cryosphere in a Changing Climate" (IPCC 2019). In the report, two scenarios for GHG emissions are considered: a "low" scenario (known as RCP2.6), with strong reduction of global greenhouse gas emission, such that global warming will probably not exceed 2 °C, and a "high" scenario (referred to as RCP8.5), in which no measures are taken to limit

GHG emissions. Altogether, it is assumed that the high scenario may lead to SLR of up to 5 m of the global average sea level in 2030 (IPCC 2019).

Coastal areas are generally vulnerable to anthropogenic influences such as dense population, industrialization, and agricultural activities (Amosu et al. 2012). In the west and central African sub-regions, erosion of beaches is among the major ecological problems (Ibe and Awosika 1991). Due to coastal erosion and SLR, the surface area of the coastal administrative capital of the Gambia, Banjul, may disappear within approximately 50–60 years, thereby jeopardizing livelihood for over 42,000 people (Jallow et al. 1999). SLR causes devastating effects, which could include loss of land, population displacement, loss of economic gain, loss of urban infrastructures and amenities, submersion of agricultural lands, wetlands (or biodiversity) loss, and even the disruption of several ecosystems (Dasgupta et al. 2009).

Climate Change and Sea Level Rise (CC/SLR) and Food Security in Coastal Cameroon

Combined climate change (e.g., shifting weather patterns) and sea level rise (e.g., increase the risk of catastrophic flooding) (CC/SLR) has continued to threaten global agricultural production, socioeconomic activities and planetary health in an unprecedented manner for a while now, despite continuous efforts world over to mitigate it. There is urgent need for drastic actions, now more than ever; otherwise it will be more complex and expensive adapting to impacts of CC/SLR in the future (United Nations 2019).

SLR is generally referred to as "an increase in the level of the world's oceans due to the effects of global warming." Basically, a warming climate may cause seawater to expand and ice over land to melt. Both scenarios in combination may cause sea levels to rise (SLR). Thus, SLR is one of the major effect of climate change (CC), with rising waters threatening to inundate small-island nations and **coastal** regions in various parts of the world (Mimura 2013) and Cameroon (Fonteh et al. 2009). The effects of climate change, SLR, and both CC/SLR are discussed below.

Climate Change and Coastal Areas

Among all the environmental challenges known to have overwhelmed the planet since the 1980s, it has been estimated that more than 70% of them are linked to climate change (Lambi and Kometa 2014). In the wake of natural disaster such as droughts, SLR, floods, tropical depressions as hurricanes, storms, and heat waves, there has been an overwhelming negative impact on humankind, the environment, and economic livelihoods (Living with Risk 2002; Associated Program on Flood Management 2009; Brown et al. 2013). Cameroon is exposed to the impacts of climate change particularly her territories located in the Sahelian zone (which are extremely threatened by effects of desertification) and coastal areas (that are highly vulnerable to SLR) (Banseka and Levesque 2018). Partly due to the impacts of

CC/SLR, coastal Cameroon is already facing extreme weather phenomena such as heavy rainfall, violent winds, high temperatures, and drought, which endanger communities' ecosystems and the services they provide (Molua 2006; Fonteh et al. 2009; Banseka and Levesque 2018).

The major risks of climate change are inundation, soil erosion, and saltwater intrusion (Gopalakrishnan et al. 2019) and which negatively affects agricultural productivity, with the worst impact in the coastal areas. Additionally, it is speculated that by 2080, coastal West Africa may experience a high-risk level of flooding provoked by climate change (Nicholls and Tol 2006).

In addition to the social and human costs, the economic cost of the impacts of climate change is immense. This includes decrease or losses in agricultural productivity due to droughts and increased variability of rainfall due to increased numbers and intensity of natural disasters such as SLR (Banseka and Levesque 2018). It is speculated that, if nothing is done to address climate change, the "cost of inaction" may be huge and is estimated to be between 5% and 20% of world GDP, whereas the cost of "acting" is estimated at only 1% or 2% (Stern 2006).

In order to contain the devastating effects and or influences of climate change on the environment, agricultural productivity, and ecosystem (animal, human, plant, environmental) health, which has jeopardized the entire planetary systems, two types of policy response measures are needed: mitigation (efforts to limit GHG emission) and adaptation (actions taken to reduce the negative consequences of changes in the climate).

Adaptation capacity designates the ability for society to plan for and respond to change in a way that makes it better equipped to manage its exposure and sensitivity to climate change. Nearly 2.4 billion people (about 40% of the world's population), live within 100 km on coastal strip around the globe, making a total of 60 miles of total land surface occupation per/inhabitant of the coastal strip. Thus, oceans coastal and marine resources are very important for people living in coastal communities, which represent 37% of global population (United Nations Factsheet 2017). The term coastal zone is a region where there is interaction of the sea and land processes, for example, the city of Limbe in the coastal Cameroon.

Globally, the most common adaptation and mitigation measures used is the "Ecosystems Based Adaptation" (EBA) approach. This involves the conservation, sustainable management, and restoration of ecosystems to adapt to the advert effects of climate change (Convention on Biological Diversity (CBD) 2009, 2018). This approach will help people to take into account, manage ecosystems in ways that permit them to adapt to climate change in coastal areas. The United Nations Environmental Program (UNEP) has laid-down foundation guides for EBA options under the UNEP building capacity for coastal EBA for small islands Development States (project funded by European Commission). This guide is a strategic resource geared at helping environmental and adaptation managers and planners, mainly in governmental departments and civil society organizations. It facilitates baselines knowledge and built broad understanding of the principles and concepts of coastal EBA (UNEP 2016).

In synopsis, “EBA implement and support, environmental decision makers in choosing, implementing, monitoring, evaluating and over time adaptively managing coastal areas.” Mangroves, coral reef, estuaries, seagrass beds, dune communities, and other systems on or near shorelines do serve critical ecological functions which are beneficial to human society. Some of these functions include fisheries, storm protection, floods mitigation, erosion control water storage, ground water recharge, pollution abatement, retention, and cycling of nutrients as well as sediments. In a similar manner, the Convention on Biological Diversity (CBA) has also acknowledged and recognized the potential importance of EBA in meeting this challenge (CBD 2009, 2018).

Around the globe, the coastal zone management Act (CZMA) introduced in 1972 is equally applicable. This sought to balance economic development with environmental conservation, mainly by avoiding the scenario of specifying a defensive definition approach to climate change management. The National as well as international CZMA programs encourage various countries of the globe to develop and implement CZMA plans to protect, restore, and develop the resources of their national coastal zones for present and future generations. A good number of states still recognize the importance pre-emptive action to address their vulnerability to climate change (C2ES 2011). Some mitigation innovations include beach nourishment, coastal fortification, and a reactionary approach which includes seawalls, groin and jetty construction, and inshore artificial reefs.

In Cameroon, the reality of climate change is widely acknowledged. It is the consequence of increasing temperatures caused by atmospheric GHGs, altering the functioning of the ecosystems. According to the Fourth Assessment Report of the **IPCC**, the efficiency is difficult to assess because of natural adaptation and non-climatic factors (IPCC 2007c). Furthermore, 70% of GHG emissions observed between 1970 and 2004 was caused by human activities (IPCC 2007a). The IPCC Synthesis Report suggests that a continuation of the present policies to mitigate climate change would probably lead GHG emissions to further in the coming decades (IPCC 2007d). Therefore, for improved and sustainable agricultural production, there is a need for continuous monitoring and forecasting and use of crops and varieties that are more resistant to drought and adaptation of suitable planting methods (Molua 2006). Furthermore, there is need for expansion of farm size, livelihood diversification, and usage of organic fertilizers as potential adaptation options (Epule and Bryant 2016). However, non-climatic factors such as deforestation, poor governance, inadequate access to farm inputs (e.g., fertilizers, increased economic opportunities elsewhere and a breakdown of cultural practices) cannot be minimized (Epule and Bryant 2016).

Sea Level Rise (SLR)

The impact of sea level rise (SLR) on developing countries is overwhelming (Dasgupta et al. 2009). The effects will likely be more in coastal lowlands. SLR is expected to pose unique challenges partly due to the resultant saline contamination.

SLR may provoke more salt in soils and too much salt in soil can ruin crop yield (e.g., through restriction of water and nutrient uptake by the plant) and render farmlands or fields useless (Schiermeier 2018). SLR in coastal zones could potentially lead to land loss through inundation, erosion of coastal lands, increased frequency and extent of storm-related flooding, and increased salinity in estuaries and coastal freshwater aquifers (Gopalakrishnan et al. 2019).

Fonteh et al. (2009) have revealed possible implications of future SLR on the ecosystems and economic activities along the coast of Cameroon using mapping and valuation approaches. This was partly associated with the high ecological and economic value of the area. It was speculated that an estimated 112–1216 km^2 (1.2–12.6%) of the coastal area is likely to be lost from a 2–10 m (equivalent to a low scenario by 2050 and high scenario by 2100) flooding, respectively. Furthermore, approximately between 0.3% and 6.3% of ecosystems (estimated to worth US$ 12.13 billion/year) could be at risk of flooding by the years 2050 and 2100. The areas under a serious threat contain mangroves, sea and airport, residential and industrial areas, and to a lesser extent, main plantation crops of banana and palms (Fonteh et al. 2009). Although there is inadequate information on the consequences, it may be speculated that this may have adverse effects on coastal agriculture production and may be a threat to food security and safety, as well as on the socio-economy of the coastal Cameroon. Wetland losses and loss of productive mangrove ecosystem will also occur with a SLR. According to the TOPEX/Poseidon and Jason satellite data, the rate of SLR in Cameroon is 2–2.4 mm/year between 1993 and 2004 (NASA 2008). Thus, the low-lying coastal areas are physically and socioeconomically vulnerable to impacts of SLR. There is need to take prompt actions toward mitigating the effects of SLR provoked natural disasters in coastal Cameroon (Fonteh et al. 2009).

Climate Change and Sea Level Rise (CC/SLR)

Climate change and sea level rise (CC/SLR) are not new concepts, even though their synergistic effects seem minimized and less talked about vis-à-vis climate change or food security alone or in combination. SLR is a direct consequence of global climate change. It appears to get worst as population growth increases (Gommes and du Guerny 1998). The CC/SLR constitute a major hindrance to agricultural productivity (Schiermeier 2018; Ogbuabor and Egwuchukwu 2017) and may exert adverse effects on ecosystem health (Nicholls et al. 2011) in coastal areas.

As climate change continues to provoke SLR in coastal Cameroon, inundation of low-lying coastal areas increases continuously and with saltwater, and gradually contaminating the soil. Although rainfall can dissipate these salts, climate change is also increasing the frequency and severity of extreme weather events, including droughts and heat waves. This leads to intensive use of groundwater for drinking and irrigation, which further depletes the water table and allows salt to leach into soil. In some parts of the world, especially low-lying river deltas, local land is sinking (known as subsidence), making sea levels that much higher (Nicholls et al. 2007).

Thus, even without climate change, coastal areas such as coastal Cameroon would still experience slow relative SLR due to these non-climatic processes and hence increased flooding and damage cost through time (Nicholls 2002; Nicholls et al. 2007, 2011).

In addition to adverse impact on agricultural productivity, CC/SLR constitute a nuisance in coastal ecosystem health and socioeconomic activities. This is particularly worse in the developing countries with inadequate capacity to manage associated repercussions on land use, populations' evacuation/displacement and juxtaposition of livelihood sources, i.e., agriculture and touristic activities in the case of coastal Cameroon and elsewhere. For example, in coastal Cameroon, CC/SLR may lead to flooding which may provoke internal displacements with associated joblessness. The coastal Cameroon's situation is made worse by the eruption of Mt. Cameroon, which releases lava flow that further reduce agricultural land and destroy crops and marine lives whenever it erupts – a scenario which is arguably by the assumed post eruption increase in soil fertility. Apparently, coastal zones in different geographic areas, with varied anthropogenic activities, non-similar efforts against SLR, and varied effectiveness of erosion-driving forces such as waves and tides, are expected to react differently to SLR. Thus, considering the CC/SLR projected likelihood of high-risk flooding in the lowlands of coastal West Africa (including Cameroon) by 2080 (Nicholls and Tol 2006), there is a need for constant monitoring and timely mitigating actions to salvage coastal Cameroon from the natural disaster. To this effect, we speculate that relevant efforts to mitigate and adapt to CC/SLR may include intensive farmers' education on good agricultural practices, creation of nurseries for improved and climate smart food varieties, irrigation and vertical farming, and a shift from subsistence-to-industrial farming. Application of these strategies may enhance food security, ecosystem health and socioeconomic and touristic activities in the coastal Cameroon.

Conclusions and Future Prospects

Food security is a major public health priority in Cameroon, vis-à-vis the ever-increasing population growth with associated challenges. Risk factors to agricultural productivity such as combined climate change and sea level rise (CC/SLR) require attention, particularly in coastal Cameroon. CC/SLR have negative impacts on agricultural productivity and socioeconomic activities in coastal morphology. This is through its contributions to natural disasters including erosion, flooding, inundation of coastal lowlands, and saltwater intrusion, which all have a significant impact on crop productivity and output. Socioeconomically, these disasters may provoke adverse animal, human, and environmental health implications; reduction in tourism; and potential close of some socioeconomic activities (e.g., beer parlors, and small roadside restaurants) that constitute as secondary (after agriculture), or main source of livelihood/income for many coastal indigents.

Sustainable agricultural productivity in Cameroon is essential, moreover in coastal Cameroon amidst CC/SLR. This requires concerted actions of stakeholders' (government, local civil society organizations, individual, and common initiative farmers groups, and international bodies). Such efforts may propose and develop sustainable strategies toward adaptation and mitigation of risk factors of agricultural production and socioeconomic growth in coastal Cameroon. Potential adaptation options may span from agricultural (CC/SLR and non-climatic) to educational intervention socioeconomic strategies. CC/SLR strategies include expansion of farm size, usage of organic fertilizers, creation of nurseries for improved and climate smart crop varieties, irrigation and vertical farming, and a shift from subsistence-to-industrial farming. Non-climatic strategies may include afforestation, good governance, ensuring adequate access to farm inputs (e.g., fertilizers), promotion, and increase of local agribusiness opportunities. Educational intervention socioeconomic strategies may include intensive farmers' education on good agricultural practices, and the diversification of livelihood. These strategies may provide a small contribution toward a wider multi-stakeholder pool of strategies and which, when applied, may enhance food security in coastal Cameroon amidst CC/SLR and promote socio-economic and touristic activities while reducing negative implications on animal, plant, human, and environmental health.

Abstract

Global climate change poses a great threat to poultry production. Greenhouse gases (GHGs) are released through both natural and anthropogenic sources into the atmosphere. Though poultry production contributes little to the release of GHGs, the subsector has been shown to be greatly affected by climate change and global warming. Poultry production as a major subsector of agriculture has provided the teeming population with a supply of needed animal protein in terms of meat and egg production all over the world. It is yet a major global employer of labor. Though it occupies a vantage position in meeting human needs, it is being threatened by climate change, especially in Africa where necessary structure to tackle the menace is nonexistent. Broiler chickens that are reared mainly for chicken meat cannot tolerate the high ambient temperature that prevails mostly in the tropical environment. Chickens are homeotherms that homeostatically regulate core body temperature within a narrow range. Elevated ambient temperature above thermal comfort zone, such as envisaged in climate change scenarios, will trigger series of neuroendocrine modulations that are detrimental to the welfare and productivity in broiler chickens. Such birds are said to be undergoing heat stress (HS). Negative effects of HS include reduced feed consumption, growth rate, feed digestion and efficiency, immunity, welfare, and survivability. Various adaptive measures that could be harnessed by broiler farmers, ranging from housing, feeding, watering, stocking, breeding for thermotolerant strains, thermal conditioning, use of phytochemicals, and much more, are reviewed upon in this chapter.

Keywords

Acclimation · Acclimatization · Broiler chickens · Environmental temperature · Heat stress · Thermal comfort zone · Thermoregulation

Introduction

Climate change is defined by Ngaira (2007) as deviations in the patterns of climate over a long period of time while the Intergovernmental Panel on Climate Change (IPCC) recognized it as a change in the state of the climate that can be identified (using statistical tests) by changes in average and standard deviation, and that persists for a long period of time, typically more than one decade or longer (IPCC 2007). It poses a great threat to agricultural and socioeconomic development (Niang et al. 2014). The problem of climate change will add to the burden of heat stress (HS) usually experienced in the tropical regions of Africa because of the predicted increase in global temperature. Though Africa contributes the least of the global GHG emission, yet evidences had shown that most developing countries in Africa would be the most affected because of low infrastructural capacity to cope. This is also hinged on the fact of widespread poverty, prevailing slash-and-burn agriculture, erosion, and burning of firewood and farm residues. The problem of desert encroachment and deforestation is also a contributory factor to climate change. All facets of human life will be affected by climate change. Poultry production, a subsector of agriculture that had helped in supplying the needed human protein requirements from chicken, turkey, duck, guinea fowl, geese, and ostrich is not spared. Productivity and welfare of poultry species in Africa will be negatively impacted upon by climate change. Chicken being the most populous and important among poultry species will be most impacted upon. Global chicken population was over 22 billion in 2017. Broiler chickens, raised mainly for meat production with high feed-to-meat conversion efficiency, is the most sensitive to the effects of elevated temperature in the environment among other strains of chickens. Its productivity is grossly affected once the required environmental conditions, especially temperature, are compromised. These necessitate the development of a review of all available options for adaptation of broiler production to the prevailing and envisaged global warming.

Climate Change and Its Evidences in Africa

Livestock subsector was viewed as a victim until it was implicated as a major contributor to global emission of greenhouse gases (GHGs) such as CO_2 and CH_4. FAO's report *Livestock's Long Shadow* opened up the minds of many stakeholders to this fact (FAO 2006) that the subsector contributes 18% of global GHGs. These gases cause warming of the globe by entrapping heat on the earth crust not allowing it to be reflected to the atmosphere. Resultant global warming and climatic variability have been reported to have both direct and indirect impacts on livestock production, including reduced growth and reproductive efficiency, low quality and quantity of feed materials, and increased prevalence of disease due to rise in temperature (Renaudeau et al. 2012). Africa is the most threatened all over the world with predicted effects of climate change (Ngaira 2007). Though, the continent is the least emitter of these GHGs of all continents, unlike other industrialized nations that are emitting these in tonnes daily.

Predicted temperature rise of 2–6 °C is expected over the land of Africa within the next 100 years and a rise of 1.5–3.0 °C by 2050. This is much more severe than experienced in other regions. The presence of climate change in Africa is evident in that the three warmest years over African land since 1950 had been identified as 2010, 2016, and 2017, all occurring within the last decade. Average deviation from the mean temperature of 1961–1990 was +1.41, +1.26, and + 1.20 °C, respectively. The warming rate per century recorded in Africa (+3.7 °C) is an alarming signal. ACMAD (2017) stated that temperature anomalies varied over the different subregions of Africa in 2017. Northern Africa experienced the average temperature anomaly was 1.1 °C warmer than the long-term mean. Similar to the experience in the North Africa, 2017 had temperature anomaly of 1.2 °C above average over the West African region. Central Africa had a temperature anomaly of 1.3 °C above average. Over Eastern Africa land, 1.2 °C was recorded above average while anomaly of 1.0 °C above average was reported over the Southern Africa region in 2017. However, temperatures in 2017 were mild over the island countries in the Indian Ocean. For instance, one of the coldest years in Madagascar is 2017, with temperature deviation of 0.3 °C below the mean. Climate change will pose considerable risks to the livelihood of the dwellers of most countries in Africa that mainly depend on agriculture (Hummel 2015).

Poultry farmers in Africa are aware of climate change because many of them have been taken cognizance of variability in rainfall amount and pattern, heat spells, and variability in other climatic elements. Indigenous technical knowledge and systems that had been explored by farmers in adapting to high environmental temperature abounds.

Impacts of Climate Change to Poultry Production

In Africa, there are two main poultry production systems. Distinguishing factors between the two are associated with the scale of production, stock, management system, and productivity. The two systems are the commercial poultry and the rural poultry. The former is on large to medium scale, stocking improved/exotic breeds, reared intensively with adequate care for feeding, health, and welfare of the birds in modern facilities in large number. In terms of productivity, the commercial gives higher returns. On the other hand, the latter, *also known as* village or backyard poultry, is usually on small scale, stocking the locally adapted indigenous breeds of birds. The productivity is lower with the village poultry system. In history, the latter is far older than the former. Meanwhile, intermediate system between the two systems has evolved over time. Commercial poultry system includes breeding farms where grandparent (GP) and parent stocks are raised. Day-old chicks (broiler and layer lines) are produced by the breeding farms. Commercial broiler farms raise the chicks till table size of around 2.5 kg in 6–8 weeks. The effort to genetically improve commercial stocks of broiler chickens began in earnest in the USA in the 1940s (FAO 2020). And since then, it has been the stories of great leaps in improvement of growth rate and feed conversion efficiency. The successful breeding company started exporting chicken hybrids with improved strains into African countries in the 1950s. This coincided with the rapid development of commercial poultry systems in Africa.

All these systems are under the threats of the climate change but the most affected of them is the commercial poultry system. Impacts of climate change on poultry production (Fig. 1) could be categorized into two.

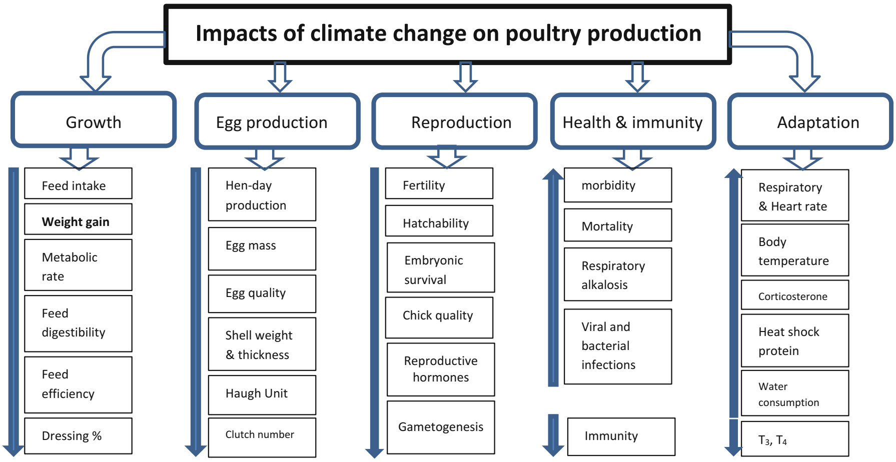

Fig. 1 Diagram illustration the effects of climate change on poultry production

Direct Impacts

Climate change has impacts on poultry production by way of imposing stress on the homeostasis in the birds. It may come in the form of extreme climatic situations: elevated temperature, flood or drought, and water scarcity (Tiruneh and Tegene 2018). Common among these is increased global temperature. Extreme weather conditions lead to production losses (reduced growth rate, lowered egg hen-day production, and increased morbidity and mortality) in poultry birds (Attia et al. 2011). Poultry birds can adapt to hot environment. However, the mechanisms of coping subject the birds to losses and diversion of nutrients meant for production to thermoregulation.

Growth performance of the birds is grossly affected by perturbations in weather conditions in the surroundings. The most important of these is the pen temperature. Changes in humidity work synergistically with high environmental temperature to impact negatively on poultry birds. In hot environment, feed consumption is reduced in order to limit metabolic heat production. Available nutrients in the system are utilized for heat loss mechanisms instead of profitable usage for muscle accretion. Digesta mobility in the gastrointestinal tract (GIT) is drastically reduced and efficiency of nutrient digestion and assimilation in the intestines is lowered. Histomorphometric studies show that the epithelial cells of the intestines are affected by HS (Santos et al. 2015). Vasodilation of blood vessels at the periphery reduces blood flow across GIT of the birds thereby lowering the efficiency of digestion and nutrient uptake. All these factors cumulatively contributed to the lowered final liveweight and dressing percentage usually obtained in heat-stressed chickens (Syafwan et al. 2011).

Productivity in laying chickens is negatively affected by elevation in temperature by reducing the number and size of eggs produced. Internal and external quality traits of the eggs are compromised by changes in weather conditions around the birds. High ambient temperature lowers egg fertility, hatchability, and chick quality in breeder stocks (Ayo et al. 2011). Impact of climate change will be felt on the synthesis and the release of reproductive hormones (FSH, LH, progesterone, estrogen, and testosterone) with resultant reduction in efficiency of gametogenesis in male (spermatogenesis; Al-Saffar and Rose 2002; Karaca et al. 2002) and female (oogenesis) birds (Rozenboim et al. 2007). Heat-stressed cocks produce semen with low sperm concentration and quality. Immunity of the birds is lowered under HS conditions (Calefi et al. 2017).

Indirect Impacts

Indirectly, climate change will impact on feed ingredient availability and quality for the poultry birds; availability of adequate good quality water; and pest and diseases infestation in Africa. Climate has effects on the yield and quality of produce of crop husbandry from where most of the feed ingredients are sourced. Feed ingredients such as maize, groundnut cake, cotton-seed cake, wheat offal, and rice bran are gotten from agronomic activities. Semiarid regions experiencing low rainfall amount and irregular pattern cannot boast of bountiful harvest. This may trigger skyrocketing of the feed price for poultry species and exacerbate the animal-human competition for feed materials except irrigation systems are employed. Rain-fed cropping in the forest vegetation will also be affected by high temperature and insufficient rainfall.

Availability of adequate good quality water is essential to productivity in poultry production. Climate change has reared up its head in reduction in water in the ponds, streams, rivers, and the seas immediately after rainy season all around Africa because of increased rate of evaporation (Alemayehu and Woldeamlak 2017). Water shortage adversely affects body weight and lymphoid organs (Mustafa et al. 2010). Changes in the existing pattern of pest and disease infestations are envisaged under different climatic change scenarios. This will affect productivity of poultry in terms of morbidity, mortality, and the cost of vaccinations and medications.

Broiler Production

Broiler chickens are reared mainly for meat production. The production cycle lasts for 5 to 8 weeks, with high rate of turn-over of feed to meat from day-old chicks to market age. Chicks are obtained from specialized lines called breeder chickens. At market age, the liveweight of 40–55 g at day-old would have multiplied by 50 times to give about 2.5 kg chickens. Both male and female sexes of broiler chickens are reared for meat, though male chickens grow faster than the female counterparts. Most of the strains of broiler chickens reared in Africa are developed in the temperate regions of the world such as the USA and the Netherlands but are imported into Africa. The birds are incapable of expressing the inherent growth potentials because of HS and the productivity is often below what is obtainable in their counterparts in the cooler climes. Broiler chickens are sensitive to elevation in ambient temperature during growing phase. Production and demand for chicken meat has increased tremendously worldwide over the last few decades. This results from different selection and cross-breeding techniques that are employed to improve growth rate of broiler chickens, reaching market weight within a short span of time than what is obtained in the past. To continue enjoying the gains of several years of broiler development, efforts toward ensuring adaptation of broiler chickens to prevailing high environmental temperature expected in climate change are worthwhile.

Heat Stress and Broiler Chickens

All farm animals in the tropical region suffer from HS at one time or the other because of constant elevated ambient temperature (Altan et al. 2000). People and livestock in the temperate regions are exposed to HS induced by elevated environmental temperature during summer. HS is an adaptive response that occurs in a bird when the rate of thermolysis is below thermogenesis and the ability to lose body heat exceeded by the heat load acquired through exposure to high ambient temperature (Al-Saffar and Rose 2002).

Broiler chickens are homeothermic animals capable of maintaining the body temperature within a narrow range irrespective of the environmental temperature. They possess an internal homeostatic mechanism that regulates internal body temperature. The internal body temperature of adult chicken is normally between 41.2 °C and 42.2 °C (Mitchell et al. 2005). Newly hatched birds have a body temperature approximately 2–3 °C below that of the adult birds. Additional source of warmth is needed by the chicks during the first 21 days post-hatch to maintain body temperature for normal growth and development. However, as the birds increase in age and size, their requirement for supplemental heat declines. This results from the development of insulating feathers, higher metabolic heat production, and maturation of the thermoregulatory system of the birds. In general, the thermal comfort or thermoneural zone (TNZ) for broilers declines from about 32 °C at hatching to around 24 °C at 3 to 4 weeks of age and to about 21.1 °C thereafter. The birds at this period are capable of heat regulation to maintain core body temperature. As temperature increases beyond 21.1 °C around adult chickens, mechanisms for heat loss are triggered.

The fast-growing broiler lines are susceptible to high temperature mostly during growing-finishing phase. The high susceptibility to HS results from resultant inferior development of their cardiovascular and respiratory systems (Yahav 2000). As well, chickens do not possess sweat glands (Mitchell et al. 2005). In addition, their rapid growth rate is supported by high feed intake, thus, as they grow, metabolic heat production increases but their heat dissipation capacity does not. Broiler chickens gain heat from metabolism, physical activity, and environment. This heat load must be dissipated to maintain constant body temperature. Metabolic heat production in broilers is particularly high because of their high feed intake compared to other strains of chickens. Their growth rate is supported by feed consumption which leads to generation of heat in the body system. Increased heat production does not have

Fig. 2 Diagram showing broiler chicken exhibiting panting behaviour

any adverse consequence on the birds in TNZ and cold environments. But as ambient temperature overshoots the upper limit of the TNZ, the ability of the bird to dissipate heat is compromised making excessive heat production built-up. The condition leads to hyperthermia (increased core body temperature) which is potentially life threatening. Before this stage, the body temperature is regulated mainly by loss of heat to outside environment through conduction, convection, and radiation, *also known as* non-evaporative heat loss. Effectiveness of these three means of heat loss is limited to lower temperatures (Borges et al. 2003).

As the temperature peaks, chickens exhibit panting, an evaporative heat loss behavior (Fig. 2; Video 1). Panting involves evaporative cooling of the bird by losing heat from the respiratory tract. They also display wing-raising to expose the poorly feathered sides of the body and under-wing area. Sometimes, they dig into the litter to sit on a cooler floor in the pen during hot periods. Panting occurs when the deep body temperature of poultry reaches 42 °C. Respiratory rate may increase from 25 to 150 breaths per minute over a 20-min period in response to an increase in ambient temperature from TNZ. In a healthy chicken, hyperventilation through panting will remove approximately 0.54 Kcal/g water lost in the lungs. Chickens increase saliva secretion during this period because of the need to the surface of the respiratory tract wet during panting.

Negative Effects of Heat Stress in Broiler Chickens

The adverse effects of HS can be seen in decreased feed consumption, increased water intake, rise in body temperature, respiratory rate, heart rate, electrolyte imbalance, changes in hematological parameters, hormone levels and enzymatic activities, and perturbations in blood *pH* (respiratory alkalosis; Lara and Rostagno 2013). All these negatively affect productivity of the animal. An increase in body temperature above the regulated range, because of exposure to hot environmental conditions, may lead to a cascade of irreversible thermoregulatory events that may be lethal for the birds. Generally, broiler chickens try to lower its heat production by reducing its feed consumption during heat episodes. The reduction in feed consumption can be as high as 1.5% per 1 °C increase in temperature above TNZ. Reduction in feed consumption consequentially leads to insufficiency of essential nutrients. Coupled with this is the lowered digestibility of feed in the gastrointestinal tract of the birds. Growth rate is therefore reduced in broiler birds when environmental temperature rises because even the little energy obtained from the small feed consumed is expended in panting. The result is that birds had lower final body weight. Chronic HS increases the time to reach market weight and impairs feed digestibility. More feed is required to lay down unit weight of chicken than in TNZ conditions. Exposure to hot weather leads to high mortality in broilers and loss of immunity. Efforts to increase feed consumption during HS by force-feeding have been shown to decrease survival. Mortality in broilers up to 10% of the total production has been reported during HS. Egg production, fertility, and hatchability are said to be grossly affected in both grandparent and parent (broiler breeder) stocks. Time expected for feeding is expended in panting and beside water troughs. Birds consume more water during HS exposure. Excessive loss of CO_2 in exhaled air during panting results in high blood *pH*, a syndrome called *respiratory alkalosis*.

Adaptation Options to Climate Change for Broiler Chickens

Housing System and Climate Amelioration

Ideal broiler chicken environment must meet the requirement of the birds for adequate pen temperature, relative humidity, and air circulation. Broiler houses are closed system in most industrialized countries where the temperature and humidity are fully controlled, unlike in developing countries where open-sided housing units are common. Foggers, tunnel ventilators, fans, and misters are used to cool the environment in closed systems. However, the cost of installing and maintaining fans, foggers, ventilators, misting pumps, and so on in poultry houses is often beyond what most farmers can afford.

Attaining the optimal range of climatic variables in the open-sided poultry houses common in the tropics is difficult and almost impossible (Abioja 2010). However, proper ventilation is essential in minimizing the effect of heat in African poultry housing units. As the higher environmental temperature is expected all over Africa, the following should be considered for broiler housing:

- Orientation of the housing units should allow for cross–ventilation.
- Low-walled structures completed with wire mesh to ensure cross-ventilation (Fig. 3). High walled structures trap heat inside and will not be applicable.
- Mud wall houses provide cooler interior than brick wall housing unit.
- Roofing style should be such that allow for proper ventilation.
- Roofing materials must be considered. Asbestos roof is preferred to corrugated iron sheet. Local materials that enable heat transfer such as palm fronds, long grasses such used for thatched roof could be used.
- Tree planting around broiler housing units will provide coolness (Fig. 4).
- The use of mobile pens with wire mesh floor placed under shade of trees.

Fig. 3 Low-walled broiler housing units

Fig. 4 Tree shade beside broiler housing unit

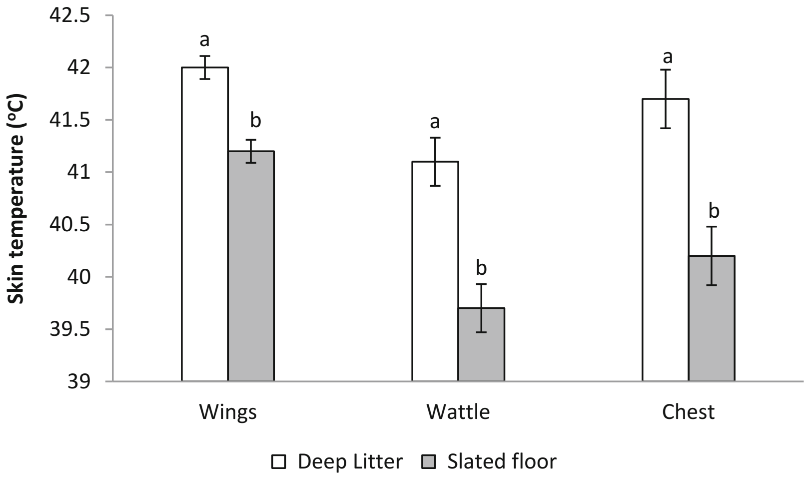

Fig. 5 Effect of floor type on skin temperature of broiler chickens during hot-dry season

Table 1 Effect of floor type on rectal temperature, respiratory rate, heart rate, and skin temperature in broiler chickens during hot season

	Floor		
Parameter	Deep-litter	Wire mesh	*p*
Rectal temperature, °C	42.7 ± 0.07^{a}	42.0 ± 0.07^{b}	0.000
Respiratory rate, breaths/min	138.8 ± 2.28^{a}	125.3 ± 2.28^{b}	0.000
Heart rate, beats/min	198.4 ± 2.96^{a}	188.6 ± 2.96^{b}	0.023

[a, b]Means within the same row with different superscripts differ significantly ($P < 0.05$)

Broiler chickens are commonly raised on deep-litter floor in most areas of the world, but the use of cage for broiler is becoming common (Shields and Greger 2013). Type of floor has been reported to influence liveweight, feed intake, protein efficiency, and feed conversion ratio in broiler birds reared during winter and summer (Simsek et al. 2014). Wire mesh floor decreased skin temperature, cloacal temperature, respiratory rate, and heart rate of broiler chickens compared to deep-litter floor during hot season (Fig. 5, Table 1; Abioja 2020 –*Unpublished data*).

Feed and Feeding Manipulations

Special attention should be given to the nutrition of broiler birds under high temperatures expected under climate change. The major problem of broiler chickens under HS conditions is the fact of reduction in feed consumption. Reduced dietary intake limits available metabolizable energy to sustain normal output. The following suggestions may be of help in feeding broilers during heat spells:

- More energy should be delivered in the form of fat instead of starch (because heat increment from metabolizing fat is lower than that from carbohydrate however rancidity of fat should be given a consideration).
- Balancing of amino acids in the diet especially methionine and lysine is necessary to augment for deficiencies resulting from low protein intake.
- Diets with low protein level should be recommended in order to reduce heat production in broiler chickens under HS because protein has the highest heat increment of all nutrients.
- Anti-oxidant vitamins (A, C, and E) supplementation has also been credited to improve performance of broilers during HS.
- Wet feeding (Awojobi et al. 2009; Dei and Bumbie 2011) was found to help in improving the final liveweight and weight gain of the birds in a hot climate. Syafwan et al. (2011) stated in a review on HS and feeding strategies in meat-type chickens that wet feeding may be profitable under HS conditions. Feeding wet diets might facilitate an increased water intake. This ensures availability of adequate water for evaporation during panting, hence helping cooling of the bird.

Other areas to be considered for adaptation of broiler chickens to climate change include feeding time (Farghly et al. 2019). Feeding time should be organized in a way that the peak metabolic heat production will not coincide with the highest point in environmental temperature.

Water Supply

Water is one of the limiting factors in broiler production. It is an essential nutrient that must be taken into consideration if expected productivity is to be achieved. Factors that are of importance in drinking water for chickens include quantity, quality, temperature, salinity, and microbial load. Water supply to the broiler houses must be clean and constant. Broiler chickens consume more water during hot period than in cold climate (Manning et al. 2007; Bruno et al. 2011). Its restriction was reported to raise heterophil-lymphocyte ratio, a major indicator of stress in broiler chickens. Availability of drinkable water during hot spells must be ensured. Water restriction caused reduced weight of lymphoid organs in broiler chickens (Mustafa et al. 2010), which may negatively impact the innate immunity of the birds. In South-Eastern Nigeria located in the rain forest zone, water restriction up to 1.2 liters per day was found to have deleterious effects of the hematological parameters and caused increased activity of liver enzyme which is an indicator of cellular necrosis in broiler chickens (Iheukwumere and Herbert 2003). Water restriction had negative effects on the renal functioning, digestion, immunity, and other vital body systems. Birds subjected to water restriction had an altered behavior, becoming aggressive and irritated. Therefore, water restriction irrespective of the magnitude must not be allowed in broiler production.

Water temperature is another important factor that must be put into right perspective. Warm water is nauseating and not readily acceptable to chickens.

Table 2 Rectal temperature and respiratory rate in broilers offered water of two different temperatures

Parameter	Water temperature		Standard error of means (sem)
	Ordinary	Low	
Water temperature (°C)	30.0	16.0	0.09
RT at 08.00 h (°C)	41.7[a]	41.5[b]	0.03
RT at 16.00 h (°C)	42.5[a]	42.1[b]	0.04
RR at 08.00 h (breaths/min)	54.0[a]	46.7[b]	1.13
RR at 16.00 h (breaths/min)	85.2[a]	62.6[b]	2.11

Abioja MO (Unpublished data)
[a, b]Means with differing superscripts within a row were significantly different ($P < 0.05$)

Chilled water is preferred to water at ambient temperature. Offering water at low temperature may reduce heat load and respiratory rate in broiler chickens (Table 2). This has been proved to help combat HS in broilers (Abioja et al. 2011, 2013). Practical activity in cooling water may involve having water reservoirs placed under shade to disallow overheating by direct sunlight during hot periods. Many poultry managers in all over Africa have been supplying their birds with water cooled with ice cubes during the dry season. The enhanced respiratory rate during HS is critical for body temperature maintenance because of its resultant evaporative cooling.

Specific consequences of the acid-base perturbations have indeed been identified. Electrolytes lost can be replenished with sodium (Na), potassium (K), calcium (Ca), magnesium (Mg), chlorine (Cl), bicarbonate (HCO_3), and sulfate (SO_4) salts in water (Ahmad and Sarwar 2006). The addition of the electrolytes to the drinking water not only alters the bird's osmotic balance by replenishing those depleted during HS but also stimulates water consumption and influences water balance. Some African native chickens had been found to have tolerance for water shortage. Chikumba and Chimoyo (2014) reported that Southern African naked neck chickens was found to performed better than Ovambo chickens under conditions of water restriction and would be ideal to raise for meat and egg production in locations where water shortages are a major challenge.

Stocking Density

Each bird in the flock emits radiant heat to the environment. Low stocking density reduces the number of birds producing heat and the amount of heat that must be removed from the house to maintain temperature. Recommended stocking density appropriate for different housing type should be strictly adhered to. Assuming each bird weigh 2 kg at slaughter, for controlled environment, the maximum stocking density at slaughter should be 30 kg/m^2; controlled environment during hot period, 24–26 kg/m^2; open-sided house, 20–22 kg/m^2; and open-sided house during hot period, 16–18 kg/m^2. Abudabos et al. (2013) reported that increasing the stocking density rate from 28 to 40 kg of body weight/m^2 had evident negative effects on the growth performance of broiler chicken. Higher stocking density does jeopardize the well-being of the chickens.

Epigenetic Adaptation to Thermal Assaults

Chickens are precocial birds having the development of body functions starting early during the embryonic phase (Nichelmann and Tzschentke 2002). Thermoregulatory mechanisms start during prenatal stage but not fully matured as at pre- and peri-hatch periods (Tzschentke and Basta 2002; Tzschentke et al. 2004). At this point, exposure to a level of stress can trigger an imprinting in chickens. Acute changes in the environmental conditions especially thermal environments induce as a rule, first uncoordinated and immediately nonadaptive reactions. Later, the uncoordinated (immediately) nonadaptive reactions change into coordinated (adaptive) reactions (Tzschentke 2007). Stress is usually avoided because of its perceived repercussions on living tissues. However, evidences are emanating from various research works that exposure of broiler chicks to mild stress at early age help in acquiring thermotolerance at latter age. This was first reported in rats by Levine (1962). The author discovered that mild stress at early age affects the adrenocortical functioning during adulthood.

It was later confirmed in broiler chickens (Yahav and Plavnik 1999; Zulkifli et al. 2000; Liew et al. 2003). From this assertion, there are two strategies that have been explored: thermal conditioning (TC) and early feed restriction (EFR). TC involves exposing chicks at early age post-hatch to elevated ambient temperature (Arjona et al. 1990; Yahav and Hurwitz 1996; Yahav and McMurtry 2001) within the first 6 days while EFR subjected the chicks to varying degrees of hunger during the same period (Zulkifli et al. 1994). TC has been demonstrated to be effective as a tool for thermotolerance acquisition in poultry but its application is not practicable in the traditional open-sided poultry houses common in most tropical and developing countries. The cost of heating poultry house to a desired temperature is high. Besides, the technicality associated with thermal conditioning such as length and degree of heat exposure may not be easily mastered by the local farmers. This leaves the only option for thermotolerance acquisition in the developing and underdeveloped world to application of early feed restriction.

Sublethal stress imposed by feed withdrawal in the early age post-hatch on broiler chicks has been noted to confer inherent capability in the birds to cope with stress in latter age (Liew et al. 2003). Abioja et al. (2014) have found that applying EFR to broiler chicks of d5 post-hatch for 24 h may help reduce hyperthermia that is common during heat spell in pen at market age. It is not known whether the response will be the same during transportation as in the acute heat spell. Improved thermotolerance in broiler chickens at market age will help against losses that do occur during transportation. Adopting feed restriction during early period of life in broiler chickens as a means of improving thermotolerance in broiler chickens is easier for farmers than adjusting pen temperature. Induced thermotolerance is generally referred to as the state at which an organism is transiently more resistant to killing by heat due to a short pretreatment at moderately elevated ambient temperatures. This usually takes place before the brain is fully matured for thermoregulation. During ontogeny in chicken, embryo undergoes a transition from poiklothermy to homeothermy, which is completed, at the early post-hatching. Full-blown homeothermy starts at approximately 10 days post-hatch. Early age thermal conditioning by exposing young chicks to 40 °C for 24 h reduces body temperature and improves long-term broiler resistance to HS without negative effects on growth and feed conversion ratio.

Zulkifli et al. (2000) reported that acute HS resulted in increase in heterophil/lymphocyte ratio for all feed-restricted groups and the ad libitum group. But broilers restricted from 60% of daily feed requirement on day 4, 5, and 6 had the least heterophil/lymphocyte ratio. The authors concluded it appeared 60% feed restriction is beneficial in improving growth and survivability of female broiler chickens exposed to HS later in life. The authors restricted the feed by percentage on three consecutive days (day 4, 5, and 6). Exact feed intake of the birds may not be ascertained: feed intake depends on strain, genotype, environmental condition in the pen, body weight, etc. Farmer may have problem calculating the feed intake. Besides, percentage feed restriction may not give the exact day the EFR is most effective. Therefore it is important to determine exact day of life the chicks should be subjected to early feed restriction by farmer which ensures best acquisition of thermotolerance.

Use of Honey and Other Natural Phytochemicals

The age-long conventional use of antistress antioxidant formula containing a mixture of vitamins and minerals to help broiler chickens cope during heat spell in rearing has proved to be effective. However, the use of phytochemicals that possess or are suspected to possess efficacious antioxidant properties in the management of HS in poultry production is becoming more popular (Abioja et al. 2012). Efficacy of honey and some other naturally occurring materials from plants such as coconut water, olive leaf extract, and propolis during stressful conditions in chickens had been reported in literatures. Honey has recently been reputed as a possible natural source of antioxidant in broiler chickens (Abioja et al. 2012; Osakwe and Igwe 2015; Oke et al. 2016) with some positive results because of its phenolic and flavonoid compounds content and various phytochemicals that possess antioxidant properties. It has been used during acute heat and transportation stress conditions. Honey is effective because some of its components are substances known to have physiological actions in the body systems of animals. Diluted drinking water of concentration 20 ml honey dissolved in a liter drinking water had positive effect on respiratory and heart rates, calcium metabolism, bone formation, and some internal organs in heat stressed broiler chickens. Honey in drinking water could be of help in improving the welfare of broiler chickens during stress episode by increasing the packed cell volume, red blood cell count, and hemoglobin concentration according to Abioja et al. (2019). It helps in protecting gastrointestinal tract, liver, kidney, pancreas, eye, plasma, red blood cells, and reproductive organs against oxidative stress in rats (Zaid et al. 2011; Erejuwa et al. 2012).

The presence of phenolic compounds and flavonoids in honey had been primarily implicated as the reason for its antioxidant activity. Phenolic compounds are good in free radical scavenging, hydrogen donation, singlet oxygen quenching, and metal ion chelation. Phenolics and flavonoids do help in correction of the redox perturbations in the body by counteracting the damage caused by oxidants such as oxygen, hydroxide, superoxide, and/or lipid peroxyl radicals. Exogenous nonenzymatic antioxidants in honey synergistically support the endogenous antioxidant enzymes, such as superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPX), to eradicate reactive oxygen species. Honey has various antioxidant constituents that act together for the same goal but at different cellular and subcellular levels (Erejuwa et al. 2012; Oryan et al. 2016; Kamaruzzaman et al. 2019).

It contains no fat and cholesterol contents. However, the use of honey must be with caution. It was reported that there were infiltrations of fat cells in the liver tissue of albino rats fed with honey over a long period. This may result in nonalcoholic fatty liver disease or in other unpleasant conditions harmful to health if not well managed. It has been discovered that long-term administration of honey caused deformation and atrophy of specific reproductive apparatus in laying chickens. Other authors had earlier stated that chronic consumption of unprocessed Nigerian honey resulted in decreased bile flow, increased bile cholesterol, and decreased plasma cholesterol in albino rats. The fear that more cholesterol molecules especially much dreaded low-density lipoproteins may be deposited in the eggs of chickens offered honey is pervading the air. Besides, vitamin A content is important in human nutrition. Improvement in vitamin A content of eggs will go a long way in correcting its deficiency and contribute to the welfare of consumers. Millions of preschool-aged children in developing countries are suffering from vitamin A deficiency, which may lead to blindness (Underwood 1998). The deficiency of vitamin A is a public health issue that needs attention. Fortification of eggs for the children will be a welcome idea, should honey help in achieving this. By-products of honey such as honey slum gum (Babarinde et al. 2011), propolis (Chen et al. 2009), and bee pollen (Wang et al. 2005; Haščík et al. 2012) had been used in broiler production and found to be effective.

Honey is good but must be used with caution, especially in its application in poultry production. In literature, it has been reported that there were infiltrations of fat cells in the liver tissue of rats which was dosage-dependent (Avwioro et al. 2012), decreased bile flow, increased bile cholesterol, and decreased plasma cholesterol (Alagwu et al. 2009) in Albino rats and hypertrophy of follicle, giving it a deformed shape instead of the usual round shape in laying chickens (Abioja and Adekunle 2018). The authors concluded that chronic consumption of honey may increase the risk of hepatic damage.

Naturally occurring solution found inside the fleshy eatable part of coconut called coconut water could also be used as antistress in broiler chickens during heat spells. It contains a lot of bioactive metabolites which have not been explored (Reddy and

Lakshmi 2014). Preliminary studies (Abioja et al. 2015) with diluted coconut water in drinking water as a viable candidate in lowering body temperature in heat and transportation stressed broiler chickens gave a promising results. Saat et al. (2002) stated that coconut water has been used in humans after physical exercise or long journey as an ideal rehydrating and refreshing drink. Its sugar content and mineral composition (electrolytes) have been identified as reason for the usefulness. Coconut water stimulates higher water consumption, which ensures availability of enough water in the body to facilitate evaporative cooling (panting) under hot environmental conditions. Chickens ingest more water under HS conditions. Prades et al. (2012a, b) reviewed the uses, composition, properties, preservation, and processing of coconut water. Major constraint in the adoption of coconut water as antistress in broiler production is in quantity that would be required for a large-scale commercial broiler industry. More research works are necessary to ascertain the appropriate concentration of diluted coconut water for the chickens. However, it can be used easily in small scale, backyard, and family poultry production. Other materials that could be used in ameliorating the negative effects of HS are raffia palm wine, olive leaf extract, and orange peel extract.

Breeding for Thermotolerant Strains in Africa

Broiler chickens reared in the tropics were developed in the cooler regions of the world and introduced into the tropics. They often respond differently under the new environment, mostly growing at lower rate than in their home environment. Thus optimal poultry production in the hot regions therefore requires an adequate and appropriate management system that can reduce the effects of HS to the minimum. Olori (2008) in a review stated that to develop broiler chickens for Africa, an understanding of the factors affecting poultry production such as the climate, production systems, and available feed resources in Africa is required. One of the major constraints in broiler breeding is the fact that productivity traits are negatively correlated with thermotolerance. The available major genes (naked-neck, frizzle-feather, and dwarfism) in locally adapted breeds of chickens all over Africa must be explored. FUNAAB-alpha broiler lines were developed by Professor Olufunmilayo Adebambo and her team from several crosses and selection activities among flocks of Nigerian local chickens. The newly developed chicken lines had just been registered and tested in different agro-ecological zones of the Nigeria and parts of West African coast.

A recent report on the on-station performance evaluation of improved tropically adapted chicken breeds for smallholder poultry production systems in Nigeria was given by Bamidele et al. (2019). The authors in the study identified FUNAAB Alpha and Noiler as being more suitable for dual-purpose functions (egg and meat), while Sasso and Kuroiler (meat) and Shika-Brown (egg) were observed to be better suited for single purpose functions. Chickens bred taken into consideration the climate of African land should be given preference as the pangs of climate change is envisaged. Breeds like FUNAAB-alpha, Kuroiler, Noiler, Sasso, and Shika-brown chickens are now becoming popular in the hot regions of Africa.

Others Adaptation Options

Organization of enlightenment programs, workshops, and trainings for the broiler producers and stakeholders on adaptation of broiler chickens to climate change from time to time by governmental agencies is necessary in Africa. Awareness and advocacy about climate change should be extended to the young people and other categories of people. Sustainable Development Goals should involve younger generations of African populace in schools where they can be furnished with adequate and up-to-date information about climate change. Indigenous technical know-hows of the African peoples, in forms of herbs, extracts, and other phytochemicals should be explored in keeping broiler chickens adapted to impending global warming.

Conclusion

As the evidences of climate change are becoming more pronounced over Africa, various adaptation options available for broiler production in literatures include building housing systems that ensure climate amelioration for the birds, manipulations of feed and feeding systems, supplying adequate water of good quality, ensuring adequate stocking density, use of natural phytochemicals that ensure balanced oxidative status in the body system, and breeding for thermotolerant strains in Africa. Enlightenment programs should be organized for poultry farmers by governmental and nongovernmental agencies on the climate change mitigation, adaptation, and resilience strategies in order to improve livelihood of the people in a sustainable manner.

Contents

Abstract

This chapter examines the impacts of climate change on three tropical crops and assesses the climate change adaptation options adopted by rural farmers in the region. The study was conducted among farming communities settled in three major ecological zones in Nigeria. Over 37 years of data on rainfall and temperature were analyzed to examine climate change impacts on three major crops: rice, maize, and cassava. Farmers' adaptive capacity was assessed with a survey. Climatic data, crop yields, and survey data were analyzed using both descriptive and inferential statistics. The relation between rainfall/temperature and crop

yields was examined using the Pearson correlation coefficient. Results show a high variation in the annual rainfall and temperature during the study period. The major findings from this research is that crops in different ecological zones respond differently to climate variation. The result revealed that there is a very strong relationship between precipitation and the yield of rice and cassava at $p < 0.05$ level of significance. The results further showed low level of adaption among the rural farmers. The study concludes that rainfall and temperature variability has a significant impact on crop yield in the study area, but that the adaptive capacity of most farmers to these impacts is low. There is a need for enhancing the adaptation options available to farmers in the region, which should be the focus of government policies.

Keywords

Adaptation · Climate change · Crop yield · Impacts · Nigeria

Introduction

Given their impacts on both natural and human systems, climate variability and climate change have become topical issues in recent research. As the changing nature of weather and climate directly relates to crop yields, climate change impacts on the agricultural sector and food systems have been the focus of a growing number of works, including research in many African countries (Adenle et al. 2017; Morton 2017; Serdeczny et al. 2017; Molua 2020). Such studies have reported that rainfall and minimum and maximum temperatures are the most important climatic elements for agricultural production. The scenario over the years is that these climate parameters, especially rainfall patterns, have varied, with some high confidence of change in their patterns in recent years, as perceived through indigenous knowledge of people globally (Adejuwon 2005; Ayanlade 2009; Sowunmi and Akintola 2010; Moylan 2012; Adamgbe and Ujoh 2013; Pablo and Antonio 2015; Ayanlade et al. 2017). The multi-hazard events climate change occasions comprising of windstorms, wildfire, rainstorms, droughts, and dust storms which maybe become more frequent with increased severity in the nearest future. There are several pieces of evidence in the literature that land use and land cover change (Ayanlade 2017; Fourcade et al. 2019), sea-level rise (Agboola and Ayanlade 2016; Varela et al. 2019), and changes in onset will pose significant long-term challenges. There have been changes that can be identified by alteration in the mean or variability of climate properties and that have persisted for an extended period. Consequently, climate change will pose imperative short-term and long-term bottlenecks to agricultural production, particularly for rural farmers who depend on rainfall for cultivation (IPCC 2007; Heltberg et al. 2009; Ayanlade et al. 2018b; Ayanlade and Ojebisi 2020).

Agriculture is vulnerable to climate change as crops are sensitive to rising temperatures and changing rainfall patterns. Rising temperatures and erratic rainfalls threat food crop production, thus exacerbating food insecurity and poverty (Sanchez 2000;

Oluoko-Odingo 2011; Seaman et al. 2014). The impacts of climate change on agriculture are likely to intensify in the future as climate models have predicted increasing temperature and more erratic rainfall with the potential increase in the intensity and frequency of extreme weather events (Wright et al. 2014; Ayanlade et al. 2018a; Hein et al. 2019). For example, some studies have suggested that climate change will reduce the yield of crops like maize, rice, and cassava by 15–25%, partly because climate change will alter the incidence and severity of pest and disease outbreaks, indirectly affecting crop production and yield (Harvey et al. 2018). Even though climate change portends serious dangers to agriculture, current studies on climate change impacts on the agricultural systems of Nigeria suffer from several gaps. First, previous studies have mostly focused on crops like yam, coffee, cocoa, sorghum, etc. (Ayanlade 2009; Ayanlade et al. 2009; Ajetomobi 2016). Other studies on the topic have used short-term data, although long-term data is more accurate in delineating climate change effects on agricultural practices (Adejuwon 2005, 2012). Thus, previous research on this topic has treated Nigeria as a single ecological zone. To fill these gaps, the present study focuses on climate change impacts on three crops that have not previously received attention (i.e., rice, maize, and cassava) and using data from three (3) different states in Nigeria, falling within three different ecological zones: Ondo (Rainforest), Ogun (Freshwater), and Kwara state (Guinea savanna). This spread will importantly give room for spatiotemporal comparison. More so, this study involves the indigenous knowledge of climate change, effects, impacts, and adaptation practices among the rural farmers. Rural farming is very important in this part of the world for the provision of food and productive employment for many people.

Climate Change Assessment in Selected Ecological Zones in Nigeria

Research as conducted in three different sites (Fig. 1), representing three different ecological zones: Ondo (rainforest located within latitude 7°10′N, 7°15′N and longitudes 5°5′E and 5°83′E); Ogun (freshwater, located between on latitude 6°12′N and 7°47′N and longitude 3°0′E and 5°0′E); and Kwara (savanna, located between latitude 7°45′N and 9°30′N and longitude 2°30′ and 6°25′E). The three sites fall within the tropical wet and dry climate of Koppen's climate classification, dominated by a wet and a dry season. There are, however, some variations between sites. The climate of Ondo State corresponds to a lowland tropical rain forest type, with a mean monthly temperature ranging from 19 °C to 30 °C (mean monthly value of 27 °C) and a mean relative humidity 75% (Owoeye and Sekumade 2016). The mean annual total rainfall exceeds 2,000 mm. In the northern part of the state, there is marked dry season from November to March with little or no rain, for which the total annual rainfall in the north is of about 1,800 mm (Jamie 2016). Differently, Ogun state is characterized by a tropical climate consisting of two distinct wet and dry seasons. The long dry season extends from November to March. The annual rainfall value ranges between 1,400 and 1,500 mm with a relatively high temperature of an average of 30 °C. The average temperature value varies from one month to another,

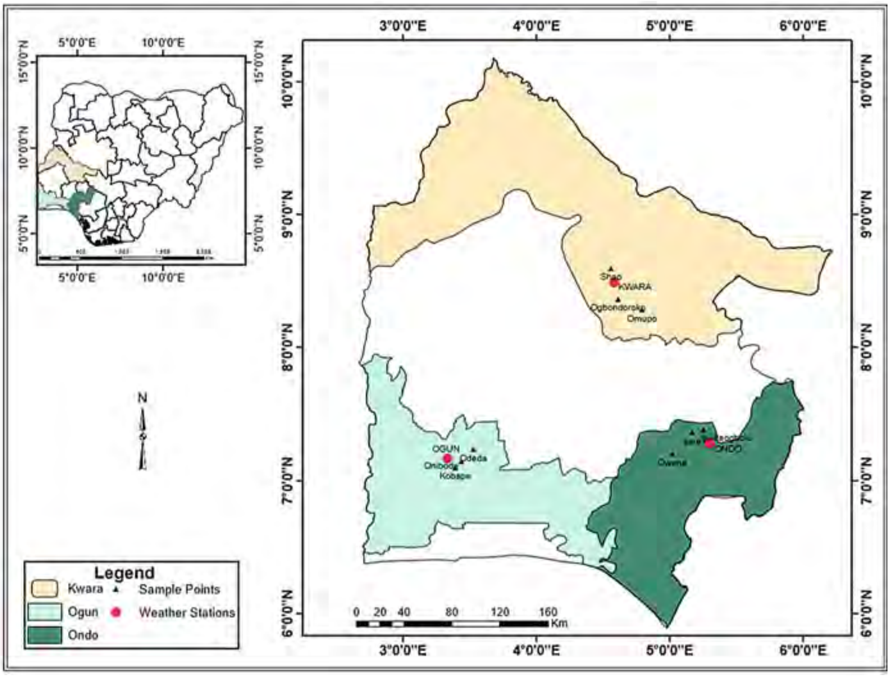

Fig. 1 Study area: Ondo, Ogun, and Kwara states in western Nigeria

with a minimum average of 25.7 °C in July and a maximum of 30.2 °C in February. The humidity is lowest at the peak of the dry season in February usually at 37–54% and highest between June and September with a value of 78–85% (Adeleke et al. 2015). Kwara state (Oladimeji et al. 2015) enjoys an annual rainfall ranging from 1,000 mm to 1,500 mm with the rainy season beginning at the end of March and lasting until September while the dry season starts in October and ends in March (Oriola et al. 2010). The temperature of the state is uniformly high and ranges between 25 °C and 30 °C throughout the wet season except for July and September in which the cloud cover prevents direct insolation. In the dry season, the temperature ranges between 33 °C and 34 °C. In the rainy season, the relative humidity in Kwara state ranges between 75% and 80% while in the dry season it is about 65% (Akpenpuun and Busari 2013).

Ondo is an agrarian state with large-scale production of crops like cocoa, yam, cocoa, coffee, and rubber and huge forest reserves of about 2,008 km^2 which produce timbers for furniture, fuelwood, and industrial uses. Ogun is also an agrarian state with the production of arable crops like maize, rice, cassava, and melon. Several other identifiable modern economic activities exist in Ogun, including insurance, motor companies, petrol stations, and light and heavy industries. The major economic activity of Kwara state is farming, with a particular predominance of cash crops like cocoa, coffee, kolanut, tobacco, beniseed, and palm. Food crops like cereals (rice, maize, millet) and tuber crops (yam, cassava, cocoyam, etc.) are grown in Kwara (Oluwasusi and Tijani 2013).

Daily climatic data of rainfall and minimum and maximum temperatures were used for this study. The data, spanning for a period of 37 years (1982–2017), were collected from the synoptic stations (Fig. 1) located at Akure (Ondo state), Ilorin (Kwara state), and Abeokuta (Ogun state). The data were collected by the Nigerian Meteorological Agency (NIMET) at the stations using the British Standard Rain gauge and Dine's tilting siphon rainfall recorder for rainfall and thermometer for temperature. To establish the pattern of climate, a year running mean was used in the analysis to show the annual fluctuation of rainfall and temperature. Mean of daily data were averaged to get the annual mean for temperature (minimum and maximum) and rainfall using MS Excel. Sigma Plot (Version 10.2) was used to plot the graph for annual rainfall, and minimum and maximum temperature against the year covering the study period; the curves were then fitted to show the linear trend. Three crops, that is, maize (cereal), rice (cereal), and cassava (tuber), were used for this study. In this research, climate factors are seen as one of the important requirement for the yield of the crops, as normal seasonal water requirements of maize, for example, is between 400 and 600 mm (Phiri et al. 2003). Maize and rice are common crops in all three zones. Crop yield data were obtained from the archives of Agricultural Development Project (ADP) offices in Ondo, Ogun, and Kwara states. Data were analyzed using the Pearson correlation coefficient between crop yields and climatic data. This was done using the formula below:

$$r = \frac{N\sum xy - (\sum x)(\sum y)}{\sqrt{\left[\sum x^2 - (\sum x)^2\right]\left[N\sum y^2 - (\sum y)^2\right]}}$$

where N is the number of pairs of scores, $\sum xy$ is sum of the products of paired scores, $\sum x$ is sum of scores, $\sum y$ is sum of y scores, $\sum x^2$ is sum of squared x scores, $\sum y^2$ is sum of squared y scores, x is the crop yield, and y is the climate data.

Social survey data for the study were collected from farmers with the aid of questionnaires and focus group discussion. Our survey instrument was designed to assess farmer's adaptive capacity. Data were collected among farmers who are purposively selected across the three states under consideration. Criteria for inclusion in our sample were to be in a settlement where maize, rice, and cassava are cultivated and to be 30 years and above. These criteria ensured the collection of data among experienced farmers who had witnessed different farming seasons. The responses from the questionnaires were analyzed using both descriptive and inferential statistics. The major aim of social survey is to obtain information from the farmers on how the yields have been over the years and compare it with changes in climate.

Annual Variability in Rainfall and Minimum and Maximum Temperature

Rainfall data for a 37 years period revealed a variation in the annual mean amount of rainfall (Fig. 2). Rather than an absolute change, results for all the three stations show rainfall variability. The rainfall in Kwara is below normal, a little above normal

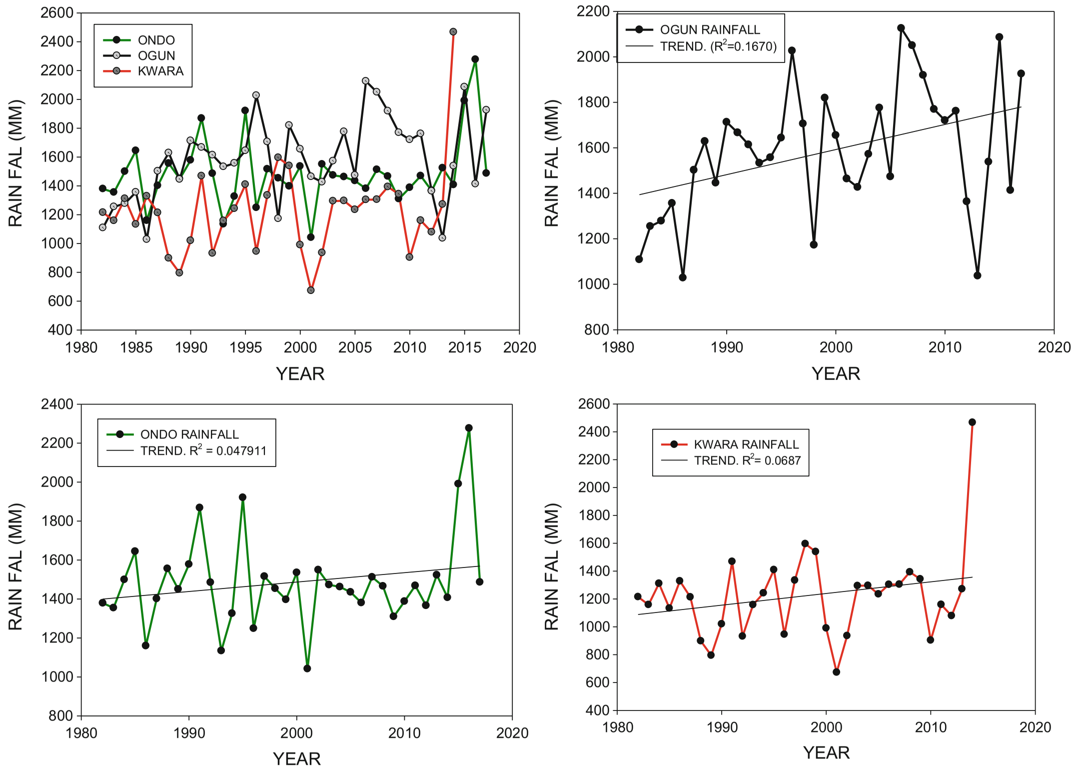

Fig. 2 Rainfall variability in the study area

in Ogun, and varied in Ondo. The rainfall variability found in the data can be attributed to seasonal and interannual climatic variability, which is much more several particularly in the savannah region where Kwara is located (Adejuwon 2004; Odekunle et al. 2007; Ayanlade 2009). As depicted in Fig. 2, annual rainfall was mostly below average before 2010, but varies greatly in the last decade, with readings above average in all the stations. Rainfall peaked in 1991 (with 1,982 mm) and 1995 (1,999 mm) in Ondo state, with 2016 (2,206 mm) recording the highest rainfall during the study period (Fig. 2). In Ogun state, rainfall peaked in 1996 (2,026 mm), 2006 (2,216 mm), and 2015 (2,086 mm), with 2006 recording the highest rainfall. Finally, in Kwara, rainfall peaked in 1991 (1,468 mm), 1995 (1,409 mm), 1998 (1,596 mm), and 1999 (1,539 mm), with the highest peak recorded in 2014 (2,467 mm) with a very unusual high value. Generally, the annual average of rainfall was lowest (673 mm) in Kwara state, with similar values in Ogun (1,028 mm in 1986 and 1,037 mm in 2013) and Ondo states (1,041 mm). Values follow an expected pattern, with higher values in the rainforest ecological zone close to the ocean and lower values in inward zones closer to the savanna. Ogun state received the highest rainfall between 1995 and 2010. The highest rainfall within a year was recorded in 2014 in Kwara, the state belonging to Guinea savanna ecological zone, which recorded a value slightly above the peak of rainfall in Ondo (which belongs to the forest ecological zone).

Climatic variability in the study area can be linked to global climate oscillating systems as El Niño – Southern Oscillations, sea surface temperatures (SSTs), and Inter-Tropical Discontinuity (ITD) have been reported to be responsible for inter-annual variability in Africa climate (Stige et al. 2006). Such climate variability can cause negative departures from normal climate, as documented in a part of Nigeria and elsewhere (Ashipala 2013; Owusu et al. 2015; Ayanlade et al. 2018a). Studies have further revealed that rainfall associated with SST strongly influences rainfall variability in Nigeria in conjunction with the role of the ITD as the equatorial displacement of the Atlantic Subtropical High suppresses the northward summer migration of the ITD thereby resulting into rainfall variability (Bello 2008; Ayanlade et al. 2019).

High variability was observed in the maximum temperature of all stations between 1982 and 2017 (Fig. 4). The temperature was highest in Kwara state, the northernmost state which falls within the Guinea savanna – an area dominated with relatively low rainfall and high temperature – and lowest in Ondo state, the southernmost state. Ondo and Ogun state recorded temperatures below average between 1982 and 2010. However, temperatures have experienced an increase from 2012 till date, especially in Ogun state with the temperature higher gradually increases. As shown in Fig. 3, all the stations experienced similar minimum temperatures patterns from the early 1980s. Temperature oscillations in the maximum temperature were recorded between 1990 and 2010 in Ondo and Ogun with an upward trend observed only in Kwara, though from 2010, the temperature has generally increased in all stations (Figs. 3 and 4).

As shown in Fig. 3, the annual minimum temperature is highest in Ogun state with the lowest value in 1994 (22.8 °C), a value that coincides with the highest

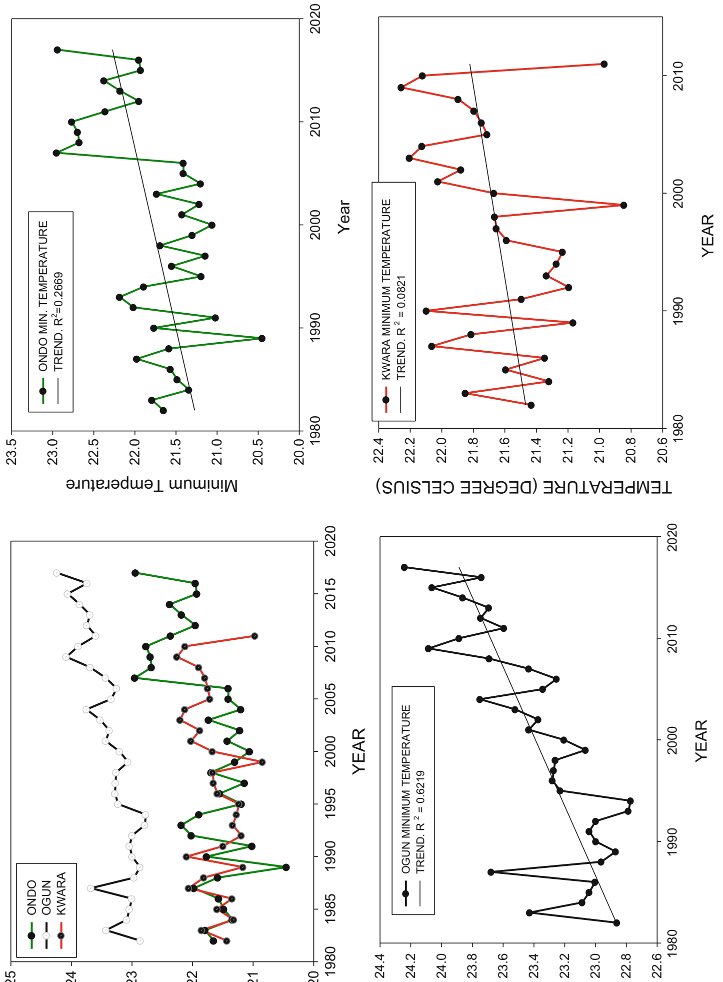

Fig. 3 Minimum temperature variability

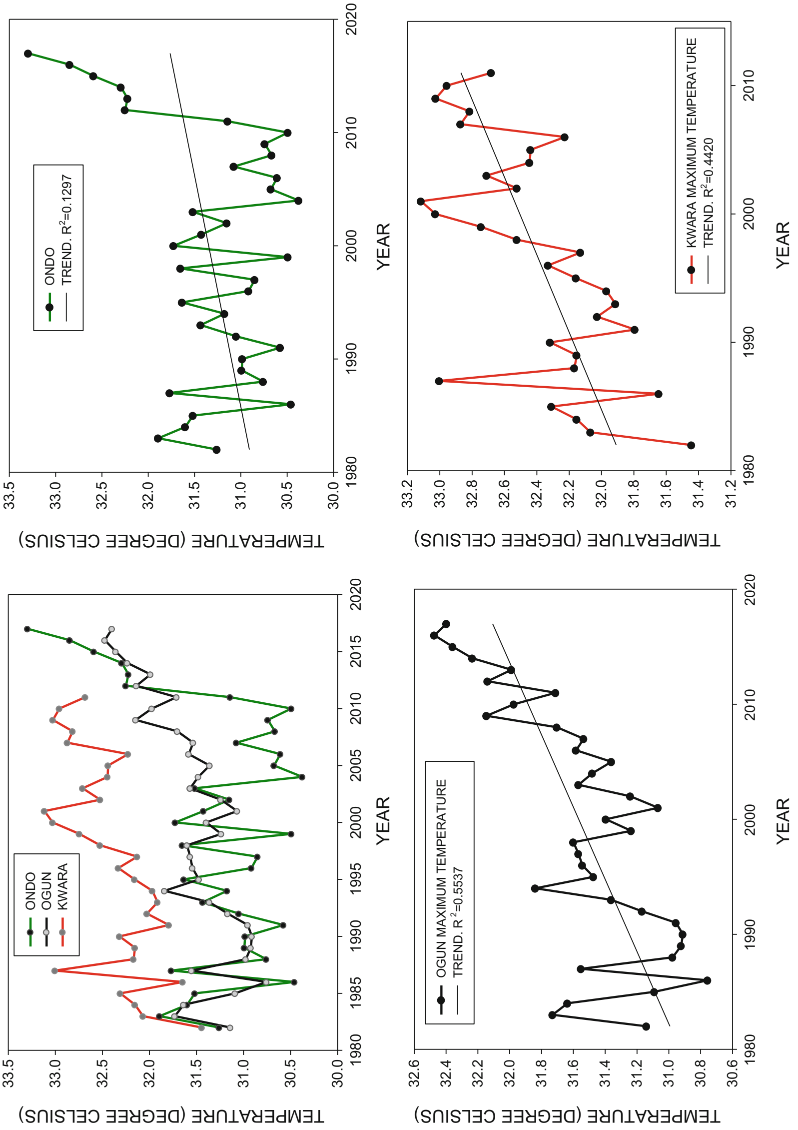

Fig. 4 Maximum temperature variability

minimum temperature in Ondo state. Despite the southern location of Ogun state, the minimum temperature is generally above the minimum temperature for the other two stations, among which Ondo displays the lowest temperature than Kwara. These values represent the highest temperature difference in Kwara and the lowest temperature difference in Ogun state. The period of temperature increase in Kwara state (i.e., years 2000, 2001, and 2002) corresponds to the period of rainfall decrease which could be attributed to increasing temperature and decreasing rainfall as a result of the increasing evapotranspiration and desertification also reported in other areas of Nigeria (Ayoade 2003). The trend of the maximum temperature varies considerably in all stations. However, while the trend is irregular in the early years of the study period, an upward increasing trend was observed in the later years. This recent increase in temperature could be linked to the effect of changes in climate and to the rapid urbanization in the ecological zones under consideration (Mabo 2006).

Relationship Between Climate and Crop Yield

The results of the Pearson correlation analysis between annual minimum temperature and crop yields during the growing season are shown in Table 1. Annual minimum temperature had positive but weak correlation with maize in Ondo (0.142) but not significant at $p < 0.05$, a weak and not statistically significant negative correlation of −0.078 at $p < 0.05$ in Ogun state, and a positive correlation of 0.219 in Kwara at $p < 0.05$. Rice, on the other hand, had a positive but weak correlation of 0.167 which is statistically not significant at $p < 0.05$ in Ondo state while in Ogun state with a positively strong and statistically significant correlation coefficient of 0.674 at $p < 0.05$ and a strong positive and statistically significant correlation coefficient of 0.481 in Kwara state at $p < 0.05$. The correlation coefficient for cassava in Ondo state is a weak and statistically not significant value of 0.22 at $p < 0.05$ while a strong positive and statistically significant correlation coefficient of 0.82 at $p < 0.05$ in Ogun and a positive but not significant correlation of 0.25 at $p < 0.05$. Generally, annual minimum temperature had a strong, positive, and statistically significant correlation coefficient at $p < 0.01$ and $p < 0.05$ in rice for Ogun and Kwara states and cassava only in Ogun state.

Table 2 shows the result of Pearson correlation analysis between annual maximum temperature and crop yields during the study period. The annual maximum temperature had a positive weak and statistically not the significant relationship with maize in Ondo (0.198) at $p < 0.05$, a weak and not statistically significant negative

Table 1 Correlation between minimum temperature and crop yield

	Maize	Rice	Cassava
Ondo	0.142	0.167	0.220
Ogun	−0.078	0.674*	0.820*
Kwara	0.219	0.481*	0.248

*Significant at $p < 0.05$

Table 2 Correlation between maximum temperature and crop yield

	Maize	Rice	Cassava
Ondo	0.198	0.160	−0.115
Ogun	−0.337	0.884**	0.870**
Kwara	0.342	0.773**	0.626**

*Significant at $P \leq 0.05$; **Significant at $P \leq 0.01$

Table 3 Correlation between rainfall and crop yield

	Maize	Rice	Cassava
Ondo	−0.151	−0.091	−0.076
Ogun	0.003	0.136	0.046
Kwara	0.08	−0.220	0.064

*Significant at $P \leq 0.05$; **Significant at $P \leq 0.01$

correlation of −0.337 at $p < 0.05$ in Ogun state, and a positive correlation of 0.342 in Kwara at $p < 0.05$. Rice had a positive but weak correlation of 0.160 which is statistically not significant at $p < 0.05$ in Ondo state while in Ogun state with a positive, very strong, and statistically significant correlation coefficient of 0.88 at $p < 0.05$ and a very strong positive and statistically significant correlation coefficient of 0.77 in Kwara state at $p < 0.05$. The correlation coefficient for cassava in Ondo state is a negative, weak, and statistically not significant value of −0.12 at $p < 0.05$ while a very strong positive and statistically significant correlation coefficient of 0.87 at $p < 0.05$ in Ogun. A positive and significant correlation of 0.63 at $p < 0.05$. Generally, the annual maximum temperature had a strong, positive, and statistically significant association with rice and cassava yields in Ogun and Kwara states but not in Ondo state. The maximum temperature was not associated with maize yields in any of the states.

The result of the Pearson correlation analysis between annual rainfall and crop yields during the study period is shown in Table 3. Annual rainfall had a negative, weak, and statistically not a significant relationship of −0.15 with maize Ondo at $p < 0.05$, a weak and not statistically significant positive correlation of 0.003 at $p < 0.05$ in Ogun state and a positive correlation of 0.08 in Kwara at $p < 0.05$. Rice showed a negative but weak correlation of −0.091 which is statistically not significant at $p < 0.05$ in Ondo state while in Ogun state with a positive, weak, and statistically significant correlation coefficient of 0.14 at $p < 0.05$ and a weak, negative, and statistically not significant correlation coefficient of −0.22 in Kwara state at $p < 0.05$. The correlation coefficient for cassava in Ondo state is a negative, weak, and statistically not significant value of −0.08 at $p < 0.05$ while a positive and statistically not significant correlation coefficient of 0.046 at $p < 0.05$ in Ogun was observed. And a positive, weak, and not the significant correlation of 0.06 at $p < 0.05$ was observed for Kwara state. Generally, annual rainfall had a weak and statistically not significant association with maize, rice, and cassava yields in the three studied states.

Farmer's Adaptive Strategies

Figure 5 shows the percentage error graph of farmers' coping or adaptive capacity toward extreme climatic conditions. According to our results, 16.7% of the respondents are engaged in agricultural diversification, 17.3% are engaged in changing the crops they cultivate, 20.2% are engaged crop rotation, and 19.6% are practicing mixed farming.

As shown in Fig. 5, the farmers are coping or adapting to extreme climatic conditions but generally with low capacity. This is because the results show that 19% of farmers had implemented changes in the size of farmland, 14.9% are engaged in different crop composition, 33.3% are engaged in agricultural intensification, 30.4% are engaged in bush fallowing, 29.8% are changing the daily working time, 47.6% are presently engaged in agroforestry, 27.4% are changing the seasonal timing of sowing, 41.1% are changing the harvest time, 35.7% are into irrigation, 31.5% are into the use of fertilizer, 32.1% are into the use of pesticide, 56.5% are into getting loan and credit facilities, 32.7% are into getting other sources of income so as not to depend on their farm only, 44% are changing the method of storing their food, 27.4% are changing the quantity of food consumed by the family, and 24.4%

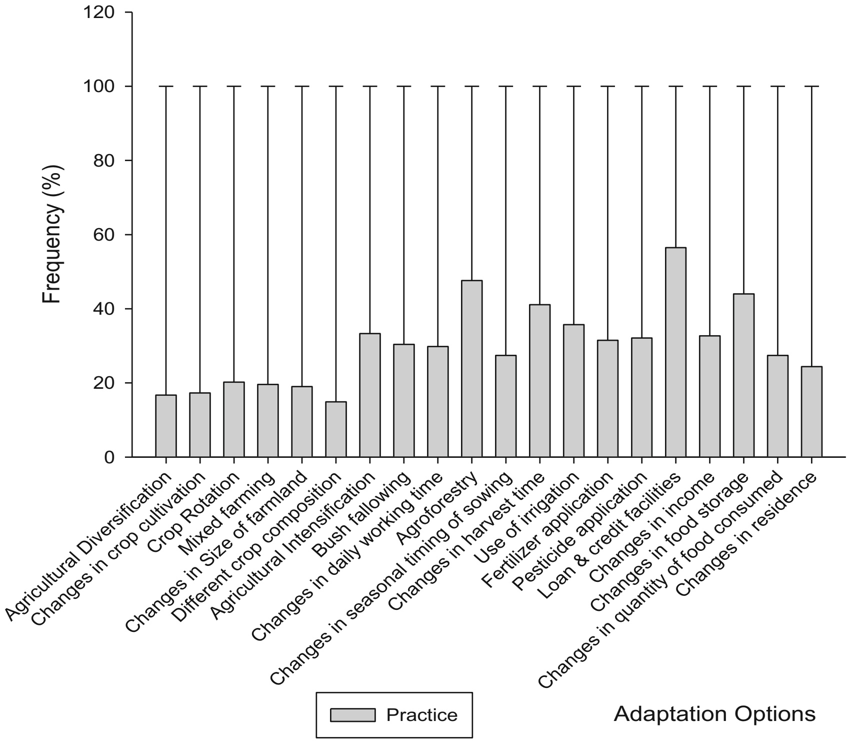

Fig. 5 Adaptation strategies adopted by farmers in the region

are changing their residence by moving to another area for farming. From Fig. 5, seeking for loans and credit facilities, changes in food storage, agroforestry, changing the time of harvest, use of irrigation, use of fertilizer, and agricultural intensification, among others, are the most practiced adaptation options.

Conclusion

The effects of climate variability or climate change on selected crops in selected ecological zones in Nigeria were examined in this study. Results show that minimum temperature, maximum temperature, and rainfall varied both spatially and temporally. The annual minimum temperature, maximum temperature, and rainfall showed that there is the year-to-year fluctuation with pronounced peaks and depressions. While some years show upward trends, some showed a downward trend. Also, there is the month to month variability in minimum temperature, maximum temperature, and rainfall. Crop yields did not depend on rainfall and minimum and maximum temperatures alone. In all the stations, maize yields were less sensitive to minimum temperature than rice and cassava yields. While there appears a negative but weak relationship that is not statistically significant between minimum temperature and maize in Ogun, it has a positive but weak relationship in Ondo and Kwara. Maximum temperature showed a strong positive and statistical association with rice and cassava yields in Ogun and Kwara states. Finally, rainfall was associated with maize, rice, or cassava yields in any state. Many other studies have reported the similar finding of the climate-crops relationships in China (Zhang et al. 2016; Gao et al. 2019; Ding et al. 2020), Southern Africa (Mafongoya et al. 2017; Nhamo et al. 2019) and East African countries (Sridharan et al. 2019; Thomas et al. 2019). These results dovetail with results from previous research. Thus, although an increasing trend in rainfall and temperature may affect rice yields, a study in Bangladesh showed that despite an increasing rainfall and temperature, the yield of rice is not negatively affected (Rahman et al. 2017). Matched with the results of the present study, the rainfall can, therefore, have a positive or negative impact on the yield of crops depending on its distribution and intensity over the growing season. Furthermore, the present study revealed that farmers' perception of climate variability/change impacts on crop yield varied spatially. The majority of farmers believed that average temperature of the coldest month, rain generally, rain during the rainy season, and rain during the dry season were believed to have changed in recent years in Ogun and Kwara by higher numbers of respondents, while statistical analyses showed that there is variation while in Ondo state, the farmers believe that "the temperature is warmer generally, the temperature of the hottest season is warmer, rain is higher in the rainy and dry seasons with extreme drought less frequent, onset earlier, rainy season duration longer." The temperature of the hottest month was believed, though, to be warmer by a higher proportion, as claimed by the farmers. Many believe that extreme floods are more frequent while extreme drought and duration of the rainy and dry seasons have remained the same. According to Tripathi and Mishra (2017), farmers are aware of long-term changes in climatic factors (temperature and rainfall) but are unable to identify those changes as climate change. However, many farmers are not taking concrete steps in dealing with perceived change in climate but are changing their agricultural and farming practices (Ayanlade et al. 2018a) which can be said to be passive response to climate change. Farmers' perception of climate is probably responsible for low adaptation to climate change.

Acknowledgments This study is part of the research project carried out with the aid of a grant from the International Development Research Centre, Ottawa, Canada, and with financial support from the Government of Canada, provided through Global Affairs Canada (GAC), under the framework of the Mathematical Sciences for Climate Change Resilience (MS4CR) program administered by AIMS (2018 cohort of AIMS). The research was also partly funded by an ERC Consolidator Grant to Reyes-García (FP7-771056-LICCI).

Plants and Plant Products in Local Markets Within Benin City and Environs

18

Moses Edwin Osawaru and Matthew Chidozie Ogwu

Contents

Abstract

The vulnerability of agriculture systems in Africa to climate change is directly and indirectly affecting the availability and diversity of plants and plant products available in local markets. In this chapter, markets in Benin City and environs were assessed to document the availability of plants and plant products. Markets were grouped into urban, suburban, and rural with each group having four markets. Majority of the plant and plant product vendors were women and 88 plant species belonging to 42 families were found. Their scientific and common names were documented as well as the parts of the plant and associated products available in the markets. Most of the plant and plant products found in local

markets belong to major plant families. Urban markets had the highest diversity of plants and plant products. Three categories of plants and plant products were documented. Around 67% of the plants and plant products were categorized as whole plant/plant parts, 28% as processed plant parts, while 5% as reprocessed plant/plant parts. It was revealed that 86% of these plants are used as foods, 11% are for medicinal purposes, while 3% is used for other purposes. About 35% of plants and plant products across the markets were fruits, which is an indication that city and environs are a rich source of fruits. The local knowledge and practices associated with the plants and plant products can contribute towards formulating a strategic response for climate change impacts on agriculture, gender, poverty, food security, and plant diversity.

Introduction

The utilitarian nature of humans is driving the massive extinction of biodiversity, climate change, and ecological vulnerability. However, a greater understanding of plant-human interactions can contribute to sustainable development, addressing climate change and biodiversity loss, food security, and poverty reduction. All plants are considered important and can potentially serve to fulfill one or more of our basic needs – food, shelter, and clothing as well as environmental integrity. Plant product refers to goods and services derivable from plants and may include whole plant or plant part (used as ingredients and condiments). Proper local and scientific identification of plant materials is necessary to determine and predict the role of a plant and this will require a general knowledge of botany, sociology, and anthropology. Plant is essential for our continued survival on earth as they directly or indirectly provide food for survival, medicine, fibers, chemical products, and other commodities as well as to protect and maintain the environment against erosion, used to cure disease and relieve from suffering. Many industries are dependent on plants for their raw materials. Some of the most outstanding materials of modern civilization are obtained from plants, such as wood, tanning materials and dyestuffs, oils, resins, gums, varnishes, beverages, etc. Plants provide raw material for industrialization and are basis of the green revolution and a pillar for food security. The esthetic value of plants has no small influence on man's overall life satisfaction, as evidenced by the host of garden enthusiasts and flower lovers. Plants are also the basis of a vegan lifestyle.

In the economy of nature, the production and distribution of plant products have a profound influence on the environmental, economic, and social life of a nation with both domestic and international influence. The maintenance of an adequate supply of food and plant-based industrial raw materials is essential to the existence, as well as the prosperity, of any nation (Burkill 1985). Additionally, plants also have important roles in the tribal, social and cultural life of man (Osawaru and Dania-Ogbe 2010; Osawaru and Ogwu 2014a). Local markets are an integral part of life and cultural practice of the people especially in developing countries as a social, economic, and ecological institution. Plant products available in the market can be used as an indicator for biodiversity richness, climate changes effects, and agricultural vulnerabilities. This is more important in Africa, which according to Ogwu (2019) the environment and agriculture systems are most vulnerable climate change. Markets in rural parts of Africa are often scheduled at considerable day interval, whereas in urban and semi-urban centers, it is mostly open every day or night. Sellers have their stalls or place while hawkers also patrol the market with their various plants and plant products. Markets are rich sources of information on plants and plant products as well as an easily accessible and cost-effective place for plant-based fieldwork and germplasm collection. Markets can provide qualitative and quantitative data concerning cultural, social, and economic aspects of a plant's usage (Bye and Linares 1983; Martin 1992; Cunningham 2001). Moreover, markets are recognized as a vital botanical record of the history of useful plants in a region (Whitaker and Cutler 1966). They are places of intensive interaction between people and plants.

Local traders (mostly women) are very knowledgeable about the uses of plants and their seasonal availability. This knowledge is vital in the global response to global climate change and massive loss of biodiversity in this sixth extinction era. In Nigeria and West Africa, market vendors are known to deal in certain types of plants and plant product and are found clustered together, which imposes a sort of market influence such as fixed prices for their commodities. However, traders have certain concession such as monopoly to regular customer and slight price variations. Moreover, the survey of marketplaces provides information about food and nutritional value of plant and products as well as their ethnobotany (Nguyen 2005). Findings from such studies have been used to draw interesting conclusions and hypothesize about human-environmental-plant interactions and relationships. Climate change, migration, and economic forces can influence the availability of certain plant and plant products in the market. Obiri and Addai (2007) surveyed economic plants in Kumasi central market and documented a total of 150 plant species from 55 families most of them had multiple uses – 57% and 20% used for medicinal and food purposes, respectively. Idu et al. (2010) documented the medicinal plants sold in markets in Abeokuta, Nigeria, revealed 60 medicinal plant species used for traditional health management. The ethnobotanical survey of Yaradua and El-Ghani (2015) reported 54 plants belonging to 33 families from Katsina metropolis markets. The objective of this chapter is to identify and document the plants and plant products sold in local markets in Benin City and environs.

This chapter will compare the diversity of the plants and plant products available in local markets in urban, peri-urban, and rural centers in Benin City, Southern Nigeria. Thereafter, this chapter will categorize the plants and plant products based on the level of processing it was subjected to as well as their taxonomic families. The results will seek to promote local markets as a reservoir of plant germplasm and contribute towards understanding of how climate change vulnerability is affecting agriculture system in Edo state, diversity of plant and plant-based food materials available in local markets that can potentially contribute to addressing food security, poverty, and sustainable development. It will also highlight the plant parts and plant products sold in the markets.

Plants and Plant Products in Local Markets: The Case of Benin City and Environs

There are numerous open markets in Benin City (latitude 06° 19′00″ E to 6° 21′00″ E and longitude 5° 34′00″ E to 5° 44′00″ E; average elevation of 77.8 m above sea level; 2006 est. pop. 1,147,188 with an annual growth rate of 2.9%), which is one of the oldest cities in Nigeria and the capital of Edo State, Southern Nigeria. It is within the tropical rainforest zone of Nigeria with an estimated area of 550 km^2. Geologically the city has a sedimentary formation of the Miocene-Pleistocene age. Benin has an undulating topography with a vegetation type characterized by lowland rainforest and an annual average rainfall of 800 mm. A 35-year study by Floyd et al. (2016) revealed massive climate fluctuations especially in average rainfall, temperate, humidity and suggested that it is impacting plant production and environmental changes due to soil erosion. The fluctuation is attributed to high anthropogenic activities in Benin City (Efe and Eyefia 2014). With increased warming, flooding, and urbanization, agriculture and food production are threatened in Benin City (Atedhor et al. 2011).

Benin is the center of Nigeria's rubber industry, but processing palm nuts for oil is also an important traditional industry. Benin has numerous local markets strewn across the city to cater to the needs of its inhabitants as well as to serve as a sales outlet for the numerous farm produce cultivated in the rural areas of the state as well as in urban home gardens. The nodal nature of Benin makes it an ideal place for various commercial activities as these farm produce can be easily transported to cities like Lagos, Abuja, and Port Harcourt. Benin City is endowed with a wide diversity of plants and plant products. The sales of plants and plant products play a key role in the sustenance of livelihoods of people providing income, employment, food, and medicines among others in Benin City and environs. Some of the local markets in Benin City and environs are God's Market (Ekiosa), Oba Market (Ekioba), New Benin Market, Santana Market, Uselu Market (Ediaken Market), Oliha Market, Ugbogiobo Market, Evbuotubu Market, Oregbeni Market (Ikpoba Hill Market), Ekiadolor Market, Iguobazuwa Market, Ehor Market, and Usen Market.

The sampling frame considered markets within Benin City and environs, which were delimited into three categories according to the status defined by Osawaru and Odin (2012) – urban, peri-urban, and rural. A reconnaissance visit was undertaken to all the local markets in Benin City and environs. Twelve markets were randomly selected for sampling. They consist of four urban, four peri-urban, and four rural markets (Table 1).

Table 1 Sampling sites for the survey of plants and plant products in Benin City and environs

Market	Category	Local government area
New Benin	Urban	Oredo
Uselu	Urban	Egor
Oba	Urban	Oredo
Oregbene	Urban	Ikpoba-Okha
Evbuotubu	Peri-urban	Egor
Ugbogiobo	Peri-urban	Ovia North East
Ugbiohioko	Peri urban	Egor
Iguobazuwa	Peri-urban	Ovia South West
Ehor	Rural	Uhunnwode
Usen	Rural	Ovia North East
Ekiadolor	Rural	Ovia North East
Ugbogui	Rural	Ovia South West

In each market, ten traders of mixed age and sex were randomly selected and plants and plant products in their stalls were assessed. Each market was visited three times. First, to map out the randomly selected informant, secondly, to administer the questionnaire and inventory the plants and plant products, and finally, to seek clarity for some questions outlined in the questionnaire. Responses via the questionnaires were retrieved from the questionnaires, translated and scored by typing into Microsoft Excel, and analyzed quantitatively. Plants and plant products were categorized according to Osawaru and Odin (2012) i.e.,

1. 1^0 of plants and plant products-whole plant/plant part
2. 2^0 of plant and plant product-processed plant part
3. 3^0 of plant and plant product-reprocessed plant/plant part

Majority of the traders encountered in the markets were women. This confirms the findings of De Caluwe (2011) and Agea et al. (2011) that trading in plant and plant products are dominated by women. In a different study, Osawaru and Ogwu (2014b) also established that women contribute significantly to holding plant germplasm. These findings underscore the importance of women in the fight to address the effects of climate change especially food security and sustainable agriculture. Moreover, the sales of plants and plant products in the different markets were practiced by different tribes and ethnic groups in all the markets surveyed.

A total of 88 plants and plants product was found in all the local markets assessed (Table 2). The botanical and common names, forms, diversity, and categories of the plant and plant products sold in local markets within Benin City and environs are presented in Table 2. These 88 plants and plant product are distributed into 42 families. Presence of plant and plant products varies in the different markets. For instance, *Adansonia digitata*, *Brassica oleracea, Cucumis sativus, Cucurbita pepo, Cyperus esculetus, Dialium guineense, Ricinus communis, Pennisetum glaucum, Pentaclathra macrophylla, Myristica fragans,* and *Phoenix dactylifera*

Table 2 Diversity of plants and plant products in 12 local markets within Benin City and environs

Botanical name	Family	Common name	Form/product type	Local name (Bini)	Urban market	
					New Benin	Uselu
Abelmoshus esculentus L.	Malvaceae	Okra		Ikhiav-bo	+	+
Adensonia digitata L.	Malvaceae	Baobab			+	+
Allium cepa L.	Liliaceae	Onion		Alubara	+	+
Allium sativum L.	Liliaceae	Garlic			+	+
Amaranthus caudatus L.	Amaranthaceae	Spinach		Ebaafor	+	+

were more common in urban markets than in rural markets. On the other hand, *Tetrochidium didymostemon, Xylopia aethiopica, Anacardium occidentalis*, *Bombax buonopozense,* and *Dacryodes edulis* were found mostly in rural markets. However, this trend might not translate directly into plant diversity in urban and rural centers but their utilization patterns. In Benin City, peri-urban markets mostly act as a transition zone for rural and urban markets. Previous investigations of rural markets in Nigeria by Johnson and Johnson (1976) recorded 58 species of plants sold in Nigeria, Keratela and Hussain (1990) reported 21 species, Gill et al. (1993) recorded 93 plants, Idu et al. (2010) reported 103 and Osawaru and Odin (2012) reported 117. The difference in the number of plants recorded from the different study might be related to the season when the study was undertaken as well as the agricultural yield of the previous seasons and change in attitude, taste, where vendors source their plants, prevailing economic and environmental conditions. Mekasha and Tirfe (2019) highlighted that the marketing of agricultural produce requires planned production, grading of products, transportation to markets, distribution, pricing, and advertisement. Most of the plant species found in the markets are exotic. This supports the report of Muhanji et al. (2011) and Ogwu et al. (2016, 2017) which opined that the colonial era introduced and promoted the production and sale of plants exotic to Africa. Overall, the plants and plant products distribution across the market ranged from 58 to 83 in all the markets assessed (Fig. 1). There are more plants and plant products in urban markets compared to peri-urban and rural markets. This might be due to the higher food demands of the growing urban population, urbanization policies, greater economic power, and migration (Romanik 2008; Ogwu 2019). If the current urbanization trend is left unchecked, it might increase the vulnerability of African cities to climate change as well as challenges associated with food security. Another reason for the high distribution of plant species in urban markets might be the large size of these markets and the age-long attitude of rural dwellers to bring their farm produce to city centers for sale. The least diversity was in Usen Market while Uselu Market had the highest species composition. Overall, the urban markets had higher species composition. Next to the urban markets were peri-urban markets in plant and plant product abundance.

Plant products found in the different markets were assessed based on the level of processing that has been done to the plants. The classification of plant processing included first, second, and third-degree of plant and plant products (Fig. 2). The first degree of plant and plant products refers to the whole plant or plant part, while the second degree of plant and plant products and third degree of plant and plant products are processed and reprocessed plant or plant parts, respectively. It was also observed that most plant products were only processed once before been presented for sale in the markets (Fig. 2).

Plants and plant products in the local markets can be grouped into cereals (e.g., maize, rice, guinea corn, millet etc.), legumes (e.g., beans, groundnut, soybean etc.), stem tubers (e.g., yam and Irish potato), root tubers (e.g., cassava, carrot and sweet potato), fruits (e.g., pawpaw, orange, pineapple, mango, banana, pear, etc.), vegetables (e.g., waterleaf, bitter leaf, *Amaranthus* sp., *Celosia* sp., pumpkin leaf etc.), nuts (e.g., coconut), oil (e.g., palm fruit), spices (e.g., pepper, onion, ginger, garlic etc.).

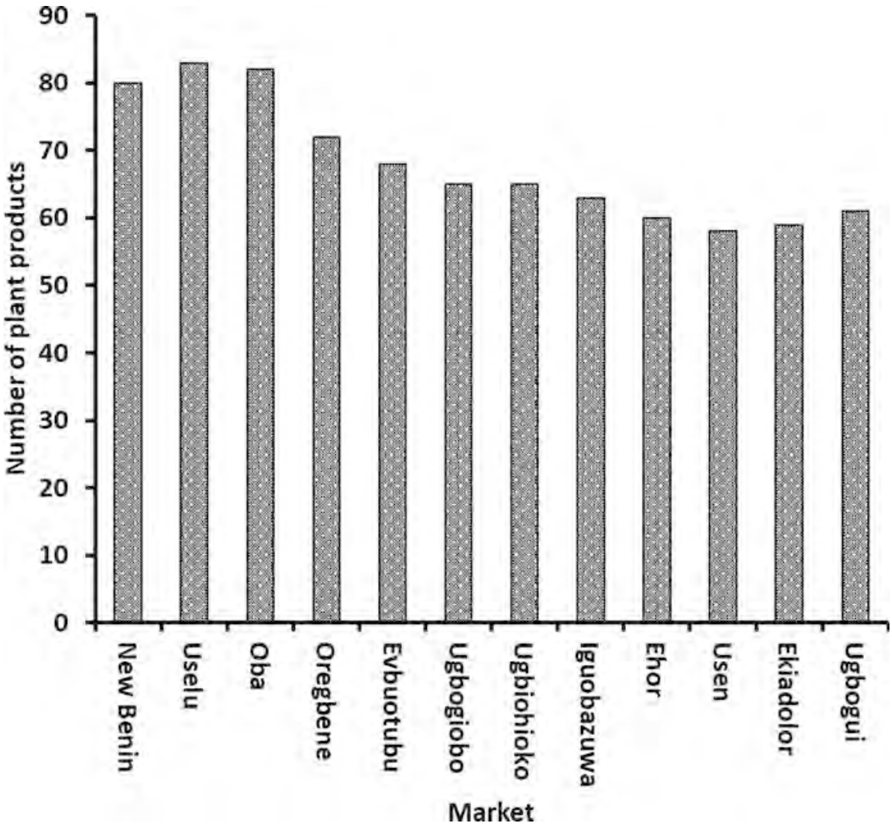

Fig. 1 Number of plants and plant products in local markets in Benin City and environs

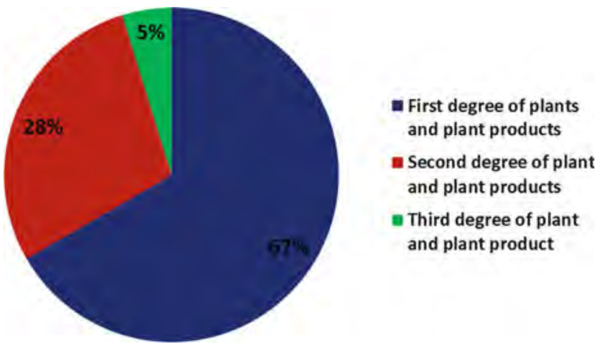
Fig. 2 Category of plants based on forms in which they are available in the market



The dominance of first degree processed plant products could be attributed to the near lack of government support for the agriculture sector of Nigeria. It also suggests Nigerians might prefer plant products that have undergone little to no processing. It was observed that the availability of plants and their products rely on seasonal variations. The plants and plant products were seen in different forms in the markets depending on the season. Markets are made up 90–99% of plants and plant products. Some of these products may have been to the 3rd degree of processing, for example, Rain boot, etc. However, not all part of the plant may be essential. These forms are fruits, leaves, rhizomes, bulbs, corms, stem tuber, root tuber and also in processed forms such as fufu, gari, and cassava flour from cassava; oil, broom, and basket from oil palm; tomato paste from tomato, etc. These different forms are the status in which these plants and plant products are best sold and preserved. This is in line with the report of Idu et al. (2005).

The utilization pattern of the plants and plant products is presented in Table 3. Major categories included cereals, legumes, roots and tubers, fruits, fats and oils, sugar crops, fiber crops, spice and condiments, beverages, medicinal, and others. It was observed that 86% of the plants and plant products are used for foods, 10% are used for medicinal purpose while 3% is used for other purposes. However, the highest percentage was noticed in fruits, which are 35%.

The habit of plants found in local markets in Benin City and environs range from grasses, herbs, shrubs, and trees to vines. Overall, the composition was 39%, 20%, 17%, 15%, and 9% for trees, shrubs, grasses, herbs, and vines, respectively (Fig. 3). This is an indication that for plants and plant products gotten from tree crops, buyers, and vendors will have to wait for months or years before parts that are available to be harvested for sale or consumption.

The plant species recorded in the study are mainly used as a source of food, cash or medicine. Others supply diversity, essential nutrients, vitamins, or minerals in diets that would otherwise consist primarily of carbohydrates (Johns 2004; Johns and Sthapit 2004). Our investigation revealed that most of the plants and plant products are mainly for foods while a few are for medicinal and other uses. Often, they reflect cultural values and as a pool of health and nutritional information for the public and health practitioners (Johns and Eyzaguirre 2002). The availability of diverse plant and plant products in the market relies on local agriculture system, seasonal variations, local knowledge and practices, as well as plant germplasm. Produce are mainly sourced locally from home gardens and distant farms. Therefore, the vulnerability of agriculture systems in Benin City to climate change might not be affecting the production of the plants reported in this chapter in the short term. However, the interplay of diverse external factors and climate change is likely to affect the availability of plant and plant products currently found in open markets in the long term. It is recommended that the roles of women, soil health, and plant diversity be assessed in order to formulate a policy to mitigate and adapt to climate change impact on agriculture and food security in Benin City and other parts of Nigeria and Africa.

Moreover, considering that Muhanji et al. (2011) reported that there might be 45,000 plant species in Africa, the amount of plant and plant products recorded in open markets in Benin City only represent a small portion of that diversity. About 86% of the plants and plant products found in the markets in Benin City and environs are used for foods, 11% are for medicinal purpose, while 3% are used for others

Table 3 Utilization pattern of plants and plant products in local markets within Benin City and environs

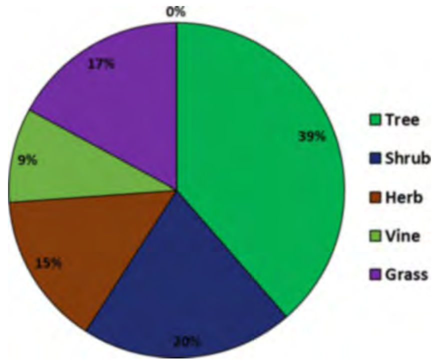
Fig. 3 The habit of plants and plant products in local markets within Benin City and environs



purpose. Of the 86% used for food purpose, fruits and vegetable had the highest percentage of usage, which are 35% and 9% for fruits and vegetables, respectively. This is an indication that the markets in Benin City and environs have rich and diverse pool of fruits and vegetables, which are of great nutritional value. This is in line with the study of Odhav et al. (2007) and Ogwu et al. (2016) wherein they pointed out that indigenous vegetables and fruits represent inexpensive but high quality nutrition sources for the poor segment of the population. Since many indigenous food plants grow wild, they are accessible, they can be collected freely and are thus available to everyone, including the poor (Kabuye et al. 1999). Fruits and vegetables are of great nutritional value. They are important sources of vitamins and minerals that are essential for human health and well-being. Their consumption ensures the intake of various essential vitamins and mineral elements thus avoiding the problem of malnutrition (Yamaguchi 1983). There is a wide variety of indigenous vegetables and fruits found in Africa, which are chief sources of nutrients, vitamins, antioxidants, minerals, and proteins (Odhav et al. 2007; Ogwu et al. 2016; Ogwu 2020). Some of the indigenous vegetables and fruits are mainly used for medicinal purposes (Eifediyi et al. 2008).

Names and naming are important determinant factors in local society and contributing to promoting sustainable plant utilization and conservation (Penny 2001; Ogwu and Osawaru 2014; Ogwu et al. 2014). Plants are more easily recognized by their local names in every part of the world. These local names play a vital role in ethnobotanical study of a specific tribe or region (Singh 2008). The local names of crop plants, especially in Bini language, are reported among tribes surveyed. Documentation of local names is highly valued by Rogers (1963), Rogers and Applan (1973), Allem (2000), Bressan et al. (2005), Sawadogo et al. (2005), and Osawaru and Dania-Ogbe (2010). Local names are used to promote and trade plant and plant products in all the local markets assessed with little to no reference to their scientific nomenclature. Although local names are not directly recommended for scientific discussions because they lack uniformity and consistency (Singh 2008), yet they may certainly be considered as a useful tool for obtaining useful information on plants. Local names provide means of reference by local people in a particular area. Also, in some cases, the plants are well known with their local name than the common names. This is the case of "ebolebo" and "dogoyaro" for Indian almond and neem, respectively.

In conclusion, plants provide valuable functions as foods, raw materials, socio-economic development, as well as sustainable environmental development and indicator of climate change impacts. They have been used as a means of livelihood sustenance and preservation of indigenous knowledge through their utilization pattern for centuries. This chapter established that local markets are a data bank for economic plant species. The diversity of these plants and plant products in the various local market assessed suggest that despite ongoing climate change, some level of plant production and plant-human interaction is ongoing. This chapter also revealed that urban markets have a higher number of plants and plant products compared to peri-urban and rural markets. This is a reflection that lesser populated markets are less diverse in terms of plants and plant products in the market. Additionally, majority of the plants and plant products are utilized as food with fruits being the predominant part that is used as food. Overall, the vendors/sellers are predominantly women and their interaction with plants in the market makes them an important group in the fight against climate change, food insecurity, and biodiversity crisis.

Abstract

Background: Scientific progress and developments in technology have improved our understanding of climate change and its potential impacts on smallholder farming systems in sub-Saharan Africa (SSA). The persistence of such smallholder farming systems, despite multiple exposures to climate hazards, demonstrates a capacity to respond or adapt. However, the scale and intensity of climate change impacts on smallholder farming systems in SSA will overwhelm any indigenous coping mechanisms developed over centuries. Therefore, there is need to co-develop resilient farming systems with farmers and extension workers in anticipation of the looming food security challenges in the midst of climate change.

A survey comprising of participatory rural appraisal, focus group discussions, participatory resource mapping, and SWOT analysis was carried out for the purposes of farming systems diagnosis in reference to their resilience to climate change in three districts cutting across dry arid zones of Botswana agricultural landscape. The survey also sought to identify vulnerability of the farming systems to climate change and subsequently co-develop with farmers and extension workers new climate proofed farming systems.

Results: Detailed evaluation of current systems and their strengths and weaknesses were identified. Farmers highlighted constraints to their production being mainly drought related but also lack of production inputs. These constraints are location and context specific as extension areas within a district highlighted different challenges and even different CSA practices for similar production constraints. Through participatory approaches, farmers were able to identify and rank potential climate-smart agriculture practices that could ameliorate their production challenges and subsequently developed implementation plans for these practices.

Conclusions: The study demonstrates that climate change is already having significant adverse impacts on smallholder farming systems and therefore, climate proofing these systems is necessary if livelihoods of smallholder farmers are to be sustained. Therefore, retrofitting current farming systems to be climate resilient is the first step to climate proofing smallholder farmers' livelihoods.

Botswana · Farming systems · Adaptation strategies · Climate change · Smallholder farmers

Introduction

Agriculture is a proven path to prosperity as no region of the world has developed a diverse, modern economy without first establishing a successful foundation in agriculture. This trend is going to be critically true for Africa where, today, close to 70% of the population is involved in agriculture as smallholder farmers working on parcels of land that are, on average, less than 2 hectares. As such, agriculture remains Africa's route for growing inclusive economies and creating decent jobs mainly for the youth. In Botswana, the agriculture economic sector is limited mainly to range resource-based livestock and pockets of arable farming based on rainfall and limited irrigated agriculture at several places (Alemaw et al. 2006). However, despite this aforementioned and the recent slowing in economic growth across much of the continent mainly due to the sharp drop in the global prices of oil and minerals, the prospects for African agriculture looks favorable. The African food market continues to grow with World Bank estimates showing that it will be worth US$1 trillion by 2030 up from the current US$300 billion (World Bank 2007, 2010). Demand for food is also projected to at least double by 2050. These trends, combined with the continent's food import bill, estimated at a staggering US$30–50 billion, indicate that an opportunity exists for smallholder farmers – Africa's largest entrepreneurs by numbers – who already produce 80% of the food to finally transition their enterprises into thriving businesses (AGRA 2017). Botswana is a net food-importing developing country (NFIDC); thus there is an opportunity to increase domestic production of basic foodstuffs, particularly cereals (grain sorghum and maize) and pulses. The national demand for cereal stands at 200,000 t per year, of which only 17% is supplied through local production (GoB 2019). Therefore, investments in arable agriculture will stimulate private sector development, create employment, value-addition opportunities, and enhance food security and ultimately exports.

Climate change poses a challenge to the attainment of agricultural potential. Climate change is threatening to undo decades of agricultural development efforts in developing countries with scientific projections pointing to a warmer climate characterized by increases in both intensity and frequency of extreme climate events, particularly in sub-Saharan Africa. Nkemelang et al. (2018) observed an increase in extreme weather events such as heat waves and late and high spatial and temporal rainfall variability across Botswana. Therefore, although climate adaptation is a global requirement, the need for adaptation is considered higher among developing countries where vulnerability is presumably higher (Adger 2003) and also in the interest of individual farmers who rely on the revenue generated from agricultural production (Holzkämper 2017). The need for adaptation is especially true in Africa as the population is highly dependent on rainfed agriculture (the most climate-sensitive sector) and particularly for smallholder farmers as they generally have limited adaptive capacity (Morton 2007), hence considered among those who will suffer most from the impacts of climate change (Easterling et al. 2007). Mogomotsi et al. (2020) highlight the vulnerability of smallholder rainfed famers to climate change and variability in Botswana. Smallholder agriculture has long been characterized by adaptive and flexible strategies to reduce vulnerability to climate natural variability and soil depletion (Adger et al. 2003; Tschakert 2007; Thomas et al. 2007; Eriksen et al. 2008). African farmers, particularly in dry land areas, have developed both on- and off-farm adaptation strategies in response to reoccurring droughts. Cooper et al. (2008) observed that coping better with current climatic variability in rainfed farming systems of sub-Saharan Africa is an essential first step in adapting to future climate change, while Muyambo et al. (2017) highlight the role of indigenous knowledge in drought risk reduction.

Nevertheless, climate change is going to negatively affect smallholder farmers beyond their coping capacity for naturally-occurring droughts, hence the need to hybridize traditional drought coping mechanisms with technology through co-development of climate resilience farming systems involving farmers, extension workers, and agricultural experts. Hence the need to retool farmers and extension officers for climate. Williams et al. (2019) observed that smallholder systems heterogeneity requires local specific climate adaptation for reducing the negative impacts of changing climate in regions heavily relying on small farms agriculture.

Due to the instability of agricultural production as a result of complex, dynamic, and interrelated factors such as climate, markets, and public policy that are beyond farmers' control, there is a need for farmers to develop new farming systems that incorporate innovations in their objectives, organization, and practices adapted to changing production contexts (Martin et al. 2013). While Thornton et al. (2018) highlighted that the scale of change required to meet the sustainable development goals, including those of no poverty, zero hunger, and the urgent action needed to address climate change, will necessitate the transformation of local and global food systems. Thus the main aim of this chapter is to develop resilient farming systems in Gantsi District and Bobirwa and Boteti sub-districts of Botswana. The chapter is premised on the following specific objectives: to evaluate current farming systems in the three districts and identify climate-smart practices within each district; identify alternative livelihood options (off-farm) in the catchment areas; identify indigenous knowledge of agricultural practices (ethno-veterinary and ethno-botanical) to cope with effects of climate change and co-identify (farmers and extension workers); and recommend potential climate-smart agricultural practices. The Republic of Botswana is a landlocked country with an area of 582,000 km^2 (Fig. 1). The climate is semi-arid to arid with high spatial rainfall variability. Rainfall decreases and temperature range increases westward and southward, varying from 650 mm per annum in the east to 230 mm in the south-west.

Agriculture plays a significant role in the lives of rural communities where it provides food and income and employs a majority of the rural inhabitants. However, the Intergovernmental Panel on Climate Change (IPCC 2007) has identified the country as vulnerable to climate change and variability, probably due to its low adaptive capacity and sensitivity to many of the projected changes. Therefore, it implies that with climate change, including high temperatures and frequent droughts conditions for agriculture, will worsen. For example, models have predicted that parts of Botswana will become much drier and hotter (IPCC 2001). Currently, there are projected statistically significant decreases in mean rainfall and increases in dry-spell length at each global temperature level (Nkemelang et al. 2018). IPCC special report on global warming of 1.5°C underlined that areas in the south-western region, especially in South Africa and parts of Namibia and Botswana, are expected to experience the largest increases in temperature (Engelbrecht et al. 2015; Maúre et al. 2018).

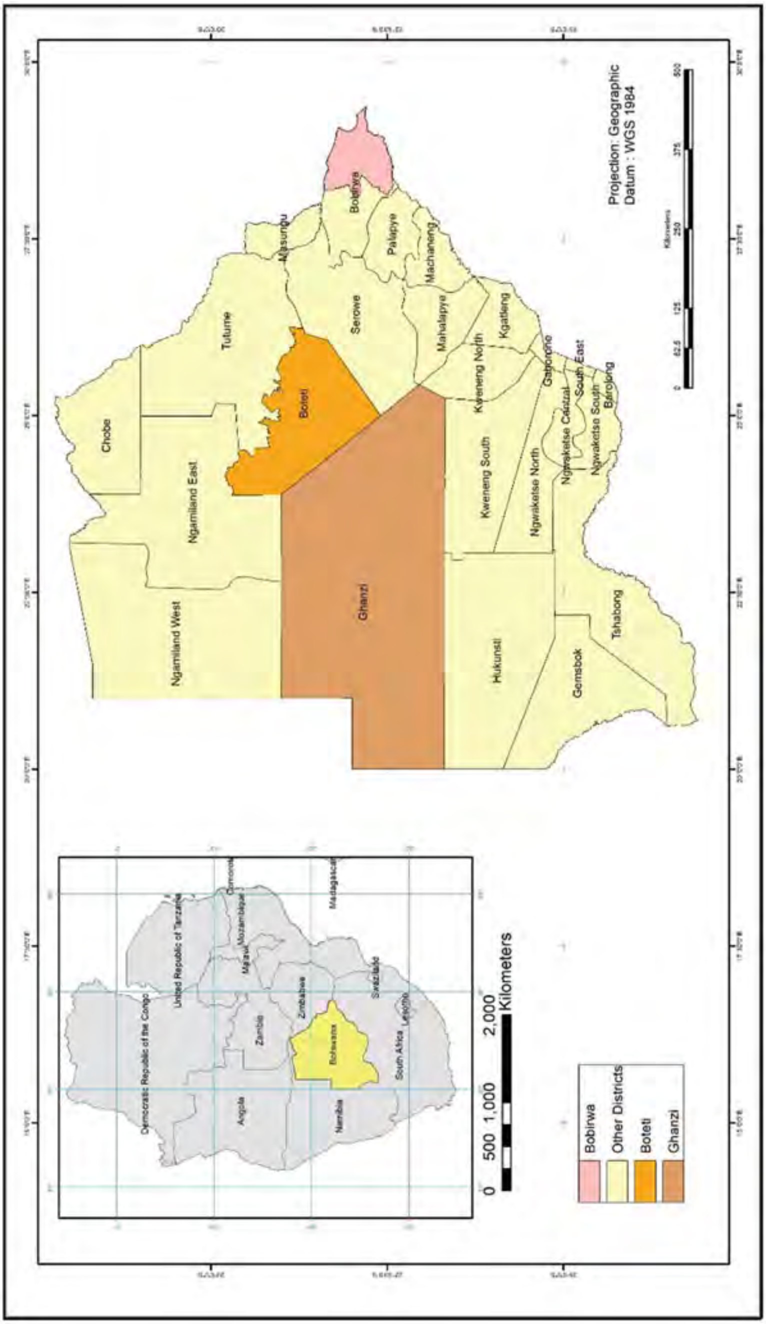

Fig. 1 Botswana location and the three study districts

Gantsi District and Bobirwa and Boteti Sub-Districts

Although the three areas of interest are very similar in their vulnerability to climate change impact, they vary in terms of land area, population, and physiography. Gantsi District has mostly sandy, infertile soils with low water holding capacity. Farming is the dominant economic activity in the district with pastoral being most dominant although of recent there has been an increase in irrigated agriculture. Bobirwa sub-district has relatively fertile soils although some. Integrated pastoral and arable rainfed farming are major activities in the district. Boteti sub-district practices both arable and pastoral farming.

A farming system model by Collinson (1987) was used to aid with farming systems diagnosis of the three districts (Fig. 2). In the model, there are visible and observable aspects, which are represented by solid boxes, and those that are deduced from the description of these aspects and verified by a discussion with farmers and extension officers, represented by perforated boxes.

Information on current farming systems in each district was acquired through key informants, farmers, and extension workers. Two extension areas were randomly selected in each district.

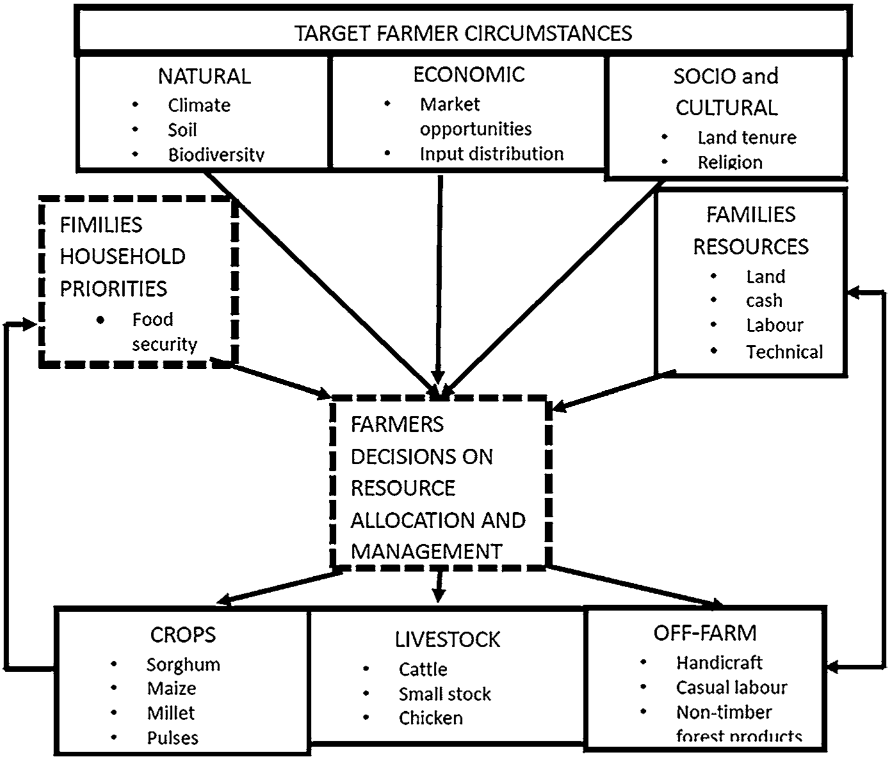

Fig. 2 Farming system diagnosis by Collinson (1987)

(i) Gantsi District (Charles Hill, Ncojane)
(ii) Boteti sub-district (Mosu, Moremaoto)
(iii) Bobirwa sub-district (Bobonong, Gobojango)

Multistage sampling technique was used to determine the ideal sample size of participants in the focus group discussion (FGD) using Krecjie and Morgan (1970) formula. The multistage sampling process was conducted with the assistance of extension areas workers who provided facilitators with the number of active farmers in their catchment. Triangulation was applied where specific information was needed. A SWOT analysis was used to evaluate current farming systems, their strengths (resilient to climate change and droughts), and weakness (vulnerability to climate change and droughts).

The sharing of ideas (experience) among farmers and extension workers allowed them to evaluate the shared experience and seek more solutions to the prevailing livestock and crop production challenges and CSA practices in their respective extension areas. The list of proposed CSA options was discussed with participating farmers to ensure a common understanding was reached between them, facilitators and extension workers. During the discussion, farmers were encouraged to come up with additional practices especially those relating to indigenous knowledge practices (ethno-botanical and veterinary practices). At the end, ranking of the proposed CSA practices was done according to Khatri-Chhetri et al. (2017).

The discussion of the predetermined options was designed into a participatory action plan that addressed the resources needed for implementation of the ranked CSA potential practices. The action plan and the developed activity plan was a step-by-step process that helped these groups of farmers together with their extension workers and facilitators to design and deliver solutions to address proposed climate-smart agricultural practices. Farmers ranked potential CSA practices for developing climate-resilient farming systems and together with extension workers developed their implementation guidelines. Figure 3 is a summary of the methods that were used to collect data needed to co-develop climate-smart resilient farming systems across the study areas.

Facilitators used a stated preference method to analyze the farmers' preference of CSA practices. In the stated preference method, participating farmers were asked about their preferences in a list of practices (Khatri-Chhetri et al. 2017).

Current Farming Systems in Gantsi District and Bobirwa and Boteti Sub-Districts of Botswana

Table 1 displays CSA practices currently found in the three districts. Such practices can be divided into crop and livestock related. Crop technologies that were common to all areas included fodder production and intercropping, whereas disease control and public health as well as ethno-veterinary practices were the only two livestock practices that cut across the three districts. Fodder production included planting of cowpea, lablab, maize, melons, forage sorghum, napier grass, and soybean. Cowpea

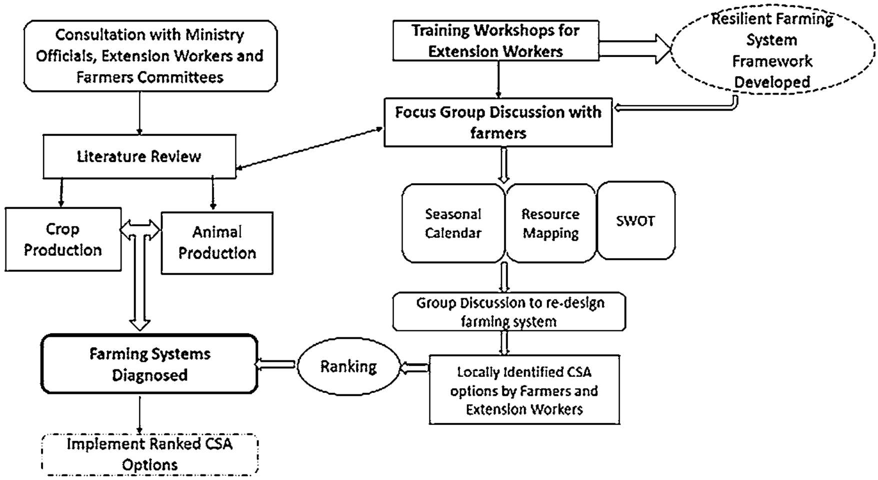

Fig. 3 Flow of methods used in developing the farming systems

and maize were not specifically planted as fodder, but their stover is normally fed to livestock after harvesting. Intercropping involves planting of rows of cereals such as maize, sorghum, and millet alternating with legumes such as cowpeas, lablab, and soybean and is part of integrated pest management as it provides conducive environment for natural enemies (Obopile et al. 2018) and also in maintaining soil fertility through biological nitrogen fixation (Pule-Meulenberg et al. 2018).

Current farming systems in Gantsi District is predominantly livestock farming as observed from the large number of cattle posts (livestock holdings) (Fig. 4). The rearing system is free ranging based on rainfed natural pastures. This resource (natural pastures) is prone to droughts and overgrazing leading to a large number of livestock mortalities.

As an adaptation move, farmers are moving toward some integrated crop-livestock systems with production of fodder crops, while some large commercial cattle ranchers use parts of their farms for diversifying into vegetable production. Smallholder farmers are also practicing small-scale irrigated gardens. Maize and cowpeas are the main rainfed arable crops in the area, and because of low drought tolerant of maize, yields are low in most years (Fig. 5). Minimum tillage is practiced and pioneered as a conservation agriculture (CA) in the district. However, due to the sandy nature of the soil, farmers complained of the disappearance of planting pits/basins, making their construction a laborious task that has to be repeated every year.

Boteti sub-district just like Gantsi District is a predominantly cattle-rearing area although has more rainfed arable farming. Figure 6 shows the spatial distribution of land uses in the sub-district. The main crops grown are maize, cowpeas, sorghum, and millet; the latter two being drought-tolerant crops, whose limitation is susceptibility to bird damage. Of recent, crop damage by wildlife especially elephants have increased in the sub-district.

Table 1 CSA practices currently found in the Gantsi District and Bobirwa and Boteti sub-districts

Current CSA practices	CSA details	Gantsi District	Bobirwa Sub District	Boteti Sub District
Planting in tires	Vegetables	x		
Irrigation	Combination of different types of vegetables	x		
Holistic livestock management	Planned grazing in fenced farm	x		
Fodder production	Cowpea, lablab, Maize, Melons, Forage sorghum, sugar cane, soya	x	x	x
Intercropping	Intercropping legumes and cereals	x	x	x
Crop rotation	Cereals rotated with legumes	x		x
Backyard gardening	Different types of vegetables	x

Supplemental feeding	Using commercial and fodder	x	x	
Disease control and public health	Construction pit latrines to curb the spread of beef measles	x	x	x
Poultry production	Constructed poultry houses which control temperatures using natural ventilation. Collection of chicken manure to sell for vegetation production		x	
Small stock production	Apply recommended management practices that follow small stock calendar		x	x
Production of marula oil cake	Marula by products used for animal feeds		x	
Utilization of indigenous tree species for livestock feeding	Cutting *Vachellia* spp. (*Vachellia tortilis* and *V. erioloba*) species and mixing with stover to make livestock feeds		x	
Pigs production	About 300 individual pigs housed in large paddocks		x	
Minimum tillage (ripping using tractor)	Mainly cowpeas, watermelons, maize, sorghum			x
Minimum tillage (ripping using donkeys)	Cowpeas, watermelons, maize, sorghum			x
Planting pits/basins	Cowpeas, watermelons, maize melons, maize	x		x
Cover cropping	Mainly cowpeas, pumpkins, lablab, watermelons, melons		x	x
Fertilizer application as per soil analysis	Use of fertilizers on sorghum, maize			x

Table 1 (continued)

Current CSA practices	CSA details	Gantsi District	Bobirwa Sub District	Boteti Sub District
Kraal manure application	Application of kraal manure on maize			x
Provision of housing	Housing for goats' kids			x
Vaccinations	Vaccinate against livestock and poultry diseases	x	x	x
Use of solar energy	Solar panels to generate electricity			x
Ethno veterinary practices	Examples: wood ash for retained placenta; powdered dead/sun bleached millipede skeleton to treat eye infection	x	x	x
Use of tolerant breeds	Use of Tswana goats, Boer goats			x

Figure 7 displays current farming systems for crops and livestock in Letlhakane extension area of Boteti sub-district. In order to minimize drought impacts on both livestock and crops, it is imperative to increase the number of people that practice climate-smart agriculture technologies such as conservation agriculture, fodder production, and the use of drought-tolerant germplasm.

Of the three districts, in terms of both physiography and farming systems, Boteti lies at the transitional zone between Gantsi and Bobirwa in having some aspects of sandy predominant in Gantsi but also having the more fine-textured fertile soils found in Bobirwa. Similar to Gantsi District, livestock production is dominant in the Boteti sub-district. In Boteti sub-district, rainfed arable agriculture comprising sorghum, millet, maize, and cowpeas are among the major crops grown similar to Bobirwa.

Alternative Livelihoods in Gantsi District and Bobirwa and Boteti Sub-Districts

Table 2 shows alternative livelihoods outside the agricultural sector. It is evident that Gantsi District had many more alternative livelihood activities compared to the two sub-districts of Bobirwa and Boteti. This is probably due to the fact that Gantsi township is more urban compared to the villages of Bobonong and Letlhakane, which are the sub-district headquarters for Bobirwa and Boteti sub-district, respectively. In each of the three study areas, livelihood activities were varied as shown in Table 2. The common activities that cut across the three districts included employment through the Ipelegeng program (a Government of Botswana poverty alleviation scheme), sale of veld product, running of tuckshops, domestic work (being a maid), taxi services, sale of traditional brews, and catering services.

Table 2 Alternative livelihoods for Gantsi District and Bobirwa and Boteti Sub-Districts

Alternative livelihoods	Gantsi District	Bobirwa sub-district	Boteti sub-district
Employed in Ipelegeng projects	x	x	x
Traditional herbalists selling traditional medicines	x	x	
Selling of veld products	x	x	x
Provision of mechanical services mainly in Gantsi township	x		
Renting out houses	x		
Performing arts	x		x
Sale of traditional brews in shebeens	x		
Micro-enterprises (tuckshop)	x	x	x
Sales agents	x		
Farm work (livestock herding)	x		
Horse racing (jockeys)	x		
Dog racing	x		
Domestic work	x	x	x
Mobile safari	x		
Sale of game meat from community trusts	x		
Taxi services	x	x	x
Hired donkey carts for transport	x		
Game farming	x		
Handicrafts	x	x	x
Traditional brews	x	x	x
Labor for destumping arable fields	x		
Illicit substances (marijuana)	x		
Provision of transport for goods	x		
Cattle sales agent	x		
Brick molding	x		x
Poaching and hunting	x		

Bakery	x		
Dependency on male/female partners	x		
Garbage collection	x		
Fishing		x	x
Harvesting wood, grass and poles		x	x
Catering services	x	x	x
Sewing (tailoring)		x	x
Pottery			x
Thatching		x	x
Food processing			x
Sale of secondhand clothes		x	x
Sale of ornamental and fruit trees		x	
Sale of semi-precious stones		x	
Using recycled paper to make flower pots		x	
Sale of empty cans		x	
Recycling old tires to make livestock troughs		x	
Leatherworks		x	
Hair salons			
Wood carving		x	x
Destumping to increase hectarage in fields		x	
Panel beating and motor mechanic		x	
Pottery			x
Welding			x
Upholstering			x

The types of veld products sold are area specific although there are some common ones. For example, they include the morama bean (*Tylosema esculentum*), mongoose seed (*Bauhinia petersiana*), and wild berries such as *Grewia flava*. In Bobirwa, some of the veld products being sold are the mopane worm (*Imbrasia belina*), fruit of baobab (*Adansonia digitata*) tree, marula (*Sclerocarya birrea*) fruits, monkey orange, *Grewia flava* berries, *Vangueria infausta* fruits, *Mimusops zeyheri*, and wild vegetables such as *Cleome gynandra*, *Amaranthus* spp., and wild okra. For the Boteti sub-district, veld products include the harvesting of the water lily which is as a condiment for meat and sale of indigenous vegetables as described for Bobirwa and wild fruits as baobab (*Adansonia digitata*) and marula (*Sclerocarya birrea*). The sale of firewood and handicrafts was also common among the study areas, the difference being the type of species that is being sold.

It is noteworthy that veld products are dependent on climate because during prolonged droughts when crops fail and livestock die, wild plants are equally affected; hence such products go off the markets. This situation is also true for traditional brews that are either made from mainly sorghum or wild fruits. During drought years, they would also not be available. This scenario shows the extent to which smallholder farmers are exposed to the effects of climate change, hence the need to adopt climate-smart technologies, on and off farm.

The recurring droughts leading to asset losses have driven communities in these three districts to develop some alternative livelihoods strategies for coping with drought challenges. Nevertheless, these alternative livelihoods strategies developed to cope with natural droughts are unlikely to match the severity and frequency of climate change-induced droughts because of their short-term nature (Table 2), hence the need for coming up with CSA technologies by Government and other stakeholders. However, the adoption of these CSA technologies has not been promising due to among other obstacles, weaknesses as highlighted in Table 3. These weaknesses or malalignment of the current CSA technologies used in the districts or their implementation may be due to that they were never meant for farming systems and cultures found in the three districts, therefore could have been adapted for these systems before implementation. Mwongera et al. (2017) noted that approaches that aim to identify and prioritize locally appropriate climate-smart agriculture technologies will need to address the context-specific multidimensional complexity in agricultural systems.

Therefore, to improve the adoption of CSA technologies, there is need for co-development of technologies with farmers and extension workers at the local level. Through participatory approaches, farmers ranked various CSA interventions. The examples in Table 4 below shows that preferences vary at local extension levels within a district and also between districts, highlighting the importance of considering local context and dynamics of farming systems when designing CSA practices and interventions (Tables 4–9). Khatri-Chhetri et al. (2017) noted that farmers' priorities for CSA technologies are linked with prevailing climatic condition of particular location, socio-economic characteristics of farmers, and their willingness to pay for available technologies.

Table 3 SWOT analysis of current CSA farming practices in Gantsi District and Bobirwa and Boteti sub-districts

Strengths	Weaknesses
Improved soil fertility Technologies are adaptable to climate change High carbon sequestration Improved food and nutrition security Both males and females participate in farming activities Availability of underground water Availability of arable land Supportive Government policies Mild winters Availability of veldt products (natural resources) Fertile soils Moisture conservation Pest and weeds control (break life cycle) Reduction of soil erosion	Use of hybrid seed destroyed traditional crop varieties Destruction of CSA crop structures by wind erosion and livestock Unavailability of equipment for CSA crop practices The decision to sell livestock is predominantly done by males The decision to sell crops is predominantly done by females Shortage of livestock grazing land and grazing resources Poor vegetation Shortage of farming equipment Lack of farm input suppliers Poor roads and infrastructure Lack of research and development (e.g., abattoirs) Long-time taken by Land Board to allocate land Shortage of labor Very interested to do fish farming No financial assistance for fisheries Few trained officers in Aquaculture Unreliable rainfall Reliability on Government hand out Conflict on Government policies Unwillingness to change by farmers to new technologies High farmers to extension worker ratio Lack of documentation on fish farming in Botswana Blanket application of fertilizers
Opportunities	**Threats**
Adaptation with co-benefits Resilience to drought due to irrigation Diversified crop production Employment creation High demand for fish Commodity clusters of farmers can be helping in farming systems (e.g., poultry and dairy) Agro-tourism Diversification in farming Fish has a potential to grow since it is a new in Bobirwa sub-district and has a high nutritional value Enhanced import substitution Availability of sunlight for usage of solar power No Market for cattle to BMC because Bobirwa Sub District is not a green zone Irrigation (crops, fodder production) almost the whole year Multiplication of Musi breed Improved soil fertility (legumes)	Occurrence of extreme weather conditions (e.g., change of start of rainy season) Emergence of new pests and diseases Introduction of alien grass species in the rangelands (e.g., *Cenchrus biflorus*) Competition of labor with Government programs Other farmers may not cooperate in rotational grazing and correct stocking rate in communal areas Human-wildlife conflict (elephants) To develop small stock slaughtering facility Human-wildlife conflicts The rain pattern has changed Heat waves Lack of raw materials for feeds Use of hybrids seeds Use of exotic livestock and poultry breeds Lack of buy in by the Government on the programs for fisheries (just like LIMID) High budget to start fish projects Invasive species Stock theft from the neighboring countries Aging farmers Conversion of arable land to other land uses (e.g., tourism and settlements) Contamination of environment

Table 4 Indigenous (ethno-veterinary) practices in the Gantsi, Bobirwa, and Boteti

Practices	Gantsi District	Bobirwa Sub District	Boteti Sub District
Use of charcoal for diarrhea in calves			x
Use of charcoal for dressing livestock wounds		x	
Use of charcoal to treat poisoning in dogs		x	
Use mix of dry donkey dung, salt, and wood ash and administered orally for retained placenta in small stock			x
Use of *Senna italica* (sebete) for the treatment of calf paratyphoid	x	x	x
Ximenia spp. for the treatment of foot rot in livestock			x
Use of sugar to treat visually impaired eyes and eye branding	x	x	x
Bandaging a fracture with wood and soft cloth		x	x
Use of *Aloe* spp. (mokgwapha) for foot rot			x
Use of wood ashes mix for snake bites			x
Use of cow dung after branding or dehorning			x
Thamnosma rhodesica (moralala) for prevention of miscarriage and still birth		x	x
Diospyros lycioides (letlhajwa) for control of *Pasteurella*			x
Use of *Aloe* spp. (mokgwapha) in birds against Newcastle disease and coccidiosis	x	x	x
Use of "thobega" against fractures in livestock		x	x
Dry old bleached millipede is crushed and applied to treat visually impaired eyes	x	x	x
Use of sugar to treat visually impaired eyes	x	x	x
Use of *Ziziphus mucronata* leaves to treat eye infections			x
Ziziphus mucronata pounded leaves and paste applied to dress wounds	x		
Use of wood ash mainly *Combretum imberbe* (Motswere tree) to control external parasites in chicken and puppies		x	x
Use of burnt cow dung against mosquitoes			x
Use of wild cucumber (mokapane) for the treatment of wounds			x
Use of dried cow dung smoke for the treatment of mastitis; burning cow dung is placed under the udder of the animal for the smoke to cover the udder			x
A string is tied on the warts and left until it falls off			x
Ash of *Vachellia mellifera* is mixed with water and administered orally when an animal has retained placenta; can also be used to control weevils in grain	x		x
Use of hot ring iron to treat eye infection			x
Cutting of tail and ears for treatment of animals against *Pasteurella*		x	x
Liquid paraffin external parasites on chicken, cats, dogs, and rabbits		x	

(continued)

Table 4 (continued)

Practices	Gantsi District	Bobirwa Sub District	Boteti Sub District
Potassium per manganite to control chicken diseases (e.g., coccidiosis)		x	
Use of brake fluid to control mites	x	x	
Use of bitter apple fruits (thontholwana/morolana) to treat eye infection		x	
Use of charcoal to treat poisoning in dogs		x	
Use of sugar for control of uterine prolapse	x		
Use of purslane to control uterine prolapse	x		

Indigenous Knowledge of Agricultural Practices in Gantsi District and Bobirwa and Boteti Sub-Districts

Farmers across the three districts indicated that they had indigenous agricultural practices pertaining to production of livestock and crops (Tables 4 and 5). Table 4 shows ethno-veterinary practices across the three districts. A number of practices such as the use of *Senna italica* to treat calf paratyphoid, treatment of eye infection in livestock using sugar and/or branding around the infected eye, treatment of poultry diseases such as Newcastle and coccidiosis using *Aloe* spp., and the use of dried up and bleached millipede carcass for eye infections in livestock were found in all the study areas. It is noteworthy that about a third of the practices are plant based. Consequently, prolonged droughts caused by climate change will affect them, hence the need to intentionally conserve wild plants. Other practices are based on plant products such as charcoal, wood ash, and smoke.

Table 5 displays the ethno-botanical practices found in the three districts. The use of a mixture of tobacco, chillis, garlic, onions, and soap or a combination of any two with liquid soap is common among the three districts for the control of aphids (*Aphis craccivora*), red spider mites (*Tetranychus urticae*), and fungi. The digging of trenches around arable fields for control against corn cricket (*Acanthoplus discoidalis*) and the traditional magical powers to protect fields against pest were common in the Gantsi District and Bobirwa sub-districts. The use of chilli blocks to scare away elephants where crushed chillis and mixed with cow dung, dried, and burnt was practiced in the Bobirwa and Boteti sub-districts. Much like with indigenous practices for livestock, about a third of the practices are plant based. Other practices such as digging of trenches to control corn cricket, animal snares, scare crows, use of reflectors to scare away elephants, and other can be referred to as physical.

It is interesting that out of the list of indigenous practices for both crops and livestock, none deal directly with increasing production but are all for the protection of pests and diseases. Furthermore, many of the practices are plant based and therefore are equally affected by the harsh effects of climate change.

Table 5 Indigenous (ethno-botanical) practices for crops in Gantsi District and Bobirwa and Boteti sub-districts

Practices	Gantsi District	Bobirwa Sub District	Boteti Sub District
Use of wood ash for pest control			x
Mixture of tobacco garlic and onion and sunlight for aphid control	x	x	x
Trenches for control of *Acanthoplus discoidalis* (setotojane)			x
Use of scare crows			x
Foot crushing of grasshoppers			
Animal traps (snares)			
Use of sugar to attract natural enemies			x
Application of *Combretum imberbe* and *Vachellia mellifera* (motswere and mongana wood ash, respectively, around plant stems and also application in seeds/grains to protect against storage pests			x
Use of chilli block, where chillis are mixed with cow dung, then dried, and then burnt to deter elephants		x	x
Python fat is mixed with seed before planting to protect the arable fields from predators		x	
Burn mohetola (*Indigofera* sp.) to accelerate sorghum maturity		x	
Use of empty containers to scare the birds and elephants		x	
Use of metal reflectors along the fence to scare the elephants		x	
Collect human urine and pour small bits of it on strategic places around the perimeter fence to scare kudus and jackals (mark territory)		x	
Filling a clear bottle with water and placing at strategic places to scare away jackals		x	
Digging a trench around the field to control pests, e.g., corn cricket	x	x	
Magically protect (Go upa masimo) through seeds	x	x	
Use of whey to control aphids	x		
Eucalyptus for the control of weevils in grains	x		

Potential Climate-Smart Agricultural Practices Identified by Farmers and Extension Workers

When designing CSA implementation strategies at farm level, one must consider adaptation options that are well evaluated and prioritized by local farmers in relation to prominent climatic risks in that location (Khatri-Chhetri et al. (2017); FAO 2012). Table 6 is a compilation of how farmers in the three districts ranked CSA practices according to their preferences. At each district, at extension area

Table 6 Ranking of CSA practices in the Gantsi District and Bobirwa and Boteti sub-districts

No.	CSA Intervention	Ghanzi		Bobirwa		Boteti	
		Charleshill	Nojane	Bobonong	Gobojango	Mosu	Moreomaoto

level, through focus group discussions, farmers came up with a list of CSA practices that existed or was perceived to be of importance for their area. The list was presented to extension workers for validation and in many instances, extension workers added more practices to the list. Only two interventions were highly ranked across the three districts, namely, fodder production and vaccination calendar adjustment. The production of fodder is important because without good-quality animal feed, it would be difficult to have adaptation with mitigation co-benefits of reduced greenhouse gases (Herrero et al. 2013). It has been documented that one of the consequences of climate change is increased incidences of disease (Moonga and Chitambo 2010). Adjusting livestock vaccination calendar is therefore relevant and important to control disease and as seasons seem to have shifted, hence the need to vaccinate timeously. Out of the three districts, Gantsi has the most uniform physiography, for example, its soils are predominantly sandy (arenosols). Furthermore, livestock production is very important, with one of the highest livestock populations in Botswana. This scenario can explain the uniform agreement in ranking of the CSA interventions (Table 7).

Due to centuries of drought exposure, smallholder farming systems in the three districts have developed some level of resilience to natural droughts. Nevertheless, the frequent and severe climate change-induced droughts are beyond the coping capacity of these systems, hence the need to climate proof them through appropriate climate-smart agriculture practices. Effective adoption

Table 7 Implementation plan for fodder production

CSA Technology	Activities	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Fodder production	Land preparation									■	■	■	■
	Buying fertilizers									■	■	■	■
	Buying seeds									■	■	■	■
	Planting											■	■
	Fertilizer application											■	■
	Weeding	■	■	■									
	Harvesting				■	■	■						
	Drying				■	■	■	■	■				
	Milling and Packaging							■	■	■			

of climate-smart agriculture requires active participation by farmers not only in identifying constraints to their production but also in developing CSA practices for addressing the identified challenges. This approach requires hybridization of indigenous knowledge with technology. Resilient farming systems lead to sustainable livelihoods, thus, the need for an appreciation of smallholder livelihoods as the anchor on which to build them on. Successful CSA adoption requires co-development of implementation plans by farmers and extension workers.

Agroecology and Climate Change Adaptation: Farmers' Experiences in the South African Lowveld

20

Cryton Zazu and Anri Manderson

Contents

Abstract

Motivated by interest to increase the resilience of smallholder farmers to adapt to climate change through uptake of agroecology, two community development organizations commissioned a project evaluation upon which this book chapter is written. The chapter discusses how smallholder farmers were experiencing

implementing agroecology, trying to understand the reasons for adopting such an approach to farming. The chapter also explores and problematizes the relationship between trends in adoption of agroecology and the smallholder farmers' awareness of climate change and adaptation. The chapter confirms that agronomic and income generation are the key reasons for adoption of agroecology. Most of the farmers reminisced about how their crop yields had declined and soils no longer producing enough to feed the family. Other motivating factors for uptake of agroecology included lack of employment, limited income sources, access to health organic foods, and medicinal value of herbs grown. The chapter further concluded that the correlation between adoption of agroecology and farmers' awareness of it as a climate change adaptation measure is generally weak. Smallholder farmers adopted agroecology more for responding to issues of food security, than any conscious desire to adapt to climate change. Implications of this observation is that practitioners working with smallholder farmers need to rethink their approaches and design of interventions to integrate climate change education and learning, so that strong connections between the agroecological practices promoted and adaptation to climate change are made. Such an approach has potential to improve the sustainability and value of the agroecological practices adopted.

Agroecology · Permaculture · Climate change · Smallholder farmer · Adaptation · Mitigation

Introduction

Social development organizations have noticed an increase in agroecological activity among smallholder farmers in the South African lowveld in the last 2 years, including in the districts of the Kruger to Canyons Biosphere Region. Agroecology has also become the point of convergence for a network of institutions based in the biosphere and focusing on a range of environmental, climate change, and social concerns. These institutions included the Hoedspruit Hub, Association for Water and Rural Development (AWARD) Mahlatini, Ukuvuna, Kruger to Canyons Biosphere, CHoiCE Trust, Hlokomela, SANParks, and others, who have mandates ranging from agricultural training, poverty alleviation, biodiversity, and water conservation through to health, yet for different reasons have all found agroecology a critical component to realizing these mandates and notably building farmers resilience to adapt to climate change. It is against this context that two of these organizations working in partnership to promote agroecology among smallholder farmers in this area, collaborated to develop this chapter with the aim of sharing the findings of an evaluation conducted to understand the participating smallholder farmers' experiences of agroecology as both a livelihood option and a strategy for climate change adaptation.

Background Information

Kruger to Canyons Biosphere Region encompasses parts of the Limpopo and Mpumalanga provinces, as well as three southern African biomes: grasslands, Afro-montane forests, and the savannah of the lowveld. And as shown in Fig. 1 below, the region borders with the vast Greater Kruger National Park, which is home to a diversity of flora and fauna. The Kruger to Canyons region also include much of both the upper and lower sub-catchment areas of the Olifants river. Major land-use practices in this region include conservation nature reserves areas, mining (gold, phosphate, copper), exotic plantations, and the extensive nonorganic cultivation of subtropical fruits and vegetables (mainly for export) and to a lesser extent peasant farming.

Perhaps the most important contextual history of this area, when considering the development of smallholder agriculture in post-apartheid South Africa, is the remnants of the former apartheid homelands or bantustans. These were areas the apartheid government set aside for African indigenous people to live after they were forcibly removed from urban areas. It was thus the mechanism with which the government realized segregation, but with which they also successfully created labor reservoirs for the mines and other South Africa industries active at the time. It is essential to take into consideration that although the apartheid government

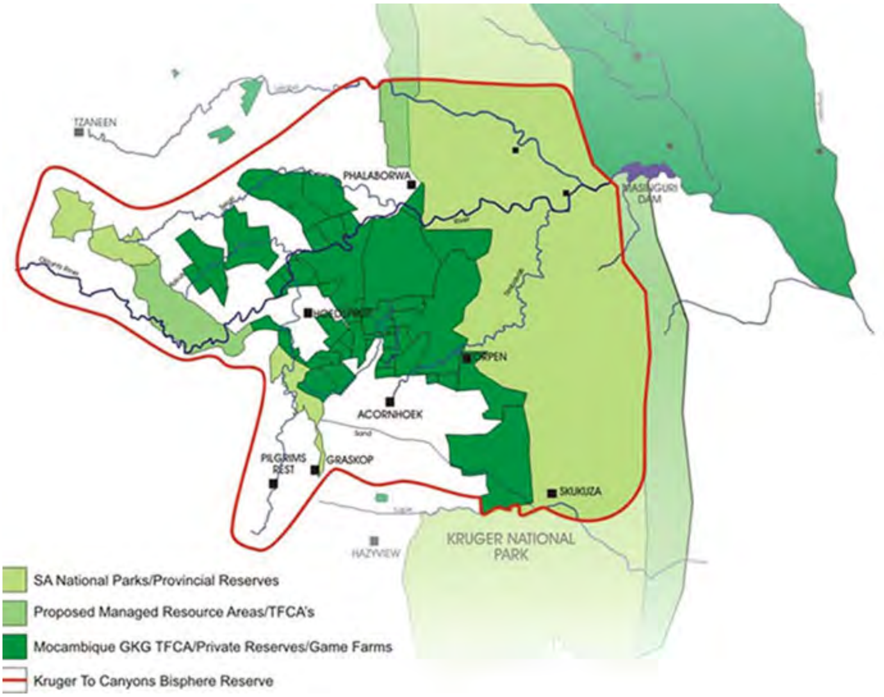

Fig. 1 Map of Kruger to Canyon landscape (AWARD 2016)

intended for these areas to eventually become independent, they were not developed and relied entirely on the larger South African economy.

Vibert (2018) wrote a poignant piece about the effects of forceful removals during apartheid, which displaced people and gathered them in the former homelands. She writes specifically about one homeland that was partly located within the current biosphere, named Gazankulu. It "was envisioned as a rural enclave for women, children, and elderly people of Tsonga ethnicity – their men were the labour force in the mines and cities. This rural-urban binary is misleading: people and resources circulated among these spaces, within and in infraction of the strict spatial regulations of apartheid. Yet rural space was, under apartheid, a space apart" (Vibert 2018). Vibert writes how women recall arriving in this new space where very little preparations had been made for their arrival, finding it inhospitable. They built houses during the day and cooked at night to start a new life. They did not have enough allocated space to grow crops such as sorghum, which they had grown before.

> ...We can't forget sorghum,' the indigenous grain they no longer have space or labour to grow. Mamayila says it's 'very painful [va va ngopfu] to remember the way we were situated. It was so nice. You had enough land to have your garden, donkeys, cattle kraal, one side for goats, one side for pigs.' Today we have 'maybe a cattle-kraal size' says Sara. (Vibert 2018)

Since the end of apartheid, not enough has been done to address the social complexities and trauma of the forceful removals or the underdevelopment of these former homelands, resulting among other social challenges, in millions of unemployed people. Given the legacy of Apartheid's forced removals, villages in Gazankulu are densely populated (Wright et al. 2013). And overutilization of natural resources combined with a lack of proper management of these resources has led to soil erosion and a loss of soil moisture and soil nutrients. These factors, together with low rainfall and poor soils in some areas, have affected smallholder farmer's capacity to produce enough food (AWARD 2016) and with climate change, their vulnerabilities are likely to increase.

Therefore, the work being done by the two development organizations is implemented within this context where historical segregation and limited formal development have left millions of people heavily dependent of agriculture and social grants as livelihoods options.

The Partnership

One of the two development organization is registered as a private company but operates as a social enterprise and training center in the Hoedspruit region. Its social development activities include a high school bursary program, and the training on agroecology, which is of interest to this chapter. The course is meant to equip smallholder farmers with skills and knowledge needed to practice agroecology as a form entrepreneurship along the organic food value chain.

Fig. 2 Map of the Olifants river sub-catchment in which agroecology projects are being implemented (AWARD 2016)

The other organization is a nonprofit organization specializing in multi-disciplinary, participatory, research-based project implementation aimed at addressing issues of environmental sustainability, inequity, and poverty, in particular relating to water conservation and management in the face of climate change. This organization's main geographical area of focus, although not exclusively limited to, is in the areas lying within the lower and upper catchment of the Olifants river – a major tributary of the Limpopo river, which is an international watercourse shared between South Africa and Mozambique. Figure 2 below is a map showing the entire Olifants river catchment.

Changes in Climate

Also, of interest in this chapter is how climate change is being experienced in southern Africa and how this will impact on agriculture. A recent piece in the Farmer's Weekly by Lindie Botha, drawing on the opinion of Prof. Francois Engelbrecht, chief researcher for climate studies, modelling, and environmental health at the Council for Scientific and Industrial Research (CSIR), states that "the average temperature increase in southern Africa due to climate change, is taking place at twice the global rate. The resulting lower rainfall figures and increase in the number of heatwaves will see agricultural landscapes shifting and veld fires growing in frequency. All of this will demand careful planning" and a type of agriculture that is climate smart (Botha 2019). She writes that the Department of Science and

Technology launched the South African Risk and Vulnerability Atlas (SARVA) in response to the changing climates observed in the last few decades. SARVA published in 2018 that rural areas in South Africa are particularly vulnerable to climate change due to its dependence on water and agriculture.

It is against this background that the two partner organizations have, over the course of the partnership, trained and supported a total of 300 smallholder farmers to implement agroecology. And the need to learn more about how the target smallholder farmers are experiencing their implementation of agroecology is what motivate the evaluation, whose findings are discussed in this chapter

Questions Investigated

In order to gain an in-depth understanding of the farmers' experiences of adopting and implementing agroecology, the project evaluation against which this chapter is developed explored the following questions:

1. Why do smallholder farmers adopt an agroecological approach to farming?
2. Is adoption of agroecology as strategy for adaptation linked to farmers' awareness of climate change itself?

Exploring these evaluative questions was done in order to confirm if the agroecological approach is indeed the most effective way to not only meet organizational goals but to enhance the building of smallholder farmers' resilience to adapt to climate change. The answers to the questions of this evaluation are thus the basis for discussions presented in this chapter, the ultimate aim being to improve the way community development organizations work with and support smallholder farmers in South Africa and beyond.

The evaluation was conducted using a qualitative interpretive research approach. The decision to use a qualitative methodology was in sync with the nature of the evaluative questions that the two organizations sought to answer and also the ontological world views of what constitute reality held by the researchers (Creswell 2009; Niewenhuis 2007). Ontology, as defined by Niewenhuis (2007), refers to how one perceives reality or think of that which can be known. Similarly, Patton (2002, 2014) argued that ontology is concerned about the constitution of reality, in the case of this study, "farmers views and experiences of agroecology," and what we are able to know about it. Creswell (2009) also pointed out that ontological world views often shape the orientation and design of the evaluation methodology preferred. Hence the qualitative interpretive paradigm within which this evaluation was conducted, and the case study method used together with the data collection and analysis techniques all reflects the ontological viewpoint of knowledge as socially constructed (Denzin and Lincoln 2011; Maxwell 2010; Yin 2013). An evaluation methodology that does not only focus on the numbers of farmers trained and now then practicing agroecology was needed. Therefore, knowledge interest that required much more than just statistics for donor reporting determined the use of qualitative methodologies. And a qualitative approach allowed the evaluators to generate more insights into farmers experiences illuminating light on some of the grey areas where future programming needed to resolve in order to achieve not only more but sustainable impact, working with smallholder farmers in Limpopo to adapt to climate change.

Using the Case Study Evaluation Method

According to Harrison et al. (2017), case study research has grown in reputation as an effective means to explore and understand complex issues in real-world settings. It has been widely used across several disciplines, particularly the social sciences, education, business, law, and health, to address a wide range of research questions.

The case study method used in this evaluation allowed for a closer examination and analysis of each participating smallholder agroecology farmer in real-life contexts (Harrison et al. 2017). It also allowed the evaluators an opportunity to select information rich participants or cases (Flyvbjerg 2006, 2011) making it possible to generate enough data and in-depth insights into how agroecology is being experienced by and changing the lives of smallholder farmers. It also allowed them to probe in detail the extent to which farmers understand the connection between adopting agroecology and building their resilience to climate change.

Fifteen carefully selected cases of smallholder farmer households drawn from 300 farmers trained and being supported to implement agroecology. These households were purposively selected on the basis of having received training and actively implementing agroecological practices. Purposive sampling meant that the researchers had to pick on the most productive sample (smallholder farmers) that could provide adequate data to answer the research questions (Marshall 1996; Flyvbjerg 2006, 2011). It also allowed for the selection of what Yin (2014) referred to as *data rich* participants. And because this was not a comparative analytical evaluation, selecting those data-rich cases made much epistemological sense.

As represented in Table 1, the farmers involved in the evaluation included those that had been trained through 17 Shaft Training in 2015 and 2016 and those trained by Hoedspruit Hub in 2016 and 2017.

Evaluation information was collected using semi-structured interviews integrated with narrative enquiry and field observation. Yin (2014) argued that semi-structured interviews allow a researcher greater freedom to pursue unexpected, but interesting and relevant comments to a greater depth. Instead of a scripted list of questions, the researcher has a good idea of the questions she would like to ask, and perhaps even an interview guide, but may ask the questions in a way that fit the context of the emerging conversation between researcher and participant smallholder farmer (Yin 2014; Creswell 2009). Also important for a qualitative evaluation such as this one the use of semi-structured interviews allowed the farmers to answer questions in their own words, potentially adding details to the data that might have been missed otherwise (Yin 2011). The interview guide used to collect demographic information relating on participants profiles also provided a way of generating quantitative data

on harvest and income trends being experienced by smallholder farmers implementing agroecology.

Information collection also entailed use of narrative enquiry where farmers were asked to tell their stories of change. Dyson and Genishi (1994) asserts that storytelling provides a useful theoretical lens through which to examine the ways in which individuals experience the world as illustrated through their own personal stories. Narrative inquiry helped the evaluators to capture the farmers' full experiences of their adoption and implementation of agroecological farming practices. Davis (2007) also argued that storytelling is a very useful way of collecting data especially from informants with low literacy levels such as the case with most of the farmers involved in this project evaluation. As such storytelling helped to make this project evaluation socially inclusive in orientation.

With the consent of participants, their stories and responses to interviews were audio recorded for data transcription and analysis. Some of the interviews were video recorded and footage stored for the future development of a short video film to support the sharing of the emerging findings of the project evaluation.

In order to deepen insights and triangulate information collected through the interviews (Shenton 2004), field observations were conducted and entailed visiting homesteads of all the 15 farmers to learn more about their agroecological practices and ascertain harvests being experienced. Photography was used to capture observations made during the field trips.

In total, 15 interviews were done, and visits to all the 15 farmers undertaken. The data generated was processed through transcribing, translation into English, making it ready for analysis

Information collected was subjected to initial analysis using Atlas Ti 7 to both locate and code the data (Friese 2014). Dohan and Sanchez-Jankowski (1998) argued that coding data with a well-designed computer program like Atlas Ti 7 can be very useful but not an end in itself. Analysis of data was thus continued using thematic data analysis where emerging themes relating to questions being pursued in the evaluation and discussed in this handbook chapter were identified and analyzed.

Evaluation Findings

Farming Sites

The 15 smallholder farmers who participated in this project evaluation were drawn from the villages as shown in the map below. All these villages are adjacent to the Kruger to Canyons Biosphere area and falls within Maruleng, Lepele Nkhumpi, and Elias Motshoaledi municipalities of Limpopo province. In terms of climate, these areas are generally quite dry with an annual rainfall of around 500 mm/year concentrated in 4 months during the summer (AWARD 2016).

Farmers were selected from villages such as Sidawa, Zebedela, Turkey, and Mametja of Maruleng, and Motetema, Tarfelskop, Makweng, Dithabaneng, Makushoaneng, and Monsterlus of Carpricorn and Elias Motshoaledi (Fig. 3).

15	48	Male	2	4	0,032
Averages	45,3		4	5,6	0,28

Demographics

Of the 15 farmers interviewed, 11 were female and 4 were male. Average age of the smallholder farmers interviewed was 45.3, with the youngest being 20 years old. On average, each household size was reported as made up six family members.

The plot sizes for most farmers ranged from 0,002 ha (an area of 4 m × 5 m) being the smallest to the largest of 0,54 ha. Each farmer was producing a good mix of vegetables with limited fruit and herbs. Those farming herbs were benefiting from the market linkage support that Hoedspruit Hub was providing. Table 2 illustrates the above demographics of the farmers.

Reasons for Adopting Agroecological Farming Practices

The chapter confirms that most of the farmers interviewed has various reasons for practicing agroecology. These reasons ranged from the need to produce more food for household consumption, desire to generate income, and influence from neighbors to the farmers' realization of declining yields.

Asked to share his motivation for taking up and practicing agroecology one of the farmers was quoted saying:

> Remember the first thing which is needed by the family before they do any job is food. So for me, I work for food first and then seek money elsewhere. (F2)

Similarly, the other farmer interviewed weighted in by pointing out that:

> When I started implementing the permaculture (agroecology) ideas, I noticed that my vegetable production doubled, compared to the first yield where I had little knowledge. This method is cheap and sustainable long term. (F4)

Asked to explain why adopting agroecology and converting from the usual conventional farming, another farmer confidently said that:

> I have a diversity of activities in order to produce a wide variety of results such as generating income, providing my family with meat and vegetables. (F7)

Two of the interviewed farmers were despite trained, however, not yet practicing agroecology. The two perceived agroecology as for mainly very small farmers, thus not very suitable for their scale of farming.

It became quite clear that the smallholder farmers interviewed were practicing agroecology because of different reasons. These as reflected above included the both the need to feed their families and earn income from selling the surplus backyard gardening produce. Producing more food to feed the family and income generation as, confirmed by responses from 66% (n = 10) of farmers interviewed, emerged the top two reasons influencing adoption and practicing of agroecology. The desire to improve household income as a reason for practicing agroecology was made much more explicit by a farmer who shared her story as quoted below.

> Life with my children and no support from their father was not a good life for me at all. I tried many things to improve the living conditions of my children. I received government benefit but it was not enough to send them to school, provide medical support and to buy the right food. One of the areas I got passionate about was farming, but I had no skills. But then I got training in agroecology and started from a small base growing a few vegetables and crops. . .. and now I earn more money and I am happy. . .. (F10)

The desire to produce food for the family, to share with neighbors, and sell the surplus to generate income is illustrated in Table 3.

Other influencing factors included realization that their soils are no longer producing as much as they used to, keeping up with the jones (learning from neighbors) and as well lack of employment opportunities especially among the youth in the lowveld. About 33% (n = 5) of active agroecological farmers were unemployed and many cited this as the original reason for starting their agroecological production units. For many farmers, continued unemployment meant no other option than to continue farming agroecologically. One farmer alluded to the medicinal value of herbs as the reasons for his interest in doing agroecology. Access to market and increasing demand for organic vegetables by local lodges were also mentioned as factors shaping the way agroecology was being adopted and implemented. Also, very interesting is that a few farmers thought that agroecology is easier and cheaper to do as it does not require heavy use of chemicals and fertilizers. Ecological reasons for implementing agroecological farming practices

Table 3 Household consumption, sharing, and selling of agro-produce

Code	Household use (%)	Sharing (%)	Selling (%)	Income p.m. (rands)

F15	20	10	70	600
Avg	33,77	16,88	49,33	1016,00

were also observed and some of the farmers talked of the need to improve soil health and save water. Asked to explain why she adopted agroecology, one farmer felt agroecology enabled communities to live in harmony with nature, and she said that,

> To me it would be beneficial if more people can farm agroecologically and if they can impart it to their children. People say they are going to pray for rain. We are not living harmoniously with nature, and not sending rain is nature's response. It's how nature talks

The desire to save water which was also linked to ecological reasons for taking up agroecology could be easily understood from the fact that most of the farmers in the area covered by this evaluation (lowveld of Limpopo) did not have reliable water supply and were actually buying water (Award 2016) to sustain their gardens. Water was therefore even without or before onset of climate change a scarce resource. Others talked of social motivations including that gardening kept them physically active and healthy, reducing stress, and keeping them out of poverty and criminal activities.

The observations made above were also reported by similar research studies. Studies done by Nilesa and Mueller (2016) revealed that farmers change their agricultural behaviors not only because of the changes in climatic conditions. The evaluation findings revealed that factors such as the inherent desire to sustain food security and the changes in the wider environment, e.g., changes in soil fertility and productivity levels, contributed to the changes in agricultural practices adopted by farmers. Scholars such as Toffolini et al. (2018) also revealed that the evolution of farmers' practices towards agroecology is mainly influenced by agronomist factors to increase food production. In a similar sense, Hubert (2012) also observed that agroecology has, in various countries, been considered a viable option for achieving sustainable food production systems. Accordingly, Altieri (1999) claimed that the agroecological approach provides an alternate path to increasing crop production because of its reliance on local farming knowledge and technologies suited to different and marginal climatic conditions such as those of Limpopo.

The Connection Between Agroecology and Climate Change

Out of the 15 farmers interviewed in this project review, only one (n = 1) of them made an explicit reference to climate change. This is a very interesting observation but one that is unusual. Such an observation can be understood from what other studies has revealed. Nilesa and Mueller (2016) pointed out that they are unaware of any studies that have examined the extent to which farmers' perception of climate change directly explains their changes in farming practices. Whyte (2014) also observed that even though the broad issue of adaptation to environmental change is not new for many indigenous peoples, it is something done out of survival instincts rather than any significant levels of climate change awareness. Closely related, Mugambiwa (2018) concluded that subsistence farmers have always adopted adaptive strategies to changes such declining crop yields. In his study, he concluded that changes in farming practices such as a shift from maize to traditional millet and sorghum that farmers in Mutoko, a district in Zimbabwe, adopted were triggered by the desire to preserve local indigenous knowledges and cultures rather than the changing climatic conditions. However, it can be argued that this change and adoption of indigenous knowledge practices as acknowledged by Waha et al. (2013) to respond to frequent droughts, scarcity of rain, and decreased crop yields is by default a strategy for adapting to climate change.

Other studies done by Arbuckle et al. (2013) and Niles et al. (2015) to investigate farmers' perceptions of climate change, its risks, and potential to influence adoption of adaptation and mitigation behaviors also confirmed that farmers relate more to weather than climate change. This observation is also reflected in what one farmer who made reference to climate change was quoted saying,

> Then I ask myself, isn't it important to know, what is hindering rain from coming? So, all these practices we are doing, it's hindering rain from coming, by contributing to climate change. We can pray and pray and pray, but if we don't change our thinking, decolonise our minds, rain will not come. We can expect drought

Farmers are therefore arguably more affected by weather-related losses than climate change per se. Thangata et al. (2002) argued that the decisions made by smallholder farmers to adopt agroecological practices, e.g., agroforestry, in the context of Zambia reflected the farmers' perceptions of worst-case weather changes such as delayed rainfall or droughts. And thus, if they were asked about how weather determines their farming practices, a good number of the farmers involved in this evaluation could have provided more explicit answers. This finding denotes the need to appreciate that for most farmers the adoption of agroecology is, at experience level, motivated more by other factors than solely climate change (Palm et al. 2010; Beddington et al. 2011; Nyanga et al. 2011).

While agroecology has been widely associated with strengthening the resilience of farmers and rural communities (Niles et al. 2015), evidence to support that adoption of agroecological practices is a direct result of the farmer's awareness of climate change remains anecdotal. Nyanga et al. (2011), in a study done in Zambia, also reported of a positive correlation between perception of increased droughts and adoption of conservation agricultural practices such as agroecology but no correlation between farmer' attitudes towards climate change itself. The increased interest in agroecology has also been not only linked to climate change but other narratives such as the green revolution. Hence the tendency to give function to agroecology and all its associated soil, water, and biodiversity conservation technologies, as a strategy for climate change adaptation, can only be referred to as of zero interest from the perspective of farmers. Other scholars have further critiqued the way agroecology has now been hijacked by the politics of the day and repackaged as climate smart agriculture. The implication of the observation made here is that it is just as important to know the priorities of the farmer implementing agroecology practice than to present it as solely a climate change adaptation measure.

Conclusion

While the work done by the two development organizations who commissioned the writing of this chapter is aimed at building resilience for climate change adaptation, it is important to note that farmers' decisions to adopt agroecology is influenced by many other factors. This observation gives added value to the need for additional interventions such as the dialogues for climate change literacy and adaptation (DICLAD) which can improve farmers' levels of knowledge and awareness of climate change, and how this relates to adopted agroecological practices being implemented.

In general, the findings discussed in this chapter also calls for a redesign of contemporary farmer extension support services. There is need to adopt approaches that not only empowers farmers with basic knowledge of climate change science but also recognize that agroecological practices and technologies have a history that is tied to a range of evolving farmer's priorities. Working with farmers and getting them to a level of consciousness that recognizes the value of their indigenous agroecological knowledges and systems for more than just climate change adaptation is what must be pursued. Therefore, advancing the climate change adaptation dimension of agroecology at the expense of the other equally important roles and values is not only reductionist but problematic.

Climate Change and Variability on Food Security of Rural Household: Central Highlands, Ethiopia

21

Argaw Tesfaye and Arragaw Alemayehu

Contents

Abstract

This chapter analyzes the impact of climate change and variability on food security of rural households in the central highlands of Ethiopia taking Basona Werana district as a case study site. Data were obtained from 123 households selected using simple random sampling from three agro ecological zones. Key informant interviews and focus group discussion (FDG) were used to supplement the data obtained from household survey. The monthly rainfall and temperature data are for 56 points of 10 × 10 km grids reconstructed from weather stations

and meteorological satellite observations, which cover the period between 1983 and 2016. Standardized rainfall anomaly (SRA), linear regression (LR), and coefficient of variation (CV) are used to examine inter-annual and intra-annual variability of rainfall. Annual and seasonal rainfalls show decreasing trends over the period of observation. The decreasing trends in annual and March–May (Belg) rainfall totals exhibit statically significant decreasing trends at $p = 0.05$ level. Kiremt (June–September) shows statically significant decreasing trends at $p = 0.1$ level. Mean annual maximum and minimum temperatures show statically significant increasing trends at $p = 0.05$ level. More than 80% of households perceived that the climate is changing and their livelihoods (crop and livestock production) are impacted. The district belongs to one of the most vulnerable areas to climate change and variability in the country where large proportions of households (62%) are under different food insecurity classes. Results suggest that local level investigations are useful in developing context-specific climate change adaptation.

Keywords

Climate variability · Rainfall and temperature trends · Food security · Ethiopia

Introduction

Africa is already affected by climatic extremes such as floods, droughts, and windstorms, which are aggravated by climate change and variability. Ethiopia is one of the African countries which is most vulnerable to drought and floods (Belay et al. 2017). Climate change in the form of rising temperature, variable rainfall, droughts, and flooding affects agricultural production and threatens food security in low-income and agriculture-based economies (Mongi et al. 2010; Mesike and Esekhade 2014). Agriculture in Ethiopia is a major source of food and contributing sector to food security. It plays a key role in generating surplus capital to speed up the socioeconomic development of the country (Adem et al. 2018; Hagos et al. 2019).

Achieving food security and end hunger in the face of the ongoing impacts of climate change and variability is at the heart of the sustainable development goals. Climate change and variability are currently the biggest challenge affecting countries where rainfed agriculture is a means of livelihood (Asfaw et al. 2017).

The impact of climate change and variability on agricultural production increases economic and social challenges. Climate change affects agriculture in a different way. Climate extremes and changes in rainfall pattern are already influencing agricultural productivity. Increased tension in households, increased lethargy, poor school performance, and a range of other social ills are the major social impacts mostly reported (Akinseye et al. 2013).

Climate change and variability affect four dimensions of food security, namely, food availability, food accessibility, food utilization, and food system stability. The most direct impact on food security is through changes in food production. Short-term variations are likely to be influenced by extreme weather events that disrupt production cycles (Alemu and Mengistu 2019). Climate change and variability affect food availability through its impacts on economic growth, income distribution, and agricultural demand markets, food prices, and supply chain (Schmidhuber and Tubiello 2007).

Historically, Ethiopia is well known for being prone to extreme events. The rainfall over Ethiopia exhibited high variability (Suryabhagavan 2017), and the country's economy has been affected by long-term changes in both rainfall amount and distribution where the country has witnessed frequent incidents of both excessive and deficient rainfalls (Zeleke et al. 2017). The most common drought periods known are 1957–1958, 1972–1974, 1984–1985, 2002–2003, and 2015–2016 (Markos 1997; Suryabhagavan 2017).

The central highland of Ethiopia, where the study area is located, is a drought- and famine-prone area. The people mainly derive their livelihood from subsistence agriculture, which is characterized by mixed farming system on fragmented land, over utilized land, and affected by erratic rainfall (Alemayehu and Bewket 2016a). Minor droughts are common every year due to climate variability. This brought an impact on the poor performance of the agricultural sector which affects rural livelihoods and food security (Asfaw et al. 2017). The central highland of Ethiopia is already food insecure, and large parts of the Basona Werana district are beneficiaries of the Productive Safety Nets Program (PSNP), which is the major food security program of the government (Alemayehu and Bewket 2017b).

Adaptation enables farmers to reduce vulnerability to adverse effect of climate change and variability. It helps rural communities cope with and adjust adverse consequences to climate change and variability (Deressa et al. 2010; IPCC 2014).

Degefa (2002), Frehiwot (2007), and Messay (2010) investigated the socioeconomic impacts of food security in different regions of Ethiopia. However, the impact of climate change and variability on food security is not addressed in their respective study areas.

Kahsay and Gebremicale (2018) investigated the impact of climate change on household food availability in Tigray region. The findings show that high prevalence of food insecurity has greater consequence among the female households. There are studies addressing the vulnerability context and impacts of climate change covering the central highlands of Ethiopia, which is also part of the present study (Bewket 2009; Alemayehu and Bewket 2016a, b, 2017a, b). This chapter links climate change and variability and food security in Basona Werana district by taking three agro ecological zones. This household level assessment is useful to identify and prioritize food insecure areas and contribute factors for adaptation planning.

Three kebeles (the lowest administrative level in the country) incorporating Kolla (lowland), Weyna Dega (midland), and Dega (highland) agro ecological zones were selected purposively to capture variations in agro ecology (Fig. 1). A total of 123 farmers were selected randomly (53 in Goshebado, 40 in Gudobert, and 30 in Kore Margfiya, respectively). Focus group discussions and key

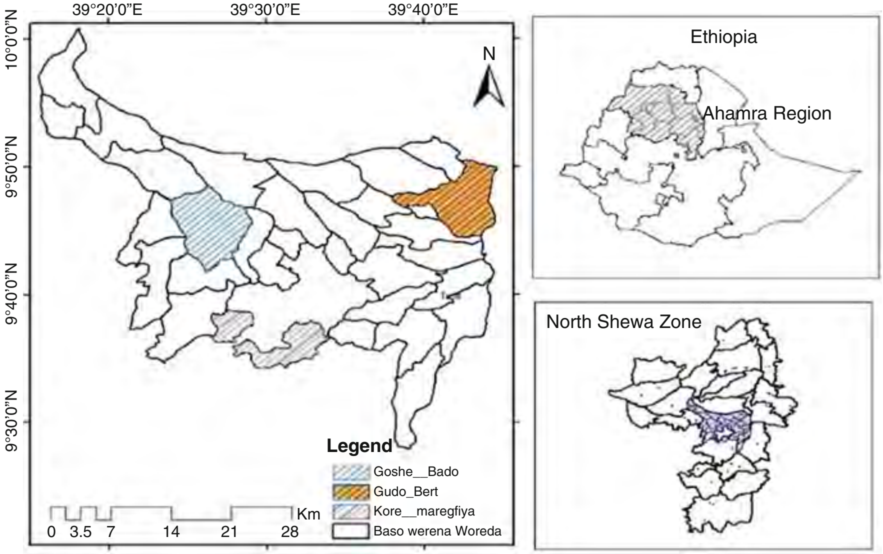

Fig. 1 Location of Basona Werana district, central highlands of Ethiopia

informant interviews were conductive to supplement the quantitative results from the household survey.

The monthly rainfall data used for this study are for 56 points (each representing areas of 10 × 10 km) for the period between 1983 and 2016. The monthly maximum and minimum temperatures are for the same points and girds, but cover the period from 1981 to 2016. All were collected from the National Meteorological Agency of Ethiopia. Rainfall and temperature data were analyzed using coefficient of variation (CV), standardized rainfall anomalies (SRA), and linear regression (LR).

CV is expressed as a percentage and computed as

$$CV = (\sigma/\mu) \quad (1)$$

where CV is the coefficient of variation

σ = is the standard deviation

μ = is the mean rainfall

CV is used to classify the degree of variability of rainfall events. The different CV classes are less (CV <20%), moderate (20%< CV <30%), and high (CV >30%).

Standardized rainfall anomalies are calculated to examine the nature of the trends and determines of the dry and wet years in the period of observation as well as frequency and severity of droughts (Agnew and Chappel 1999; Bewket and Conway 2007).

As shown in Agnew and Chappel (1999), SRA is given as

$$SRA = (Pt - Pm)/\sigma \quad (2)$$

where SRA = standardized rainfall anomaly

Pt = annual rainfall in year t

Pm = is long-term mean annual rainfall over a period of observation and

σ = standard deviation of annual Rainfall over the period of observation

The different drought severity classes are calculated as shown in Agnew and Chappel (1999): extreme drought (SRA < -1.65), severe drought ($-1.28 >$ SRA > -1.65), moderate drought ($-0.84 >$ SRA > -1.28), and no drought (SRA > -0.84).

Linear regression was used to detect changes or trends in rainfall and temperatures. It is given as

$$Y = mx + b \tag{3}$$

where y is dependent variable, m is the slope, x is independent variable, and b is the intercept.

Surface data were generated from 56 points of gridded monthly rainfall and temperature data (10 km × 10 km) using simple kriging interpolation technique with ArcGIS 10.5.

Household Food Balance Model (HFBM) (sheet) was used to analyses the status of household food security of the sample households in order to classify the households as food secure and insecure (Mesay 2010; Derara and Degfa 2016)

$$\begin{aligned} NGA = {} & (GPi + GBi + GRi + GPSi) \\ & - (HLi + GUi + GSi + GVi + NSi) \end{aligned} \tag{4}$$

where

NGA = Net grain available (quintal/household/year); a quintal = 100Kgs
GPi = Total grain production (quintal/household/year)
GBi = Total grain bought (quintal/household/year)
GSi = Total grain obtained through gift or remittance (quintal/household/year)
GPSi = Total grain obtained from previous year (stock/year/household)
HLi = Post-harvest losses due to grain pests, disasters, thievery (quintal/household/year)
GUi = Quantity of grain reserved for seed (quintal/household/year)
MOi = Amount of marketed output (quintal/household/year)
GVi = Grain given to others within a year (quintal/household/year)
NSi = Grain planned to be left by a household for next season (quintal/household/year)

Descriptive statistical methods such as frequencies, means, and percentages were used to summarize the information on food security issues and climate change perceptions, impacts, and adaptation strategies. Chi-square test is used to test the statistical significance of variations across AEZs.

Impact of Climate Change and Variability on Food Security of Rural Household

Variability and Trends in Rainfall and Temperature

As shown in Table 1, the average annual rainfall of the area for the study period is 1013 mm, with standard deviation of 125 mm and CV of 12%. Annual rainfall varies from 784 mm (2011) to 1227.2 mm (1985). The results of trend analysis of annual and seasonal rainfall are presented in Table 1. Accordingly, annual and seasonal rainfalls show statistically significant decreasing trends except Bega (October–February) rainfall where there is no clear trend. Annual rainfall shows statistically significant decreasing trend 63.58 mm/decade at $p = 0.05$ level. Belg rainfall also showed statistically significant decreasing trend at $p = 0.05$ level. Result supports previous studies by Williams et al. (2012) and Kebede (2013) who reported declining trends in Belg rainfall. Kiremt rainfall has shown statistically significant decline of 23.2 mm/decade. Elsewhere in Ethiopia, Kiremt rains support the main cropping season locally known as Meher at $p = 0.1$ level. The declining trends of Kiremt rainfall will aggravate the food security challenges in the area.

The coefficient of variation revealed that rainfall in the area has low inter-annual variability (12%) (Table 1). June to Kiremt rainfall has large contribution to annual rainfall (72%), with CV of 13%. Belg and Bega seasons have high rainfall variability each having CV of 42.6% and 56.8%, respectively. Belg rainfall contributed 17% of annual rainfall.

Rainfall distribution was highly concentrated in the few months of the year (July to September). July and August are the wettest months. July has the highest monthly rainfall (295 mm) which contributes 30% of annual rainfall. August has 287.5 mm rainfall and contributes about 29%. November and December are the driest months, having 11 mm of rainfall each (Fig. 2).

Analysis of the standard rainfall anomaly is used to show the intensity and frequency of drought and inter-annual variation at various spatiotemporal scales. The rainfall pattern showed a characteristic that a dry year is followed by another 2 or 3 dry years and vis-à-vis for the wet years.

Table 1 Trends of annual and seasonal rainfall

	Mean	LR	Wettest year	Amount rainfall (mm)	Driest year	Amount rain fall (mm)	SD	CV
Annual	1013	−63.58[a]	1985	1227.2	2011	783.8	124.4	12.3
Kirmet	733.8	−23.2[b]	1997	918.9	1987	485.3	98.6	13.4
Belg	182.4	−24.8[a]	1987	437.1	1998	58	77.7	42.6
Bega	87.5	−11.6	1997	237.2	2011	13.3	49.7	56.8

LR = linear trends (mm 10/year)
[a]Significant at 0.05 level
[b]Significant at 0.1 level

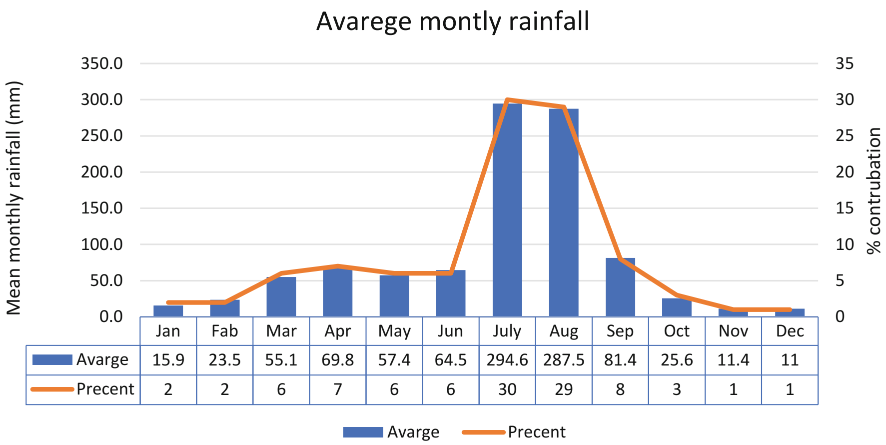

Fig. 2 Monthly rainfall (in mm) and contribution to the annual total (in %)

After the 1984 drought, annual rainfall showed some recovery, but with considerable internal variations. Extreme drought (<−1.65) is observed during the years 1984, 2008, 2009, 2011, and 2015. Severe drought (−1.28 to −1.65) is observed for the years 1989, 1995, and 2005 (Fig. 3). The years 2006 and 2007 show positive anomalies. The year 2006 was a major flood year in the country, which caused loss of life and property in different parts of the country particularly in Dire Dawa and South Omo (Alemayehu and Bewket 2017a). The proportions of negative and positive anomalies account for 61% and 39% of the total observations, respectively. The 1980s and 1990s are wet compared with the 2000s. Close to 23% of observations fall under different drought categories.

At show in Fig. 3, negative and positive Kiremt rainfall anomalies account for 52% and 48% of observations for the period 1983–2016, respectively. Extreme drought was observed in the years 1984 and 1987 and severity drought in 2008 and 2011. Belg rainfall positive anomalies account for 42% of total observation. The extreme drought is observed in 1992, 1997, 1998, 2008, 2009, 2013, and 2014. Belg rainfall anomalies are relatively more positive in the driest decade of the 1980s than the others. Generally, the findings repeat the earlier works of Bewket and Conway (2007), Rosell (2011), Ayalew et al. (2012), and Alemayehu and Bewket (2017a) who reported a similar finding for the central highlands of Ethiopia.

Figure 4 shows the spatial distribution of annual and seasonal rainfall distribution and trends over the period of analysis. Large proportion of the district (42%) receives annual rainfall of between 829 and 886 mm. About 35% of the area in the southern part of the district receives rainfall of between 77 and 829 mm. Close to 33% of the area in the in the northwestern part receives rainfall of between 886 and 955 mm. Most of the grid points of annual rainfall trend fall within −0.84 and −0.04 ranges. Result coincides with a previous study by Alemayehu and Bewket (2017a) on local scale variability, and trends of rainfall and temperature in the central highlands of Ethiopia that reported most of the grid points fall within −0.1 and −0.7 range which

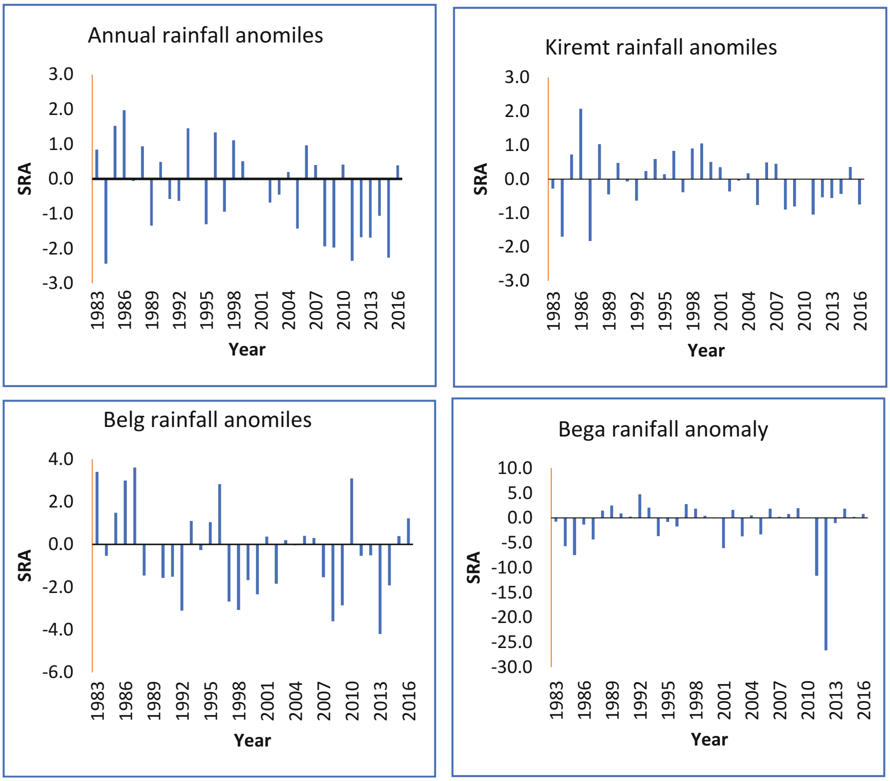

Fig. 3 Temporal variations in the annual and seasonal rainfall anomalies

exhibit strong negative trend of annual rainfall. The implication is that drying trends in the district have adverse consequences on the already poor performance of the agricultural sector in the area. Drying trend of Belg rainfall (−0.4 to −0.02) in the area is observed. The implication is on the Belg season production, which is important for household level food security in the locality (Alemayehu and Bewket 2017a). In the case of Kiremt rainfall (−3 to 2) trends in the upper part of the district is observed. In the middle part of the district (0 to 2), positive trends were observed, whereas the lower part of the district negative trends (−3 to −1).

The mean annual temperature is 13.2 °C. The lowest and highest mean annual temperatures are experienced in 1999 and 2009, respectively. The lowest temperature is 12.1 °C and highest temperature 14.5 °C with a standard deviation of 0.46 and coefficient variation of 0.03. The lowest temperature is −2.1 °C (December) with a standard deviation of 0.8 and coefficient variation of 0.12. The highest temperature is 24.4 °C (February) with a standard deviation of 0.42 and coefficient variation of 0.02. The mean annual minimum temperature ranges from 4.83 °C (2000) to −2.1 °C (1998), and the long-term mean is 6.3 °C. The mean annual maximum temperature ranges from 23.4 °C (2009) to 15.8 °C (1994), and the long-term mean is 19.7 °C.

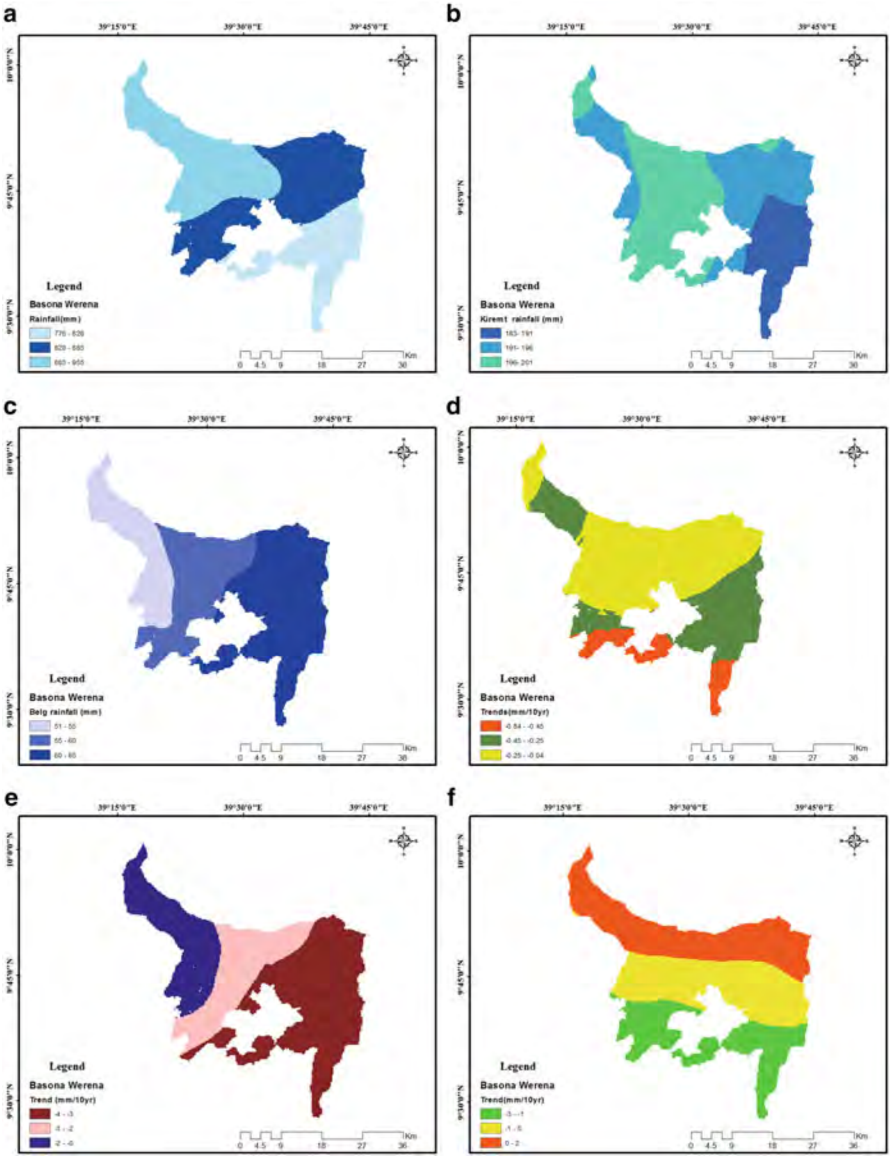

Fig. 4 Spatial distribution of annual rainfall and seasonal rainfall (A, B, C) and annual rainfall and seasonal trends (D, E, F)

The mean annual maximum temperature shows warming trends for the period 1983–2016. The warming trend in the maximum temperature (0.2 °C/decade) is statistically significant at $p = 0.05$ level.

As show in Table 2, Bega and Belg season's maximum temperature experienced statistically significant increasing trends at $p = 0.05$ and 0.1 levels, respectively.

Table 2 Annual and seasonal trends in the mean maximum and minimum temperature

	Mean maximum and minimum temperature °C							
	Annual	LT	Kiremt	LT	Bleg	LT	Bega	LT
Maximum temperature °C	19.7	0.02[a]	19.36	−0.1	20.96	0.03[b]	19.6	0.28[a]
Minimum Temperature °C	6.29	0.42[a]	8	−0.015	7.27	0.0114[b]	3.61	0.013

LR = linear trends (0[c]/10 year)
[a]Significant at 0.05 level
[b]Significant at 0.1 level

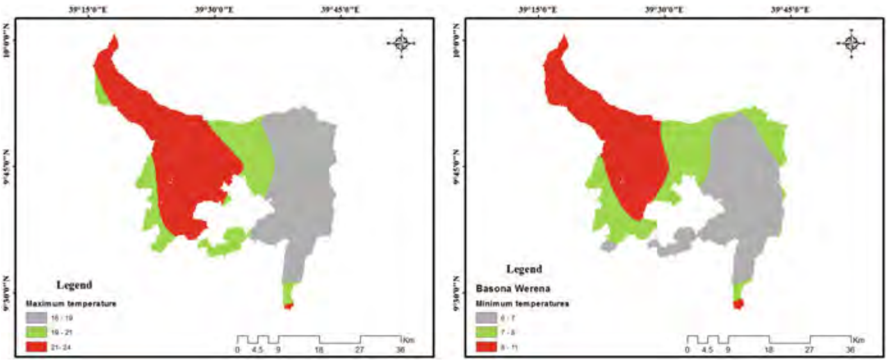

Fig. 5 Spatial distribution of mean maximum (left) and minimum temperatures (right)

Kiremt season's maximum temperature experienced statistically nonsignificant decreasing trend.

The annual minimum temperature shows positive trend. Minimum temperature has experienced statistically significant increasing trend at p = 0.01 level. Kiremt minimum temperature shows declining trend at p = 0.05 level. The trends for the Bega and Belg minimum temperatures are similar with the maximum temperature; statistically significant increasing trends at p = 0.05 and 0.1 levels, respectively, are observed (Table 2). Earlier studies by Conway et al. (2004), NMA (2007), Jury and Funk (2012), Tesso et al. (2012), and Taye and Zewdu (2012) also reported a warming trend of the minimum temperature in their respective study areas and periods.

Figure 5 shows the spatial distribution of mean maximum and minimum temperatures. Both mean maximum and minimum temperatures are higher in the northwestern part of the district and decrease in the southeast. The maximum temperature for northern parts of district ranges from 22 °C to 24 °C and the lowest southeast 10–20 °C, whereas the minimum temperature of the district is lowest in the southeast ranging from 6 °C to 7 °C in the study period.

Rural Household Perceptions of Climate Change and Variability and Their Impacts

Table 3 shows that about 88% of farmers perceived that the climate has been changed. Close to 94% of households in the Kolla agro ecological zone perceived that they have been experiencing climate change and variability. This is followed by Dega agro ecological zone where 93% of households perceived climate change and variability.

> A key informant from Dega agro ecological zone explains: in the last three decades, Belg rains are highly variable and shows declining trends in the surrounding. Belg rains now are non-existent become history to the area. The worst case is that Kiremt rainfall is insufficient due to increasing water demand. Kiremt rainfall starts late and ends early. Coupled with other environmental changes like land degradation and soil erosion, current climate variability challenges food security; not capable of producing enough food for family members.

Results from FGDs also confirmed that rainfall is declining from time to time while temperature is getting warmer. About 67% of households in all agro ecological zones perceived that temperature shows warming trend, while 20% of households perceived that temperature shows declining trends in their locality. Close to 13% of households report no observable change of temperature. Statistically significant mean difference was observed in terms of perception of temperature across agro ecological zones at $p = 0.1$ level.

Regarding changes in rainfall patterns, close to 59% of households reported that rainfall shows decreasing trends. The other 35% of households observed changes in the timing of rainfall. Farmers in the Kolla agro ecological zone reported declining trends in rainfall (73% of households). About 53% and 52% of households from

Table 3 Rural household perceptions of climate change and variability and their impacts

Climate change/variability	Agro ecological zone			Mean	X^2
	Dega	Kolla	Weyna Dega		
Yes	93	94	70	88	11.819[a]
No	8	6	30	12	
Temperature pattern					
Increased	65	71	64	67	8.323[b]
Decreased	27	20	11	20	
No observable change	8	9	25	13

Decrease in rainfall amount	52	73	53	59	5.111
Change in timing of rain	43	24	37	35	
No change in rainfall	5	3	11	6	

[a]Significant at 0.05 level
[b]Significant at 0.1 level

Weyena Dega and Dega agro ecological zone perceived declining of rainfall trends, respectively.

Rural households' perception of changes in rainfall and temperature corroborates the results of metrological data analysis. They perceived reduced rainfall and warming temperatures. Analysis of climate data revealed declining trends of annual and seasonal rainfalls. Similarly, warming of the minimum and maximum temperatures is observed from analysis of climate data.

Regarding the cause of climate change, about 39% of households reported human interventions caused climate change. Close to 11% of households in the three agro ecological zones reported natural factors caused climate change. About 40% and 36% of households in the Dega and Kolla agro ecological zones attributed climate change with religious factors. Statistically significant mean difference was observed in terms of perceived causes of climate change across agro ecological zones at $p = 0.01$ level. Results of FGD participants and KIIs reported the effect of deforestation for different purposes is the main cause of climate change.

Impacts of Climate Change and Variability on Food Security of Rural Households

As show in Table 4, majority of the households (88%) reported changes in rainfall pattern as the main challenge of their livelihoods. The onset and offset periods of rainfall are unpredictable and affect sowing and harvesting periods. Prevalence of pest and diseases was mentioned by 82% of the households. The effect of flood is reported by 48% of the households. Snow as a challenge to food security is reported by 65% of the households. For example, months from October to December are the coldest months in the area. Thus, matured crops are more likely to be affected by frost. Drought has several negative consequences in the area; it causes extensive damages to crops and loss of agricultural production. Close to 67% of the households replied that drought was the major climate-related factor challenging agricultural productivity in the area (Table 4).

Table 4 Impact of climate change and variability on livelihood

Major climate elements	Agro ecological zone			Mean	X^2
	Dega	Kolla	Weyna Dega		
Temperature increased	79	96	87	87	6.906[a]

Table 5 Correlation between climate change and variability and food security

		Temperature change	Rainfall variability	Flood	Drought	Frost
Food security	Pearson Correlation	−0.182	−0.157	0.231	−0.150	−0.174
	Sig.(2-tailed)	0.044	0.083	0.010	0.098	0.055
	N	123	123	123	123	123

Statistically significant mean difference was observed in terms of perceived impacts of climate change and variability on livelihoods across agro ecological zones.

Bivariate correlation was used to analyze the association between food security and climate change and variability over the last two to three decades. The food security status of a household is determined by the rate of temperature and rainfall changes, occurrence of flood, drought, and frost which have adverse negative impacts on crop and animal productivity thereby affecting the food security status of rural households (Table 5).

Results of the bivariate correlation showed that food security has negative correlation with temperature change at $p = 0.05$ level. Similarly, rainfall variability and occurrence of drought and frost have negative correlations at $p = 0.1$ levels. Food security has positive correlation with occurrence of flood at $p = 0.05$ level.

Household Food Security Status

HFBM was used to determine household food security status. The result of the HFBM reveals that 62% of households are food insecure and failed to satisfy their daily minimum requirement recommended for their households (2100 Kcal/adul. equ), while 38% of the households are food secured. At agro ecological zone level, food insecurity is highest in the Dega (67% of the households) followed by Kolla (60% of the households), whereas majority of food secured households are found in Weyna Dega agro ecological zone (43% of the households). This is because of the fact that topographic and climate factors are conducive for crop production in the Weyna Dega agro ecological zone compared to others (Alemayehu and Bewket 2016b).

There are different constraints that hinder agricultural productivity and then induce food insecurity. As shown in Table 6, almost all households (99%) replied that poor soil fertility was the main factor reducing productivity thereby causing food insecurity. This is followed by climate variability (97% of the households). About 95% and 93% of the households reflected that farmland shortage and low non-farm income are among the major causes for food insecurity, respectively. Farmers felt that insect, pests, and weeds caused food insecurity. Statistically significant variation in terms of agro ecological zone is observed among the causes of food insecurity at $P = 0.01$ level.

Table 6 Cause of food insecurity

Cause of food insecurity	Agro ecological zone			Mean	X^2
	Dega	Kolla	Weyna Dega		
Traditional farm practices	98	98	96	97	1.230
Land fragmentation	100	83	63	82	16.962[a]
Shortage of labor	95	76	90	87	7.641[b]
Poor soil fertility	100	96	100	99	2.685
Climate variability(rainfall and temperature	100	90	100	97	6.884[b]
Prevalence of animal disease	70	88	67	75	5.175[c]
Deforestation	97	77	73	82	9.111[b]
Farm land shortage	100	98	88	95	8.948[b]
Drought	85	57	60	67	9.065[b]
Poor access credit	88	66	37	64	6.701[c]
Low non in farm income	89	97	93	93	3.613
Shortage of grazing land	88	72	90	83	5.719[b]
Low access market	57	80	40	59	11.936[a]

[a]Significant 0.01 level
[b]Significant at 0.05 level
[c]Significant at 0.1 level

Shortage of labor, climate variability, deforestation, farm land shortage, and shortage of grazing land as cause of food insecurity show statistical difference across agro ecological zone at $p = 0.05$ level. While lack of credit access and prevalence of animal diseases show significant difference at $p = 0.1$ level. The office of Agriculture and Natural Resources of the Amhara Regional State reported that about 15–26% of post-harvest production loss was observed. Coupled with the already low production, the post-harvest loss further affected household food security through diminishing the amount of available food reserve.

This result supported a previous study by Tilaye (2004) in Amhara Region of Ethiopia which identified different factors that cause food insecurity by deteriorating the food production capacity of households. These included drought, soil erosion, land fragmentation, population and pressure poor farming technology, and high labor west age as major causes of food insecurity.

In response, households used different coping and adaptation strategies to mitigate the adverse effects of climate change and variability on food security. About nine types of adaptation measures are identified. These are soil and water conservation, changing planting date, use of fertilizer, planting tree, animal fattening, livelihood diversification, irrigation, improved seed, and crop diversification. The majority of farmers (99%) used soil and water conservation practices as adaptation to the impact climate change variability on food security. This is followed by changing crop planting dates (98% of households). While the least strategies are irrigation (21%) and animal fattening (59%). Similarly, changing consumption pattern and sell of livestock product (butter, milk, and cheese) are the dominant coping strategies used by 88% and 83% of the households, respectively. While migration and purchase of food by credit are the least coping strategies used by 21% and 37% of the households, respectively.

Abstract

Maize farming in resettlement areas of Chirumanzu District of Zimbabwe is vulnerable to climatic variations. The Government of Zimbabwe encourages maize farmers in resettlement areas to adapt to climate variability through conservation farming and diversification among other measures. It is envisaged that the measures will improve maize farmers' resilience and ability to safeguard food and nutrition security in the country. However, the process of adaptation is dynamic, complex, and multifaceted in nature. Several problems and dangers accompany the process of adaptation. The problems and dangers are associated with intangible and indirect costs. The focus of this chapter is to explore intangible and indirect costs associated with measures adopted by maize farmers in resettlement areas of Chirumanzu in Zimbabwe. Fifty-four maize farmers from four resettlement wards provided the data through semi-structured interviews. Diversification, changing planting dates, use of drought tolerant varieties were some of the measures adopted. Several problems and dangers accompanied the adaptation measures adopted. Intangible costs such as pain and suffering, embarrassment, ridicule, and stereotyping were experienced. Indirect costs including additional and unplanned costs were also encountered. This chapter concludes that intangible and indirect costs associated with adaptation may result in reduced adaptive capacity and resilience of maize farmers. Therefore, national governments should exercise extreme caution and desist from only encouraging farmers to adapt. Rather, they should consider intangible and indirect costs involved while providing solutions to reduce them to avoid situations where farmers are worse off while facilitating sustainable adaptation.

Keywords

Unintended adaptation effects · Nonmarket adaptation costs · Smallholder farming community · Maize farming · Resettlement areas

Introduction: Adaptation, an Overview

Adaptation is an appropriate way to build resilience to climate variability (Biagini et al. 2014; Costinot et al. 2016; Menike and Arachchi 2016) especially under smallholder maize farming. As such, adaptation has been broadly accepted as a policy priority, which explains why it has received extraordinary attention from politicians (Basset and Fogeliman 2013). Following the refusal of some well-developed nations to support the greenhouse gas emission goals of the Kyoto Protocol of 2001, adaptation emerged as the major viable option for furthering the designing of the Climate Change Policy (CCP) (Schipper 2009). The Intergovernmental Panel for Climate Change (IPCC) (2014) states that it recognizes adjustments made even by smallholder farmers in an attempt to reduce vulnerability of farming activities.

Following the agrarian land reforms introduced in 1980 and the Fast Track Land Reform Programme (FTLRP) of 2000 in Zimbabwe, a vulnerable community of farmers emerged in the professed resettlement areas. Since then, the country has been experiencing food insecurity challenges, with almost 50% of the population being vulnerable to hunger due to the combined effect of unsustainable land reforms and extreme climate variations (Sachikonye 2003). As such, concerns about food and nutrition security have seen the Government of Zimbabwe (GoZ) put more emphasis on adaptation. The Zimbabwe National Climate Change Response Strategy of 2015 acknowledges that farmers in resettlement areas are vulnerable to climatic variations that are currently prevailing in the country. Thus, the GoZ is encouraging maize farmers in resettlement areas to adapt to climate variability so that they can improve resilience and ability to fulfill the massive role of safeguarding food and nutrition security.

Major success stories on adaptation to climate variability have been documented around the globe including the African region and in Zimbabwe. Overall, adaptation has improved maize yields by an average of 15–18%, although effectiveness of measures varies significantly across regions (IPCC 2014). Rurinda et al. (2013) showed that improved timing of planting and adjusting soil nutrient inputs stabilize maize yields under variable rainfall conditions in Zimbabwe. However, it is important to note that adaptation is an investment (Adam and Wiredu 2015) associated with costs as the process introduces new ways of doing things thereby calling for some tradeoffs between new and old ways.

The Cost Associated with Adaptation to Climate Variability

The process of adaptation is dynamic, complex, and multifaceted in nature. This is because it occurs in biophysical, technical, social, and psychological dimensions that are not static but evolving. Adaptation initiatives are associated with costs (Arfunuzzaman et al. 2016). The IPCC (2014) confirms and highlights that it is costly to adapt to climate variability especially when resources are scarce and capacity is limited which is the case with most of the maize farmers in resettlement areas of Chirumanzu District of Zimbabwe. Literature on climate adaptation, in general, does not fully acknowledge intangible and indirect cost of implementing adaptation plans (Milman and Arsano 2014). Yet failure to include the intangible and indirect costs would result in underestimates and misrepresentations of the total cost of adaptation. Adaptation cost literature is still evolving (Fankhauser 2009; Agrawala et al. 2011; Doczi and Ross 2014). It is regarded scant, uncertain, and consensus on overarching cost estimates is lacking (Kumar et al. 2010). There is little peer-reviewed literature on the subject.

Attempts have been made to estimate total adaptation cost. However, adaptation cost estimates only exist at a global level. It is estimated that total adaptation cost ranges from USD9 billion to USD109 billion per year by 2030 (Agrawala et al. 2008; Chambwera et al. 2014). For the agricultural sector, adaptation cost estimates are rare. Agrawala et al. (2011) indicated that with the exception of Mccarl (2007) literature on the cost of adaptation in agriculture is lacking. Mccarl (2007) used a top-down approach to estimate the cost of adaptation in the Agriculture, Forestry, and Fisheries sector. It is estimated that adaptation will cost USD14.23 billion per year by 2030. It is clear that methods that have been used to estimate adaptation costs are quantitative giving much attention to attaching a monetary value to tangible and direct costs. Intangible and indirect costs that do not have a market value are rarely considered.

Agrawala et al. (2008) also observed that there are no accepted metrics for assessing the cost of adaptation measures. As such, multiple definitions for adaptation cost exist. Existing definitions commonly refer to the cost associated with adjustments (Fankhauser 1998) and development initiatives (World Bank 2010) required to reestablish farming conditions prevailing before the occurrence of variations in climate while the IPCC (2014) consider the cost associated with planning, preparing for, facilitating, and implementing adaptation measures in farming practices including transaction costs. The definitions illustrate that there is no consensus as to what constitute adaptation cost. There are various aspects being considered by different authors and organizations. Another challenge is that there is no distinction according to type and/or class of adaptation costs. This makes the issue a complex phenomenon.

In this chapter, some components of the above definitions were adapted. Other considerations mentioned by Smith and Ward (1998) and Meyer et al. (2013) while assessing the costs of natural hazards were also infused. As such, in this chapter, intangible adaptation cost refers to problems and dangers that maize farmers encounter while planning, preparing, and implementing adjustments that cushion the impact of climate variability shocks on maize farming. The problems and dangers are not measurable in monetary terms, as they are not traded on the market as Smith and Ward (1998) illustrated. On the other hand, indirect adaptation cost refers to secondary unintended effects that unfold during implementation of adjustments to cushion the effect of climate variability. The secondary unintended effects include interruptions of normal day-to-day operations, extra demand on available resources such as labor and post adaptation effects that may arise. These may be measurable but not necessarily in monetary terms and are secondary effects of adaptation.

Climate justice scholarship on adaptation raises questions of fairness (Adger et al. 2013; Forsyth 2014). To achieve fairness, intangible and indirect costs arising from the implementation of adaptation measures especially among social classes within societies should be recognized. This chapter builds on the concept of "fair adaptation" (Adger et al. 2013; Forsyth 2014; Mikulewicz 2017) and draws upon components of distributive and procedural fairness (Graham et al. 2018) to explore intangible and indirect costs arising from the implementation of adaptation measures among farmers in Chirumanzu. Emphasis is on one of the four principles of fair adaptation, "putting the most vulnerable first" in order to ensure equitable outcomes among those at risk (Paavola and Adger 2006). Thus, concern is on redressing existing inequalities and preventing future ones (Graham et al. 2015) through prioritizing vulnerable resettlement farmers in Chirumanzu District of Zimbabwe and other smallholder farmers elsewhere in similar settings.

Of particular interest to this chapter is the fact that existing adaptation costs have been largely direct and tangible (Meyer et al. 2013). Apart from that, adaptation cost literature has concentrated on attaching cost figures (Mundial 2006; United Nations Framework Convention on Climate Change (UNFCCC) 2008; World Bank 2010) to existing direct and tangible costs yet there are other costs difficult to measure in quantitative terms. This implies that literature on adaptation cost to date does not fully enhance understanding of the overall picture of the cost associated with adaptation. This problem makes it difficult for smallholder farmers to make sustainable decisions and adopt and maintain adaptation plans apart from diminishing adaptive capacity and resilience. Yet governments, researchers, and international organizations are increasingly encouraging adaptation among smallholder farmers.

This chapter, therefore, responds to the necessity of understanding the intangible and indirect components of the cost of adaptation to climate variability. Intangible and indirect costs associated with adaptation to climate variability for smallholder maize farmers in resettlement areas of Chirumanzu District of Zimbabwe were explored. To achieve this, problems and dangers associated with adaptation measures arising from implementing adaptation plans are established. Subsequently, intangible and indirect aspects are discovered. Three important questions are answered in this chapter: What adaptation measures did maize farmers in resettlement areas of Chirumanzu commonly adopt? What problems and dangers are associated with adaptation measures commonly adopted? What are the intangible and indirect costs associated with the problems and dangers?

Location and Climate of Chirumanzu Resettlement Areas and Rationale for Selection

Figure 1 shows the location of Chirumanzu in Zimbabwe and the resettlement areas in the district. The District lies between longitudes 29°50E and 30°45E and latitudes 19°30S and 20°20S. Chirumanzu District is located in the Midlands Province of Zimbabwe. At least 90% of Chirumanzu District lie in Natural Region III while the remainder falls under Natural Region IV (Gwamuri et al. 2012). Natural Region III receive rainfall ranging from 500 to 750 mm, while Natural Region IV receive 400–510 mm per annum (Musara et al. 2011).

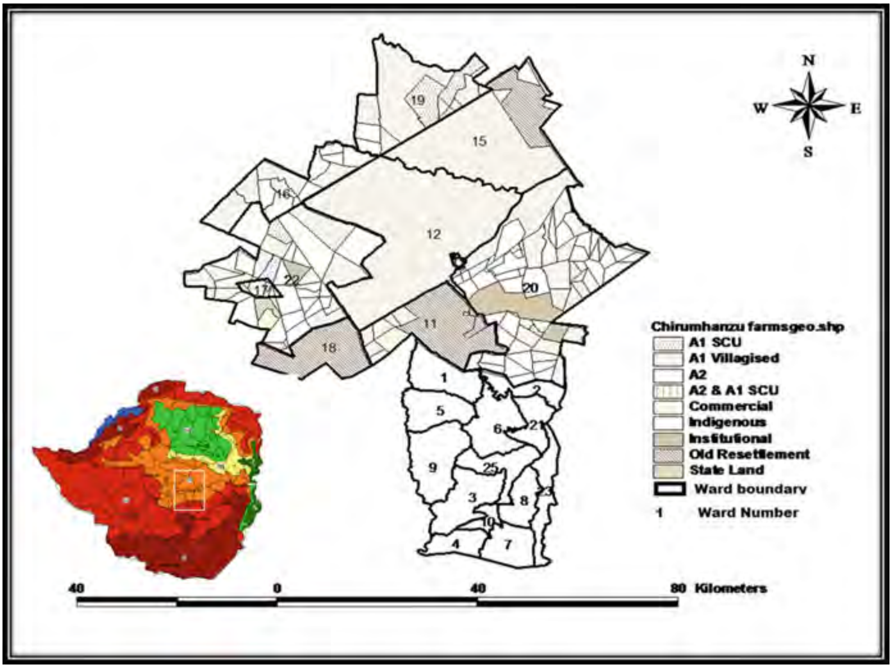

Fig. 1 Map of Chirumanzu District, Zimbabwe showing resettlement areas

Chirumanzu resettlement area experiences extreme weather events in the form of severe mid-season dry spells and frequent seasonal droughts (Simba and Chayangira 2017) yet rain fed agriculture is the major source of livelihood in the area with maize farming being the major farming activity as it is the staple food. Maize farming is largely for consumption. Surplus is often sold providing a source of income for the resettlement farmers. Such a rural setting that is continually battered by climate variations and extreme events presented the need for farmers in the resettlement areas to adapt making them suitable candidates for the study thus presenting a platform for interrogation.

Of the 23 wards in Chirumanzu District, nine (Wards 11, 12, 15, 16, 17, 18, 19, 20, and 22) are predominantly resettlement areas. These resettlement areas were a result of both the old resettlement program in the 1980s and the Fast Track Land Reform Program (FTLRP) of 2000. Farmers were resettled under A1 and A2 models. This chapter focuses on beneficiaries of the A1 model because these are local communities where the effects of climate variability are largely felt as recognized by the IPCC (2014). Model A1 was designed to address poverty and vulnerability for the landless poor. Furthermore, it was expected that by doing so, the congested communal areas would be depopulated resulting in relatively small farms that could sustain families (UNDP 2002).

Model A1 has three settlement schemes namely villagized, self-contained (Njaya and Mazuru 2014), and old resettlement. In the villagized scheme, each farmer is allocated about one hectare to build homesteads in a village set up. Each resettled farmer got 5–6 hectares away from the village. Grazing area is designated to be communal. In contrast to the villagized scheme, self-contained plots ranging from 15 to 30 hectares are allocated per farmer for both cultivation and grazing. Old resettlement scheme is similar to the villagized scheme in its setup. As Thebe (2018) reveals, A1 farms were established on former ranching farms with varying land quality characterized by poor sandy soils to rich black loams. Chirumanzu resettlement areas lie over four main soil types. These are deep sandy, clay, shallow sodic, and sandy loam. These soil types are more or less similar to those found in most smallholder farming communities across Zimbabwe and Southern Africa. Therefore, the information provided in this chapter is of greater applicability to most smallholder farmers.

To explore the intangible and indirect costs of adaptation, four out of the nine resettlement wards were selected. The enquiry was therefore, conducted in Wards 11, 12, 15, and 20. Dominant soil types and resettlement schemes in Chirumanzu District were considered specifically to capture intangible and indirect adaptation cost experiences of different maize farmers operating under different circumstances. There are four dominant soil types in Chirumanzu resettlement areas and three A1 resettlement schemes. Each ward represented a specific soil type and resettlement scheme.

Wards 11, 12, 15, and 20 represented sandy loam, shallow sodic, clay, and deep sandy soils, respectively. Apart from this consideration, Ward 11 represented the old resettlement scheme and farmers with relatively more farming experience but with relatively small farm sizes. Ward 12 was selected to represent the villagized scheme and farmers with less farming experience with relatively small farm sizes. Ward 15 was selected to represent self-contained scheme and farmers with less farming experience with relatively larger farm sizes. Ward 20 was unique because it has both the A1 villagized and self-contained resettlement schemes. Furthermore, there is need to note that the imbalance in the main soil types and resettlement models justified inclusion of Ward 20 in the investigation.

Characteristics of A1 Maize Farmers in Chirumanzu Resettlement Areas

Fifty-four A1 maize farmers were identified from the selected wards so that they could serve as the sources of data through semi-structured interviews. The inclusion and/or exclusion criterion that suited the theme of the investigation was A1 maize farmers who have adapted to climate variability and still had operational adaptation systems in place during the time of the study. Intensive consultation with the District Agricultural Extension Officer and Ward Extension Officers led to the identification of A1 maize farmers who met the inclusion/exclusion criteria.

Out of the 54 farmers, 10 were female. Farmers' age showed skewed outcomes. Forty-three farmers were in the 61–70 and 71–80 age groups with only two being 31–40 years old. Farming experience varied from six to more than 30 years. Thirty-one farmers attained secondary education. Only three farmers had tertiary qualifications. Five farmers did not have any formal education but could read and write. Most of the farmers were settled during the period 1998 and 2002 implying that they were settled under the FTLRP. All farmers in Ward 11 were settled in the 1980s reflecting that they were settled under the old resettlement scheme. Only seven farmers were settled in the 1990s and beyond 2002. Farmers settled under the Fast Track Land Reform were either under villagized or self-contained schemes. Farm sizes for farmers under A1 old resettlement and A1 villagized schemes were either five or six hectares while those in the self-contained scheme were either 15 or 30 hectares. Thirty-five farmers had at least 6 hectares of arable land while more than 50 farmers had between 3 and 10 hectares of arable land under maize production.

Data Gathering

Semi-structured interviews were conducted with the selected A1 maize farmers. Interviews were conducted in Shona, which is the local vernacular language. This ensured that the respondents had a common understanding of the meaning of the questions compared to the situation had English been used. A semi-structured interview guide with open-ended questions was used to gather data on commonly adopted adaptation measures, associated problems and dangers, as well as the related intangible and indirect costs. Detailed notes of the interviews were taken. Concurrent audio recording of the interview proceedings helped enhance accuracy of farmers' responses.

Data saturation was reached between the 8th and 9th farmer in all the wards. Instead of terminating the interviews, they were continued until the 15th farmer in Wards 11, 12, and 20. This was done in line with the Peterson (2019) advice that seeks to obtain deeper insights. However, in Ward 15 interviews were terminated after interviewing the 9th farmer. An unexpected commotion developed during interviewing, which created hostile conditions that made it impossible to continue with the data collection as originally planned. In total, 54 farmers were interviewed. This final sample was decided on based on the Morse (2016) recommendation that in a grounded theory research such as this one, 30–50 interviews should be conducted. Four additional farmers were included based on the assumption that new and rich data could be generated from them. In addition, Onwuegbuzie and Leech (2007) argue that it is important to ensure that a sample is neither too small to achieve data saturation nor too big to manage.

Data Handling and Analysis

All audio-recorded interviews were first transcribed verbatim. Textual data from audio recordings and notes taken were stored as a MS Excel spreadsheet on a case-based entry as illustrated by Friese (2016). The file was imported into Atlas.ti Version 8. A grounded theory approach was adopted during the thematic content analysis carried out in Atlas.ti Version 8. Inductive thematic content analysis was performed through reading responses given by the farmers. Textual responses were used to develop preliminary codes through inductive coding. It was performed via open and in vivo coding, in line with the Friese (2016) method. Open coding involved reading the text responses, sentence by sentence while forming detailed and structured themes. In this way, a grounded analysis was guaranteed. Simultaneously, codes and resulting code groups that were drawn from primary data were certified while avoiding missing important data. The same approach was used for in vivo coding. In this case, a word or phrase from textual responses was used to represent a code or code group.

Similar or related codes with the same meanings were merged to avoid unnecessary repetition. Irrelevant codes were deleted. Preliminary codes were grouped and merged into code groups. Groups with preliminary codes that were combined yet reflecting two or more concepts were split. Selective coding was used to create qualitative visual representations of the data in the form of network diagrams. Relationships and patterns were created using the resulting codes and groups linking them with quotations to create network diagrams, which were then exported to MS Word for use in presenting results and research report.

Adaptation Measures Adopted by Maize Farmers in Resettlement Areas of Chirumanzu

Maize farmers in resettlement areas of Chirumanzu adopted six common measures to cushion the impact of climate variability shocks on maize farming. The nature of the adaptation measures suggests that maize farmers in resettlement areas commonly adopt autonomous, *ex-post* measures (Smit et al. 2000) in response to climate variability shocks and impacts. The act of adaptation is done after farmers have already experienced significant impact costs. This signifies that adaptation is an act of restoration among maize farmers in Chirumanzu rather than intentional. Farmers adopted measures out of desperation in order to restore the losses incurred due to the impact of climate variability. This corresponds to Shoko et al. (2016) who compared adoption rates and preference of adaptation measures among smallholder farmers and found out that for some measures, adoption rates were low while preference was high and vice versa. It was therefore concluded that often farmers adopt adaptation measures not because they prefer them but out of desperation.

It is noticeable that some measures were highly adopted in some wards than in others possibly due to different characteristics of farmers. Of particular importance to this chapter are the soil types and resettlement schemes. Deviant and exceptional cases, adopted by only a few or even one farmer, were also observed among the measures adopted by maize farmers. Furthermore, some measures were adopted for specific stages in the maize value chain, while some were adopted for more than one production stage. Apart from that, some measures were adopted to address several climatic variations.

In some cases, some of the measures adopted were contradictory, while others ended up disadvantaging farmers leaving them in a worse off situation. It is also important to note that out of the six adaptation measures, female farmers adopted five which is a competitive number. This outcome challenges the binary male-female view of gender that women are passive victims of climate change (Nellemann et al. 2011) and confirms that women are proactive agents when it comes to climate adaptation (Mitchell et al. 2007; Dankelman 2010). In the following section, the main adaptation measures that maize farmers in resettlement areas of Chirumanzu commonly adopt are described and discussed.

Changing Planting Dates

Maize farmers in resettlement areas change planting dates in various ways. Farmers either plant early (dry planting), well before the rains start, or late as they are forced to wait for effective rains (sometimes late December or even January). Early and/or dry planting is adopted to address late onset of rains while avoiding delayed planting and falling behind production schedule. Late planting while waiting for effective rains is also normally adopted to address late onset of rains while avoiding poor germination rates and poor crop stand. In some cases, farmers plant their maize crop at different dates of the farming season (staggering). Staggering is adopted to address recurring climate variability shocks and evade total crop failure. Early and late planting are contradictory measures suggesting that adapting to climate variability is not “a one size fits all” approach. Different farmers take different routes depending on background characteristics bringing out farmer heterogeneity.

Use of Drought Tolerant Varieties

The use of drought tolerant varieties is one of the highly adopted measures in resettlement areas of Chirumanzu. Drought tolerant varieties increases yield in most drought stricken areas by an average of 600 kgs per hectare (Lunduka et al. 2019). Drought tolerant varieties endure moisture stress for a period of six weeks and have high tolerance to dry spells especially during the critical stages of development (Cairns et al. 2013). Due to recurring droughts that are experienced almost every three years in resettlement areas of Chirumanzu, farmers use drought tolerant varieties to improve yields. Drought is one of the limiting factors in rain-fed maize farming especially in sub-Saharan Africa particularly in Zimbabwe (Lunduka et al. 2019). This explains why the use of drought tolerant varieties is one of the highly adopted measures in resettlement areas of Chirumanzu. Common drought tolerant varieties grown by maize framers in resettlement areas of Chirumanzu are hybrid varieties, SC513 and SC403.

Although at times a considerable proportion of farmers receive drought tolerant varieties from the government, some are always not fortunate enough to get access. As such, despite most of the resettled farmers being resource poor (Mushunje et al. 2003; Chinamatira et al. 2016) and confronted with a variety of challenges in acquiring inputs including hybridized seed, Mkodzongi and Lawrence (2019) opined that resettlement farmers strive to self-finance farming activities. This can be argued to include adaptation investments such as the use of drought tolerant varieties. In that case, the use of drought tolerant varieties is an act of desperation that farmers implemented in order to restore and or prevent the losses from the impact of climate variability.

Good Crop Establishment Practices (No Regret Measures)

Good crop establishment practices were mainly "no regret measures." These measures include effective and timeous weeding, timeous application of fertilizers, timeous harvesting, and irrigation. According to Hallegatte (2009), no-regret measures are measures that yield benefits even if climate variability does not occur. Similarly, good crop establishment practices are normal practices conducted during maize farming whether there is climate variability or not. Such measures illustrate manipulative behavior and it is argued that they are a subset of adaptive behavior (Thomsen et al. 2012). Good crop establishment practices such as timeous weeding are an example of measures adopted for specific production stages in the maize value chain. Timeous weeding was adopted solely for weed control stage. On the other hand, irrigation is one of the exceptional cases adopted by only a few farmers in resettlement areas of Chirumanzu.

Conservation Farming

Conservation farming is mainly practiced through the use of planting basins and mulching in resettlement areas of Chirumanzu. These adaptation measures are mainly adopted to conserve moisture while at the same time reducing moisture stress. Planting basins is the use of shallow pits that allow accumulation of water, facilitating rapid infiltration into the soil (Rusinamhonzi 2015). The use of planting basins is highly debated in literature. In Zimbabwe, it is referred to as "*dhiga ufe*" translated as the "dig and die" technology (Andersson et al. 2011) due to the high labor requirements associated with the practice. Mulching is the use of crop residue and/or other organic material to maintain a permanent or semi-permanent soil cover with the intention of conserving soil moisture (Nyamangara et al. 2014). Maize farmers in resettlement areas of Chirumanzu often use grass and old leaves since crop residue is not adequate to cover large areas of land. Conservation farming is common in Ward 11 with sandy loam soils that quickly loses soil moisture due to accelerated drying of sandy loam soils.

Wetland Farming

Maize farmers in Chirumanzu often move from their original farms to the wetland areas due to recurring droughts, mid-season dry spells, unpredictable, and unreliable rains. In these wetlands, they can plant as early as September because the soil has enough moisture to sustain germination. Wetland farming is an irregular measure that is an unusual feature in existing research. The adaptation measure is also a characteristic of certain places that have wetland areas, for example, Ward 20 of Chirumanzu. Maize farmers in Ward 20 relocated to the wetland areas in the same locality as their original farms. This is not fully consistent with the conservative narrative on disaster-induced migration (Gray and Mueller 2012). The conservative narrative predicts that climate variability consistently increase long-term population mobility and effects are most visible for long distance moves. However, in Chirumanzu Ward 20, effects are most visible for internal moves. It also important to note that wetland farming is a form of maladaptation. According to the IPCC (2014), maladaptation refers to actions that increases the risk of adverse climate-related outcomes, increases vulnerability to climate variability, or diminishes welfare, now or in the future. The concept of maladaptation as Magnan et al. (2016) puts it focuses on the importance of accounting for potential side effects of adaptation to avoid solutions that are worse than the original problem. Moving to the wetland shifts environmental pressures elsewhere and is thus considered a form of maladaptation (Magnan et al. 2016).

Diversification

Diversification was practiced to avoid the effects of continual decline in maize yield and total crop failure. It is practiced in three different ways. These are crop, enterprise, and income diversification. Farmers grow multiple crops such as small grains, groundnuts that are more resilient to extreme climate variability than maize. Farmers venture into new enterprises like broiler production and look for alternative activities such as gold panning as alternative sources of income than relying on maize alone. Diversification is adopted by farmers with larger farms mostly in the self-contained scheme with more than 15 hectares of land. This illustrate findings by Amare et al. (2018) who projected that farm size has a significant and positive effect on the adoption of diversification to combat climate change impacts.

Problems and Dangers Associated with Adaptation Measures Adopted by Maize Farmers

Maize farmers in resettlement areas of Chirumanzu experienced several problems and dangers while implementing adaptation measures. Figure 2 shows an imported network diagram depicting a visual representation of the problems and dangers associated with adaptation measures adopted by maize farmers. The network diagram displays code groups (key problems and dangers) and codes (associated problems and dangers). Seven code groups and 32 codes were comprehended. This implies that 32 problems and dangers were identified.

Code groups are presented in red boxes on the network diagram and associated codes in white boxes. Associated codes are linked to code groups with arrows showing how they are related to respective code groups.

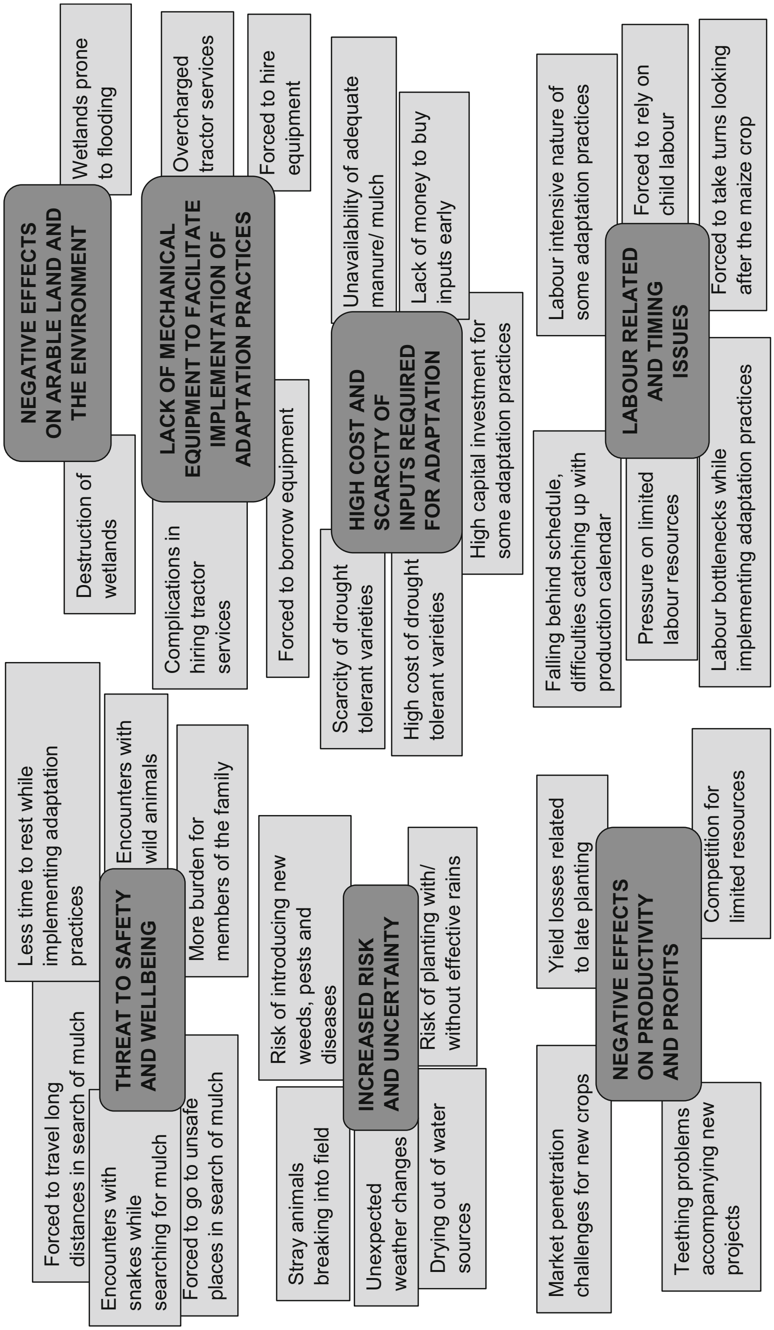

Fig. 2 Network diagram showing problems and dangers associated with adaptation measures adopted by A1 maize farmers

Threat to Safety and Wellbeing

Some of the adaptation measures implemented by maize farmers pose threat to safety and wellbeing of farmers. Tedious and laborious adaptation measures such as conservation farming result in less time to rest. Mulching forces farmers to travel long distances in search of mulch material. Sometimes they were forced to go to unsafe places in search of grass and old leaves which they normally use as mulch material. Encounters with snakes while searching for mulch material are common.

Lack of Mechanical Equipment

Lack of mechanical equipment that facilitates implementation of adaptation practices is a major problem. Implements such as ploughs, picks, spades, and hand hoes are required to facilitate implementation of adaptation plans. However, due to resource constraints, farmers do not always have these tools at hand when needed. Farmers are forced to either borrow or hire equipment to execute adaptation plans. However, there is no guarantee that when they borrow they will get the implements. On the other hand, the process of hiring equipment is complicated and this leads to delays and interruptions in implementing adaptation activities. Tractor services are scarce in the area and a few who have them overcharged the services.

High Cost and Scarcity of Inputs

High cost, scarcity, and continual increase in prices of inputs is also a major problem for farmers while adapting to climate variability. Inputs required to implement or maintain some adaptation practices are not readily available. Where these inputs were found, usually on the black market, they are often charged double the normal price. Scarcity and high cost of inputs hinders farmers from implementing adaptation plans on time.

Increased Risk and Uncertainty

Farmers encounter increased risk and uncertainty while adapting to climate variability. Unexpected weather changes ruin adaptation plans in general. Planting early pose a risk of stray animals breaking into the field since during September when most people in the area start early planting, people will still be sending their cattle away without someone attending to them. Planting without effective rains often leads to poor germination posing the risk of seed rotting and subsequently seed wastage. Irrigation is associated with the risk of drying out of water sources.

Labor Related and Timing Issues

Labor related and timing issues is another key problem that farmers encounter during adaptation. Waiting for effective rains results in delayed land preparation subsequently leading to delayed planting. Resultantly, farmers fall behind schedule. Sometimes they plant late December or January. This puts pressure on labor resources as they try to catch up with production calendar. The effectiveness of their work is compromised as they do things hurriedly. Some adaptation measures are labor intensive. The use of planting basins requires a lot of labor. Such measures burden farmers and they end up relying on children to assist. Furthermore, such measures are limited by labor bottlenecks.

Negative Effects on Productivity and Profits

Some adaptation measures call for extra production costs. This threatens the sustainability of maize enterprises. Where they practice wetland farming, they plant as early as mid-September. Farmers will need to buy fence to create a barrier in case stray animals might enter into the field and eat maize while they are not watching. Equally, diversification demands extra investment costs to start new project ventures. Farmers ventured into the production of horticultural crops, broiler production, and production of small grains. However, these production activities present a new set of challenges for farmers. Teething problems are experienced as farmers start these new project ventures. Competition for resources is escalated since there is need to balance the resources for all the activities. Farmers who diversify into small grains face marketing strategies as there is no established market for small grains.

Intangible Costs Associated with Adaptation to Climate Variability

Problems and dangers encountered by maize farmers while adapting to climate variability have several intangible costs. Intangible costs do not have a market value therefore cannot be valued in monetary terms. Tables 1 and 2 summarize adaptation measures adopted by maize farmers, associated problems and dangers, as well as the related intangible costs.

Health, Wellbeing, and Safety Concerns

Some adaptation measures threaten farmers' wellbeing raising health and safety concerns. Due to the lack of mulch material, farmers and household members are forced to travel long distances and go to unsafe places in search of adequate and suitable materials. As such, there is less time to rest and exposure to danger due to the risk of encountering snakes. With wetland farming, farmers are forced to take

Table 1 Intangible and indirect costs associated with adaptation measures adopted by A1 maize farmers

Adaptation measure	Problems and dangers associated with adaptation measures	Associated intangible costs	Associated indirect costs
Conservation farming	Tedious and labor intensive	Reliance on child labor leading to violation of children's rights	Family labor opportunity cost
		Extra burden on members of the family	
	Lack of mechanical equipment	Setbacks in implementing	Loss due to delays
	Forced to borrow equipment	Embarrassment associated with borrowing	–
		Ridicule and stereotyping associated with borrowing	–
		Availability and access of equipment not guaranteed	–
	Forced to hire equipment	Effort put in hiring equipment	Unplanned, additional hiring cost
		Availability of equipment not guaranteed	–
	Complications in hiring equipment	Effort put in negotiating deals	Opportunity cost of lost time negotiating
	Overcharged services for equipment	–	Extra, often unplanned cost
	Lack of mulch material	Setbacks in implementing	–
	Forced to travel long distances	Less time to rest	–
		Wellbeing concerns	–
	Forced go to unsafe places	Encounters with snakes	–
		Safety concerns	–
	Possibility of introducing new weeds, pests, and diseases with mulch	–	Yield loss related to the risk of new weeds, pests and diseases

(continued)

Table 1 (continued)

Adaptation measure	Problems and dangers associated with adaptation measures	Associated intangible costs	Associated indirect costs
Changing planting dates	Risk of falling behind schedule and difficulties catching up while waiting for effective rains	Worry, anxiety and uncertainty	Yield losses related to timing
		Extra burden	Opportunity cost of labor
	Unexpected weather changes	Pain and suffering due to losses	Yield losses related to unexpected weather changes
	Possibility of replanting associated with dry planting as seed fail to germinate due to insufficient moisture	Pain and suffering due to poor germination	Losses due to seed wastage
		Threatened emotional wellbeing	–
		–	Cost of additional seed for replanting
		–	Additional labor cost for replanting
	Late planting is associated with yield losses	–	Yield loss related to late planting

turns in looking after the maize crop in case stray animals might break into the field and destroy the crops. While looking after the maize crop, they encounter wild animals such as wild pigs and baboons which may attack them.

Burden on Household Members

Adapting to climate variability exert excessive burden on household members. Conservation farming, for example, is generally labor intensive, tedious, and time consuming. Farmers usually rely on family members particularly children and women to provide the required labor as they cannot afford to hire or contract workers.

As a result, children get to school late, often miss school, and have little time to play as they are expected to help with implementing adaptation activities. The female folk are excessively burdened as farmers implement adaptation activities. Women are forced to disregard other activities such as going to church. Other important activities like tending to the cattle and goats are left to the children.

Looking after and taking care of the home is put on hold or sometimes neglected. Women face difficulties in coping and balancing household and adaptation chores. Household members struggle with abnormal day schedules and unusual working

Table 2 Intangible and indirect costs associated with adaptation measures adopted by A1 maize farmers

Adaptation measure	Problems and dangers associated with adaptation measures	Associated intangible costs	Associated indirect costs
Use of drought tolerant varieties	High cost of drought tolerant varieties	Effort spent looking for better priced DTVs	Opportunity cost of time
	Scarcity of drought tolerant varieties	Effort spent looking for DTVs	
Good crop establishment practices	Tedious nature of practices such as effective weeding	–	Investment cost for efficient system
	Time consuming	–	–
	High startup costs associated with irrigation	–	Investment cost for irrigation system
	Risk of drying up of water sources	Uncertainty and worry over water source	
Diversification	Capital investment for new project	–	Investment cost for new project
	Teething problems while starting a new project	Pain and suffering as project fail to take up	Losses due to failure of new project
	Competition for resources	Indecision/difficulties allocating resources	–
	Market penetration challenges for new products	Difficulties penetrating the market	–
Wetland farming	Risk of stray animals breaking into field, Need to take turns to look after maize	Taking turns looking after maize, forced to forego other activities	Opportunity cost of activities foregone
	Encounters with wild animals	Possibility of attacks from wild animals, threat to safety	–
	Wetlands prone to flooding and waterlogging	Difficulties accessing wetlands	–

hours as they sometimes spent the whole day in the field and sometimes wake up as early as 3 o'clock in the morning. Priority is given to adaptation activities more than other household activities. This shows that adaptation activities disproportionately burden the vulnerable (Barnett and O'Neill 2010) particularly women and children. Reliance on family labor increases vulnerability of women and children. Adaptation in resettlement areas of Chirumanzu is therefore not socially equitable for women and children (Barnett and O'Neill 2010).

Worry, Anxiety, and Uncertainty

Farmers fall behind schedule when they change planting dates to wait for effective rains. Farmers worry and feel anxious as they wait with uncertainty for rains to come. Farmers feel helpless as they wait with uncertainty as to when the effective rains will come. Farmers who irrigate also worry over the risk of drying out of water sources.

Pain and Suffering

Farmers experience pain and suffering due to the poor germination rates and poor crop stand due to insufficient moisture associated with changing planting dates through early and/or dry planting. They are distressed over the inputs, resources, and effort wasted. After early and/or dry planting sometimes very little rains come and they result in seed rot thereby wasting seed, fertilizers, and labor. Farmers also experience pain and suffering as new project ventures fail to start up progressively when they diversify.

Effort Spent to Facilitate Smooth Implementation of Adaptation Measures

The high cost and scarcity of drought tolerant varieties force farmers to spend a lot of time going from one place to the next, sometimes from one town to the next looking for better priced seed. Drought tolerant varieties are no longer readily available on the market in Zimbabwe. Since 2009, the traditional suppliers of drought tolerant varieties have been failing to meet demand because they were unable to cope with hyperinflation (Dekker and Kinsey 2011). Since then drought tolerant varieties have been scarce on the formal market only covering less than 50% of the demand (Willems 2014). This facilitated the mushrooming of a parallel market for drought tolerant varieties where they are charged double or more. Incidentally, this forces farmers to make effort looking for better prices drought tolerant varieties they can afford.

Indecision During Allocation of Scarce Resources

Farmers experience difficulties in allocating scarce resources as they diversify into new project ventures. Potential conflicts in labor allocation and capital investment sharing are common to farmers who diversify. Indecision is therefore common while allocating resources as all the projects will be important to them.

Ridicule and Embarrassment Associated with Borrowing Equipment

The lack of mechanical equipment forces farmers to borrow. When they borrow the implements, they are subjected to ridicule and experience feelings of embarrassment. This shows that support networks for adaptation practices sparsely exist among maize farmers in Chirumanzu. Instead of offering social support to other farmers while implementing adaptation practices (Townsend et al. 2015), fellow community members ridicule them. Cooperation and solidarity which are important mechanisms determining the extent to which adaptation measures are adopted are nonexistent among maize farmers in resettlement areas.

The above narrative can be drawn back to the way in which the resettlement program was structured. In particular, the A1 model, communities were created overnight and by chance since most of the times farms were allocated by picking out a number from a hat (Chiweshe 2014). This led to the establishment of “stranger neighboring households” (Barr 2004: 1753) who did not know one another and were therefore forced by to settle and interact. As such, different groups of people with competing views, opinions, and interest would create a conducive environment for noncooperation (Chiweshe 2014).

Indirect Costs of Adaptation to Climate Variability

Indirect costs are secondary unintended effects of adaptation activities. Although measurable, they are not valued directly on the market. They are unintentional and often unplanned effects of adaptation with a time lag. Tables 1 and 2 summarize adaptation measures adopted by maize farmers, associated problems and dangers, as well as the related indirect costs.

Family Labor Opportunity Cost

The use of family labor to implement adaptation measures raises the issue of family labor opportunity costs. Although family labor opportunity cost has been identified in existing literature, the indirect aspects surrounding it are not well articulated. In existing literature, labor is considered a variable cost that is direct and tangible as is measurable in man-days per hectare. However, despite the existence of several family labor opportunity cost valuation measures, a common unit of measurements that specifies the cost of important activities foregone while providing labor for adaptation plans is nonexistent.

Maize farmers in resettlement areas rely mostly on family labor. In most cases, farm owners, household members including women and children are forced to forego other important activities while providing labor for adaptation plans. All members of the household provide the required labor for adaptation activities. Commonly, the labor hours provided by household members go unnoticed and mostly unpaid. Hence, the net value of time spent in the next best activity would have been foregone. Major effects are on children who are excessively burdened as they are obliged to help before they go to school and after school. As such, adaptation disproportionately burdens the most vulnerable (Eriksen and O'Brien 2007) groups of children in resettlement areas which constitute unsustainable adaptation.

Existing literature on family labor does not go further to establish potential conflicts in labor allocation between adaptation through measures such as planting basins and other household duties. Yet, Rusinamhonzi (2015) indicated that there are indeed potential conflicts in labor allocation between adaptation through planting basins and other activities. This tally with findings of this study where adaptation practices were often drawn back by labor bottlenecks. This study illustrate that the use of planting basins disproportionately burdened maize farmers and their families while reducing the incentive to adapt (Barnett and O'Neill 2010). This explains why very few farmers in Chirumanzu adopted it. Potential conflicts in labor allocation among adaptation plans and competing household duties are a form of adaptation cost that is unnoticed.

Additional and Unplanned Cost of Production

Maize farmers are confronted with additional often unplanned costs while implementing adaptation plans. Adaptation measures that require special equipment result in maize farmers incurring unplanned hiring costs. Farmers are constrained by the lack of necessary implements such as hoes, ploughs, and tractors to execute adaptation plans. Farmers resort to hiring implements at a cost paid either paid in cash or in kind. This increase the cost of production and most farmers cannot afford it. Wetland farming calls for extra production costs since farmers need to buy fence to create a barrier that obstructs stray animals from entering the field and eat the maize while they are not watching. This relates to the contention of Adger et al. (2009) and Morrison and Pickering (2012) that inadequate technology presents additional unplanned costs for farmers while executing adaptation plans. Payments made in kind are not given much thought; hence, the cost associated usually goes undetected. Early and/or dry planting often results in replanting twice or thrice when seed fail to germinate due to climate variability extremes such as little rains. This generates additional seed, fertilizer, and chemical requirements per hectare thus raising total input cost. These costs are usually misconstrued as normal variable costs without considering the indirect, additional, and unplanned costs associated.

Yield Losses Related to Risk, Unavoidable Delays, and Timing

Some adaptation measures increased the likelihood of loses rather than gains (Pittelkow et al. 2014). For example, late planting results in grain yield loses of up to 5% for each week of delayed planting (Nyagumbo 2008). In Zimbabwe, Nyakudya and Stoosnijder (2015) mentioned incidences of pests and diseases as the other reasons why late planting often give lower yields. Similarly, this study established that farmers who diversified with small grains ended up failing to get a market for this alternative crop. Nonetheless, since literature on adaptation largely focuses on benefits brought forth by adaptation and neglects the costs, these processes are rarely deliberated in adaptation cost assessments.

Huge Investment Cost for Some Adaptation Practices

Diversification demands huge investment costs to start new enterprises. Equally, irrigation requires high start-up costs to secure the water source pump and other irrigation facilities for an efficient system. Maize farmers are resource constrained as such these costs are enormous for them.

Conclusion

Investing in measures that reduce the impact of climatic variation in maize farming is indeed the missing link for A1 farmers in resettlement areas of Chirumanzu. Measures such as conservation farming, use of drought tolerant varieties, changing planting dates, practicing good crop establishment, wetland farming, and diversification may strengthen maize farmers to fulfill their massive role of safeguarding food and nutrition security. The Government of Zimbabwe intends to make adaptation a national priority. On the international front, adaptation has been identified as the only solution for furthering the Climate Change Policy. This has seen an extensive adoption of various adaptation measures around the globe particularly among smallholder farmers including A1 farmers in Zimbabwe. Several success stories on adaptation have been widely documented. Despite considerable variations in effectiveness of adaptation measures in maize farming, yields have been reportedly improved. Overall, adaptation reduces vulnerability and improves resilience while at the same time reducing incidences of rural poverty. However, overall adaptive capacity and resilience among smallholder farmers especially in the African region including Zimbabwe is reportedly still low. This is partly due to the problems and dangers that accompany the process of adaptation. As such, caution must be taken especially in communities that are making efforts to adapt so that the problems and dangers are managed accordingly. The problems and dangers originate from planning, executing, monitoring, and maintenance of adaptation systems. The problems and dangers are associated with some intangible costs that are difficult to measure in quantitative terms and therefore challenging to assign a monetary value which makes them repeatedly ignored in adaptation cost assessments. The problems and dangers are also associated with indirect costs that are secondary effects of adaptation and cannot be easily comprehended at face value as they are not directly measured in monetary terms. This chapter brings to light the fact that in some cases, adaptation results in problems and dangers that limit adaptive capacity and increase vulnerability to some extent. This chapter contributes to existing literature and argues that adaptation does not only bring positive outcomes. The chapter progresses the argument that intangible and indirect costs are an enormous part in adaptation planning and cost assessments. This chapter advocates for prioritization of the intangible and indirect costs associated with the problems, dangers, and unintended adaptation effects of adaptation to increase uptake and enhance sustainability. Stakeholders in the climate adaptation arena should not overlook intangible and indirect costs associated to the problems, dangers, and unintended effects that come with adaptation activities in order to enhance social and environmental justice. It is time to practice what is being preached in the climate adaptation arena and not neglect crucial prerequisites of adaptation such as the "first do no harm principle."

Climate Variability and Rural Livelihood Security: Impacts and Implications

23

Contents

Abstract

In a typical Nigerian village, the majority of the population comprises old people who are mostly economically unproductive due to reduced or loss of physical strength brought about by ageing and ill health. Many of these rural old people still work, and do so outside the formal sector, and are particularly susceptible to the effects of climate variability and change. Few studies have reported on climate change and the rural aged and there is a research gap as regards rural elderly peoples' perception of climate variability impact on them. Since little is known

about their perception of climate variability impacts and implications on the rural aged especially in relation to their livelihood activities in Sub-Saharan Africa, this chapter therefore examined the impact of climate variability on the livelihood security of the rural aged in different ecological zones of Nigeria.

Both qualitative and quantitative methods were used for data collection. Qualitative data were obtained through interviews with four aged and four aged women selected purposively in each rural community and analyzed using Content Analysis Method. Quantitative data were obtained through structured questionnaire administered to an aged male and an aged female population available in selected houses (the aged are people 60 years and over in age) in selected rural communities in selected ecological zones of Nigeria. Where there was no combination of the two (aged men and aged women), either of the two was also sufficient.

It was discovered that the ageds' experiences of climate variability impact relate to the prevailing climate variability characteristic of each ecological zones. The impact on their livelihood in these zones is seen in terms of livestock death, lack of pastures for herds, scarcity of water, pest invasion, delayed planting crop failure, need for irrigation, water logging, drowning of small animals, human and animal illness. This means that planning decisions related to climate change issues should take cognizance of the views of the aged populations especially of those residing in rural areas as they are the most affected by the impact.

Keywords

Climate variability · Rural aged · Livelihood security · Ecological zones

Introduction

Climate change implies a shift in the main state of a climate or in its variability, persisting for an extended period that can be decades or longer (Intergovernmental Panel on Climate Change 2007). It has been known for a while to have major global environmental, social, and economic impact (Scholze et al. 2006; Douglas et al. 2008) and poses a major serious threat to sustainable development with adverse effects on the environment, human health, food security, economic activities, natural resource management, and physical infrastructure (Government of Kenya (GOK) 2010). Climate change poses serious risks to society because of the physical characteristics of the planet, the biological resources on which human lives depend, and current social systems that are adapted to existing rather than changing climate conditions (Higgins 2014).

Climate change is rapidly emerging as one of the most serious global problems affecting many sectors in the world especially livelihood. Negative consequences in Africa are already prevalent in terms of frequent floods, droughts, and shift in marginal agricultural systems (Collier et al. 2008). Deschenes and Greenstone

(2012) explained that climate change affects the two most important direct agricultural production inputs, precipitation, and temperature, which in turn affects livelihood. Studies have shown that Africa is getting more vulnerable to climate change/variability impact on livelihood compared to other parts of the World. This is because the livelihoods for 80% of the African population are dependent on rainfed agriculture which are vulnerable to multiple stresses such as climate change (World Bank 2008). Countries in sub-Saharan Africa may likely suffer most from these consequences because of their greater reliance on climate-sensitive resources like agriculture for sustenance of livelihoods (Eboh 2009).

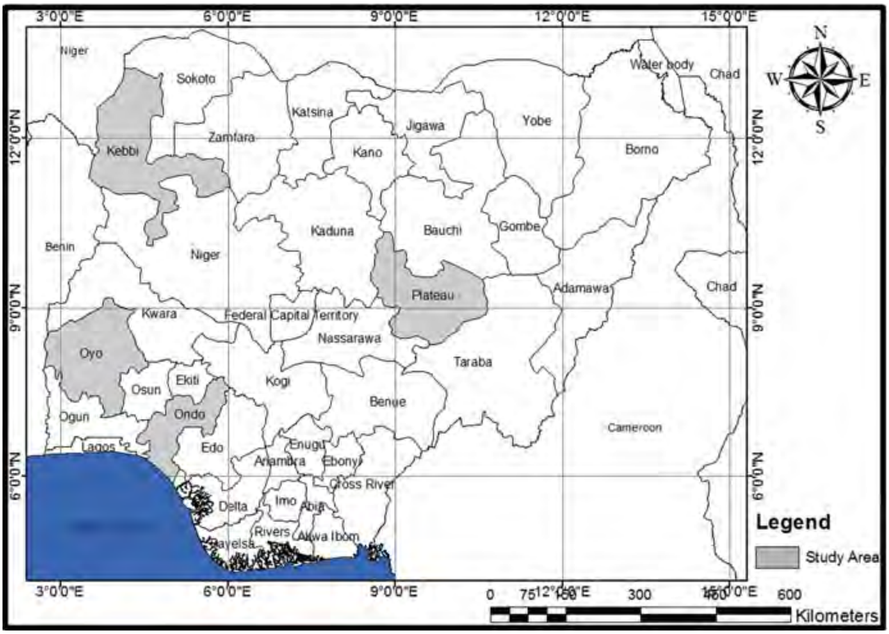
In Nigeria, about 60% of the populations are rural residents depending on agriculture for their livelihood (Central Bank of Nigeria 2006) and studies have confirmed serious effects of climate change on this population. Their vulnerability to climate change impacts is largely due to the socioeconomic and political context (Thornton et al. 2014). However, all households within a community are not equally vulnerable to climate change impact (Adger 2003). This is because vulnerability is highly differentiated (O'Brien et al. 2007) and varies across: age, gender, income, and type of livelihood. In Nigeria, women, children, and the elderly will be most vulnerable to climate change impact, especially the rural elderly who are economically less productive due to physical weakness brought about by ageing and ill health (Anele 2012).

Mcleman and Hunter (2010) explained that climate change events, impacts on livelihood and vulnerability differ considerably across geographic and ecological regions. This is because livelihoods are ecologically dependent and some regions and activities are more sensitive to climate change than others (Saarinen et al. 2012). It is therefore relevant to consider ecological characteristics in relation to climate change impacts on livelihood. Also in Sub-Saharan Africa, extreme droughts is already constraining production of food and rearing of livestock (Kebede et al. 2011). For 2050, it is projected that, especially in West Africa, yields could drop by 20–50% due to variability of rainfall reducing length of the growing season (Sarr 2012). There are many studies on climate change/variability and livelihood (Ofoegbu et al. 2017; Ubisi et al. 2017; Aniah et al. 2016; Egbe et al. 2014; Okonkwo et al. 2015; Zeleke and Aberra 2014). For instance, Aniah (2016) examined the effects of climate change on livelihoods of smallholder farmers in the Upper East Region of Ghana. The results revealed that droughts, floods, pest and diseases, postharvest losses, declining crop yields, and animal production have threatened smallholder farmers' livelihood activities. Also, Ubisi et al. (2017) investigated the perceived effects of climate change on crop production and household livelihoods of smallholder farmers in Mopani and Vhembe district, South Africa. Their study showed that subsistence farmers perceived prolonged droughts as an impact of climate change leading to low crop yield and high crop failure. These studies focused on the impact of climate change/variability on livelihood activities but the impacts on the livelihood activities of the aged were not considered. Against this backdrop, we have reason to believe that climate change impact on livelihood among the rural aged is likely to vary with geographic location and livelihood activities. Based on Nigeria as a case, this chapter provides answers to this question: How does the perceived climate variability affect rural livelihood activities of the aged population in selected rural communities of the different ecological zones of Nigeria?

Multistage Selection of Ecological Zones and the Aged

Nigeria, situated in West Africa on Latitudes 4°0 to 14°0′ North and Longitudes 2°2′ and 14°30′ East, is bounded in the west by the Republic of Benin, in the East by Chad and Cameroon, in the North by Niger Republic, in the South by Gulf of Guinea, and in the North-East by Lake Chad (Map 1). Nigeria is a multiethnic and culturally diverse society divided into 36 autonomous states (World Bank Group 2017). Nigeria has two seasons, the dry and the rainy season, and six ecological zones: Mangrove zone, Forest zone, Montane zone, Guinea savannah zone, Sudan savannah zone, and Sahel savannah zone. This chapter is set in four ecological zones with one state representing each zone–Guinea savannah zone of Oyo State (Oyo State), Mangrove zone of Ondo State (Ondo State), Sudan savannah zone (Kebbi State), and Montane zone (Plateau State) (see Map 1).

In the initial stage, the ecological zones (They are: Mangrove zone, Rain forest, Montane region, Guinea savannah, Sudan savannah and Sahel Savannah) were identified based on Keay (1949), Kueppers (1998) classification. Four Ecological Zones were randomly selected out of the six zones. They are: Guinea savannah zone,



Map 1 Map of Nigeria showing the selected states. (Source: Adopted from Popoola and Ajayi 2019)

Mangrove zone, Montane zone, and the Sudan savannah zone. One State was then selected from each of the selected ecological zones. The states are Oyo State in the Guinea savannah zone (Guinea savannah zone of Oyo State), Ondo State in Mangrove zone (Mangrove zone of Ondo State), Plateau State in Montane zone, and Kebbi State in the Sudan savannah zone. In the next stage, two local government areas were selected from each of the States based on their rurality and climate change impact. The local government areas are: Ilaje and Eseodo in Ondo State; Oorelope and Atisbo in Oyo State; Riyom and Kanke in Plateau State; Jega and Yauri in Kebbi State. In the third stage, three rural settlements were selected from each of the local government areas through a simple random selection process. They are: (Ilepete, Obenla, Ebijimi) in Ilaje LGA; (Igbalekagbo, Uropati, Olorunpupa) in Ese-odo LGA; (Alaguntan, ologundudu, Sooro)in Oorelope LGA; (Alakuko, Sabe, Yowere) in AtisboLGA; (Ambob, Tahoss, Kwakwi) in Riyom LGA; (Tse, Jinglay, Lebwit) in Kanke LGA; (Akalawa, Duduke, Gindi) in Jega LGA; (Unguwar Kurya, Zara Bimi, Giwa Tazo) in Yauri LGA. To ensure a fair draw for all settlements each settlement in the respective local government area was assigned a number written on a piece of paper, placed in a container, and then drawn from the container without replacement. In the fourth stage, snowball approach was used to identify the houses where the rural aged resides. The aged were defined as people who are at least 60 years of Age.

Both qualitative and quantitative data were used (Primary Data Source). The quantitative data were obtained through structured questionnaire administered to an aged male and an aged female available in the selected houses in the selected rural communities of the selected ecological zones. Where there were no combinations of the two (aged men and aged women), either of the two was also sufficient. The qualitative data includes observations, key informant interviews, and open as well as semi-structured interviews with four aged men and four aged women selected purposively in each of the selected villages. The interviewer used progressive focusing to ask the participants both new and follow up questions. Detailed field notes and audio recording were made throughout the field observations. Data collected was disaggregated by gender to recognize the different experiences of male and female and analyzed using various methods such as descriptive statistics (frequencies and percentages) and SPSS. In the qualitative analysis, Content Analysis Method was used to identify commonalities in terms of recurring aspects and themes as well as differences and contradictions in terms of deviating views and outliers.

Ageds' Experience of Climate Variability Impact on Their Livelihood Security

In this section findings of climate variability impact on livelihood security of the rural aged in selected ecological zones of Nigeria was presented. In focus, the following domains: agriculture and food security; environment; energy; and water resources; as well as human and animal health; dwellings, transport, and migration were placed. According to Ashwill et al. (2011), climate change impact refers to the social and environmental consequences in terms of water scarcity, loss in agricultural yields, and drops in livestock production, to mention a few. It is important to examine the climate variability impact on livelihood security of the people because it helps informing and tailoring directions for adaptation (Mendelsohn 2008). It is also important to examine the impact on livelihood by gender and geographical locations. Examining the impact by gender helps to understand that the different roles, resources, opportunities, and agency of men and women influence how they experience, perceive, and respond locally to climate change (Ashwill et al. 2011). Vulnerability to climate change impact is highly correlated with its geographical peculiarities (Callo-Concha et al. 2013). Therefore, examining the impact by geographical location helps to determine both the perceived need to adapt and the acceptability of particular adaptive measures because of factors such as: attachment to place, cultural values, social identity, and regional risk attitudes (Adger et al. 2009).

Figure 1 shows the climate variability impact on livelihood security of the rural aged in selected ecological zones of Nigeria. Findings revealed that climate variability has affected the livelihood of the aged to a great extent. For instance, from the table, in Guinea Savannah Zone, 68.3% of the men and 69% of the women complained of water shortage and 60% men and 49.2% women felt the need for irrigation. Also, 42.4% men and 26.2% had to delay their planting; 94.6% of the men and 91.8% of the women lamented about crop failure; 37% of the men and 35.9% of the women worried about their animals getting weak and sick while 32.6% men and 27.9% women had their livestock dead. All these can be attributed to climate

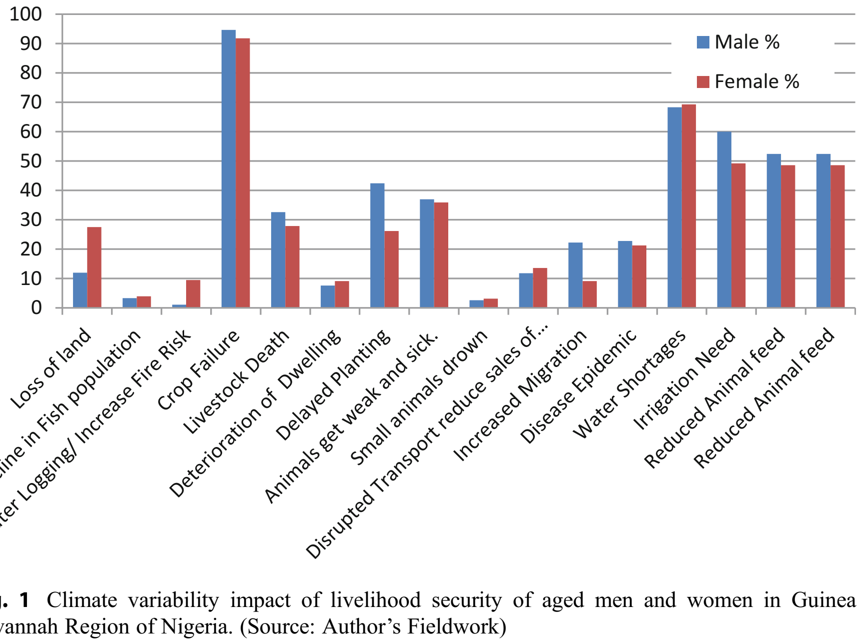


Fig. 1 Climate variability impact of livelihood security of aged men and women in Guinea Savannah Region of Nigeria. (Source: Author's Fieldwork)

variability impact. Below, selected comments from aged men and women sharing their experience of climate variability impact on their livelihood security in the different selected villages of Oorelope and Atisbo Local Government Areas of Oyo State, Guninea Savannah Region of Nigeria were included.

> Before the change in weather, we planted maize twice a year. But now, we plant it only once. If we try to plant the second time, which is usually done in the eight month, the produce will be very small and not profitable. Just like the one I am holding now (respondent holding a sample maize), who will buy this from us? (**Waliu Hamuzat, Male, 64 years**)
>
> Our yam produce is not as big as before again. The presence of yam leaf is a positive sign of a possible bountiful harvest. During the 10th and 11th month of plantation, some cultivated yams will still have their leaves intact, like before, but now, in the 9th month, some yams would have lost their leaves. Infact, the period when tubers had begun to grow proper, that is when we usually experience the lack of rain (drought). And it is usually when the yam needs the rain the most. Most importantly, these are the periods we usually have constant rainfall before. Now the story is different.
>
> Take for example, if I planted about 3000 yam and I was only able to harvest 100. This can only be related to the heat generated from the dry land and I cannot be at peace with such result (**Kazeem Lawal, Male, 65 years**)
>
> There is shortage of food and water, and our cows are going seriously hungry. This has led to a clash between farmers and the Fulani herdsmen because the cows now go to feed on people's farmland. Any cow caught on a farmland, automatically belongs to the farmland owner. In addition, a lot of cows cannot even stand up on their own again due to hunger. The herdsmen at times usually help them up (**Yussuf Dammani, Male, 62 years**)
>
> Fever most especially, and several other ailment usually surface at this period. Since food is what our body needs most, a shortage of it will lead to sickness in the body (**Durodola Lamina, Female, 73 years**)
>
> The little rain we had was more of heavy storm than water. The storm was too much; in fact the structure we erected as mosque was totally destroyed by the storm. It also destroyed a lot of buildings. The storm is a new experience in this area (**Ajao Abebi, Female, 68 years**)

Figure 2 also shows the climate variability impact on livelihood security of the aged men and women in the Coastal Zone of Nigeria. The table indicated that 81.8% of the men and 72.5% of the women complained about decline in fish species and populations. This is because in a small-scale fishing community, many households are involved in fishery-related livelihood activities such as fishing, postharvest fish processing, fish trading, making and mending of fishing materials (OECD 2001). Therefore, decline in fish species and populations will affect their means of livelihood. Also 79.2% of the aged men and 42.9% of aged women in the area complained about water logging and 59% men and 40.6% women had their small animals drown in the water. Moreover, 69.7% men and 40.9% lamented and worried about the deterioration of their dwellings because of heavy rainfall and flood. In most rural coastal communities of Nigeria, many dwellings are built on piles and raft foundations. These houses easily deteriorate during harsh weather conditions and thus affect the habitability of the aged in the region.

However, in some instances climate variability has some positive impacts on livelihood of rural coastal communities. For instance, one of the positive effects of flooding in the rural coastal communities is the increase in fish catch, especially

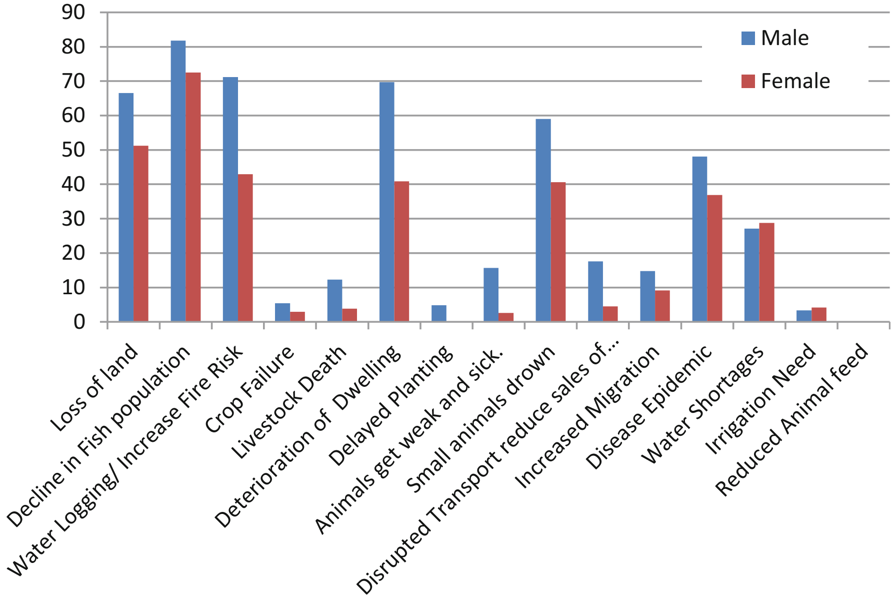

Fig. 2 Climate variability impact of livelihood security of aged men and women in Coastal Zone of Nigeria. (Source: Author's Fieldwork)

during ocean flooding (Fabiyi and Oloukoi 2013). The study revealed that the Atlantic brings large fish to the continental shelf and some large fish are even found in the creeks during extensive flooding. Therefore, climate variability impact is not necessarily negative but can also be positive. Below, are some of the views on the impact of climate variability on their livelihood shared by aged men and women in Ilaje and Eseodo LGAs of Ondo:

> Floodwater does not damage our land and properties in the past, it comes for some few hours and subsides back into the ocean but within the past few years it has been staying longer than a month, destroying lives and properties (**Olayemi Elijah)**
>
> Floods are usually associated with heavy rainfall and ocean tides causing damages to our properties and drowning a number of people and animals. During Heavy rainfall, between June and July houses and land becomes waterlogged. The soil becomes saturated with water making it difficult for us to move from one place to another, disturbs our daily activities and causes retrogression in our socio-economic activities. (**Thomas Ogunmola, Male, 67 years**)
>
> Flood has destroyed our crops, fishes and animals. Many of our animals die because of high salt level in the water. The flood water after mixing with sea water becomes polluted causing purging in human. The crude oil clogs the mat making plant (ifere), degrades the bamboo plantation (Opee), and also kills the aquatic animal, which serves as the major source of income to us (**Osamoluwa Male, 71 years**)
>
> Socio-economic activities comes to a standstill during the flooding period, we women will not be able go to the market to trade. There is also high mortality rate in infants and the pregnant women during child labor because we lack health facilities. The only health centre

available is too far from the community and there is no means of transportation most especially during the time of flooding (**Adeola Ebijiimi Female 75 years**)

In this year, from January to April, the rainfall was so scanty, resulting into heat wave, the weather became unbearable hot and the soil became too dry and too hot to grow crops on, any crop planted at this period dies off, but from May to July the rainfall became so intense which eventually resulted into flooding (**Ebipatei Jonathan)**

We do encounter a lot of health and environmental hazard, these includes: rheumatism, purging, death of animals, degraded water and soil, erosion, drowning of our children and loss of life in general. (**Obele**)

Many of us aged suffer from rheumatism due to extreme cold weather while some of us have lost their lives due to drowning during flooding or tidal surge (**Eyinmiieka Ayebogbon**)

Figure 3 also indicated the impact of climate variability on livelihood security of the rural aged men and women in the Sudan Savannah Zone of Nigeria. The table revealed that 77.2% of the men and 89.3% of the women complained about loss of land. 85.3% of the men and 78.0% of the women complained of reduced pasture for their animals. 78.3% of the men and 71.4% of the women are worried because of water shortage and 67.7% men and 48.9% women felt the need for irrigation. Also, 90.6% of the men and 82.1% of the women lamented about crop failure and 77.2% men and 42.9% lamented about their dying livestock. From all these analysis, it is obvious that livelihood in Sudan Savannah Zone are affected by climate variability impact of drought and irregular rainfall. This is in line with Challinor et al. (2007) who explained that agricultural potential of the Sudan Savanna in West Africa is limited by insufficient water availability due to high rainfall variability and frequent droughts.

Our major occupation here is faming and rearing of livestock animals. Everything is okay. The only change is the issue of rain and drought. Before, rain starts around April and

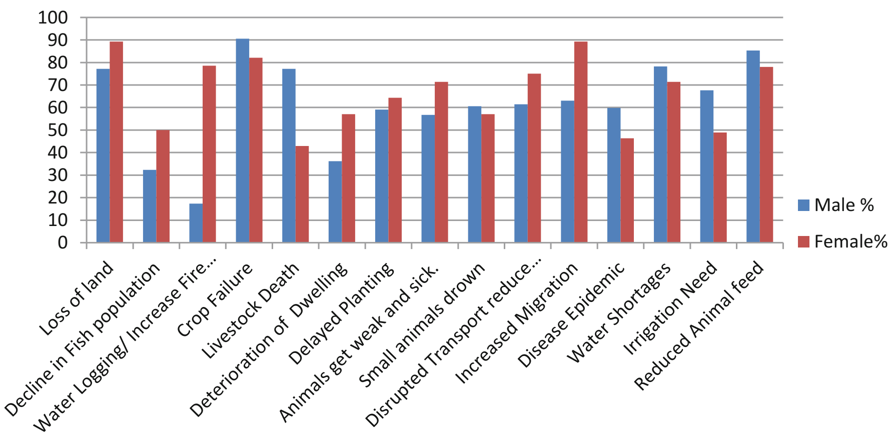

Fig. 3 Climate variability impact of livelihood security of aged men and women in Sudan Savannah Region of Nigeria. (Source: Author's Fieldwork)

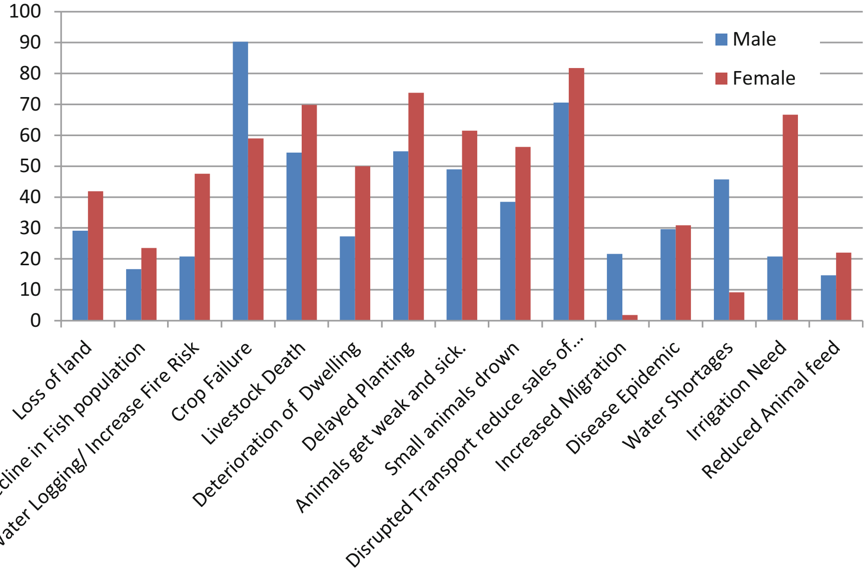

Fig. 4 Climate variability impact of livelihood security of aged men and women in Montane Region of Nigeria. (Source: Author's Fieldwork)

sometimes March. But now, that the climate has changed, it may start around June or July (**Al Haruna**)

We have a river here. Sometimes this river overflows and leads to flood. There is nothing we can do about such a situation because we do not have a choice. (**Aisha Muhammad**)

If you observe the route we followed here, the erosion has affected the bridge there. We have got about 30 bags of cement to do the bridge again. Even as we speak, if rain shouldfall, no one will be able to leave this town until the water level reduces (**Kulu Galadima**)

The drought usually affects our cultivated crops, in most cases we do re-planting after the drought might have destroyed the cultivation. So we plant immediately after the first rainfall that comes after a drought. For the flood, there is nothing we can do about it. What we do in most cases is to gather the redeemable crops and plant again after flood. (**Amina Hakimi**)

Figure 4 reveals the impact of climate variability on livelihood security of the rural aged men and women in the Montane Zone of Nigeria. The table revealed that 70.6% of men and 81.8% of women were not happy about disrupted transport reducing sales of goods; 58% of the men and 59% of the women complained of crop failure; 54.8% men and 73.8% talked about delayed planting; 49% of men and 61.5% of the women worried about their animals getting weak and sick while 54.4% men and 69.8% women complained about their dead livestock. This analysis was further corroborated with comments on the experiences of the aged men and women's climate variability impact on their livelihood security in the different selected villages of Plateau State of Montane Zone of Nigeria.

In this area we do not experience flood, but over there (neighboring village), all their houses and roads are filled with flood **(Sunday Gaarus**)

> Lot of houses are usually affected. But for crops, only rice will do well in such condition. Last year we harvested plenty rice because rice needs a lot of water to grow. But crops like corn, guinea corn did not survive the weather. Millet also, for those farmers that had enough rain harvested it as well. We got millet here last year because we cultivated it around July ending to October ending, because it also can survive heavy rain. But crops like the ones I mentioned earlier, corn, and guinea corn will not survive it (**Zababiya**)
>
> In other places, they have not even had any rainfall at all this year. But we here are very lucky to have experienced several rainfall, though heavy. If we now start complaining about heavy rain, what should other places that have not experienced rain say? We do not know why God has decided to do it this way. So, to tell you I have an idea is unexplainable. Everything is God's doing (**Mrs Ngyuk**)

Generally, the impact and the experience of climate change on livelihood security of the aged men and women is peculiar to each ecological zone. This is because each ecological zone has its own peculiar characteristics. This is in line with Callo-Concha et al. (2013) that says vulnerability to climate change impact is highly correlated with its geographical peculiarities. Therefore, the impact on the respondents is relative to the geographical characteristics.

Conclusion

Climate change is rapidly emerging as one of the most serious global problems affecting many sectors in the world especially rural livelihoods in agriculture, cattle rearing, crop farming, fishing, hunting, mining, tourism, and craft and weaving. It was found that the rural aged populations in Nigeria are highly vulnerable to climate change impact, especially in their livelihood security which was discovered to differ by region and by activity. This is in line with Garai (2014) which assessed climate change impact on the livelihoods of coastal people in the south-western part of Bangladesh revealed the elderly as part of the most at risk and vulnerable to climate change impact because of their inability to adapt to unfavorable environmental condition.

While some areas are generally more sensitive to climate change (Saarinen et al. 2012), some livelihoods and activities are more ecologically dependent and exposed to climate change impact. In consequence, the rural aged experience climate variability impact on their livelihood differently in different ecological zones, and their experience is based on the prevailing climate variability characteristics in each ecological zone.

In the Guinea and Sudan savannah zones, the prevailing climatic variability characteristics are drought, desertification, excessive heat and increased temperature, decline in rainfall, delayed onset of rainfall to mention a few. This is also in line with Ayanlade and Ojebisi (2019) which assessed herders' responses to climate variability and changes in the Guinea Savannah region of Nigeria. The study confirmed climate variability characteristics like excessive heat, reduced and delay onset of rainfall, prolonged dry spell, drought to mention a few in the area. Also in the Coastal zone the prevailing climatic variability characteristics are flooding, earlier onset of rain, erosion, increased frequency in storms. The impact on their livelihood in these zones is mainly associated with livestock death, lack of pastures for herds, scarcity of water, pest invasion, delayed planting crop failure, need for irrigation, water logging, drowning of small animals, human and animal illness. This implies that government planning and decision making related to climate change should take the views of the aged populations into consideration, especially for those rural areas affected most by climate change impact.

Acknowledgments This research was supported by funding from Department for International Development (DfID), in the UK, under the program Climate Impacts Research Capacity and Leadership Enhancement (CIRCLE), implemented by the African Academy of Sciences and the Association of Commonwealth Universities.

Abstract

Climate affects the quantity of soil moisture within the surface of the earth and this is obtained by affecting the amount of radon flux density escaping from the land surface. This chapter contains the evaluation of climate change conditions as it affects the variability of soil water for the purpose of estimating the health effects of radon flux density within Ogbomoso metropolis. The simulated soil moisture content around Ogbomoso was done for a period of 34 years using the hydrological model, Soil Water Assessment Tool (SWAT). The calibration and validation of the SWAT model was done using the daily observed soil moisture content. The simulated daily soil moisture within Ogbomoso showed good performance when calibrated and validated. A 20 years prediction of the daily soil moisture content was done using the SWAT model. The estimation of the radon flux density for the study area was obtained using the simulated soil temperature and soil moisture from the SWAT model. In this chapter, the UNSCEAR radon flux formula was used for the radon flux estimate. The result showed that the UNSCEAR radon flux formula performed well in estimating the radon flux density in the study area. The mean value of the radon flux density of 15.09 mBqm^{-2} s^{-1} falls below the estimated world average of 33 mBqm^{-2} s^{-1} by UNSCEAR stipulated for land surface. The results showed that Ogbomoso region is not prone to high risk of radon exposure to the public. The estimation of the radon flux density value suggested that there is no radiological health hazard such as lung cancer or any other respiratory tract diseases to the inhabitant of Ogbomoso, Nigeria.

Introduction

Climate change has been reported to have significant effects on the amount of soil moisture within the land surface (Schery et al. 1989). This is attainable by managing the quantity of radon emanating from the earth. The main hydrology and climate variable that affects the land surface processes is soil moisture (Tanner 1980; Schery et al. 1989). Soil moisture is a major variable for a large number of uses, including numerical weather forecasting, flood prediction, agricultural drought evaluation, water resources management, and health evaluation (Zhang et al. 2008). Despite the principal importance of soil moisture to agricultural performance, crop observation, and yield prediction, soil moisture statistics is not widely obtainable on a territorial scale in Nigeria. Only finite data sets of soil moisture exist in Nigeria because it is a strenuous property to measure. Soil moisture is naturally diverse because of dissimilarity in moisture-holding abilities of the soil at a very small scale and topography. The soil moisture is mostly measured by agro-meteorological experimental stations which are very insufficient in Nigeria. The data obtained from these stations are too few to investigate how the atmosphere relates with the land surface because they are measured basically for agriculture. Apart from these, agro-meteorological experimental stations are not available in Ogbomoso metropolis. It is paramount to seek a way to simulate this limited variable.

Investigation has shown that variation in soil moisture have evidential effects on changes in radon concentration (Radon-222) in the atmosphere (Brookins 1990). Radon is a natural radioactive inert gas whose inhalation in excess dose may lead to adverse health effect such as lung cancer. Factors such as climatic parameters, diffusivity, and radon concentration have been identified as some of the factors that determined the concentration of radon in the atmosphere (Zahorowski et al. 2004; Fields 2010). Soil moisture is a major parameter that determines the amount of radon exhalation from the earth surface and radon concentration in the atmosphere (Tanner 1980; Ball et al. 1983; Zhou et al. 2005; Sheffield and Wood 2008). The purpose of this chapter is to assess the health effects of radon flux density due to the impact of climate change on soil moisture within Ogbomoso metropolis, Nigeria. This chapter will provide an all-inclusive, evidence-based, measurable estimation of simulated and forecasted soil moisture for assessing radon flux–related health effect in Ogbomoso, Nigeria.

In this chapter, the simulation and forecasting of the soil moisture from the available meteorological data and other relevant data using the Soil Water Assessment Tool (SWAT) model was investigated to estimate the health effects of radon flux density distribution in the atmosphere. This chapter, therefore, seeks to use the relationship between soil moisture and radon emanation from the ground surface to estimate radon flux density distribution in the atmosphere within Ogbomoso. The objective of this chapter is to investigate the effects of change in climate on the variability of soil moisture for the purpose of estimating radon flux density in the Ogbomoso, Nigeria. The specific objectives of this chapter are to obtain a quantitative estimation of (a) the simulated soil moisture, (b) the forecasted soil moisture, (c) the radon flux density above the land surface, and (d) to investigate the health risk of the estimated radon flux density.

Climate Change and Soil Moisture

In the interaction of land and the atmosphere, the amount of water in the top soil plays a very principal role (McColl et al. 2017; Koster et al. 2004). Soil moisture is propelled by climate, more significantly by precipitation and temperature (Feng and Liu 2015). Precipitation is the major source of soil moisture, and changes in precipitation will impact the amount of water in the top soil. Furthermore, changes in temperature also affect soil moisture by managing evapotranspiration (Wang et al. 2018a). The application of soil moisture for weather prediction (Alexander 2011; Wang et al. 2018b), drought observation (AghaKouchak 2014), hydrological modeling (Wanders et al. 2014), and vegetation variation (Chen et al. 2014) are gaining wide application in recent time. The global warming today and movement of the water cycle may cause changes in soil moisture variability (Sheffield and Wood 2008). It has been reported that changing vegetation can also alter the amount of water in the top soil (Sterling et al. 2013). Vegetation variation has been discovered to affect field ability and soil penetration, thus altering soil moisture (Ouyang et al. 2018). These factors, through some complex relationships, alter soil moisture. Climate variation has been discovered to impact soil moisture greatly. The effects of change in climate and change in vegetation have been reported in literatures.

This chapter considers the implications of change in climate on soil moisture for estimating the health effect of radon flux density. The various soil moisture measuring stations, which are few in number, do not consider the different soil types, soil characteristics, land cover and land use, topography, etc. on the soil moisture. The observation of soil moisture is very scarce. Instead of making use of observation that is limited, numerical models have been employed over time to investigate the changes in hydrological processes and soil moisture, which play a key role in this regard. Numerous hydrological models exist today that can be used for the purpose of simulating the hydrological processes of a watershed. Each model possesses its own pros and cons. The purpose to which an investigation is carried out determines the choice of model to be used. This chapter seeks to examine the Soil Water Assessment Tool (SWAT) model (Arnold et al. 1998) which was chosen due to its ability to simulate hydrologic processes. Another strength of the SWAT model is the fact that it takes into consideration the effects of vegetation properties, topography, soil characteristics, and land type and land cover on the hydrological processes of the soil. This is made possible with the aid of a Digital Elevation Model (DEM) with a very high resolution. Over the years, the SWAT model has become accepted on a global scale as a strong modeling tool suitable for simulating watershed hydrology (Gassman et al. 2007). The SWAT has found application in extensive scope of environmental situations, watershed scales, and framework analysis as described by Gassman et al. (2007). In this chapter, some meteorological data collected from NIMET for Ogbomoso metropolis were fed into the SWAT model to simulate and forecast soil moisture over Ogbomoso. The simulated soil moisture data were used to estimate radon flux density, thereby examining the health effect over Ogbomoso region.

Radon and Human Health

Over the years, radon gas has been studied for two primary purposes. The first purpose is to investigate the extent to which the general public is exposed to it. Secondly, it was studied to detect the various transfer processes in the atmosphere. The breathing in of radon and its momentary progeny account for about half of the effective dose from all natural sources of ionizing radiation. One of the main challenges of radiation protection to the public is the development of lung cancer as a result of inhalation of the progeny of radon (UNSCEAR 1993). Whenever radon is inhaled in high concentration, it usually leads to diverse health implications.

Atmospheric radon, which is an inert gas with a half-life of 3.82 days, has been identified as detectors for atmospheric transport. It also doubles as indicators for evaluating and simulating environmental activities (Brookins 1990; Iida et al. 1996; Wang et al. 2004, Zahorowski et al. 2004; Ohkura et al. 2009). Radon concentration in soil and radon exhalation from the soil surface depend on many physical characteristics. These characteristics are related to soil parameters, such as radium content and the internal structure of the soil. Other physical parameters include type of the mineralization, soil porosity, grain size of the soil, permeability of the soil, and emanation coefficient (Mazur et al. 1999; Aburnurad and Al Tamimi 2001). The release of radon gas from the soil to the atmosphere is associated with some of the same processes that control the soil/air exchange of important greenhouse gases like CH_4, CO_2, and NO_2. Radon does not go through complex chemical reactions and its source term is relatively well known (^{226}Ra in soil).

Measurement of radon concentration in the atmosphere has been used for the validation climate models. Due to insufficient radon flux density measurement, measurement of atmospheric radon has been employed in the validation radon flux density from the soil (Kritz et al. 1998; Gupta et al. 2004; Zhang et al. 2008). Therefore, statistics on the territorial distribution of ^{222}Rn exhalation from the earth's surface is regarded as useful for recognizing areas with a health risk of high radon exposure to public. This chapter therefore aimed to use the simulated and forecasted soil moisture to estimate the health effects of radon flux density of Ogbomoso metropolis. Studies of the radon flux densities are able to provide information on the interaction of exchange of gases between the soil and the atmosphere for the purpose of estimating pure health implications of the inhalation of these gases.

Silmulation and Forecasting of Soil Moisture Within Ogbomoso Using the Swat Model

The SWAT Model

Soil moisture, which is the amount of water in the upper layer of the soil, has been proven to be affected by changes in climatic properties due to alteration in some meteorological parameters such as precipitation, temperature, relative humidity, solar radiation, and wind speed. The alterations in these parameters are employed in the simulation and forecast of the soil moisture over a particular region provided that relevant data for that region are available. The Soil Water Assessment Tool model known as the SWAT model was used for this purpose within Ogbomoso metropolis. Ogbomoso, which is geographically situated within 4°10′E to 4°20′E longitude and 8°00′N to 8°15′N latitude, is investigated in this chapter. The area is situated within the crystal-like Vault of Nigeria (MacDonald and Davies 2000). In Ogbomoso, rocks are classified as either quartzites or gneisses (Ajibade et al. 1988). The agricultural watershed considered in this research work where the simulation and forecasting of soil moisture was carried out is situated within Ogbomoso North Local Government Area as shown in Fig. 1 (Adabanija et al. 2014). Simulation of

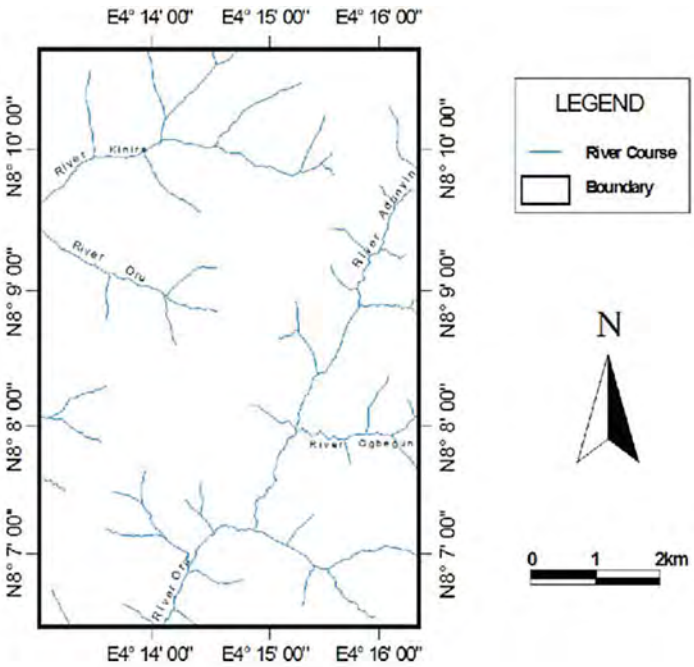

Fig. 1 The map showing the area within the agricultural watershed (Adabanija et al. 2014)

hydrology within this agricultural watershed was considered under diverse topography, vegetation, climatic condition, and soil. The total drainage of the Ogbomoso watershed accounts for a total of 8.58 km^2. Ogbomoso, which lies between the savannah and the rain forest, has wet and dry tropical climate. The temperature of the region is fairly uniform throughout the year. It has an average rainfall and temperature of 1200 mm and 26.20 °C annually, respectively. The territorial district of Ogbomoso has four seasons similar to other southern Nigeria. The initial raining season in the region starts from April to July characterized by high humidity and heavy rainfall. It is usually interrupted by a short dry period in August before the rainy season resumes again, this time for a short wet season between September and October. The fourth season is the harmattan season which spans between November and ending in the middle of March. The region experiences a relative humidity between 75% and 95%. Ogbomoso region, being a low land forest, has agricultural activities as major activities of the inhabitants. Figure 1 shows the region of investigation within Ogbomoso metropolis.

"The SWAT has been employed to simulate watersheds globally, it is most frequently chosen due to its vigorous ability to compute the impacts of land management practices on hydrological processes, water quality, and crop growth" (Arnold et al. 1998). In this chapter, the QSWAT, which is a type of the SWAT2012 model, assembled with QGIS 1.4 was employed. The SWAT model operates by breaking a watershed into sub-basins, connected by a stream grid. The Hydrological

Standard	>0.6	>0.5	≤15%

Response Unit (HRU) is the place where the simulation was carried out, which is logged in each basin. The simulated variables (water, sediment, nutrients, and other pollutants) are first simulated at the HRU and then passed through the stream to the water outlet (Arnold et al. 1998; Neitsch et al. 2005). The study on soil moisture simulation and forecasting was first investigated within Ogbomoso by Oladapo et al. (2018) with the aid of climatic data inputs such as precipitation, maximum and minimum temperature, solar radiation, relative humidity, and wind speed. Secondary data of daily precipitation, maximum temperature and minimum temperature data, solar radiation, the humility, and the wind speed were all collected from the Nigerian Meteorological Agency. The data cover between 1979 and 2017. Other data sources including the digital elevation model, land use data, soil data, and climate progression data of the study were used in the simulation and the forecast of the soil moisture in the area (Table 1).

Since Ogbomoso is a natural hydrological setting, five years daily satellite-based soil moisture data (2006–2010) from ESA CCI soil moisture project for the region under investigation were used for the SWAT model calibration. The laid down method of calibration for the SWAT model was carefully followed (Santhi et al. 2001; Neitsch et al. 2005). Due to lack of long-term in situ measurement of soil moisture at the study area, both the short-term in situ measurement of daily soil moisture taken at the study area between April and July 2017 (Oladapo et al. 2018) and five years daily soil moisture data from ESA CCI (2011–2015) were used to validate the SWAT model (Oladapo et al. 2018). Three different model performance statistics were carried out. They are Nash and Sutcliffe efficiency (E_{NS}), percentage difference (D), and the regression coefficient (R^2). A calibration and validation of E_{NS}, D, and R^2 for hydrology at $E_{NS}>0.5$, $D\leq 15\%$, and $R^2>0.6$, respectively, for SWAT model was adopted (Santhi et al. 2001; Moriasi et al. 2007). The three statistical model performance used in the calibration and validation procedure for the soil moisture are presented in Table 2.

Soil Moisture Observation

Five-year satellite-based soil moisture observation data from daily soil moisture data of ESA CCI (2011–2015) and observed soil moisture from the study were obtained. Figure 2 shows the trend in the daily observed soil moisture values during the rainy season (April–July 2017). The highest, lowest, and the mean precipitation are 98.35 mm, 1.98 mm, and 48.64 mm, respectively (Oladapo et al. 2018). An increasing precipitation trend was observed from April to July 2017 in the study area. The increasing soil moisture is likely related to the increasing precipitation between April and July which is the rainy season in the study area. This is largely due to reducing temperature during this period. A short variation in daily precipitation was observed in the region as shown in Fig. 3. Model simulated daily soil moisture values from the sub-basin were compared with the daily observed soil

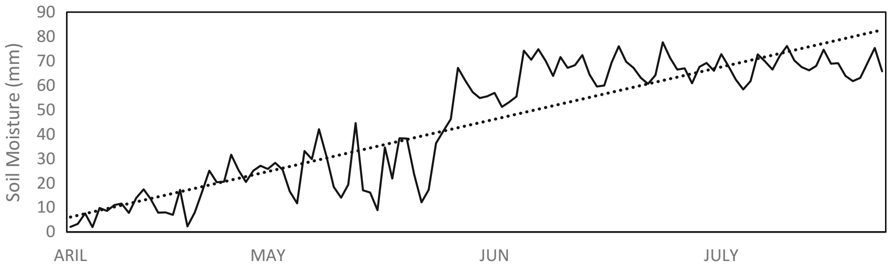

Fig. 2 Trend in the daily soil moisture values observed in 2017 (Oladapo et al. 2018)

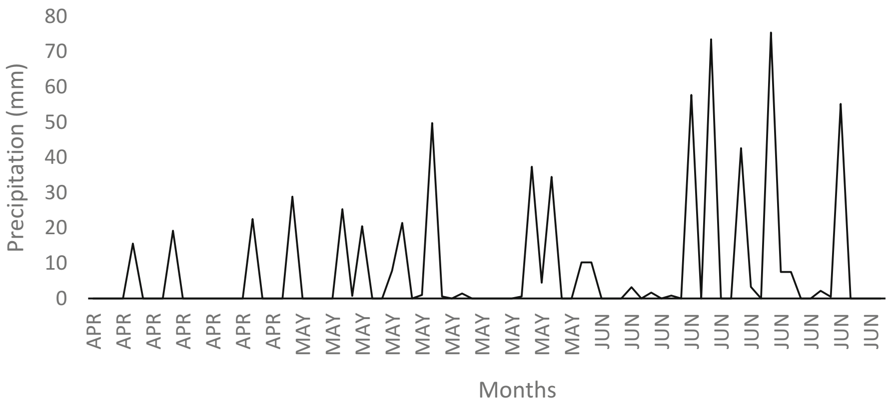

Fig. 3 Precipitation distribution at the watershed during the rainy season in 2017 (Oladapo et al. 2018)

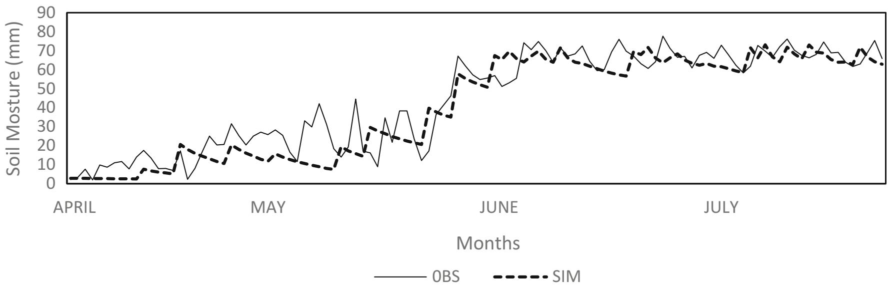

Fig. 4 Comparison between daily means of observations and SWAT simulated soil moisture (April to July 2017) (Oladapo et al. 2018)

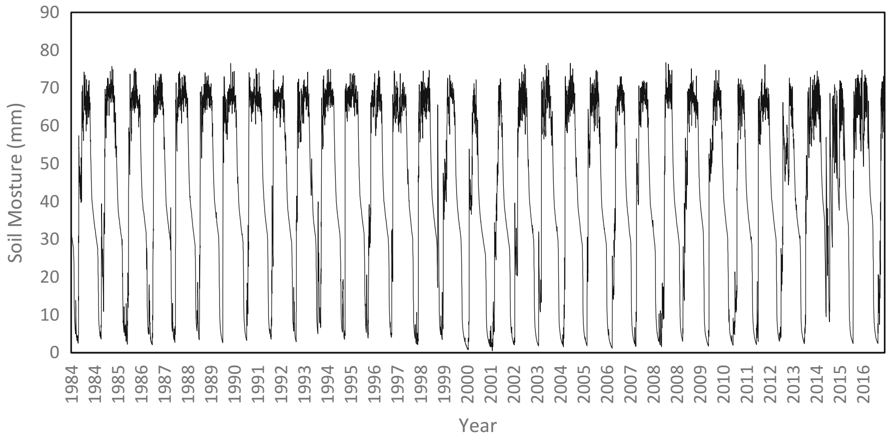

Fig. 5 The 34-year soil moisture simulated by SWAT over Ogbomoso watershed (Oladapo et al. 2018)

moisture values from the field where the sub-basin is located for this four months period. Figure 4 shows that the model closely follows a similar curve to observed value.

Soil Moisture Simulation

The model simulation allows for a 5-year warm-up period. Therefore, a 5-year secondary climate data inputs obtained from NIMET for Ogbomoso metropolis were used for this purpose. The SWAT was used to simulate the soil moisture in the Ogbomoso watershed for 34-year period (1984–2017). Figure 5 shows the temporal variations of soil moisture in the sub-basin of Ogbomoso watershed over the last 34 years. For the 34-year period, the simulated soil moisture declines slightly.

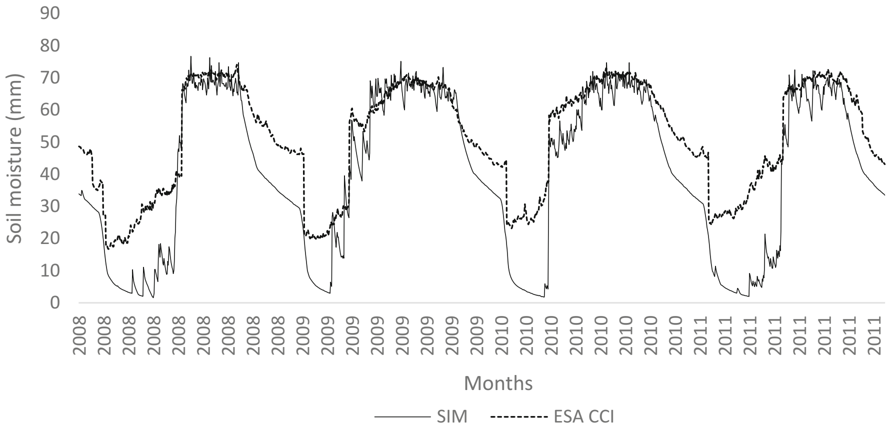

Fig. 6 Comparisons between daily means of SWAT simulated and ESA CCI soil moistures from January to December between 2008 and 2011 (Oladapo et al. 2018)

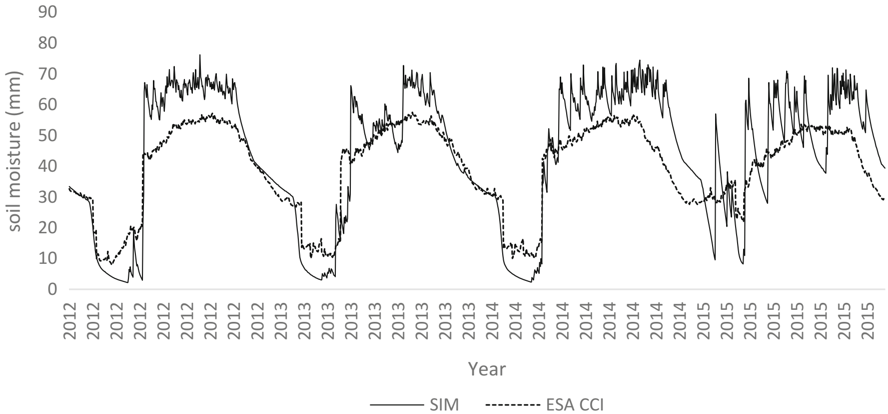

Fig. 7 Comparisons between daily means of SWAT simulated and ESA CCI soil moistures from January to December between 2012 and 2015 (Oladapo et al. 2018)

Figure 6 shows the calibration of the simulated soil moisture with the daily satellite-based soil moisture. There was a good correlation between them. The comparison showed a similar pattern when four years (2012–2015) daily simulated soil moisture from the sub-basin was used for validation as shown in Fig. 7.

The noticeable variation between the daily simulated soil moisture and the satellite-based values of ESA CCI in Figs. 6 and 7 could be traced to the physical and hydraulic parameters associated with the soils, such as soil texture and rainfall, and land cover and land management practices in place. Furthermore, the seasonal variations of the SWAT simulated soil moisture for years 1984, 2000, and 2016 were compared as shown in Fig. 8. Seasonal variations investigated for three years at random showed a similar pattern for the years 1984, 2000, and 2016. The soil

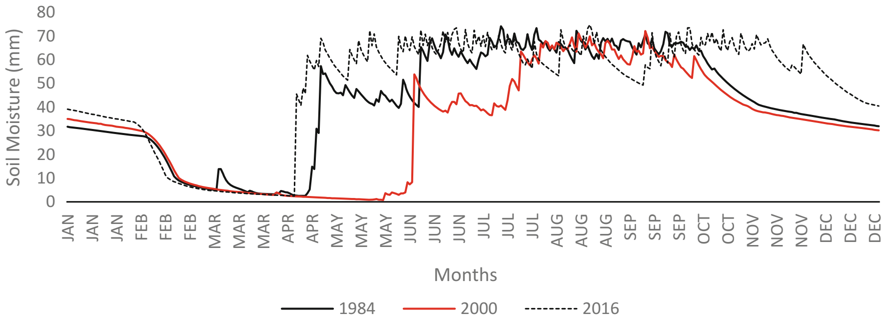

Fig. 8 Seasonal variation of the simulated soil moisture from January to December for year 1984, 2000 and 2016

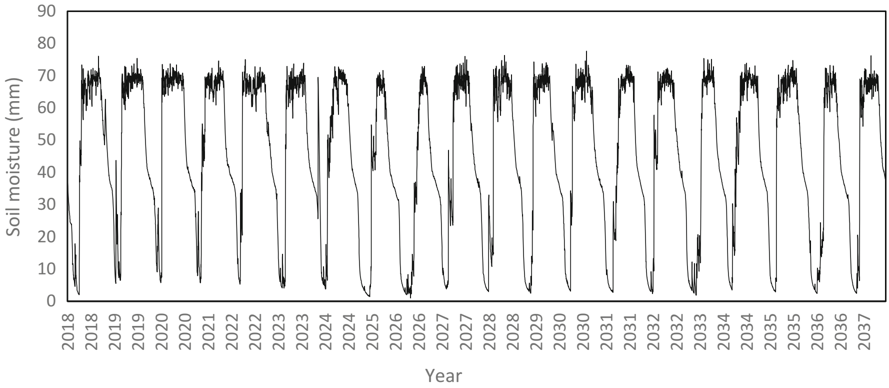

Fig. 9 The 20-year soil moisture forecasted by SWAT over the Ogbomoso watershed (Oladapo et al. 2018)

moisture declines greatly from January till March when the onset of rainfall begins again. This is largely due to reduction in the air temperature of the region. The soil moisture begins to pick up in April being the onset of the raining season and continues to increase till mid-October when it begins to reduce again. The variation in the simulated soil moisture in Fig. 8 is mainly due to the distribution of precipitation in the area.

Forecasted Soil Moisture

The RCP 8.5 projection was used to forecast soil moisture in the region with the assumption of slow growth income and increased population density (Riahi et al. 2011). The RCP 8.5 projection scenario means that there will be increase in the greenhouse gas emission due to the fact that energy is in high demand in the long-term absence of climate change regulations and policies (Riahi et al. 2011). Fig. 9

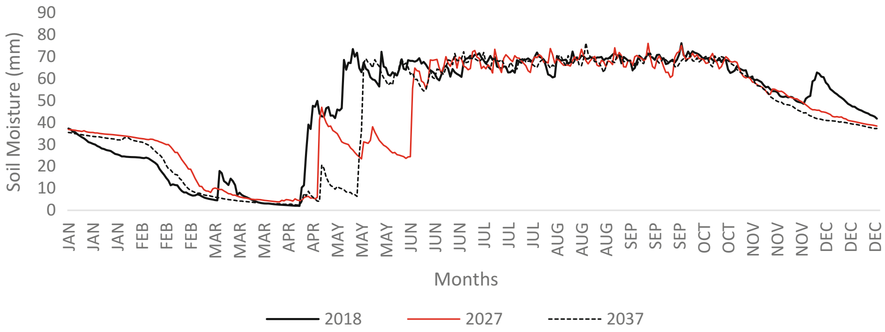

Fig. 10 Seasonal variation of the forecasted soil moisture from January to December for 2018, 2027, and 2037 (Oladapo et al. 2018)

shows the temporal variations of forecasted soil moisture in the sub-basin of the Ogbomoso agricultural watershed in the next 20 years (Oladapo et al. 2018). The forecasted soil moisture showed a general drop in trend which may suggest that there is likely to be a decrease in precipitation and a rise in air temperature in the region within the next 20 years.

Seasonal variation of the SWAT forecasted soil moisture in Fig. 10 which bears similar pattern with that of the simulated soil moisture confirms the key role rainfall plays in the quantity of soil water reserve.

Estimation of Radon Flux Density

The release of radon gas from the soil can take place either by emanation or through the process of transport. The process whereby a ^{222}Rn atom escapes from ^{226}Ra-bearing grains to the pore space in soil is called emanation. The process of radon transport, which occurs in the pore space of the soil, involves the process of advection and diffusion. Diffusion is a product of slope in the radon concentration. Meanwhile, the pressure difference between the ground surface and pore space gives rise to advection. In this chapter, the process of diffusion alone will be considered. This is because influence of most meteorological parameters on the advection can be assumed to be negligible when averaged over one month. Provided that soil under investigation is homogeneous, a one-dimensional diffusion equation can be used to derive the radon flux density from the soil within the region (Goto et al. 2008). There is usually a rise in the radon released into the atmosphere when the soil moisture is low leading to an increase in radon flux density from the soil surface. However, when a certain soil moisture is reached, the radon diffusion and advection process is reduced. This is because the pore space being filled with water slows down the radon flux density from the soil surface (Koarashi et al. 2000; Iimoto 2002). The result of this work is similar to other works on the relationship between soil moisture and radon flux density from the earth surface (Koarashi et al. 2000; Iimoto 2002). The radon flux density values estimated in this work will serve as reference since radon flux data are scarce around the world.

The influence of the soil moisture and soil temperature on the radon flux density is considered. The radon flux density, from the soil surface, was estimated using the UNSCEAR radon flux formula (Zhou et al. 2005).

$$F = R\rho_b\, \varepsilon\left(\frac{T}{273}\right)^{0.75}\sqrt{\lambda Dop \exp\left(-6Sp - 6S^{14p}\right)} \tag{1}$$

where R is the soil ^{226}Ra content (Bq kg_1), ρ_b is the soil bulk density (kg. m^3), ε is the emanation coefficient of ^{222}Rn in soil, which is a function of the soil temperature (T, in Kelvin scale) and the water saturation fraction (S), λ is the ^{222}Rn decay constant (s^{-1}), p is the soil porosity, and D_o is the ^{222}Rn diffusion coefficient in air (1.1×10^{-5} $m^2 \cdot s^{-1}$). The emanation coefficient (ε) of ^{222}Rn in soil was estimated from the fitted formula of Zhuo et al. (2005).

The values of the soil moisture and soil temperature simulated by SWAT were inputted into the equation. The evaluation result showed that the UNSCEAR radon flux formula performed well in estimating the radon flux density in the study area when calibrated with observed atmospheric radon concentration in the study area. The values of the estimated radon flux density ranged between 4.03 and 37.30 $mBqm^{-2} \cdot s^{-1}$ with a mean of 15.09 $mBqm^{-2} \cdot s^{-1}$. The overall average radon flux density in the area lies below the world mean value (UNSCEAR 2000). The mean value of radon flux density in the area indicated that Ogbomoso metropolis is not prone to risk of radon exposure and may not cause any health risk such as lung cancer and other respiratory tract diseases. For this reason, it is safe to conclude that the radon flux density will not have any radiological health risk to the inhabitants of Ogbomoso metropolis. However, field measurements of the radon flux density within and outside of Ogbomoso are needed to further verify the reliability of these estimates. Since there exist insufficient radon flux measurements around the globe, these set of estimated radon flux densities in Ogbomos will serve as baseline data for future references. Note that the estimated radon flux densities within Ogbomoso investigated in this chapter are between the soil and the atmosphere, hence the health risk is very negligible. The health effect of radon exhalation within buildings in Ogbomoso which is expected to be higher may, however, pose some radiological health risk. For this reason, it is important to review the health implication of radon exhalation values which are triggered by climate change within Ogbomoso.

Conclusion

The effects that climate change has on the variation of soil moisture are the focus of this chapter for the purpose of estimating the health effect of radon flux density within Ogbomoso. A 34-year simulation of soil moisture content was executed within Ogbomoso watershed using the hydrological model, Soil Water Assessment

Tool (SWAT). A 20-year forecast of the soil moisture was also done. The calibrated and validated SWAT model performed well for the simulation of daily soil moisture. A general decline in trend was observed for both the simulated and forecasted soil moisture. This decline in trend may be largely due to rainfall reduction and temperature rising in the region. The SWAT model has proven to be suitable for simulating and forecasting soil moisture in the region. The radon flux density for the study area was estimated using the UNSCEAR radon flux formula. The mean value of the radon flux density of 15.09 $mBqm^{-2}\cdot s^{-1}$ falls below the estimated world average of 33 $mBqm^{-2}\cdot s^{-1}$ by UNSCEAR. The result of the estimated radon flux density showed that Ogbomoso region is not prone to high risk of radon exposure to the public. In other words, the estimated radon flux density in the study area will not pose any radiological health risk such as lung cancer or any other respiratory tract diseases to the inhabitant of Ogbomoso metropolis.

Abstract

Global warming has emerged as a major challenge to development and human wellbeing in Sub-Saharan Africa in general and Nigeria in particular. Periodic incidents show that this challenge will continue and increase in impact on all aspects of natural resources – agriculture, ecosystems services, biodiversity depletion, environmental degradation and human health. Recognizing the enormous potential of underutilized plant genetic resources (PGRs) is crucial as sources of solutions to a number of these threatening challenges emanating from climate change (food and nutrition insecurity, genetic erosion, loss of agro-biodiversity, green job growth and income generation) cannot be overemphasized. *Sphenostylis stenocarpa* (Hochst. *ex*. A. Rich) Harms., commonly known as African yam bean (AYB) belonging to the leguminous Fabaceae, is an underutilized PGR with rich portfolio which could serve as vital source of robust adaption and resilient germplasm for vulnerable local communities in Nigeria. Its substantial nutritional, environmental, cultural, social, medicinal, industrial and soil restorative potentials underpins its position as climate – smart species. Enhancing the potentials of African yam bean via robust innovative approaches for wider utilization through accelerated research, farmer seed exchanges, in-situ and ex-situ conservations, farmers selection, and policy programs such as seed sovereignty will accentuate its adaptation and used as resilient climate –smart species for the vulnerable groups in Nigeria to cushion impact of climate change.

African yam bean · Climate smart species · Adaptation climate change · Resilience · Conservation · Nigeria

Introduction

The Intergovernmental Panel on Climate Change (IPCC) reported that global warming of 1.5 °C and greater upsurge of 2 °C is projected for 2046–2065 and that these will have consequential impacts on food and water security, health, and other components of sustainable development, limiting strategies for adaptation, losses and damages to biodiversity and ecosystem services (IPCC 2018). All players are potential culprits to these increase, and accordingly need to undertake considerable behavioral changes to counteract this life threatening global warming, particularly in Sub-Saharan Africa. However, the above scenario is dependent on the level of anthropogenic activities on future greenhouse gas emissions (Pachauri and Meyer 2014).

Resilience is required within any systems to deal with climate stresses and disturbances and this include the willingness to change, skills to learn and capacity to adapt to such changes. It is therefore the zeal of managing changes and adaptations that can stand the test of current and future climate risks.

Population Increase and Challenges of Food Security

There has been a geometric increase in global population over the last 200 years and it is projected to continue to rise. United Nations forecast stated that due to exponential growth, that population will rise from the current 7 billion to reach 9.7 billion by 2050 and subsequently 10.9 billion by 2100 (Fig. 1). This brings with it a number of life threatening challenges, especially in the absence of adequate food production technology, integrated programs which simultaneously address those community needs for food and reproductive health and impact of climate variability and change (World Bank 2014). The consequential effects of this population increase will be greater in Sub-Saharan Africa due to many factors such as, higher fertility rate, demographically younger population entering childbearing life phase, joblessness and a more volatile employment market.

Rapid national population growth has induced and intensified major environmental changes in response to climate change and variability which have led to the emergence of novel pests and diseases, loss of crop genetic diversity and a decline in resources such as water (Dobermann and Nelson 2013). Despite these, current global food production rates being at there highest level, they still fail to match population demand. Given the predicted population increase, food production will need to increase to meet demand by between 59% and 98% by 2050 (Elferink and Schierhorn 2016). United Nations Food and Agriculture Organization (FAO 2010) estimated that about 795

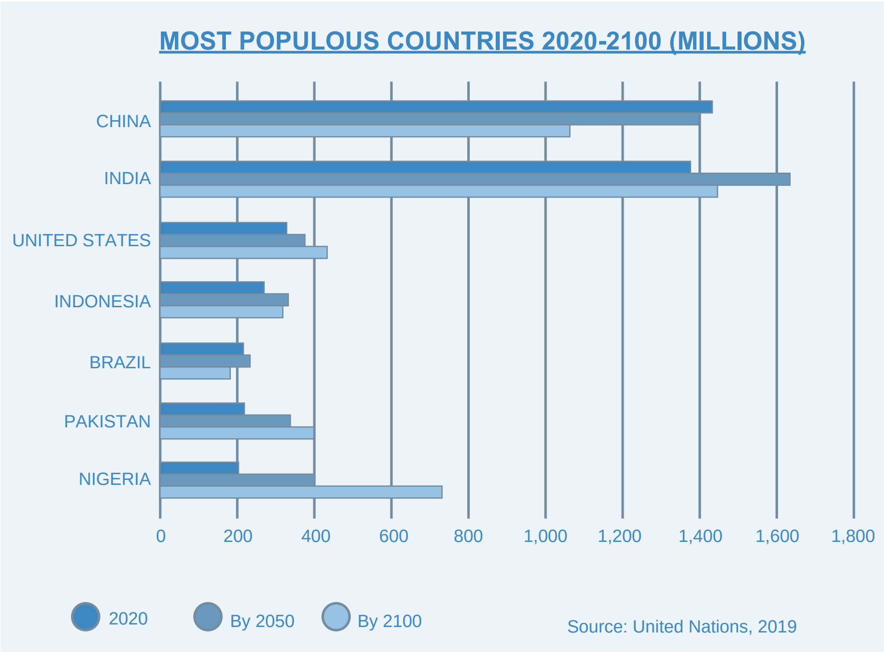

Fig. 1 Predicted population growth for 2020–2100

million people, of the current 7.3 billion population, suffered chronic malnourishment between 2014 and 2018 and majority of these people lived in developing countries. The Global Hunger Index (Grebmer et al. 2019) shows that multiple countries have higher hunger levels now than in 2010, and approximately 45 countries in current reality will not be able to achieve lower levels of hunger by 2030.

Poor monotonous diets, low in calorific quantity and quality with respect to nutritional level, variety and diversity are the primary cause for poor human health in many developing countries. Coincidentally, while the number of mouths to feed is increasing more rapidly than those farmers who are able to produce food. Hunger, malnutrition and famines and many endemic diseases, desertification, and floods continue to pose high risks in developing countries with low resilience which will be further exacerbated by climate change and climate variability aboard (Dobermann and Nelson 2013).

Nigeria ranks 93rd out of 117 qualifying countries with a score of 27.9, showing that its population is malnourished with high number of hungry people. This is an indication that out of the 162.5 million people, 1 in every 7 go to bed hungry (Grebmer et al. 2019). Mary Robinson, an Adjunct Professor of Climate Justice, Trinity College Dublin and former UN High Commissioner for Human Rights stated that “it is a terrible global indictment that after decades of sustained progress in reducing global hunger, climate change and conflict are now undermining food security in the world’s most vulnerable regions.” She concluded that with the number of hungry people rising from 785 million in 2015 to 822 million in 2018, “we can no longer afford to regard the 2030 Agenda and the Paris Climate Agreement as voluntary. This could be inferred from the level of changes over time in West Africa (Fig. 2). The above scenario needs vital actions and collective change of

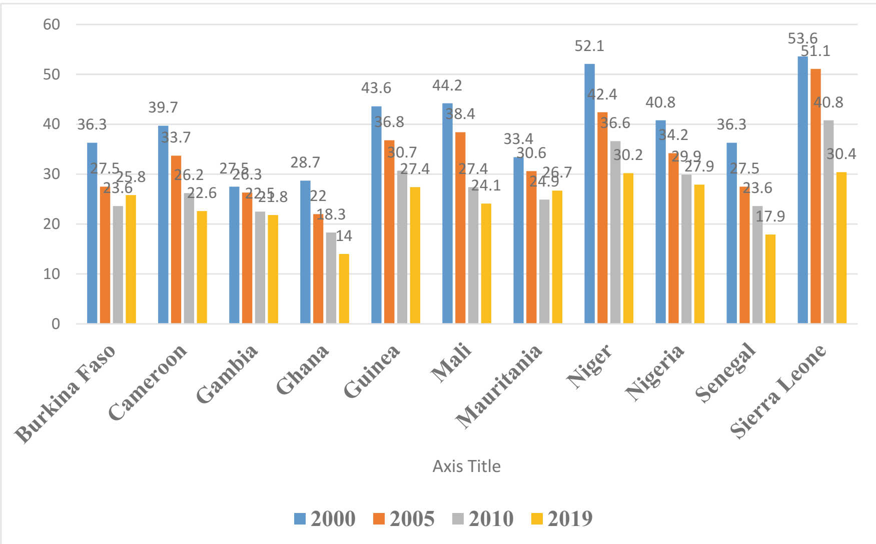

Fig. 2 West Africa Global Hunger Index scores, and changes over time. (Source: Grebmer et al. 2019)

attitude at both global and local levels in order to secure a habitable world for our forthcoming generations" (Grebmer et al. 2019).

Proffering Solution with Neglected and Underutilized Plant Genetic Resources

Plant genetic resources (PGR) are those varieties of heritable materials confined in traditional selections and modern domesticated cultivars together with their wild relatives and other wild plant species locally used as food, feed for domestic animals, fibre, clothing, medicine, shelter, wood, timber, energy and for recreational activities.

Neglected and underutilized plant genetic resources are domesticated and wild plants species which have been used for centuries as sources of food, fibre, fodder, oil, or have medicinal properties (stimulants, narcotics, aromatics), but their importance has remained unharnessed, abandoned, replaced with exotic foods or only very slowly now being considered for use. They are known by various names, including orphan, abandoned, lost, forgotten, neglected, underutilized, local, minor, poor man's food, traditional, alternative, niche, or underdeveloped plants (Padulosi 2017). Their underutilized potentials can be significantly exploited to combat climate change, as a future "smart crop" to improve food and nutrient insecurity. Here we adopt a progressive and positive approach to their potential exploitation as a source of "smart food," with an emphasis on their exploitation and/or development into viable future crops which are climate resilient. The Global Facilitation Unit for Underutilized Species (Bhat and Taiwo 2015) defines these species, as those with a potential not fully exploited; with respect to contributing to food security and poverty alleviation, combined with their strong links to local community cultural heritage. Their limited or poor documentation by research are evidenced by their adaptation to specific agro-ecological niches, a weak or non-existent seed supply systems, fully in the domains of traditional users only. They are produced with little, or no external inputs.

Our ancestors used over 7000 plant genetic resources (PGRs) as food, from which farmers produced about 70% of the global food supply (Bhat and Taiwo 2015). Currently, very few of these PGRs are still exploited in sustaining humans. Making food and nutrient security dependent on a handful of crops with 65% requirements for protein, calories and minerals met by wheat, rice, yam and cassava (FAO 2017). This shrinking portfolio of PGRs, shifts in life style, and the preference for fast foods are currently contributing factors involved in food and nutrient insecurity. These are reducing the capacity of farmers to adapt to changing markets, to innovate, to develop supply chains, and our ability to cope with climate change variability and its extremities (IPGRI 2003). Recognizing the considerable potentials which underutilized PGR can provide is crucial in finding solutions to the impacts of climate change on food and nutritional insecurity, genetic erosion, conservation of agro-biodiversity, green growth jobs and income generation (Padulosi et al. 2013; Nnamani 2015).

Nigeria as a nation holds a rich variety of PGRs linked to food, and other treasured traits. However, most of these species have received little, or no attention with respect to support for basic research, breeding improvement, commercial exploitation of germplasm selections, or consideration by policy itineraries to support enhanced utilization, thereby leaving them neglected. In order to meet food security challenges for a growing population under changing climate, it is necessary to identify and valorize these neglected and underutilized species (NUS) to develop greater resilience within local communities and the adaptation potential to increasing climate unpredictability and change.

African Yam Bean an Underutilized Plant Genetic Resources

Sphenostylis stenocarpa (Hochst. ex. A. Rich) Harms, customarily called African yam bean (AYB), is a legume of the subfamily Faboideae and family Fabaceae. *Sphenostylis* as a genus is represented by only 7 species (Potter and Doyle 1992). African yam bean is an orphan crop cultivated and utilized by local communities. It is a climbing annual, prostrate, or erect and approximately 1–3 m tall. The leaves are trifoliate, about 2.7–13 cm long and 0.2–5.5 cm broad. The inflorescence could be a raceme which shows an acropetal variety of flowering with pink colour intermingled with purple, twisted backward characteristics of the Fabaceae family (Fig. 3).

African Yam Bean is synonymous with African continent only, its geographical distribution is tolerated mainly within the soil, climate, and vegetation of Africa especially within the range of latitudes 15° North to 15° South and longitudes 15° West to 40° East (Adewale et al. 2008). The above geographical range could be referred to as the center of diversity of AYB (Fig. 3) since there is no record of the origin of the crop in any other continent beyond Africa (Potter and Doyle 1992). It is a crop of African origin, made for Africans and utilized as such in Africa, hence this

Fig. 3 Growth habit, floral and fruits features of African yam bean. (Photo © Adewale, B. D. and Nnamani, C. V.)

confirming the common claim that the crop is a tropical African legume. The rich hot spots of *S. stenocarpa* is found in Chad and Ethiopia in northeast tropical Africa, Kenya, Tanzania and Uganda for east tropical Africa, and in Burundi, Central African Republic and Zaire for west-central tropical Africa. It is also found in West Africa in places like Cote d'Ivoire, Ghana, Guinea, Mali, Niger, Nigeria and Togo while in south tropical Africa it is cultivated in Angola, Malawi, Zambia and Zimbabwe (USDA Agricultural Research Service 2015) (Fig. 4).

In South-east, Nigeria, the plant is diverse in distribution and geographical range thriving more in the derived savanna vegetation zone (Fig. 5).

Nutritional Potentials of African Yam Bean for Climate Change Adaptation

The seeds and tubers of AYB are highly rich in protein, minerals, and vitamin (Fig. 5). It is a promising source of plant protein for resource poor rural and semi-rural communities. The amino acid (lysine and methionine) has been reported to be higher than those of pigeon pea, cowpea, and bambara groundnut (Uguru and Madukaife 2001). Omeire (2012), noted that the amino acid (g 100^{-1} g) profile of AYB comprised of lysine (6.1), histidine (3.1), arginine (6.5), aspartic acid (9.1), glycine (3.9), alanine (4.1), valine (5.0), and phenylalanine (5.1) (Fig. 5). Its lysipne and methionine contents were similar or better than those of soybean protein (Yetunde et al. 2009) and comparable with whole chicken eggs (Ekpo 2006). The protein profile of the tubers compares favourably with that of other African root crops such as yams and sweet potatoes and has almost two and half times the protein value of cassava tubers (National Research Council 1979; Amoatey et al. 2000; Adewale and Aremu 2013) (Fig. 6).

African yam bean is cultivated for its edible seeds and tubers (Fig. 7), which have sustained indigenous community's livelihoods. A report of its medicinal value was reported in a traditional Igbo settings at Enugu State, Nigeria. The seed is an important ingredient utilized in the topical treatment of stroke, insomnia, diabetics, measles and stress. Extract of mashed AYB, after cooking, is used to induce lactation in mothers after child birth, while the fried seed coat is ground and used in the treatment of stroke (Nnamani et al. 2017). Culturally, it is used traditionally to entertain guests during traditional marriage ceremonies and serves as a famine food when every other crops have failed. Industrially, African yam bean flour is used to fortify conventional wheat flour which is frequently lower in protein content (Nnamani et al. 2017).

Nomenclatural Etymology of African Yam Bean to Climate Change

Sphenostylis stenocarpa is botanically synonyms in numerous literatures with *Sphenostylis ornata* A. Chev., *Sphenostylis congensis* A. Chev., *Dolichos stenocarpus* Hochst. ex. A. Rich., *Sphenostylis katangensis* (De Wild.) Harms, *Vigna katangensis* De Wild., and *Vigna ornata* Welw. ex. Baker. However, the

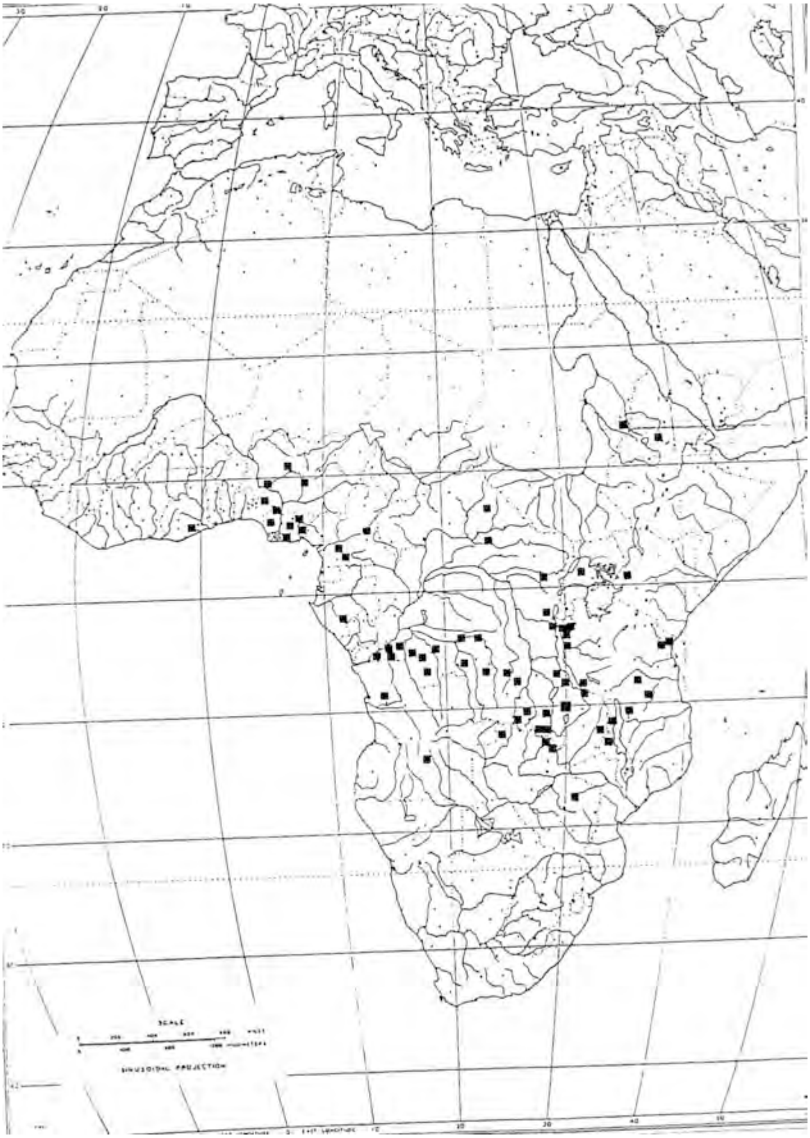

Fig. 4 Center of diversity of African Yam Bean in Africa. (Source: USDA Agricultural Research Service 2015)

current acceptable nomenclature is *Sphenostylis stenocarpa* (Hochst. ex. A. Rich) Harms (Adewale et al. 2012). Keay (1989) reported the followings common names as “Diegemtenguere” (Mali), “Girigiri” (Hausa, West Africa), “Norouko” and/or “Roya” (Sudan). Adewale and Odoh (2013) reported on some of the tribal synonyms of the crop in Nigeria: it is known as “Azama” (Ebonyi, State), “Akidi” or “Azima” or “Okpududu” (Ohafia, Abia State) and “Uzaaku” or “Ijiriji” (Nsukka, Enugu State)

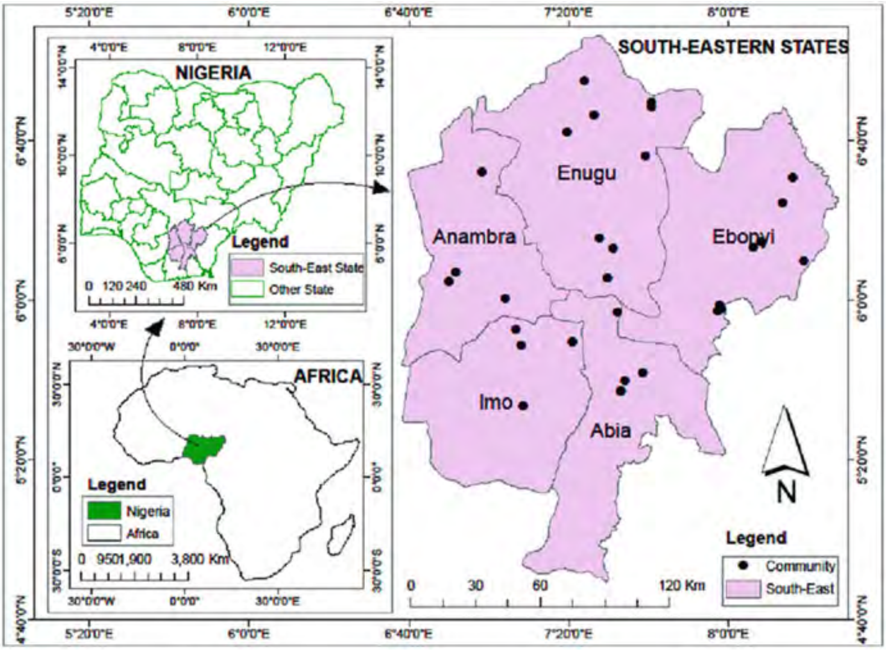

Fig. 5 Geographical distribution of African yam bean in south-east Nigeria. (Source: Nnamani et al. 2017)

in Igbo land; it is "Ewe" (Ijesha, Osun State), "Otiili" (Ekiti, Ekiti State),"Ekulu" (Ipe-Akoko, Ondo State), "Orogodo" (Owo, Ondo State), "Peu" (Ijebu, Ogun State) and "Sunmunu" (Iseyin, Oke-Ogun, Oyo State), Yoruba land. Some other tribal names for AYB in Nigeria are "Ihiehie" (Ishan, Edo State), "Iye" (Estako, LGA, Edo State),"Ahuma" (Tiv, Benue State), "Nsama" (Efik-Ibibio, Akwa Ibom) and Cross River State) (Adewale and Odoh 2013).

Al Azharia (2006) noted that throughout human history, folk nomenclature has been the underpinning factor for plant selection, improvement and conservation. It was and still is customarily for the local custodians to recognized species which have accomplished high serviceable and cultural values by custodians of such plants worldwide. When folk names given to species it often carries etymological meaning such as healing effects, morphological features, mythical connotations, adaptive strength, mitigating capability and allegorical values (Nnamani et al. 2019). Etymological data showed the AYB had sustained the lives of the local communities for ages. Indigenous lingual synonyms for AYB in Nigeria have etymological significances relating to how this crop had interfaced with the livelihood and environmental conditions of the local communities in different scenarios in the past (Table 1). These names often convey relationships to specific plant therapeutic effects, nutritional capacity, morphological features, mythological connotations, and ecological conditions playing out at a particular point in time in their environs (Leyew 2011; Rankoana 2012).

African Yam Bean, the Choice for Climate Change Resilience

"Neglected and Underutilized species (NUS)" are plant species which are sidelined, ignored or completely underexploited, by researchers, breeders and policy makers. They have great prospects to improve people's livelihoods, guaranteeing food security and self-sufficiency to the users. Their environmental restoration ability are not yet fully appreciated due to their limited competitiveness with fundamental

Table 1 Etymology of African yam bean in South-east, Nigerian

S/ no.	Ethnic group	Name	Meaning	Etymological facts
1	Izzi	Azama	Feeder of people in hard times (mitigating food)	They believed that God had answered their prayer by giving them this crop to feed them when other crops have failed in the land
2	Ezza	Azama	Healing food for the people (medicine)	In the past when kwashiorkor (malnutrition/hidden hunger was the major problem facing the people of Ezza, boiling the crop, eating AYB and the use of water from the cooked seeds to bath provides healing
3	Ikwo	Azaaki	Multiple seed-food provider (resilient seed)	They named AYB Azaaki because of the multiple food types it provides, which help poor farmers when they cultivate the crop. They believe that cultivating AYB is a way of avoiding hunger
4	Ngbo	Azaakuru	Plant small and harvest plenty (dominating and climate–smart crop)	Aza-akuru because, it is a passive crop but when planted, it will dominate the whole farm and yield lots of food types both seed and the tuberous root. A dominating crop that God gave to help poor farmers during famine
5	Ntezi and okpoto	Etiti	“Subduer of hunger” (the central hungry killer)	They believed that God has given them the crop to feed them during a time of famine. AYB is the only crop that can feed people even when the quantity is small
6	Afikpo	Azuma	Food server God and medicine	They name this crop Azuma because of its great feeding capacity and its ability to stop some illness, e.g., stomach disorder. They believed that God answered their prayer in times past
7	Ohozara	Aza-ama	Dominating food crop God and medicine	Prayer answered by God for the crop provides food even when other crops have failed. It yields great food for the poor. When the poor cannot cultivate other crops as a result of environmental changes

(continued)

Table 1 (continued)

S/ no.	Ethnic group	Name	Meaning	Etymological facts
8	Nkalagu	Azaku	Food helper of the poor	They called it "Azaku" because of the role it played during famine in times past. They believed that God provided it to help the poor through its simplicity in cultivation and survival
9	Ohafia-Agba	Azama	Feeder of people Adaptation to climate change	They believed that the God of harvest has provided this crop to sustain his people when other crops do not perform very well on the farm. AYB can compete in and adapt to many difficult environments
10	Agba, Nkalegu and Igboasa	Eriwa	Minor crop that feeds many people Gender	It's a women's crop that helps to sustain the women's little income when the major crops (the men's crops like yam, rice and cassava) are finished in the bans, particularly after planting. AYB is usually intercropped with other crops by women hence it is termed women's crop
11	Ezza and Ikwo	Onyiaoduru	Sustainer and friend of the farmer Sustainer	Respondents believe that after eating AYB, the consumer keeps drinking water through the day and it gives sufficient energy to work without getting exhausted
12	Ngbo and Izzi	Mgbadumue	Saving seed Seed	When labourers are hired to work on farms. They eat the food in the morning and it will keep them active until evening

crops in conventional use. Although their potential may not be fully realized at national or international levels, they are of significant importance locally, because of their high adaptation capacity to marginal, complex, and difficult environments contributing significantly to diversification and resilience of agroecosystems (Padulosi et al. 2011).

Shyam et al. (2014) stated that climate modeling is the commonest approach used today for predicting the responses of species to climate change. Species which have resilience biotic characteristics are often informative when used in climate modelling and underutilized plants frequently have an array of stress resistance traits. They are of significant importance locally, highly adaptable to marginal soil, complex and changing environments and agriculturally degraded land. They are hubs contributing meaningfully to diversification and resilience to community agro ecosystems, this is because of their long-standing use with little, or no, conventional breeding improvement. As orphan crops, notwithstanding their intrinsic low-yield potential, they still have the capacity of resisting climate stresses, having been selected and exploited in local climate stress adaptation within the local communities for generations. In this regard, underutilized PGR could contribute to further building of community resilience over the long-term in response to impending climate change adaptation after effective valorization of a PGR's potential (Mabhaudhi et al. 2019).

African yam bean usefulness as a climate smart species for communities to achieve resilience to climate stresses is based on its ability to survive and even thrive (reliable yield annularly) in marginal soils and environments where other crops fail in the absence of often unavailable resources, such as nitrogen fertilization and adequate irrigation. AYB, as a legume, improves soil quality and function through its beneficial effects on soil biological, chemical and physical attributes. Such benefits include enabling improvements in crop N-supply, increasing soil organic matter reserves, stimulating soil microbial diversity and activity, and improvements in soil structure, reducing soil erosion while increasing soil aeration and enhanced soil water-holding capacity. AYB is suitable for wide climatic conditions (Anochili 1984; Betsche et al. 2005) and nitrogen fixation (Oganale 2009; Tettey 2014). Ojuederie and Balogun (2019) obtained better tuber production from genotypes in a year with lower rainfall and sunshine hours. This is a display of smart features.

Policy and Conservation African Yam Bean

Intergovernmental Panel on Climate Change (IPCC 2018) reported the likely consequences of rapid global climatic change on species and their habitats. Such changes could cause a shift in the conservation status of so many species, pushing some towards the red line list of International Union for Conservation of Nature (IUCN). African yam bean has not received much conservation attention to date. Currently, much of its germplasm is in the hands of the local custodians as landraces (Nnamani et al. 2018), while the Genetic Resources Centre at the International Institute of Tropical Agriculture (IITA), Ibadan, Nigeria also hold some quantity of AYB germplasm. The disadvantages of poor conservation technology include the limited access to germplasm by researchers, breeders and farmers, the vulnerability of AYB to natural disasters, genetic erosion and loss of crop diversity are there.

Enhancing the potentials of African yam bean by policy via robust innovative approaches for wider utilization through accelerated research, farmer seed exchanges, in-situ and ex-situ conservations, farmers selection, and policy programs such as seed sovereignty will accentuate its adaptation and used as resilient climate – smart species for the vulnerable groups in Nigeria to cushion the impact of climate change.

These species may be conserved in-situ or ex-situ for future generations. On-farm (in-situ) techniques have several advantages compared with ex situ conservation, as the former allows for evolution of traits through continued natural and human-driven selections, which will contribute to greater crop adaptation and resilience to abiotic climate stress (Padulosi 2017).

Through the recognition of its promising nutritional potentials, policy could be synchronized in the conservation, promotion, marketing network and utilization of AYB by mainstreaming it into various dietary menus and products to include a range of food products appropriate for a broad range of consumption opportunities. This should include a rebranding of its nomenclature from "poor man's food" to a more widely acceptable range of producers, retailers and consumers. Decision makers could equally support the development of value chains, scale up development collaborations and information sharing of AYB among researchers, conservationists, breeders, extension workers, farmers, farmer organizations, vendors and NGOs.

Finally, there is need for policy to intensify efforts to support research on the conservation of *S. stenocarpa* through participatory engagement between the species custodians of the species for both in situ and ex situ conservation approaches. Globally the exploitation and development of legumes, which are climate resilient, will provide a significant opportunity for improving human health through integration into food-systems as a replacement, or partial replacement, of current animal sourced proteins. A programmed germplasm conservation approach is needed to collect, characterize, develop and exploit existing diversity in the provision of food, feed, nutritional security and environmental resilience.

Conclusions

Convincingly, recognizing the potential of AYB as an excellent climate smart species through active food governance policy would initiate novel business opportunities by changing the narrative via:

(i) Scaling up programs on the use of African yam bean in its various dietary forms and consumptions routes. This could rebrand the nomenclature of the species from "poor man's food" to an added value nomenclature (high protein source).
(ii) Organizing regular retailer food fairs to showcase various dietary menus accruing from AYB will encourage its selection and consumption by the publics.
(iii) Support the development of value chains and market networks for small agribusinesses for priority crops such as AYB.
(iv) Provide credit facilities and farmer/user-friendly technologies to the crop custodians to accelerate production.
(v) Promote the use of AYB through directed awareness campaigns on the nutritional benefits of the crop.
(vi) Exploit the offsetting potential AYB consumption of added value of this nutritious crop against the probable reduction in government health budget associated with alleviating malnutrition and it related conditions.

(vii) Including policy programs that enhance the selection of quality AYB seed available to farmers, with respect to climate resilience.
(viii) AYB will require more attention firstly, research-based, then technological germplasm development and subsequently supporting exploitation policy and markets. This will direct and facilitate appropriate solutions to major constraints for greater AYB cultivation and utilization.
(ix) Scaling up development via policy programs has the prospect of empowering resource poor communities who are predominantly women and the unemployed.
(x) Promote direct and appropriate consumer lead engagement and communication between knowledge acquirers and exploiters to drive AYB germplasm conservation.
(xi) Innovative biotechnological tools should be used to catalyze transformative change in AYB to promote its selection as a major staple food through a broad food product base.

Underutilized Indigenous Vegetables' (UIVs) Business in Southwestern Nigeria: Climate Adaptation Strategies

26

V. A. Tanimonure

Contents

Abstract

The impact of climate change, especially on agricultural sector, calls for a global and more localized strategies such as cultivation of underutilized indigenous vegetables (UIVs) which adapt better to local climate change. This chapter, therefore, examines the perception of UIVs farmers to climate change, their experiences of UIVs' responses to climate change, adaptation strategies

employed, and the determinants of the decision to adopt them in Southwest Nigeria. The study uses quantitative and qualitative primary household data from 191 UIVs farmers, 8 Focus Group Discussions (FGDs), and secondary climate data from the Nigerian Meteorological Agency. Descriptive and econometric analyses are employed in the data analyses. The results show that farmers' perceptions of climate change are high temperature and a high variability in rainfall pattern that has affected the yield, increased insects, pests, and diseases infestations, and reduced soil fertility. The results further show that the responses of UIVs to these resultant effects differ as such, and adaptation strategies farmers adopt are UIVs-specific. The adaptation strategies mostly employed by the UIVs farmers are cultivating UIVs along the river bank and the least is agroforestry and perennial plantation. The determinants of the decision to adopt adaptation strategies include UIVs revenue, age, years of experience, access to climate information, climate change awareness, agro ecological zone, and access to credit. Thus, promotion of UIVs business is advocated and provision of information on climate change essential and will encourage farmers to adopt appropriate climate change adaptation strategies to boost UIVs business.

Introduction

The impact of climate change forecast on agriculture has posed a threat to the sustainability of global food security and nutrition. For instance, over half a billion (525 million) people in the tropics were projected by Consortium of International Agriculture Research (CGIAR) program on Climate Change Agriculture and Food Security (CCAFS) to possibly be at the perils of hunger by 2050 due to climate change (Actionaid International 2011). Intergovernmental Panel on Climate Change (IPCC) (2014) also predicted climate change increasing current problems and also generating new ones for natural and human systems. Likewise, Boko et al. (2007) predicted that reductions in yield of up to 50% in some countries in Africa by 2020 and net crop revenue by as much as 90% by 2100 could be attributed to climate change, smallholder farmers being mostly affected, especially the rural farmers who depend largely on rain-fed agriculture (Ching and Stabinsky 2011). Until adaptive or palliative measures are inaugurated to mollify the effects of climate change, food security in developing countries in the tropics, particularly in Nigeria, will be under threat (Enete 2014), considering the high rate of population growth.

Owing to the undesirable effects of climate change, it is suggested that a blend of global and more localized strategies, along with other adaptation strategies, can help farmers weather the effects of climate change. These include conservation agriculture, organic agriculture, carbon sequestration and the capacity to withstand weather stresses, change in planting time, the breeding of a number of climate-resilient crop varieties such as underutilized indigenous vegetables (UIVs), among others (Howden et al. 2007; Omatseye 2009; Sambo 2014). Underutilized indigenous vegetables are vegetables that originate from a locality; such vegetables may be localized to that particular area or found in other places. They are reported to be grown more widely or intensively in the past but are falling into disuse for a number of agronomic, genetic, economic, and cultural reasons. They are promising species but their potentials in terms of economic, nutrition, medicinal, and resilience have not been fully harnessed. Farmers, marketers and consumers are not making the best use of these crops as much as they use others because they are less competitive compared with other crops in the same agricultural environment (Guarino 1997; Eyzaguirre et al. 1999; IPGRI 2002; Padulosi and Hoeschle-Zeledon 2004). More so, these vegetables have not been a subject of organized research until recently (Tanton and Haq 2008). For instance, in the recent times, the production, marketing, and consumption of some of these vegetables are promoted in Southwest Nigeria in projects tagged NiCanVeg and MicroVeg. Some studies also reported that these UIVs are more adaptive, resilient, and tolerant to adverse climatic conditions than exotic species (Raghuvanshi and Singh 2001; Nnamani et al. 2009; Mabhaudhi et al. 2016).

In comparison to other crops, vegetables generally are more susceptible to environmental extremities such as high temperatures and soil moisture stress. Carbon dioxide, a major greenhouse gas, influences their growth and development as well as incidence of insect pests and diseases that render vegetable production unprofitable (Devi et al. 2017; Abewoy 2018). And all these will increase in the face of climate change (Ayyogari et al. 2014). However, UIVs can be produced comparatively at lower management cost, on marginal soil, and can tolerate the dynamics of climate change better than the exotic vegetables (Raghuvanshi and Singh 2001; Nnamani et al. 2009; Padulosi et al. 2011). This offers a significant opportunity for poor people in the rural areas to withstand the effect of climate change and increase their revenue, and, thereby, be food and nutrition secure (Maroyi 2011; Ebert 2014). This is because many UIVs from the tropics are already well adapted to the climatic conditions, and, as such, respond better to climatic conditions.

Unfortunately, there is limited quantitative and qualitative information supporting all these claims (Padulosi et al. 2011; Intergovernmental Panel on Climate Change (IPCC) 2014; Chivenge et al. 2015). The knowledge of UIVs adaptation to climate change remains concealed in the indigenous knowledge systems and this may explain why certain communities have continued to preserve and utilize certain UIVs. The limited quantitative empirical information indicates that UIVs remain under-researched as well. Although, some studies identified the potentials of these neglected and underutilized crops in sub-Saharan Africa in the recent times. A research by Adebooye and Opabode (2004), for example, was particular about the conservation of these indigenous crops in order to prevent them from going into extinction, especially as the reliance on a handful of major crops has innate agronomic, nutritional, and economic risks, which is not sustainable in the long run (Ebert 2014). Ayanwale et al. (2011) and Aju et al. (2013) also studied the market potentials of some of these underutilized indigenous vegetables and envisaged good commercial prospect in them, especially for women folks who are resource constrained. Some of the representatives of these leafy vegetables, tuber crops, cereals, and grain legumes that fit into the class of underutilized crops were identified by Maroyi (2011), Shrestha (2013), and Chivenge et al. (2015). It was equally found out that they are potential future crops for smallholder farmers, as sources of nutrition and income, especially in this era of climate change. Study by Sambo (2014) showed that underutilized crops could offer scientists a rich source of genetic materials for modification, which could hold potential key to developing resilient and drought-tolerant crops. Recent research found out that these underutilized indigenous crops have the ability to grow under water-scarce conditions and that the key to future food and nutrition security may lie in their untapped potentials (Mabhaudhi et al. 2016). More recent research shows qualitatively that climate change has both positive and negative effects on indigenous vegetables and the predicted negative effect cannot be overemphasized (Chepkoech et al. 2018). Indigenous vegetables farmers, therefore, adopt a number of adaptation strategies to mitigate the effect of climate change on their production activities. Although Fadairo et al. (2019) examined the perceived likelihood impact and adaptation of vegetables farmers to climate change, their emphasis was not on indigenous vegetables which is the focus of this study. Their study advocated for locality-specific climate change adaptation strategies.

The Intergovernmental Panel on *Climate Change* (IPPC) defines *adaptation* as "any adjustment in natural or human systems in response to actual or expected *climatic* stimuli or their effects which moderates harm or exploits beneficial opportunities." Climate adaptation is termed as a correct adjustment to climate variability and change, especially for smallholder farmers to enhance resilience or reduce vulnerability to its effects (Fadairo et al. 2019).

This study, therefore, aims to examine the perception of UIVs' farmers and the responses of UIVs to climate variability and change in the study area. It assesses the adaptation strategies adopted by the farmers to cope with the adverse effects of climate change and lastly, analyzes the determinants of the decision to adopt adaptation strategies by the UIVs farmers. This will add to the existing literature on the resilience of underutilized indigenous vegetables to climate variability and change in sub-Saharan Africa.

Methodology

The Study Area

The study area is South west region of Nigeria as presented in Fig. 1. The area lies between longitude 2° 31[1] and 6° 00[1] east and latitude 6° 21[1] and 8° 37[1] norths. The study area is bounded in the east by Edo and Delta States, in the north by Kwara and Kogi States, in the west by the Republic of Benin, and in the south by the Gulf of Guinea. The region constitutes about one sixth (~163,000 km^2) of the total land area of Nigeria and comprises six states (Oyo, Ogun, Osun, Ondo, Ekiti, and Lagos) and is distinctly divided into three major agro-ecological zones (Rain Forest zone, Swamp Forest zone, and Derived Savannah zone) with diverse climatic conditions. The forest agro-ecological zone has annual rainfall in the range of 1,600–2,400 mm, with cropping seasons between April and November, while dry spells occur from December to March. The soil types in this zone depend largely on parent rock; where the underlying rocks are granite or clay, the soil is a rich clayey loam. On the other hand, the derived savannah agro-ecological zone has mean annual rainfall ranging from 800 to 1,500 mm, with cropping seasons between June and November. The soil types range from the sandy to clayey in texture, with soil reaction ranging from acidic to slightly basic. Soil fertility statuses and crop species diversity also vary widely in different locations in the region. This study is carried out in two of the three agro-ecological zones: Rain Forest and Derived Savannah zones, where UIVs were promoted in a project tagged NiCanVeg.

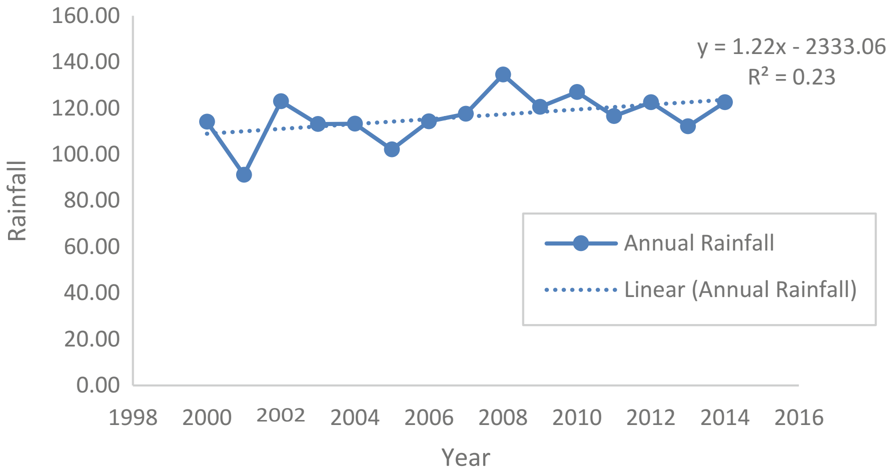

Fig. 1 Annual rainfall trend in Southwest Nigeria

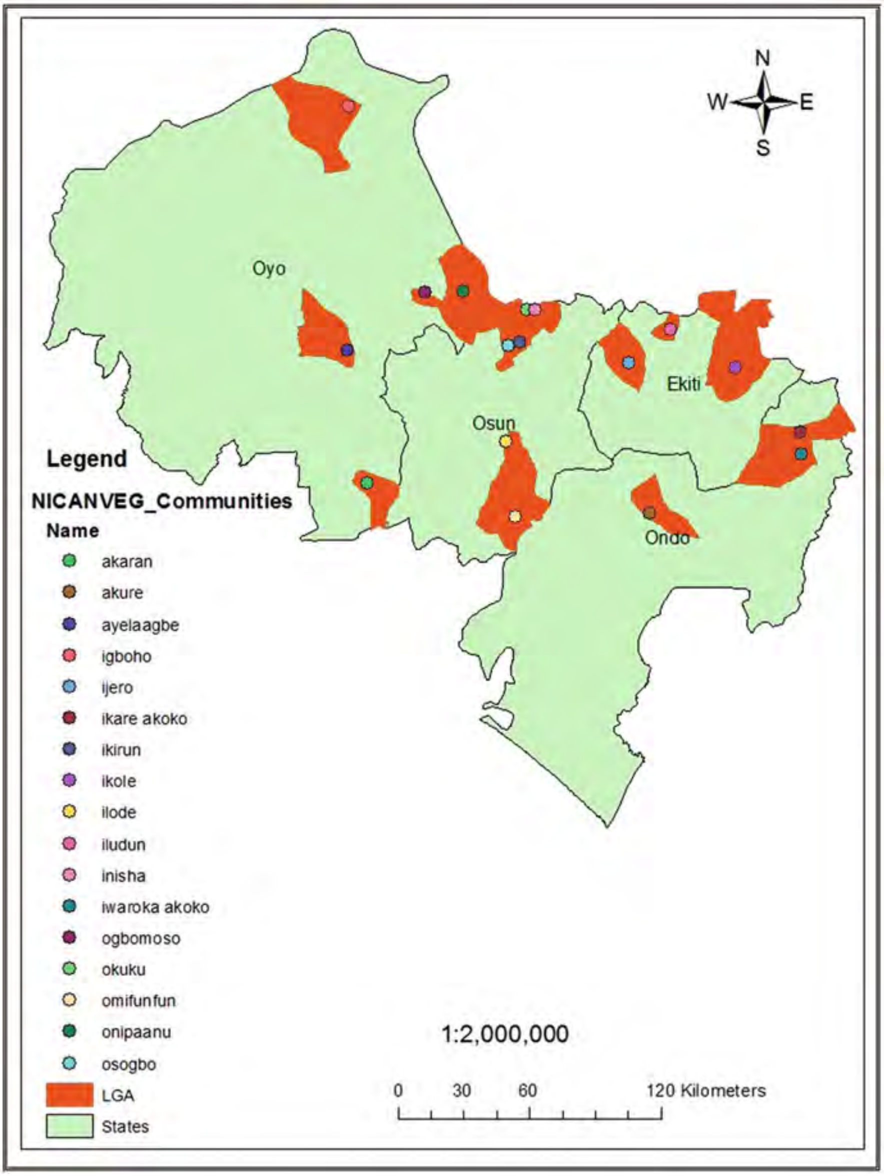

Sample Size and Sampling Procedure

All the 17 NiCanVeg communities in 16 Local Government Areas (LGAs) of the four (Ekiti, Ondo, Osun, and Oyo) states were selected for this research. In order to ensure representativeness and due to limited budget, a simplified formula (Eq. 1) developed by Kothari (2004) was used to calculate the sample size of the respondents at the community level. A 95% confidence level, 5% estimated percentage, and $P = 0.5$ were assumed in the equations.

$$\mathrm{n} = \frac{Z^2 X\ p\ X\ q\ X\ N}{e^2 X\ (N-1) + Z^2 X p\ X\ q} \tag{1}$$

where

n is the sample size
N is the population size
e is the estimated proportion
p is sample proportion, $q = 1-p$
z is the value of the standard variate at a given confidence level and to be worked out from Table showing area under Normal Curve.

Based on this formula, the respondents' sample size is approximately 191 (which was about 50% of the direct beneficiaries of NiCanVeg project in the study area).

In each NiCanVeg site, the NiCanVeg farmers were stratified into male and female to ensure random selection of both sexes, and 50% of the total farmers were randomly selected from NiCanVeg farmers' lists. This proportionate sampling procedure was necessary because of the difference in the number of farmers in each community or site.

Data

The mixed-methods research design involving both the quantitative and qualitative research approaches were employed to elicit information from the respondents. The quantitative study involved face-to-face data collection with the use of structured questionnaire. The questionnaire administration was done by the trained enumerators to ensure the quality of the data. Before the data collection, there was an "advance notification" sent to the respondents to let them know that the survey would be conducted in their communities. The enumerators were led to the communities by the NiCanVeg field officer who was already familiar with the farmers and the communities. Two Focus Group Discussions (FGDs) per state were conducted among the UIVs farmers to gather the qualitative data used for the study. The data collected include UIVs' household socioeconomic characteristics, their perception of climate change, and the various adaptation strategies adopted over the years to mitigate the effects of climate change, information on various vegetables they cultivate, the reasons why they cultivate the vegetables, and the responses of the vegetables to the perceived negative effects of climate variability in the study area. The FGDs with the farmers generated information on the type of vegetables cultivated across the four states, their order of economic importance, and the responses of these vegetables to resultant or indirect effects of climate change variables (rainfall and temperature) such as drought, flood, insect infestations, pests, and diseases. Farmers were asked to describe climate change variables expressed as changes in amount of rainfall and temperature on the extent of drought, changes in insect infestations, soil fertility, and UIVs yield. Also, UIVs producers' perceptions of climate change are compared with historical trends from Nigerian Meteorological data (average monthly temperature and rainfall) between 2000 and 2014.

Data Analysis

Both descriptive statistics and econometric analyses are used in the data analysis. Descriptive statistics such as frequency counts, means, and percentages are employed to describe the socio-economic characteristics of the respondents and the effects of climate change adaptation strategies on UIVs production. Content analysis was employed for the qualitative data collected through the FGDs. For the econometric analysis, logistic regression inferential statistic was used to analyze the factors affecting UIVs farmers' decisions to adopt adaptation strategy or not (Mahouna et al. 2018). In this study, the dependent variable is dichotomous, that is, farmers' decision to either adopt or not adopt climate change adaptation strategy. This method is appropriate because it considers the relationship between a binary dependent variable and a set of independent variables.

Results and Discussion

Table 1 summarizes the distribution of the UIVs that farmers cultivate in order of economic importance across the four States that the study covered. The summary reveals while good number of the UIVs are found across the entire region, only few UIVs are state specific. For instance, it is only in Osun State that red amaranth is produced in commercial quantity. Also, it is only in Oyo State (northern part) that *Solanum zuccagnianum* (locally called osun) is cultivated in commercial quantity. Aside Ondo State where ugu is the most economically important UIV, amaranth species remain the most economically viable UIV in the region. It is also noteworthy that respondents in Oyo State ranked two different UIVs as first economic important vegetables. While the UIVs producers in the northern part of the State ranked *Solanum zuccagnianum* as number one economically important UIV, those in the southern part ranked amaranth species as the number one in term of economic importance.

Farmers' Perception of Climate Change

Perception is the way something is regarded, understood, or interpreted. It is one of the first important steps in the process of designing some form of change in farmers' livelihood system to adapt to the changing climate. In order to get essential information and insight into farmers' perception of climate change, the two most important

elements of climate rainfall and temperature are considered in this study. Out of the 191 sample respondents, only 10 (5.24%) are of the opinion that there is no change in the climate as presented in Table 2. This result shows that farmers are well aware of climate change. This result is similar to Fadairo et al. (2019), who also found that awareness of climate variability and change was high among vegetables farmers.

Farmers' Perception of Change in Rainfall Versus Meteorological Data

The perception of UIVs farmers in the study area on the overall trend of average rainfall as presented in Table 2 shows that all the respondents who are aware of climate change perceived changes in the rainfall, although their perception of these changes differs. About 74% of the respondents perceived decrease in average rainfall; about 4% perceived increase in rainfall, while about 21% could not say categorically whether the rainfall increased or decreased, but noticed an erratic rainfall over the years. Only 1% are indifferent to the rainfall pattern. The trend analysis of rainfall from Meteorological data between 2000 and 2014 in the area under study is presented in Fig. 1. The trend shows that there is no particular trend in average annual rainfall, as the rainfall pattern has been erratic. In year 2000, the average annual rainfall is high and falls in 2001. In 2002, the rainfall increases, falls in 2003, remains a little steady in 2004, and falls in 2005. The highest average rainfall within the period under study is in 2008 and since then, the average annual rainfall keeps rising and falling, although the quantitative trend shows that there is increase in average annual rainfall amount in the study area. The result of regression analysis between rainfall and time shows that an increase in one-year period results in a corresponding increase in the amount of average annual rainfall by 1.22 mm (Fig. 1). However, the perception of most farmers of rainfall shows a view contrary to the information contained in the meteorological recorded data. The majority of UIVs producers perceived reduction in rainfall. This lack of congruence could be as a result of the farmers assessing rainfall in relation to the needs of UIVs at a particular time; small change in quantity, onset, and cessation of rain over days make a big difference in the hearts of farmers, whereas the Meteorological data is more likely to measure total and large effects (Lemmi 2013).

Farmers' Perception of Change in Temperature Versus Meteorological Data

In the case of average temperature, all the UIVs farmers who are aware of climate change perceived changes in average temperature over the years (Table 2). Majority (88.95%) of UIVs producers perceived increase in average annual temperature in the study area. Only 8% perceived decrease in the temperature, while the remaining percentage of respondents (3.31%) are indifferent to the changes in temperature. The trend analysis of the meteorological data of temperature between 2000 and 2014 shows an increasing trend. The regression between average annual temperature and time shows that an increase in one-year period results in an increase in the average temperature of the area by 0.003 °C (Fig. 2). Thus, farmers' perception appears to be in consonant with the statistical record of temperature from the meteorological station. This result is also in line with (Chepkoech et al. 2018), who also found increasing trend in the temperature of study area.

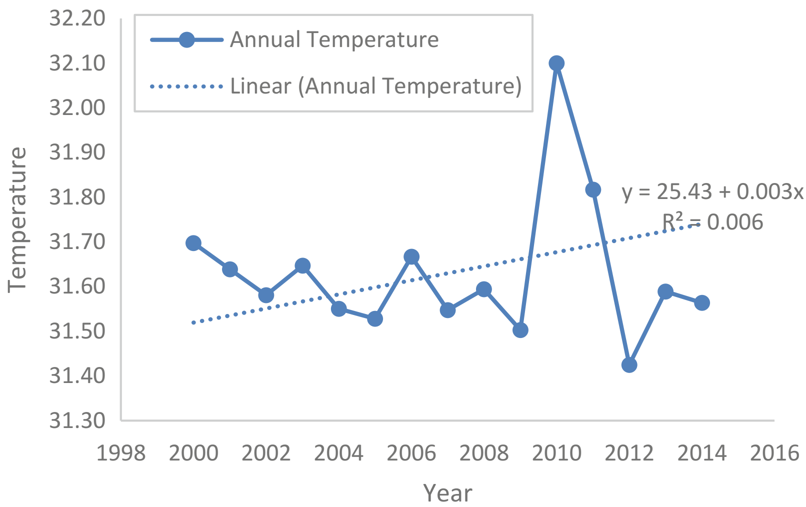

Fig. 2 Annual temperature trend in Southwest Nigeria

Farmers' Perception of Resultant Effects of Climate Change Variables

The outcome of changes in average annual rainfall and temperature results into different anomalies such as drought frequency, insects, pests and diseases infestations, loss of soil fertility, reduction in yield, among others (Chepkoech et al. 2018). Table 3 presents the perception of UIVs farmers to some of these anomalies brought about by climate change in the study area in relation to UIVs production. About 88%

of the UIVs producers believe that occurrence of drought has increased over the years as a result of reduction and/or erratic pattern of rainfall. The excerpts of the farmers during the FGDs further establish the negative effects of drought on the production activities of UIVs:

> The erratic rainfall has brought problem to farmers because most of what we plant did not germinate on time and some even got burnt in the soil as a result of prolonged drought
>
> FGD with Farmers in Ilesha, Osun State.

About 76% of the respondents indicated that the effect of insect infestation has increased greatly in recent times, compared to the past. The excerpts from the FGDs affirm this:

> There is reduction in our output due to climate change; there are some insects destroying our farm produce. To the extent that we have to take some of the species of the insect to laboratory for the scientist to help us find solution to it because the insecticide we have been using are no longer effective
>
> FGD with farmers in Ilesha, Osun State.
>
> . . . also what we have experienced this year has never been experienced before. That we plant all vegetables and insect and pest spoilt some specific vegetables. Pest also spoilt all the maize and some other crops.
>
> FGD with farmers in Ile-Ife, Osun State.

> There is no positive impact. Our expectation has been dashed because there is irregularity in rainfall. Our profits are low, insects infested our farm and destroyed it
>
> FGD with farmers in Iwaroka, Ekiti State.

Also, the response of UIVs farmers to the effect of climate change on soil fertility is negative. About 64% of the farmers are of the opinion that soil fertility has decreased greatly. More so, most (73.82%) UIVs farmers experienced reduction in yield and, as a result of this, about 73% testified to the fact that this, invariably, has drastically reduced their earnings from UIVs production. Excerpts from the FGDs conducted buttress these facts thus:

> Since there is irregularity in rainfall, we don't really get the normal output, so it has reduced our income
>
> FGD with farmers in Igboho, Oyo State.
>
> Although, there is good market for vegetables now, but the insect infestation has reduced our output which resulted in low income, and this had brought financial difficulties on farmers
>
> FGD with farmers in Ilesha, Osun State.

Comparison of Responses of UIVs to Changes in Rainfall

An understanding of the responses of UIVs to the indirect effect of climate change variables such as yield reduction, insect, pests, and diseases infestations is very crucial. This will guide farmers on the type of climate change adaptation strategies to adopt in order to reduce the negative impact of climate change on UIVs production. The responses of the farmers across the four States are harmonized and summarized in Table 4. Unanimously, the farmers across the four States agreed that the UIVs' response to resultant effects of climate change differs and it is premised on the type of UIVs and season. This finding is in an agreement with Chepkoech et al. (2018) who also found that the sensitivity of African Indigenous Vegetables to climate change variables is determined by the season and the type of vegetable, for instance, in the case of amaranth species, fluted pumpkin, jute mallow, and African eggplant; extreme rainfall does not really have effect on both their yield and the incident of insects and pests' infestations, although they experience moderate disease infestation such as yellowing of leaves. During the dry season, their yields are moderately low and moderate rate of pests and insects' infestation occur. The disease infestations are rare during this period for the vegetables.

During the high rainfall and low rainfall periods, osun, glossy nightshade, garden huckleberry, and quail grass are moderately affected in terms of yield, pests, insects, and disease infestations. In the case of field pumpkin and fire weed, there is moderate reduction in yield and disease infestation but not affected by pests and insects during the excessive rainfall period. Extremely low rainfall or dry spell reduced the yield moderately and the effect of insects and pests too is moderate and there is no disease infestation for field pumpkin. But for fire weed, the dry spell reduced the yield greatly; in fact, the fire weed may be totally unavailable in the market. While the yield of Bologi is moderately reduced by excessive rainfall, that of waterleaf is not affected. The two UIVs are not affected by insects and pests and diseases infestation during the extreme high and low rainfall but their yields are greatly reduced during the low rainfall. It is noteworthy that lots of nutrients are washed and leached away during the excessive rain fall period. From the result, it is obvious that excessive rainfall encourages diseases infestation while low rainfall or dry spell encourages insects and pests' infestation. The result is in harmony with Chepkoech et al. (2018) results. The ranking of the UIVs that are cultivated by the farmers in the study area in order of drought tolerance is also presented in Table 4; ugu is the most drought tolerant while Bologi is ranked last on the list.

Adaptation Strategies Adopted by the UIVs Farmers

A number of adaptation strategies are adopted by the UIVs farmers in order to weather the negative effects of climate change (Fadairo et al. 2019) presented in Table 4. The adaptation strategies adopted by the UIVs farmers are presented in Table 5. From the Table, only about 15% of the farmers do not adopt any strategy. This result is similar to Mahouna et al. (2018), who also identified only 14.2% of the sample respondent as nonadopter of climate change adaptation strategy but at variance with Fadairo et al. (2019) who found that all vegetable farmers adopted one form of adaptation strategy or the other. From the discussion with the farmers, it was gathered that the most important adaptation strategies adopted by UIVs farmers

Table 4 Comparison of responses of UIVs to resultant effects of changes in rainfall

UIVs	Response of UIVs to very high rainfall				Response of UIVs to very low rainfall				Order of drought tolerance
	Yield	Insects and pests infestation	Diseases infestation	Soil fertility	Yield	Insects and pests infestation	Diseases infestation	Soil fertility

Table 5 Adaptation strategies adopted by the UIVs farmers

Adaptation strategy	Frequency	Percentage	Position
No adaptation	29	15.18	8th
Crop diversification	51	26.70	3rd
Changing time of planting	45	23.56	4th
Diversification to other nonagricultural activities	121	63.35	2nd
Agroforestry and perennial plantation	7	3.66	9th
Use of integrated pest management and use of fertilizer	39	20.42	7th
Cultivating along river banks	187	97.91	1st
Good practices (mixed cropping, crop rotation, mulching, organic fertilizer)	44	23.04	5th
Irrigation	41	21.47	6th

over the years is to cultivate UIVs along the river bank during the dry season and use upland during the wet season to reduce the incident of diseases and flood from excessive high rainfall. About 98% adopt this strategy. The information gathered further reveals that about 63% of UIVs producers are diversifying from agriculture to nonagricultural related businesses as a result of their unpalatable experiences in farming. Some of the excerpts from the FGDs show that many farmers are discouraged as a result of some of their experiences. The third popular adaptation strategy option is crop diversification. About 27% of the respondents indicated crop diversification as adaptation strategy they have adopted. An excerpt from the FGD in Ile-Ife, Osun State, shows this:

> ... that was why I changed to okra plantation. When I tried it and it performed better, I decided to change to okra cultivation
>
> FGD with farmers in Ile-Ife, Osun State

Also, 23.56% changed time of planting, and about 23% also adopted agricultural good practices such as mulching, crop rotation, and mixed cropping. About 21% adopted irrigation, but the excerpts from the FGD show that where rain failed, some adopted irrigation system and it led to outbreak of insect infestations which pesticide could not handle. The excerpt from the FGD in Osun State reveals this thus:

> The first step we took when the rain did not fall was to use irrigation. Different pests and insect infestations showed up. We used different insecticides to kill the insects, but chemical compositions were no longer effective like before.
>
> FGD with farmers in Ilesha, Osun State

It was noteworthy that the least (3.66%) adaptation strategy adopted by the UIVs farmers is agroforestry and perennial plantation, and about 15% do not adopt any adaptation strategy.

Variable Description of Adopters and Nonadopters of UIVs Producers

The description of the socioeconomic characteristics of UIVs farmers and other relevant variables to this study are summarized in Table 6. The information provided in the table shows that the nonadopters are significantly older than the adopters. There is no significant difference between their years of formal education, UIVs vegetable land area, access to climate change information, agro-ecological zone, and average monthly temperature of adopters and nonadopters in the study area. Meanwhile, the adopters had significantly higher mean values of the years of UIVs production experience, net revenue from UIVs, off-farm income, average monthly precipitation, farm distances from market and main road than the nonadopters.

Table 6 Variables and summary statistics

*** = Significant at 1% level

Determinants of the Decision of UIVs Farmers to Adopt Climate Change Adaptation Strategies

Binary logistic regression analysis was used to analyze the determinants of the decision to adopt climate change adaptation strategies by the UIVs farmers in the study area. Variables such as revenue from UIVs, age, sex, household size, education, marital status of the respondents, vegetable farm size, farm distance to market and main road, experience in vegetable farming, access to climate information, climate change awareness, and agroecological zone are included in the analysis. The results of the analysis reveal that the revenue generated from the UIVs business has a positive and significant influence at the 1% threshold on the adoption of climate change adaptation strategy. The more the revenue generated from the business, the more likely the producer will be willing to adopt adaptation strategy. This implies that adoption of adaptation strategy is not free and resources for the implementation must be available for farmers to adopt. The age of UIVs producers is significant at 10% level but negative. The implication of this is that as farmers increase in age the likelihood of adopting adaptation strategy reduces. This finding is in line with Uddin et al. (2014), that as farmers age, they lose interest in adopting climate change adaptation strategy. The number of years of experience in UIVs farming has positive and significant relation at 10% threshold on the adoption of adaptation strategy. This is expected, and more experience implies more competence in weather forecasting. This outcome is similar to the result of Mahouna et al. (2018) who also found that the more the experience of farmers the more the likelihood of adopting climate change adaptation strategies. Access to climate information is also significant and has positive influence at the 5% threshold on adoption of adaptation strategy. This implies that the more access farmers have to sources of information on climate change, the more likely they will adopt adaptation strategy to ease the negative effect of climate change on their business. More so, awareness of climate change is significant at 1% level and has positive effect on the likelihood of farmers to adopt adaptation strategy. This means that when farmers are aware and well informed about climate, the likelihood to adopt adaptation strategy will not be difficult. Agro ecological zone too is significant and positively determines the likelihood of farmers adopting adaptation strategy. This suggests that the effect of climate change in various agro ecological zones differ and as such, the need for climate change adaptation strategy may also differ. Lastly, access to loan is significant at 10% level and positively relates to choice of adopting adaptation strategy. Those farmers who have access to loan will likely adopt adaptation strategy since the strategies are not free (Table 7).

Conclusion and Recommendations

This chapter presents a microlevel study on the perceived effect of climate change and adaptation strategy employed on UIVs business in Southwest Nigeria. To this end, data set from plot level survey of 191 UIVs farm was used in the analysis. UIVs

Table 7 Determinants of the decision of UIVs farmers to adopt adaptation strategy

production activities, adaptation strategies information, and meteorological data were also obtained. In conclusion, 13 economically viable UIVs are identified across the study area and their responses to the indirect climate change effect such as insects, pests, and diseases infestation, soil fertility, drought and yield, differ. While some UIVs are not affected by these climate change effects, some are moderately affected and to some others, the effect was great. The study also concludes that the occurrence of insects and pests' infestations is common whenever rain cease to fall for a long time while diseases infestation is common during the excessive rainfall in the study area during the raining season. The study further concludes that UIVs farmers adopt nine different adaptation strategies to ameliorate the effect of climate change variables on the UIVs business. The most prominent of them is the cultivating UIVs along river banks and the least practiced is agroforestry and perennial plantation.

Finally, the study concludes that the factors that determine the likelihood of farmers to adopt climate change adaptation strategy are revenue from UIVs, age of UIVs farmer, years of experience in UIVs production, access to climate information, climate change awareness, agro ecological zone, and access to credit. From the conclusion, the following recommendations are made:

- In the era of climate change, where many crops are failing, promotion of production, marketing, and consumption of UIVs is advocated for.
- Development of improved varieties of UIVs that are more tolerant to increased rainfall is needed.
- Information on climate change should be made available and accessible to farmers.
- Farmers should be trained on the right adaptation strategy to adopt, considering the type of crop they cultivate and the peculiarity of their agro-ecological zone.

Farmers' Adoption of Climate Smart Practices for Increased Productivity in Nigeria

27

B. E. Fawole and S. A. Aderinoye-Abdulwahab

Contents

Abstract

In a bid to reinforce the efforts of agricultural professionals within the domain of climate change studies and with particular emphasis on rural farmers in Nigeria, this chapter explores the mechanics for adoption of climate smart agricultural practices among rural farmers for an increased agricultural productivity. Climate-Smart Agriculture (CSA) is paramount to the success of farming activities today in the face of the menace of the impact of climate change. Climate Smart Agricultural

Practice (CSAP) is one of the major keys that agricultural development approaches aimed at; to sustainably increase productivity and resilience, while also reducing the effects; as well as removing emissions of greenhouse gases. It is pertinent to note that most of the CSAPs adopted by the rural farmers in this study are conservation agriculture, use of organic manure, crop diversification, use of wetland (Fadama), planting of drought tolerant crops, relocation from climate risk zones, prayers for God's intervention, and improvement on farmers' management skills. This study divulged and showcased the import of CSAP in boosting agricultural yield and also highlights the bottlenecks inhibiting agricultural farming practices such as lack of practical understanding of the approach, inadequate data and information, lack of suitable tools at local and national levels, supportive and enabling policy frameworks, and socioeconomic constraints at the farm level. The study concluded by recommending an aggressive awareness and mobilization campaign to boost the adoption of CSAPs in Nigeria.

Introduction

Agriculture plays a huge role in Africa's economy with about 70% of the continent's population practicing subsistence farming for their livelihood while they equally live in the rural areas. Hence, the significance of this sector in providing employment and motivating economic growth in a developing nation such as Nigeria cannot be undermined. Agriculture mainly hinges on environmental factors and any prolonged variations in average weather conditions can have significant impacts on production. Additionally; agriculture as practiced in the continent, is highly characterized by land tenure insecurity which continues to hamper agricultural growth for millions of smallholder farmers; while poor soil fertility, degraded ecosystems and climate variability are among other problems associated with agriculture in Africa (USAID 2016). Climate change adaptation has to do with any spontaneous and/or premeditated action/mechanism adopted to deal/cope with the impacts of, or reduce vulnerability to, a changing climate.

Adaptation should address immediate problems and anticipate future changes in order to mitigate adverse effects. The strategies applied in adaptation can be preventive or reactive while all the methods taken should aim at enhancing resilience and reducing vulnerability (IPCC 2012). There is a dire need to deliberately advance a rigorous implementation of the identified strategies for adaptation and mitigation. This is in a bid to minimize the effects of climate change in order that development in agriculture can be encouraged. Mitigation refers to measures that may either reduce the increase in greenhouse gases (GHGs) emissions or increase terrestrial storage of carbon, while adaptation refers to all the responses to climate change that may be used to reduce vulnerability (Ifeanyi-obi and Nnadi 2014). Indeed, there have been deliberate efforts by Heads of States to integrate approaches that have been employed to solve the impacts of climate variability. Evidence is seen in the authorization of governments to support at least twenty-five million farming households to adopt Climate Smart Agriculture (CSA) by 2025. (African Climate Smart Agriculture Summit 2014).

The concept of CSA, which came into limelight in 2010, is defined as a form of agriculture that increases agricultural production and income; enhances adaptation and build resilience to climate change impact. CSA also helps to reduce the emissions due to Greenhouse gases (GHGs) and enhances the attainment of global food safety (World Bank 2010; FAO 2014). Climate-smart ideas include activities that would ensure minimum tillage; application of organic agricultural practices rather than inorganic methods that would further deplete the soil in the long term; crop rotation and mulching to reduce evapotranspiration; and composting and planting of legumes and cover crops which assist in moderating the long-term effects of climate change by giving an enduring environmental strength to the soil (Olorunfemi et al. 2019; Ojoko et al. 2017). This chapter therefore sets to explore the CSAPs available, the benefits accruable from practicing CSA in order to increase productivity and the challenges hindering their adoption in Nigeria.

Adoption Theory as a Conceptual Framework

The choice of adopting a technology is preceded by a number of certain mental processes which include: Awareness, Interest, Evaluation, Trial, and Adoption. According to Ekong (2010), adoption process is the mental procedure from the first instance of learning of an idea/technology to the final stage of taking a decision to use it. The farmer's choice to accept or reject a technology is based on their perception of those stages earlier mentioned. This implies that a farmer can only decide to use a technology only if he was aware of it; develops interest in it; and possibly, after he must have tried it and becomes convinced that the technology is beneficial to him.

Awareness stage: At this first stage, the farmer is barely conversant with the existence of an innovation; it could be that he only became cognizant of the technology and may be deficient in the technicalities such as how to use the innovation, the cost; as well as the benefits of the innovation. The farmer may learn of the existence of the innovation through friends, relatives, mass media, extension agents or local cooperative organization. After being aware of the innovation, the farmer might crave for more information. He may want to understand how the invention works and also the benefits and usefulness. Consequently, the farmer can take the next step of making deep inquiries in order to access adequate information that would help him in reaching a decision.

Interest stage: during this second stage the farmer asks for detailed information concerning the technology. It is only normal that the farmer relies partly on their source (through which they became aware) of information to deepen their knowledge about it. The farmer can also search for better understanding from other sources which hopefully spurs them to become interested in the technology. This makes the farmer to develop interest by asking further questions and collecting information about the new idea or new product to assess its potentialities. These line of questioning can make the farmer to become curious and begin to wonder how much he can benefit should he decide to try the idea/technology.

Evaluation stage: this is the stage where the farmer mentally appraises the applicability of the technology in light of the solution to his own circumstances. The farmer makes a mental assessment by asking several questions such as: Is it/this possible? Who do I know that has done it? What was their outcome? Can I also do it? What happened the last time someone tried it? The responses to these questions and many more that the farmer might have mentally asked would be the determinant of whether he would go ahead to try it or not? If the evaluation produces a negative result, the farmer could stop showing interest in the innovation and may eventually reject it. However, if the responses he got from his mental assessment were favorable, he may then be set to try the innovation practically.

Trial stage: this is the stage where the farmer essentially implements or applies the innovation on a small scale under his personal circumstances and managerial competence. The farmer could entirely handle the trial stage all alone or they may seek the help of change agents and sales promoters. In this stage, the farmer raises the question: how am I supposed to do it? The farmer uses the innovation on a trial/experimental basis on a portion or segment of their farm. The result, positive or negative, would then determine whether the farmer would take or discard the technology.

Adoption stage: The final stage of adoption is when the farmer eventually approves the innovation and has decided to continue using it on a full scale. In this stage, the farmer extends the use of the technology to their whole plots of land. Adoption involves an enduring acceptance and repeated utilization of the technology with the hope that it will help to ease a difficult farm situation. This suggests that a farmer may stop or discontinue the use of such innovation if subsequent outcomes do not prove reliable.

According to Adekoya and Tologbonse (2011), a prospective adopter has a number of characteristics to consider before concluding on whether to adopt an innovation or not. These characteristics are as listed:

1. **Relative advantage**: A technology must be perceived by the farmer as being better than the one currently in use. This can be measured in terms of profitability, low cost, and time saving ability. It could also be in terms of factors relating to social-prestige, convenience and satisfaction. The point that matters in this case is the discernment of advantage as perceived by the adopter.
2. **Compatibility**: This means that the new idea being professed is in consonance with the obtainable values, beliefs, ancient times experiences, and desires of prospective adopters. Hence, any innovation that does not conform with the standards of a community may not be accepted as fast as one that is compatible.

3. **Complexity**: Some technologies are easily and willingly understood by majority of farmers in a community; whereas, others are more difficult and will take more time before they get accepted. Therefore, new ideas should be comparatively easy to comprehend and utilize when compared to existing ones as innovations that are simple to comprehend are accepted more rapidly.
4. **Trial-ability**: An innovation should normally be easily adaptable. What this implies is that, it will be possible to try a technology on a small scale. Any innovation that can be experimented on an installment arrangement will usually be more readily accepted than ideas that are not separable.
5. **Observability**: Farmers would normally want to be able to see the outcome of a new idea so that they could be able to discuss such results with fellow farmers. If outcomes of innovation are readily seen by farmers, then the chances of accepting such innovation become higher; whereas if there are no clear observable outcomes, it may be difficult for such ideas to be replicated and accepted.
6. **Divisibility**: It is a great idea for a technology to be divisible; this means that the innovation can be tested with small units before buying the whole gadget. Purchase of tractors or harvesters is a one-time major investment and part of it cannot be bought in order to try it out in phases. However, such technology can be hired for initial use before deciding on whether to purchase. A farmer can however, purchase and utilize a little quantity of improved seeds, fertilizer or herbicides.
7. **Accessibility**: Innovations that are easily available are more readily accepted. In this case, it is not advisable for a change agent to push for the distribution of farming inputs that farmers either cannot afford or for which infrastructure does not exist; as this would be an indication that the technology is not accessible.
8. **Visibility**: The results of the mode of operation of a given innovation should be easily seen, i.e., visible. A farmer can see a new spraying pump which has been made easier to handle; hence the likelihood of adoption becomes greater.
9. **Cost**: It has been consistently observed that innovation may not be easily adopted if it is perceived to be costlier than what currently exists; it thus goes to say that a new idea may have a relative advantage over an old one; but could meet up with resistance if the currently used practice is a lot cheaper. Generally, the higher the cost of an innovation, the more slowly it is adopted.

However, Rogers (2003) as cited by Ray (2011) argued that the choice to accept any part of an innovation depends on a procedure which is known as the innovation-decision process. Innovation-decision is conceptualized as having five stages and each of these stages can only take place after a period of time has passed. The stages are:

1. Knowledge stage: One is believed to have acquired knowledge the very moment a person is exposed to the technology reality and has achieved some perception of how such knowledge functions. The meaning of this is that knowledge role is primarily cognitive or knowing. People who acquire knowledge at an early stage; are regarded as generally more highly educated and are perceived as having higher social status; they are also more open to both mass media and interpersonal channels of communication, and they have more contact with change agents.

2. Persuasion stage: One would have passed through the persuasion stage once a person forms an opinion about the new practice/idea; though this could only happen after going through several persuasive messages from development workers, sales promoters and close associates. The persuasion function is mainly connected or related to feelings and is thus; a stage laden with so much emotional attachment and/or factors. Hence, it is expected that the potential adopter may turn out to be more psychologically involved with the innovation and would actively seek information about the innovation/new practice. It is at this stage that the would-be adopter forms a good or bad attitude/impression towards the technology.
3. Decision stage: After being persuaded about the usefulness or benefits of an innovation, one would normally engage in activities which may culminate into either of two options; that is whether to take or discard the technology. Having observed that other people use the innovation, the potential adopter can choose to adopt or refuse the technology. People would adopt an innovation only if they are convinced of its usefulness and compatibility with their values and income.
4. Implementation stage: Implementation happen as soon as a person or other decision-making unit place a technology into use. At this stage the individual is generally concerned with where to get the innovation, how to use it and what operational problems will be faced and how those problems could be solved. Implementation might entail alteration in management of the venture and/or adjustment in the technology, to go well with the exact needs of the individual who accepts it.
5. Confirmation stage: This is the last stage in the innovation process when an individual finally accepts or rejects a new practice. Confirmation culminates in repeated use. Individuals seek reinforcement for the adoption decision they have made. The consequence is that they may exhibit continued adoption or exhibit discontinuance. Meanwhile, it is noteworthy to mention that the entire innovation-decision process has a sequence of options at every stage. For instance, in the knowledge function, the would-be adopter would have to decide on which of the innovation messages to attend to while they also have to make up their minds on which ones to disregard.

In the persuasion function, potential adopters must decide on the messages to seek out and the ones to ignore, whereas; in the decision function, the available options are different from what were obtainable in the previous stages. The decision stage presents with two possibilities which are either to accept or refuse a new idea. This decision involves an immediate consideration of having to try out an innovation or not to give it a try at all. Most farmers will accept an idea/technology only after trying it out; and it is after the trial that he can then determine its suitability.

Climate-Smart Agriculture (CSA)

CSA derives from an attribute in its terminology; that is, smart way of practicing agriculture. It is a form of agriculture that sustainably increases agricultural output and earnings; it enhances adaptation and aims to build resilience to the effect of climate change by reducing or eliminating Greenhouse Gases (GHGs) wherever possible, as well as advancing the attainment of global food safety (FAO 2014). CSA is mainly targeted at integrating the three broad areas of sustainable development which are the economic, social, and environmental components; by equally justifying food security, ecosystem management, and climate change problems.

Food security can be enhanced by maintaining an increasing agricultural production efficiency while the ecosystem can be more easily managed by adapting to, as well as building resilience to climate change. On the other hand, the climate change problems can largely be well mitigated by either working to lessen and/or eradicate greenhouse gases (GHG) emissions. However, CSA is never a pre-arranged condition, neither is it a given template that can be generally applied or practiced. Suffice to say that, it is a process that calls for site-specific assessments of the social, economic and ecological conditions to identify proper farming technologies that are appropriate in any given situation. It is important to note that a key component of CSA is the incorporated landscape method which suggests that the CSA practices that are being employed and/or applied in a given environment would follow the main beliefs of ecosystem management and sustainable land and water utilization. Climate-smart agriculture aims at supporting livelihoods at farm level by ensuring food security of smallholder farmers and helping to improve the management and utilization of natural resources. It also fosters the adoption of appropriate methods and skills for the production, processing and marketing of agricultural supplies. Whereas at the national level, CSA pursues legitimate and relevant technological and financial policies that would support nations to establish/entrench climate change adaptation into their agricultural sector. There is, at the national level, a considerable progressing efforts to promote CSA in Africa while ECOWAS also made efforts to support the mainstreaming of CSA into the ECOWAP/CAADP programs (ECOWAS 2015). In Nigeria specifically, there are research institutions and colleges owned by the Federal Government; who are working on CSA in order to render their own contribution to the fight against climate change related problems (FAO and ICRISAT 2019).

Benefits of Climate-Smart Agriculture

Climate-smart agriculture, as noted earlier, underscores the importance of building evidence to highlight practicable alternatives to the existing non-climate friendly approaches. It also encourages important enabling activities that can translate into better productivity and a friendlier environment. Through CSA, attention can be drawn to agricultural systems (crop, livestock, aquaculture, and agroforestry) that support the ecosystem services as this would enhance productivity, adaptation and mitigation; in a way that would encourage smart farming practices in order to reduce the effect of climate change (Adedeji et al. 2017). The CSA process offers stakeholders, such as farmers and other main players in the sector; the techniques and gadgets, as well as management and styles required to regulate more challenging and tougher production systems.

The FAO, who has immensely contributed to the development of CSA in Africa, also trained numerous individuals on the CSA approach and have equally developed a program called Safe Approach to Fuel and Energy (SAFE) in northeast Nigeria (FAO 2019). The SAFE program is aimed at reducing the need for firewood and by extension, the release of greenhouse gas is further reduced. Among the documented efforts at reducing the impact of climate change is the Oxfam Nigeria and the European Union collaboration which designed a project named Pro-Resilience-Action (PROACT). PROACT started in Nigeria in 2016 with enhancement of food security as its purpose while helping farmers build enduring means of sustenance (FAO and ICRISAT 2019a). The project has Mubi South, Fufore, Song, and Guyuk local government areas (LGAs) of Adamawa State currently participating where certain relevant and appropriate climate-smart actions are being combined to support famers become more resilient. Some of the actions, which are rolled out in phases, are provision of farm inputs and training of farmers' groups.

In the four locations of Adamawa State (Mubi South, Fufore, Song, and Guyuk), inputs such as fertilizers and water pumps are supplied to farmers while extension workers are being trained on rural investments and formation of loan groups in order to enable them access flexible financing services (FAO and ICRISAT 2019a). So far, about 700 farmer groups (women constitute more than half of the population) have been provided with farm inputs. The scheme has documented some level of success as rice growers have seen a boost of almost 100 percent despite the dry season rice production (Adedeji et al. 2017). This was made possible due to the distribution of inputs such as improved seeds, water pumps, among others. The project did not only focus on input provision for farmers as about 70 government extension workers in Kebbi and Adamawa States have received training on better environment-friendly agricultural practices for improved cereals production (Adedeji et al. 2017; FAO and ICRISAT 2019a). Farmer Training Fields (FTF) were then established wherein the extension workers in PROACT Communities assist farmers in order to boost their capacity as well as support them to adopt the best practices that can improve their yields and productivity. It has been observed through field evidences that the FTF program has contributed to higher acceptance of CSAPs and this has translated into enhanced food safety and income for farmers (FAO and ICRISAT 2019a).

In the short run, the project aims to handover improved farming skills to farmers as well as equip them to plant 500,000 trees to battle desertification and climate change; while in the long run, it is expected that about 1,400 community investments and loan groups would have been established. Another observable CSA effort is seen in adoption of terracing as a climate-smart practice in the southern and northern parts of Borno State as a result of the rocky topography of the area (FAO and ICRISAT 2019b). A farmer, while confirming the use of terracing (even without the knowledge or advent of CSA) for more than forty years, confirmed that it helped to combat the effects of soil erosion by preserving moisture and crop nutrients on the farm.

The farmer affirmed a higher yield of sorghum and maize on terraced farms (47% higher) when compared to non-terraced ones. Added to the advantage of terracing in the area is the assertion that farm events such as weeding and spraying are better managed on terraced farms while suggesting that farming in the entire southern part of Borno might have been very unprofitable if terracing was not being practiced (FAO and ICRISAT 2019b). Among the manifestation of the benefits of CSAPs is yet another evidence as provided by a farmer, in Potiskum LGA of Yobe State, who planted improved variety of millet (SOSAT) and got higher yields over and above the traditional variety (Gwagwa) that he had been planting previously (FAO and ICRISAT 2019c). Given the nature of local farmers, he initially resisted the new SOSAT variety as a replacement for his Gwagwa local variety. Hence, he intercropped SOSAT and Gwagwa millets with sorghum and cowpea as commonly practiced around Potiskum. This was done for 4 years while monitoring the variations in yield (FAO and ICRISAT 2019c). The farmer realized 550 kg/ha from the traditional millet while SOSAT millet produced 900 kg/ha in the first year. The following 2 years, on the same plots, but only intercropped with cowpea without sorghum, produced 350 kg/ha of SOSAT over the traditional variety. The first year reflected a marked increase of 64% yield over the utilization of the traditional local variety while the next year produced yield increase of 88%. This field experiment is yet another indication that climate-smart options, such as planting of improved varieties, could help enhance crop output and diversification which can also potentially increase profits of farmers (Tiamiyu et al. 2018b; FAO and ICRISAT 2019c).

Adoption of Climate-Smart Agricultural Practices by Rural Farmers in Nigeria

Smallholder farmers have, in the past, accidentally practiced CSA as part of their habitual farming system in Northern Nigeria (Fanen and Olalekan 2014). Similarly, it was also found in another study that the foremost strategy adopted by farmers to deal with climate change was to plant drought resistant varieties (Naswem et al. 2016). Other strategies used in mitigating the effect of climate change include: relocation from climate risk zones, prayers to God for divine intervention, multiple cropping, recycling of waste product, and improvement on farmers' management skills. According to Ojoko et al. (2017), the five most used CSAPs in Nigeria included conservation agriculture, application of organic manure, crop diversification, usage of wetland (Fadama), planting of drought tolerant crops, and agroforestry. Tiamiyu et al. (2017) in their study also reported similar findings where the adoption of CSAPs included climate smart approaches such as planting of drought tolerant and early maturing varieties, application of organic compost, use of cultural practices such as intercropping and crop rotation, composting rather than burning, and erection of terraces on sloppy/hilly farmland.

In other studies, Onyeneke et al. (2018) also reported that mixed farming, high yielding cultivars, agro-forestry, and other cultural practices such as mulching and zero tillage, as well as membership in development associations were the CSAPs adopted by the farmers in their study. Further evidence had showed that farmers in Nigeria have continued to adopt climate smart practices to mitigate the effect of climate change while simultaneously increasing productivity. For instance, female farmers adopted agro-forestry in derived savannah, guinea savannah, and rain forest, while the male farmers employed organic manure, zero tillage, and crop rotation in the same agro-ecological zones, respectively (Fapojuwo et al. 2018). However, it was observed that majority of farmers in the study never made use of the climate smart practices; hence low adoption rate because they were not even aware of the opportunities (Tiamiyu et al. 2018a). Nonetheless, planting of drought tolerant varieties and high yielding cultivars appear to be the most favored options accepted by farmers while only a few of the farmers used agro-forestry and integrated pest management as a smart way to curb the effect of climate change. Moreover, Adebayo and Ojogu (2019), in their study, had reported minimum or zero tillage, crop rotation, and other cultural practices such as mulching as the most favored CSAPs by farmers.

Challenges of Climate Smart Agriculture Practices

The adoption of CSAPs is linked to a myriad of impediments as there is an array of socio-economic and institutional complications. As usual, the need for significant upfront expenditures on the part of poor farmers, inadequate access to technical information that are potential solutions to farmers' problems, and the inability of farmers to convert the knowledge gained into practice; are part of the challenges associated with the adoption of CSAPs. Furthermore, some procedures that are climatically smart in nature and which are also associated to sustainable soil management may not be compatible with farmers' customs; thereby leading to non-adoption as previous studies have shown that, the onward dissemination of ideas may greatly rely on knowledge in combination with social activities that farmers may not be capable of performing (World Bank 2018).

It had been reported that lack of funding portends a huge bottleneck in the acceptance of CSAP in Northern Nigeria while farmers also have little or no knowledge of CSAP; in addition to a poor understanding of the application of some of those practices by extension workers who would normally be the ones to disseminate technology to the famers. Other challenges include a dearth of stakeholders such as nongovernmental organizations; who can drive the campaign for CSAPs in the region (Fanen and Olalekan 2014). Moreover, while dealing with climate change, desertification poses a big threat for people, farmers inclusive. Hence, the subtle drive for tree planting by a few organizations makes the situation more problematic; thereby suggesting a neglect of the root cause. The implication of this is that there is a real need for a holistic and aggressive mobilization for tree planting. Meanwhile, limited opportunities for local managers to partake in policy formulation/decisions at international and local levels is a further weakness in the effort to combat climate change impact by encouraging adoption of CSAPs. Other hindrances restraining farmers from using CSAPs include: lack of government's support, high cost of executing the practices, and insufficient training on the practices (Adebayo and Ojogu 2019). Specific challenges of CSA, according to Williams et al. (2015) are outlined:

1. Lack of practical understanding of the approach: The need for a full comprehension of protocols surrounding the use of CSAPs is important in order for messages to be clearly communicated to farmers. Thus, the effort for scaling up initiatives will depend on the understanding of the CSA idea by relevant stakeholders.
2. Inadequate data and information: It is always a herculean task for African nations both at national and local levels to access and utilize suitable tools for climatic and landscape level data.
3. Inadequate investment in CSA: Again, it has been repeatedly found that investments required to scale up adaptation and resilience in agriculture is lacking right from national up to farm levels. The Africa's Infrastructure Diagnostic Report (Foster and Briceño-Garmendia 2010) also reported a deficit in social infrastructure such as road, transportation, communication, power and water; which are high requirements for the uptake of CSAP.
4. Socio-economic constraints: Access to productive resources like land, transportation and water, as well as human resources were the limitations at the farm level.
5. Inadequate women empowerment: Women who contribute significantly to food production in Africa are largely marginalized when it comes to access to and control over productive resources. For instance, it was found in a previous study carried out in northern Nigeria that women do not own and control productive assets such as land, crop inputs, livestock inputs, and capital (Aderinoye-Abdulwahab et al. 2016) and that this makes them to be poorly empowered. It is noteworthy that such gender stereotypes relating to access to land rights, education, technologies, and credit; are among the countless stumbling blocks to women's effective contribution in the farming sector.
6. Poor funding and efficient risk-sharing schemes: Funding devices to support the uptake of CSAP are not yet popular in Africa nations. Whereas, huge investment is required for the transition to climate-smart agricultural development pathways as farmers continue to face the risk of accepting new technologies. Meanwhile, the benefits of the technologies often only come after several years/seasons of production, thus the realization of a wider coverage of CSAPs becomes problematic.
7. Difficulty in running trade-offs from the farmers' and policymakers' perspectives: The dissimilarity in objectives between farmer groups and policy makers continues to cause a difference of opinion in respect of priorities for resource management.

Conclusion and Recommendation

The adoption of smart agricultural practice is an integral part for increasing agricultural productivity as it enhances adaptation to climate change. It also helps to reduce greenhouse gases emissions while enhancing the attainment of food security. The popular CSAPs adopted by rural farmers in Nigeria are: conservation agriculture, adoption of organic compost, use of wetland (Fadama), utilization of drought tolerant crops, relocation from climate risk zones, and use of cultural and management practices such as mulching and prayers for divine intervention. The challenges militating against the adoption of CSAPs by farmers in the study include: poor funding, lack of practical understanding of the approach, inadequate access to information on CSAPs, and socio-economic constraints at the farm level.

It would, hence, be recommended that there is a dire need for an aggressive awareness and mobilization campaign for the use of CSAPs as a solution to climate change impact in order to increase farmers' productivity. Additionally, this chapter would also recommend that government and other stakeholders should ensure that productive resources such as land, planting technologies, education and other social amenities be made available and accessible to farmers generally, but more especially women; in order to facilitate easy uptake of climate smart practices. Moreover, there is a need to motivate and encourage farmers to adopt climate smart practices, and one way of achieving this is by incorporating funding devices to support CSAPs and other climate friendly support mechanisms in policy documents.

Contents

Abstract

Agriculture is the art and science of food production which spans soil cultivation, crop growing, and livestock rearing. Over the years, it has served as a means of employment and accounts for more than one-third of total gross domestic product. Cereals, which include rice, maize, and sorghum, are the major dietary energy suppliers and they provide significant amounts of protein, minerals (potassium and calcium), and vitamins (vitamin A and C). The growth and good yield of cereal crop can be greatly influenced by elements of weather and climate such as temperature, sunlight, and relative humidity. While climate determines the choice of what plant to cultivate and how to cultivate, it has been undoubtedly identified as one of the fundamental factors that determine both crop cultivation and

livestock keeping. The chapter, though theoretical, adopted Kwara State, Nigeria, as the focus due to favorable weather conditions that support grains production. It was observed that the effect of climate change on cereal production includes: drastic reduction in grains production, reduction in farmers' profit level, increment in cost during production, diversification to nonfarming activities, and discouragement of youth from participating in agricultural activities. Also, the adopted coping strategies employed by farmers in the focus site were early planting, planting of improved variety, irrigation activities, alternates crop rotation, and cultivation of more agricultural areas. The chapter thus concluded that climate change has negative impact on cereals production and recommends that government should provide communal irrigation facilities that will cushion the effect of low rains on farmers' productivity, while early planting and cultivation of drought-resistant cultivars should be encouraged.

Agriculture and Climate Change

Our ancestors advanced from being hunter gatherers to live a more settled lifestyle since about a thousand years ago, residing in one place for a lengthy period rather than living a nomadic lifestyle. This change happened concurrently with the taming of different species of plants and animals, which were bred, kept or planted in close proximity rather than hunted. Over the periods, agriculture continued to advance although, up until the twentieth century, most of the work were undertaken by mankind and animals rather than machines. Such fauna and flora activities (which could also be natural), including human's method of cultivation as well changes in weather and climate, left the environment in a tough situation that we now refer to as climate change and its impact. Agriculture is largely reliant on weather and climate, hence climatic factors such as rainfall, sunlight, airstream, and temperature influence the distribution and productivity of crops (Sokoto et al. 2016).

Of all human endeavors, agriculture remains one of the most demanding on land. Land is thus in constant short supply given the effects of biophysical factors such as rain, temperature, and topography of an area, as well as unsustainable land management practices which include deforestation, uncontrolled soil nutrient mining, and cultivation on steep slopes (FAO 2015). The implication of such effects on land may comprise overgrazing, desertification, soil erosion, deforestation, among others and all of these further translate into shortage of land for human's endeavors. Perhaps the continued presence of these effects is one of the reasons why scholars have maintained that the ozone layer may eventually be depleted given that the earth is warming up (IPCC 2007; Mboera et al. 2012; FAO 2015) as a result of people's activities which enable greenhouse gases (GHG) like methane, water vapor, nitrous oxide, and carbon dioxide to trap heat into space.

Climate, a manifestation of weather and other atmospheric conditions, has largely been acknowledged as one of the fundamental indicators that determine both crop cultivation and livestock keeping. It is a long-term average weather conditions that directly or indirectly impact the events that play out on farms. Climatic conditions of any environment govern the choice of crop and how they will be planted, as well as the yields and nature of livestock to keep in a given location. This statement is alluded to in the work of Ajadi et al. (2011) where it was similarly shown that biophysical factors such as sunlight energy, temperature, humidity, and other climatic variables determine the global distribution and yield of crops and livestock. On the other hand, climate change is the long-term change in average temperature as a result of the earth's warming which may eventually translate into the depletion of the ozone layer. Although, an inconsistent phenomenon, climate change points clearly at threats to the future of people through the depletion of the ozone layer, thereby negatively impacting on all segments of human endeavor, agriculture inclusive. As a result of human and natural activities that release greenhouse gases (GHG) which had hitherto trapped heat within the atmosphere (Mboera et al. 2012), higher concentrations of these gases in the atmosphere leads to the earth's warming. These human activities could include but not limited to: use of fossil fuel, land use change, and agriculture (IPCC 2007; Mboera et al. 2012; Omumbo et al. 2011). Many people in developed regions prefer to assume that climate change is not real than to prepare to adjust their living standards to suit the effect of climate change (Mboera et al. 2012). Hence, there is a need to increase farmers' awareness on the effect of climate change as well as adequately prepare for its mitigation. Researches to proffer ease of living with climate change and its impact are therefore expedient.

It has equally been shown in another instance that the planet's temperature is increasing, leading to frequent changes in rainfall patterns and extreme events such as droughts (Zoellick 2009). The International Panel of Climate Change (IPCC 2007) also submitted that agriculture, forestry, and the change in land use, account for up to 25% of human induced GHG emissions while agriculture is the chief source of released methane and nitrous oxide, bearing in mind that these two gases constitute the substantial part of GHGs. Similarly, Odjugo (2010) stated that climate change is undeniable and its impacts are clearly seen in rising temperatures, low rainfalls, desertification, water scarcity, health, and agricultural problems. It has also been reported that several million hectares of crops and livestock have been destroyed due to climate-induced tragedies (FAO 2015). Climate change has therefore impacted on the economy of nations so much so that agriculture sector absorbs about 22% of the entire damage in developing countries (FAO 2015). Therefore, there is a dire need for farmers to be aware of the extent of destruction that the impact of climate change can constitute in their livelihoods as this will work to boost their preparedness for its mitigation. Reuben and Barau (2012) had similarly reported that incidences of low humidity during propagative stage will definitely result in poor yields of crops while the Food and Agriculture Organization (FAO) also poised that the crop sector is the most affected during unfavorable weather episodes (FAO 2015).

It is imperative to note that countries would feel the impact of climate change differently; while the effect may be positive in some areas, other climes might be negatively affected. Some additional degree of climate change and its impact is unavoidable regardless of the amount of measures put in place to ameliorate or forestall it. As such, there is an inevitable need to adapt farming to resilient conditions of agricultural systems. The two major means of reducing climate impact are mitigation and adaptation. Adapting agriculture to climate change and sustaining adequate food production could help to resolve the current glitches. However, with growing levels of GHGs, climate change and its consequences will continue to pose new challenges as well as mete out untold hardship on people. Currently, agriculture (and related sectors) contributes about a quarter of human-induced GHG emissions (IPCC 2007; FAO 2015), so it is highly necessary to reduce these emissions and other unfavorable effects from our environment. Many times, decreasing resource inputs and increasing efficacy goes hand in hand with mitigating emissions. If we can reduce the concentration of GHGs in our atmosphere, then extreme climate circumstances in the future would have been reduced considerably, and thus, it will be easier to adapt to climate change.

This chapter will therefore dwell on the interconnectedness of agriculture, climate change, and the effects of climate change on grain production. It will as well highlight grain farmers' coping and adaptation strategies to the impact of climate change.

Focus Study Site

Kwara State is located in a hot and humid region with two major seasons; it has tropical wet and dry climate (Olanrewaju 2009), each lasting for about 6 months. Kwara State has an annual rainfall range of 1000–1500 mm from March until early September, although this is gradually shifting forward due to climate variations; while the dry season used to be from October to March. Again, this is also on the moving trend as temperature continues to be on the high side up until April/May. Temperature is uniformly high and ranges between 25 °C and 30 °C in the wet season; while the dry season ranges between 33 °C and 34 °C. On average, the state is occupied by subsistence tuber, legume, and cereal farmers who depend solely on rain-fed agriculture; hence one can only imagine how climate change would impact on these farmers. The major occupation of the people of Kwara is largely agricultural-related as more than 70% of the population are farmers. Moreover, the plain to slightly gentle topography of Kwara State further makes it favorable for agricultural growth while other climatic patterns, vegetation, and the fertile soil make the state suitable for the farming of an extensive range of food crops such as cereals, cowpea, cassava, and tree crops, such as cashew and mango (Olanrewaju 2012). This review adopted Kwara State as a focus site because there are large number of cereal farmers in addition to favorable soil condition for production of grains such as rice, maize, millet, and sorghum, as this can favor low consumption of nutrient, low managerial procedure, as well as two planting seasons for rice and maize among others.

Agriculture and Cereal Production in Nigeria

Nigeria is an agrarian country with a reasonable percentage of its population engaging in agriculture at subsistence level (Adhvaryu et al. 2019). Like most countries in Sub-Saharan Africa (SSA), farmers in Nigeria not only live in rural areas, but their agricultural holdings are generally minute with about two-thirds of the total production being practiced with the use of simple methods and the bush-fallow system of cultivation. Agriculture, as practiced widely in Nigeria and other developing countries, is highly subjected to climate variability, and Nigeria's comprehensive range of climate differences supports a broad variety of the production of food crops (Olanrewaju 2012). Of the vast area of land for cultivation in Nigeria, cereals like sorghum, millet, rice, and corn are predominantly grown, but maize has overtaken the other traditional cereals such as wheat in terms of cultivation and popularity. Grains are rich in starches and contain substantial amounts of protein, as well as some fat and vitamins. They are essentially the world's staple food with over 70% of the world's harvested area producing a billion and a half tons of grains annually (Sokoto et al. 2016). Despite this, cereal production is set for a global increase with wheat, maize, and barley accounting for most of the rise in cereal production, while rice production is likely to maintain the increase as produced in 2018 (FAO 2019).

Rice is a starchy cereal that contains fiber, protein, vitamins, and minerals. It is consumed by more than half of the world's population (Rathna Priya et al. 2019) and is increasingly an important crop in Nigeria, with some species growing within 3 months. Africa cultivates about half of the 14 million metric tonnes of the annual global rice production (FAO 2019), while Nigeria is the largest producer and the leader in terms of consumption as well as importation in Africa. Nigeria's production has steadily advanced from two million metric tonnes to 8.0 million metric tonnes between 2008 through 2018 with the aim of reaching 18 million tonnes by 2023 (FAO 2019). This is due to rice policy reforms by the Federal Government of Nigeria who in its bid to eliminate rice importation enacted the anchor borrower's scheme that have paved way for proliferation of rice farming in the country (FAO 2019). Rice is not usually grown in isolation but with other crops such as sorghum, maize, and sweet potato. Initially, rice was noted as a luxurious food but has fast become a regular diet in every home in the country.

In Nigeria, maize is equally a significant food and feed crop which maintains an essential status for rural food security (Stevens and Madani 2016). Introduced to Nigeria in the sixteenth century, maize is the fourth most utilized cereal ranked below sorghum, millet, and rice (FAOSTAT 2014). Maize production in Nigeria is above ten million metric tons (Mundi Index 2018; FAO 2019), and it accounts for almost half of the calories and protein consumed in Eastern and Southern Africa (ESA), and one-fifth of the calories and protein consumed in West Africa. It is a significant source of carbohydrate, protein, iron, vitamin B, and minerals. Additionally, maize is essential in the cropping system of the small-scale Nigerian farmer and is frequently grown in mixture with other crops such as legumes or even cereals under traditional practice. This is not only because maize is relatively more affordable than other cereal crops, but it is also widely accepted in the region as edible plant (Sowunmi and Akintola 2010). Apart from millet, maize is the earliest grain that is harvested in any given season in Nigeria, hence offering respite to the usual food scarcity being experienced at such periods of the year while maize consumption is generally acceptable in various forms across the country (Mundi Index 2018).

It is now a common knowledge that farming activities, including cereal production, has put global populations at vulnerable climatic situations and many studies have evolved in the area (Adger et al. 2004). In Nigeria, the vulnerability to climate change can be seen in the overwhelming effects of recent climatic catastrophes in all the six geopolitical zones of the nation. The protracted droughts resulting in increased temperatures as currently being observed in the northern region and the late arrival and early cessation of rain (Apata et al. 2009) are manifestations of climate change impact. It is evidently clear that Nigeria is highly susceptible to the effect of climate change because of its wide (800 km) coastline which is prone to sea level rise and the various challenges related to the violent storms (Apata et al. 2009). In view of the foregoing, it has become expedient to assess the various adaptation strategies adopted by cereal farmers in Nigeria in order to better cope with the effect of climate change as well as serve as knowledge bridging gap for other farmers to leverage on. The next sections would highlight the effect of climate change on cereal production before drawing conclusion and recommendations that cereal farmers in the region where Kwara State is located can derive ideas from.

The Impact of Climate Variability on Agriculture in Nigeria

Climate variability may have an indirect influence on the goal of poverty alleviation in developing countries (Skoufias et al. 2011) as efforts at reducing the variations in climate help to increase agricultural yields which ultimately translate into better incomes for farmers and improved food security for the populace. This suggests that there might be efforts from development experts that could nurture linkages between climate vulnerabilities and development policies. Perhaps, such efforts and policy debates could eventually address the impact of climate change on agricultural-related practices. Falling incidences of climate variability will cushion the vulnerability levels of farmers (Skoufias et al. 2011), and the effect of climate change will normally be felt either directly or indirectly on all segments of the environment to include: socio-economy, water resources, food security, human health, ecosystems, coastal zones, and other related sectors. Fluctuations in precipitation and melting of glaciers are pointers to acute water shortages, soil erosion, and/or flooding (IPCC 2007), and these will absolutely affect agriculture produce. These climatic variations would inadvertently result in crop losses and low profits for farmers.

The steady increase in temperatures has necessitated an unavoidable shift in crop growing seasons for farmers in Nigeria and this has affected sufficient food availability and variations in the spread of disease vectors (Odjugo 2010;

Apata et al. 2009). The variations in climate amplifies vulnerability of people to diseases through the disease-carrying vectors. Moreover, upsurge in temperatures can possibly result in increased rates of extinction of many species and habitats. This, in itself, is not favorable for the ecosystem, and in a like manner, pest and diseases migrate in response to climate change with serious consequences on agriculture and the entire planet (IPCC 2007; Earth Journalism Network 2016). Such irregular temperature patterns and movements of pests lead to erratic rainfall and sunshine patterns, thereby resulting in crops' instability. It is therefore apparent that there is a heightened (above global mean) warming rate on the lands as evaporative cooling has greatly reduced, and there exists a smaller thermal inertia when compared to those found in the oceans. Boko et al. (2007) reported a similar scenario for Nigeria where the authors stated that the warming rate in Nigeria was above the mean rate for Africa.

Extreme rainfall patterns and variations in Nigeria have become a serious production risk for agricultural production system that is largely rain-fed (Olayide et al. 2016). The rain-fed agricultural production system is vulnerable to seasonal variability which affects the livelihood outcomes of farmers who greatly depend on this system of production. Previous studies have also shown that varying temperature fluctuations, heat waves, relative humidity, and rainfall are bound to compromise agricultural production as substantial losses are observed in the yield of grains such as rice, millet, sorghum, and maize in Nigeria (Sokoto et al. 2016). It was similarly found that maize along with other cereals were more susceptible to climate variability with untold consequence on the yield (Bismark and Richard 2019). Similarly, it was found that yields and productivity of maize, millet, sorghum, and rice were negatively affected by unfavorable climatic conditions such as drought, excessive temperature, and low rainfall (Bamiro et al. 2020).

The complications that are linked to climate change are not the same across the country. Nigeria, for example, has a tropical climate with two precipitation regimes spanning the north and south of the equator. The north is typically low in precipitation and high in temperature while parts of southwest and southeast are distinguishingly lower in temperatures with high amount of rainfalls (Nkechi et al. 2016; Akande et al. 2017). Obviously, the northern climate can lead to grave ecological effects as demonstrated by aridity, drought, and desert encroachment in the north, and flooding and erosion in the South (Nkechi et al. 2016; Akande et al. 2017). It was further shown through vulnerability analysis that States in the north, especially north east and north west region, experience higher degrees of vulnerability to climate change than those in the south (Federal Ministry of Environment 2014; Madu 2016). These variations in the northern climate are further compounded by desertification, loss of the wetlands, with a disturbing decrease in the volume of surface water, flora, and fauna resources on land (Abdulkadir et al. 2017; Ebele and Emodi 2016). Interestingly, the Southwest and Southeast are relatively less vulnerable when compared to other parts of the country because of the eco-friendlier climate patterns as depicted by high precipitation and relative humidity. Although, despite the relatively less vulnerability of the southern region of the country, the South-South (Niger Delta region) is most susceptible, due to sea level rise, increased rainfall, coastal destruction, and flooding, which has resulted in the dislodgment of many settlements (Matemilola 2019).

The form of vulnerability to climate change usually corresponds with agronomic activities in a given location (Madu 2016). The argument here is that the northern regions of Nigeria, which coincidentally have higher degrees of rurality, are more vulnerable to climate change (Madu 2016). Hence, the adoption of existing and new technologies for adapting to climate change and variability is a high priority for most part of Nigeria. Evidence from secondary data has shown that farmers in the focus study site (Kwara State is located in the northern part of Nigeria) are already feeling the impact of climate change in many ways (Sokoto et al. 2016). The effect of climate change on cereals production is firstly noticeable in a sharp increase in production costs and reduced grains production while this translates into decreases in farmers' profit level (Sokoto et al. 2016). Ordinarily, the cost during production could have been minimal and relatively stable but for the heightened climate variabilities. In developing countries including Nigeria, climate variability and change do encourage heat and moisture stresses thereby adding to an already long list of existing problems (Earth Journalism Network 2016). How then are countries in the tropical regions able to deal with climate change impacts?

Climate Change Adaptation Strategies for Cereal Farmers in Nigeria

Adaptation is a method through which people make themselves better able to cope with an uncertain future. Adapting to climate change will therefore entail the application of efficient actions to lessen the adverse effects of climate change (or exploit the positive ones) by making the necessary modifications in order not to greatly feel the negative impact. Emerging countries, such as Nigeria, typically perceives industrialized countries as climes with reduced vulnerability and better adaptation strategies given that such regions are better able to realize the prospects in cold weather episodes and hence make calculated moves to strengthen their agricultural production (Achike and Onoja 2014). The international community through the UNFCCC are in serious deliberations to find an effective means to battle climate change. It therefore becomes pertinent for the international community to entrench, in their future decisions, processes that will assist developing nations with transfer of knowledge, technology, and financial resources to adapt at all levels and in all sectors.

Recent study offered that farmers in Africa use crop diversification to build resilience in the agriculture sector (Mango et al. 2018), although this method may not be a favorable means among certain other farmers. However, adaptation, regardless of whatever form it takes, is already considered a major and important integral part of any future climate change regime. Some of the known technologies in use for climate change variability and impacts include: crop diversification, the adoption of drought-tolerant and early-maturing varieties of crops, and planting of cover crops (Federal Ministry of Environment 2014; Achike and Onoja 2014). Studies have shown that farmers in Nigeria are being supported by government and other non-governmental organizations to better adapt to climate change using these, as well as other methods to deal with climate change impact (Ifeanyi-obi and Nnadi 2014). In addition, relevant weather-related information and skills training that can enhance productivity can be offered by agricultural extension services (Akintonde and Shuaib 2016). Although the current irregularity of extension services in Nigeria is a limitation to the adaptation strategies (Akintonde and Shuaib 2016).

Other adaptation strategies used by farmers in SSA including Nigeria are: early planting of crops, a condition where crops would have enjoyed some reasonable amount of rain before it ceases. Rainy season, of the current year, in certain parts of Nigeria experienced a somewhat climate change, and this means that Kwara State, along with many other states in the country, did not enjoy rains in the months of July and August; supposedly, those months should have been the peak of rains when activities for farmers would normally climax. Thus, some farmers who tapped into the opportunity of early planting sowed particular grains in May/June (maize for instance) when there were initial heavy rains and those farmers were able to survive the drought occasioned by the lack of rains. However, most grains that would normally be planted later in July did not survive as this coincided with the cessation of rains in July and August and farmers lost their resources (monies, inputs, time, and energy).

Improved variety is another adaptation strategy in use in order to cope with climate change impact. Farmers now plant improved varieties that have high resistance to pest and diseases, requires low water, matures quickly, and with many more qualities. This strategy was found to be popular among cereal farmers in Nigeria. For example, close observation of rice farmers in Kwara State showed that they employed similar means to combat the impact of climate change within the region. Farmers now plant a locally crossbred rice variety from Kebbi State that germinates in 12 weeks while some other farmers are yet to tap into this innovation and are still growing older rice varieties that reach maturity in 4 months and above. The improved rice variety offers farmers the opportunity to cultivate and harvest rice twice in one growing season especially if such farmer leveraged on early planting strategy. The snag here, however, is that the improved seeds are more expensive, although on the flipside, farmers can produce seeds for the next growing season from the current one and can consequently save some costs in the next planting season. Again, this method may not work if prolonged rain shortages are experienced and there are no facilities for irrigation.

Crop rotation is also one of the strategies used by the farmers to assuage the impact of climate change. Farmers in SSA including Nigeria do not restrict themselves to sowing a mono-crop. They use grains and/or legumes to rotate across seasons. A farmer might plant corn along with other tuber crops such as cassava in one season, and then proceed to corn and cowpea in another season. There are times when farmers are able to predict what the next planting season would look like given their experiences from previous climate variation patterns and based on local climatic indicators, although their predictions may not always work as projected. For instance, farmers may envisage a favorable climate in the next growing season if temperatures in the current year are on the high and rains were too scanty. In such a situation, a farmer can predetermine which crops would offer more yield with high precipitation and less vulnerability to such weather. At the return of the rains in Kwara State at the tail end of August and beginning of September this year, farmers who have suitable lands hastened to plant soybean as this crop require less amount of rainfall and would normally germinate within 12 weeks when it is expected that the little rain that would fall in the remaining part of the season would be enough to see the crop to harvest in November. At some other times, farmers may rely on weather forecasts from relevant government agencies to determine what the forthcoming growing season would look like and adequately prepare for the crops that would thrive better in such weathers. Such information can also be leveraged on to determine what crops offer relative advantage over others, in order to make decisions as to the crops to rotate with the other in subsequent seasons. Such calculations help the farmers to plan better as well as make calculated risks that can translate to reduced climate change impacts.

In addition, farmers in Kwara State have also applied crop diversification as another adaptation strategy. For example, farmers have changed the crops grown on previously cultivated lands from a particular cereal crop to another due to climatic changes. Land that was previously being farmed for rice production because of abundance of water have now been converted to cultivation of maize and sorghum after such lands have lost their water content due to enduring droughts. The adaptation strategies adopted by cereal farmers in Kwara State are as seen in similar works where it was reported that crop diversification, adoption of drought-tolerant cultivars, early-maturing varieties of crops, and planting of cover crops are among the adaptation strategies being employed by farmers in Nigeria (Federal Ministry of Environment 2014; Achike and Onoja 2014).

Irrigation and drainage activities were also adaptive measures that farmers in Nigeria usually put into consideration during planting operations in order to secure water for plants during dearth periods (for example, as seen in northern Nigeria) and also mitigate the impact of flooding should the need arise, especially in the coastal southern region of Nigeria. This will reduce crop loss during insufficient and excessive rainfall like the full 2 months break earlier described in the current rainy season in Nigeria. Secondary data collected, observations and experiences from previous and current planting seasons showed that farmers in northern Nigeria had relied on strategies like direct interventions such as dike building to prevent flooding, large-scale relocation of farmers from excessively eroded areas, new crop selection, building of dams to expand irrigation, and crop rotation in order to curb the menace of climate change. Methods such as this would also ensure adequate yield of crops by farmers. Rice farmers in Kwara State, for instance, constructed make-shift dams at several points on their farms, where rain water is usually collected/deposited for use during dearth periods. Unfortunately, such water gets dried up whenever there is protracted or intense water shortage and farmers will sometimes need to walk long miles to areas where there are other sources of water (wells and boreholes) in order to irrigate their farms. The current prolonged lack of rains in Kwara State led to huge losses as farmers were not hitherto prepared and consequently could not cope well with the situation.

Another adaptation strategy adopted by cereal farmers in the focal site is cultivation of more agricultural areas. By this, it was observed that farmers chose not to wait until harvest period before they will discover heavy crop losses and/or damages; hence they became proactive by cultivating large expanse of lands to increase their productivity. Some farmers have increased their farm sizes through cultivation of more lands as this will make them generate more income as well as improve their livelihood. Interestingly, majority of farmers in Kwara State, like other parts of the country, do not own the lands where they farm. First of all, all lands in the country belong to the government and anyone who intends to take possession would have to seek the owner's (government) permission in the form of "registration of title" which attracts special charges. However, farmers have usually cultivated lands without the owner's permission and they are always ready to move to other expanse of lands whenever the rightful owners emerge to take over the lands. Farmers have occasionally recorded huge losses when such circumstances arise but they would rather take such risks as it has almost become a norm among them. It is only the large-scale commercial farmers that normally acquire the lands rightfully. Meanwhile, while farmers may be increasing their yields by cultivating more expanse of lands, this method is indirectly expanding land used for agricultural activities and will consequently increase their risks and exposure to climate change impacts.

Livelihood diversification is also one strategy being used by cereal farmers in the focus site. Some farmers who feel they could no longer cope with the climate change impacts have decided to change the means/source of livelihood. Some of the cereal farmers in Kwara State have attempted diversification to nonfarming activities as adaptation strategies while discouraging youths, who are becoming more interested in white collar jobs, from participating in agricultural activities. Hence, though sadly, some of the farmers have boycotted farming for artisan jobs as well as bicycle riding jobs in order to sustain their families.

Conclusion

Agricultural activities play a major role in the development of any country, and the effect of climate change on agronomic activities cannot be underrated due to its direct impact on agricultural production. Climate change may be a global issue but its effects will automatically differ between geographical regions. While food production in some areas may suffer from extreme weather and temperatures, farming in other regions might benefit from longer growing seasons and warmer climates. Early planting, crop diversification, planting of improved variety, irrigation and drainage practices, crop rotation activities, and cultivation of more agricultural land areas were the adopted strategies used in the focus site to help farmers cushion the impact of climate change. Therefore, farmers need to continue to adopt those strategies to combat this situation, in order to keep sustaining their livelihoods.

Recommendations

Based on observations and inferences highlighted, cereal farming, in Nigeria as a whole and particularly in the area of focus, would be enhanced if these recommendations are taken:

1. There is a need for meteorological agencies (for example, Nigerian meteorological agency – NiMet) to widen their scope and expand their methodology to ensure that small-scale farmers benefit from their forecasts, in order to reduce farm losses due to unfavorable weather episodes. This will make farmers to predetermine the crops and time to plant.
2. Rain-water collection systems can be made available by collaborative efforts of the farmers, while government and other stakeholders serve as buffer during dry season and early cessation of rainfall. This will help in situations like the one experienced this current season by farmers in Kwara State where farmers became helpless as a result of unexpected shortage of rains.
3. The public sector (government) can further encourage small-scale farmers by instituting favorable policies that will stimulate farmers to remain on the fields as well as enhance them to better cope with unfavorable climatic conditions. Such policies, like fertilizer subsidy and those enacted for increased rice production, would reduce cases of livelihood diversification where youths are seen to migrate to cities for alternative jobs.
4. Provision of communal irrigation facilities (every problem must not be solved at the instance of government) for use in times of water scarcity to avoid food shortages for the populace. This will also reassure farmers that their efforts would not be a waste and the fear of unexpected huge losses on their part can be allayed.

Abstract

This chapter was aimed at evaluating the responses of livestock to fluctuations in climate and the debilitating effect of livestock production on the environment. Survey of livestock stakeholders (farmers, researchers, marketers, and traders) was carried out in Sahel, Sudan, Northern Guinea Savannah, Southern Guinea Savannah, and Derived Savannah zones of Nigeria. In total, 362 respondents were interviewed between April and June 2020. The distribution of the respondents was 22 in Sahel, 57 in Sudan, 61 in Northern Guinea Savannah, 80 in Southern Guinea Savannah, and 106 in Derived Savannah. The respondents were purposively interviewed based on their engagement in livestock production, research or trading activities. Thirty-eight years' climate data from 1982 to 2019 were obtained from Nigerian Metrological Agency, Abuja. Ilela, Kiyawa, and Sabon Gari were chosen to represent Sahel, Sudan, and Northern Guinea Savannah zone of Nigeria, respectively. The data contained precipitation, relative humidity, and minimum and maximum temperature. The temperature humidity index (THI) was calculated using the formula: THI = 0.8*T + RH*(T-14.4) + 46.4, where T = ambient or dry-bulb temperature in °C and RH=relative humidity expressed as a proportion. Three Machine Learning model were built to predict the monthly minimum temperature, maximum temperature, and relative humidity respectively based on information from the previous 11 months. The methodology adopted is to treat each prediction task as a supervised learning problem. This involves transforming the time series data into a feature-target dataset using autoregressive (AR) technique. The major component of the activities of livestock that was known to cause injury to the environment as depicted in this chapter was the production of greenhouse gases. From the respondents in this chapter, some adaptive measures were stated as having controlling and mitigating effect at reducing the effect of activities of livestock on the climate and the environment. The environment and climate on the other side of the dual pathway is also known to induce stress on livestock. The concept of crop-livestock integration system is advocated in this chapter as beneficial to livestock and environment in the short and long run. Based on the predictive model developed for temperature and relative humidity in a sample location (Ilela) using Machine

Learning in this chapter, there is need for development of a web or standalone application that will be useable by Nigerian farmers, meteorological agencies, and extension organizations as climate fluctuation early warning system. Development of this predictive model needs to be expanded and made functional.

Keywords

Savannah · *Sudano-Sahel* · Climate change · Adaptation Livestock · Nigeria

Introduction

Livestock is important as sources of food (FAO 1993; Murphy and Allen 2003), fiber (Iyiola-Tunji 2012), and farm power (Srivastava 2006; Umar et al. 2013) in most part of sub-Saharan Africa. Adesogan et al. (2020) elaborated on the fact that the almost 800 million people who live in poverty (living on less than $1.90 per day) and subsist on a diet heavily based on starchy foods. They elaborated that animal source food will be required for millions more people who are slightly better off in terms of their incomes because animal source food provide not only calories but, more importantly, the nutrients required for achievement of human development potential. The dependability of some livestock keepers transcends the basic uses of the products and by-products of livestock to their uses as a form of savings for the raining days. Schmidt (2008) argued in favor of wealth storage in the form of cattle as a rational investment decision. Bettencourt et al. (2015) presented livestock feature as living savings which can be converted into cash whenever its needed, as well as a security asset influencing access to informal credits and loans and being also a source of collateral for loans.

It is expected that as the population of humans is increasing, the demands for animal products will also be increasing (FAO 2011). However, the production environments from which most of our animals are coming from in Africa are not improving commensurately to the potential demands for the stocks. The breeds of animals that are indigenous to specific locations in Africa have the advantages of adaptability to the environment from which they have lived for several hundreds of years. The environments to which these animals are adapted are heavily laden with stress. This in turn leads to low productivities. Heat stress is an intriguing factor that negatively influences livestock production and reproduction performances (Berihulay et al. 2019).

The dynamics of the environment in sub-Saharan Africa is widely varied within and between regions. In Nigeria, there are humid forest in the South and different categories of Savannah Northward. According to Abdulkadir et al. (2015), the potential impact of climate change, rainfall variability patterns and the dynamic hydrologic regimes have continued to escalate land degradation and make it imperative that the broad ecoclimatic zones could have changed. Variability of climate elements can also predispose animals to diseases. The distribution and incidence of animal diseases, specifically vector borne disease, are directly influenced by climate because the geographical distributions of vectors are predetermined by temperature and humidity (Kebede et al. 2018). Livestock production is being adversely affected by detrimental effects of extreme climatic conditions. Consequently, adaptation and mitigation of detrimental effects of extreme climates have played a major role in combating the climatic impact in livestock production (Khalifa 2003).

The level of aridity increases northward in the country. Haider (2019) reported on the challenges associated with climate change in Nigeria which are not the same across the country. The low precipitation in the North and high precipitation in parts of the South were reported to have led to aridity, drought, and desertification in the North and erosion due to flooding in the South (Onah et al. 2016; Akande et al. 2017). The more arid zones are the regions with the most population of livestock like cattle, sheep, and goats. Animals like camel and donkeys are exclusively found in the most arid regions of the country also. Over the years there had been reported cases of extreme high temperatures, drought, flooding, and some other climate-induced stressors. These phenomena always result in losses in productivity of the animals and accruable incomes to the farmers. So, in combating these problems, farmers (especially pastoralists) had adopted migration southward with their animals during the dry season when feed resources and water are not readily available. Some more adaptive measures along with the seasonal migration of stocks were evaluated in this chapter.

Apart from the effect of climate change on livestock which had been studied extensively, animals on higher production levels tend to be more sensitive to high temperature and humidity (Hahn 1989; Aydinalp and Cresser 2008; Nwosu and Ogbu 2011), there is also need for the understanding of the effect of livestock production activities that are capable of causing changes in climatic elements. Based on the submission of Brown (2019) and FAO report (http://www.fao.org/news/story/en/item/197623/icode/), rearing livestock generates 14.5% of global greenhouse gas emissions that are very bad for the environment. Livestock and their by-products account for million tons of carbon dioxide per year (Flachowsky and Kamphues 2012). Extensive system of livestock production plays a critical role in land degradation, climate change, water, and biodiversity loss. The problems surrounding livestock production cannot be considered in isolation. Economic, social, health, and environmental perspectives will be critical to solving some of these problems. There is need for development of a greater understanding of these complex issues so that we may encourage policies and practices to reduce the adverse effects of livestock production on climate, while ensuring that humans are fed and natural resources are preserved. A Human Society International report advocated that mitigating the animal agriculture sector's significant yet underappreciated role in climate change is vital for the health and sustainability of the planet, the environment, and its human and non-human inhabitants. Reducing greenhouse gasses (GHG) emissions, especially from animal agriculture is both urgent and critical (https://www.humanesociety.org/sites/default/files/docs/hsus-report-agriculture-global-warming-and-climate-change.pdf). This chapter however was aimed at evaluating the observed effects of fluctuation of climatic elements on livestock production and vice versa.

Climate Projection

The climate of the future is not clear due to how factors such as socioeconomics, technology, land use, and emissions of greenhouse gases will change and unfold (van Vuuren et al. 2011). A climate change scenario represents a specific possible future climate with for example high amounts of green technology contra a scenario with low amount of green technology. The dominant climate change scenarios are the representative concentration pathways (RCP) family of climate change scenarios. There exist mainly four RCP scenarios which are the RCP2.6, 4.5, 6, and 8.5. The two latter numbers indicate the radiative forcing target level for the year 2100 given a specific timeline, where the radiative forcing is the net change in the energy balance of the earth system due to some forcing agent expressed in watt per square meters (W/m^2) (Myhre et al. 2013; van Vuuren et al. 2011). These radiative forcers can be anthropogenic or natural, which can be greenhouse gas emissions or volcanic eruptions, respectively (Myhre et al. 2013).

The RCP2.6 trajectory signifies immediate anthropogenic intervention with strong climate change mitigation (van Vuuren et al. 2011). The RCP4.5 trajectory signifies stabilization of greenhouse gas emissions which like the RCP2.6 is also a scenario containing anthropogenic climate change mitigation but as prolific (Thomson et al. 2011). The RCP6 trajectory is similar to RCP4.5 but where climate change mitigation policies and technology implementations are not as strong (van Vuuren et al. 2011). The RCP8.5 trajectory signifies what is called as the “business as usual” trajectory with an increase in population, slow socioeconomic development, and slow innovation/implementation of technology (Riahi et al. 2011).

A core concept in the discussions around climate change is that of “adaptive capacity” or the potential of a society to adapt with the changes (if any) that might occur in the social ecological system from climate change (IPCC 2007a, b; McClanahan et al. 2008). Changes in climate have the potential to affect the agricultural industry which in turn can affect economic investment and population movements in countries. The livelihoods of many people, notably the poor and vulnerable, could be threatened if government and resource managers are not prepared for even the modest changes associated with climate change (Downing et al. 1997).

Climate of Nigeria

The climate of Nigeria is dominated by the influence of three main wind currents: the Tropical Maritime (TM) air mass, the Tropical Continental (TC) air mass, and the Equatorial Easterlies (EE) (Ojo 1977). The TM and TC air masses meet along the Inter-Tropical Discontinuity (ITD), which is a key driver of Nigeria’s climate. The position of the ITD and oscillation during the year affects the spatial and temporal distribution of key climate characteristics of the country (Adegoke and Lamptey 1999). Following the annual movement of the ITD across the Equator, the rainfall season over Nigeria advances from the coast to the inland areas from March to

August and retreats from September to November, with a pronounced dry period between December and February. The rainfall patterns in Nigeria show the southern parts of the country with annual rainfall over 3000 mm and semiarid conditions in the north with annual rainfall less than 500 mm.

Materials and Methods

Survey of Livestock Stakeholders

A survey of livestock stakeholders (farmers, researchers, marketers and traders) was carried out in Sahel, Sudan, Northern Guinea Savannah, Southern Guinea Savannah, and Derived Savannah zones of Nigeria (Fig. 1). The regions under these ecoclimatic zones cut across all the 19 States and the Federal Capital Territory (FCT) of Nigeria. In total, 362 respondents were interviewed between April and June 2020. The survey instrument used was designed as an online questionnaire (for literate respondents). The other respondents who cannot fill the online form were administered printed questionnaire for the survey.

The distribution of the respondents was 22 in Sahel, 57 in Sudan, 61 in Northern Guinea Savannah, 80 in Southern Guinea Savannah, and 106 in Derived Savannah (Table 2). The respondents were purposively interviewed based on their engagement in livestock production, research or trading activities. The researchers were sourced

through their institutional affiliations. The farmers and marketers were sourced through the Agricultural Development Programs and Ministry of Agriculture (or Livestock) of the 19 States in the Northern regions of Nigeria as well as FCT. Key informant interview was conducted with Alhaji Ibrahim Mohammed – Director, FADAMA and Infrastructural Development of Yobe State Agricultural Development Program, Yobe State. The primary data obtained from this work were analyzed using frequency counts and percentages through crosstab analysis of Statistical Package for Social Sciences (SPSS) Version 16.

Climate Data and Analysis

Representative locations were chosen for Sahel, Sudan, and Northern Guinea Savannah. Ilela, Kiyawa, and Sabon Gari were chosen to represent Sahel, Sudan, and northern Guinea Savannah zone of Nigeria, respectively. Thirty-eight years' climate data from 1982 to 2019 were obtained from Nigerian Metrological Agency, Abuja. The data contained precipitation, relative humidity, and minimum and maximum temperature. This chapter employed the use of grid data obtained from the US National Oceanic and Atmospheric Authority (NOAA) reanalyzed historic data and complimented with Soil and Water Assessment Tool (SWAT) data. The major climatic parameters used in this chapter are rainfall, relative humidity, and temperature. To understand the nature of rainfall variation and trend and to determine climate extremes, data from 1982 to 2019 (38 years) for all weather stations within the study area were used. Descriptive statistical methods such as mean and standard deviation were utilized. Furthermore, time series was used for the analysis of rainfall trend over time, and the Moving Average Technique was also used in the analyses of the data. This chapter employed the use of the 3-Year Moving Average. The moving average has the characteristics of reducing the amount of variation in a set of data. This property in the time series is used mostly to remove fluctuations that are not needed. The use of moving average resulted in the formation of new series in which each of the actual value of the original series is replaced by the mean of itself and some of the values immediately preceding it and directly following it Ayoade (2008). To estimate the value of a variable Y (i.e., rainfall), corresponding to a given value of a variable X (i.e., time), regression analysis was applied. This was accomplished by estimating the value of Y from a least-squares curve that fits the sample data.

Standardized Precipitation Index and Trend Analysis

The Standardized Precipitation Index (SPI) calculation used was based on the long-term precipitation record for the desired period. This long-term record is fitted to a probability distribution, which is then transformed into a normal distribution so that the mean SPI for the location and desired period is zero (Edwards and McKee 1997). Positive SPI values indicate greater than median precipitation, and negative values indicate less than median precipitation. Because the SPI is normalized, wetter and drier climates can be represented in the same way, and wet periods can also be monitored using the SPI.

A correlation was done to determine how well a linear equation describes or explains the relationship between variables. From this analysis, the coefficient of determination was obtained, this is given by R^2. The standardized precipitation values were calculated for all the years from the use of the long-term mean, yearly mean, and the standard deviation using the equation below:

$$\varphi = \frac{X - \overline{X}}{\sigma}$$

where φ represents the standardized departure, x is the actual value of the parameter (annual rainfall), ẍ is the long term mean value of parameter (30 years rainfall average), and σ is the standard deviation.

Confidence test was performed on the dataset used and it was verified using 95% confidence interval. Coefficients of skewness, kurtosis, and variation were also investigated.

Temperature Humidity Index

The temperature humidity index (THI) was calculated using the following formula:

$$THI = 0.8 * T + RH * (T\text{-}14.4) + 46.4$$

where T = ambient or dry-bulb temperature in °C and RH=relative humidity expressed as a proportion, that is, 75% humidity is expressed as 0.75.

Results and Discussion

Rainfall Trend/Patterns in Nigeria from 1982 to 2019

The analysis shows the standardized rainfall anomaly over different climatic zones in Nigeria from 1982 to 2019. In the coastal, tropical rainforest, guinea, Sudan savannah areas, it was observed that there are more wet years than dry years. But for the Sahel savannah, the dry years were more than the wet years during the 48 years study period. The result corresponds to IPCC projection stating that the coastal areas are prone to more wet years leading to the occurrence of flooding and rainfall induced erosion, while region around the Sahel will experience more of drought as a result of reduction in the total precipitation.

Comparison of Variations in Climatic Elements Among Sahel, Sudan, and Northern Guinea Savannah Zones

Precipitation

Figure 2 showed the weighted average precipitation for Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria. Ilela in Sokoto State was used as a reference point for Sahel while Kiyawa, Jigawa State and Sabon Gari, Kaduna State were used as reference points for Sudan and Northern Guinea Savannah zones, respectively. The number of months with substantial period of precipitation was seven from April to October at Ilela (Sahel). The maximum precipitation (7.86 mm) was recorded in July. Similar trends of duration of precipitation were also observed at Kiyawa and Sabon Gari. However, the maximum amount of precipitation was 11.97 and 12.31 mm, respectively, for Kiyawa and Sabon Gari. Figure 3 showed the average total precipitation (mm) for Sahel, Sudan, and Northern Guinea Savannah zones of

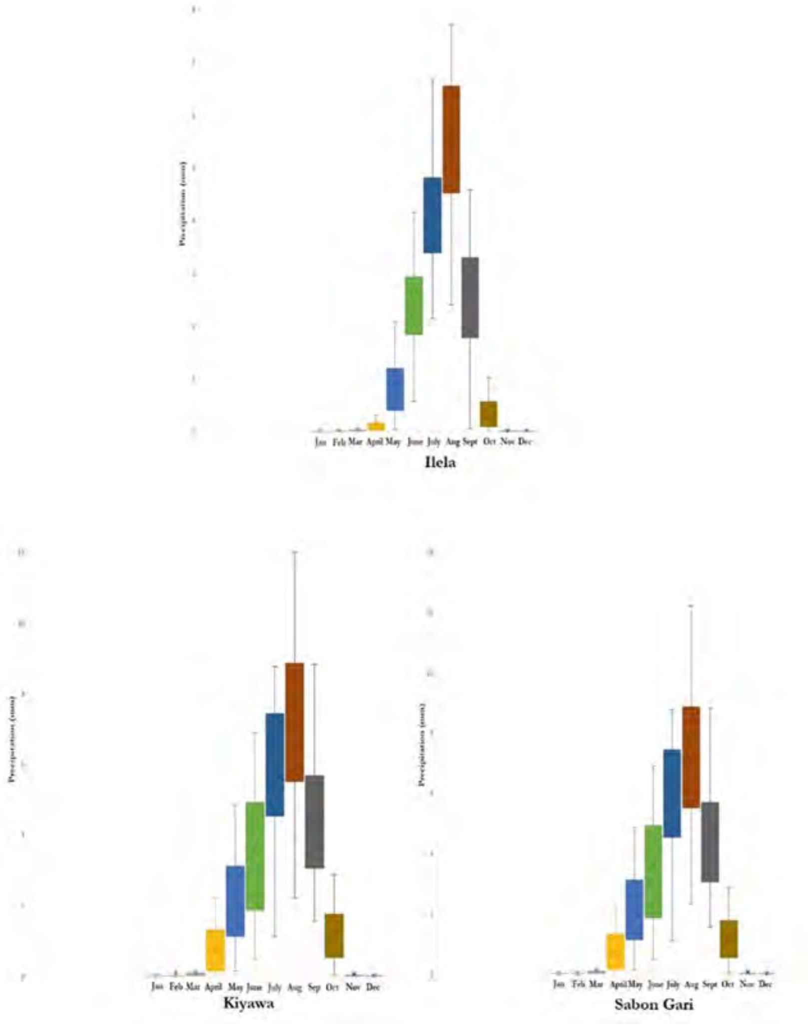

Fig. 2 Weighted average precipitation for Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria for 1982 to 2019

Nigeria from 1982 to 2019. The average total volume of precipitations within the 38 years for the three zones were 614.79, 937.32, and 958.58 mm, respectively, for the Sahel, Sudan, and Northern Guinea Savannah zones. The volume of precipitation for Sudan and Northern Guinea Savannah were almost similar for most periods of the year except for July, August, and September when the volumes of rainfall was higher in Northern Guinea Savannah zones of Nigeria. The onset and end of rainfall in the two regions were similar.

Analyses of Standardized Precipitation Index (SPI) over the Sahel Savannah of Nigeria are presented in Fig. 5. The figure showed that in the first decade (1971–1980) and the second decade (1981–1990) the whole region had mostly

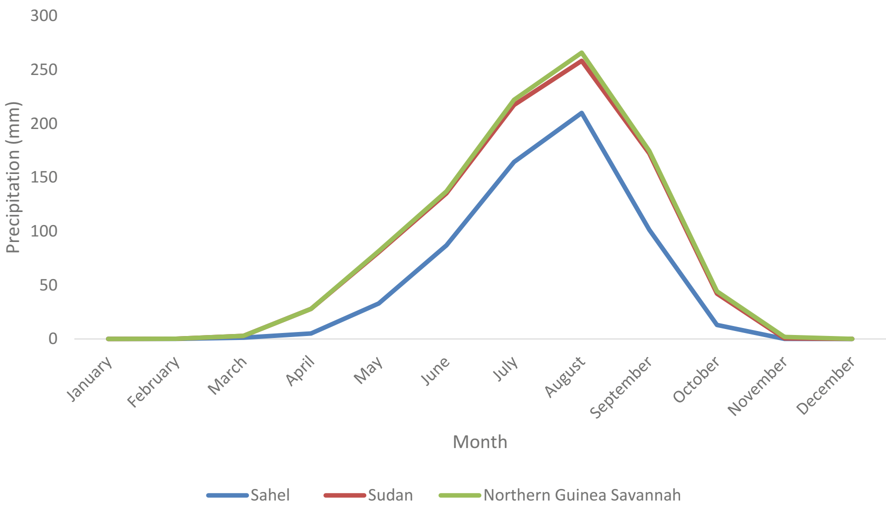

Fig. 3 Average total precipitation (mm) for Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria for 1982 to 2019

negative anomalies. This indicates the zone suffered from serious hydrological drought from 1971 to 1990. However, there was a recovery to positive anomalies in the third decade (1991–2000), fourth decade (2001–2010), and the current decade (2011–2018). The dry years were more than the wet years during the 48 years study period. The result shows the region recorded 27 dry years and 19 wet years which corresponds to IPCC (2007a) projection stating that the Sahel will experience more of drought as a result of reduction in the total precipitation. With the predominant dry years in the region, water erosion should not have been a problem. Areas affected by water erosion challenges in the region indicates the little rainfall amount recorded occurred at very short interval with high intensity thereby generating runoff. This rainfall pattern is typical under a changing climate.

The analysis shows rainfall trend over Sahel Savannah of Nigeria for 1982–2019 as shown in Fig. 1. From 1981 to 1997 rainfall was increasing and decreasing in cycle of 4–5 years, though the cycle was in a declining rainfall order. During the first decade (1982–1990), the pattern showed decreasing rainfall amount. The second decade (1991–2000) up to 2018 showed a steady increase in rainfall amount a little above the average for region. This trend showed by the moving average for the region is in line with the work of Nicholson and Palao (1993), who reported that rainfall in West Africa generally decreased with latitude with essentially zonal isohyets.

Rainfall Trend/Patterns in Guinea Savannah of Nigeria

Analyses of Standardized Precipitation Index (SPI) over the Guinea Savannah of Nigeria clearly show that the first decade (1982–1991) had positive anomalies, and in the second decade (1981–1990) the whole region had mostly negative anomalies.

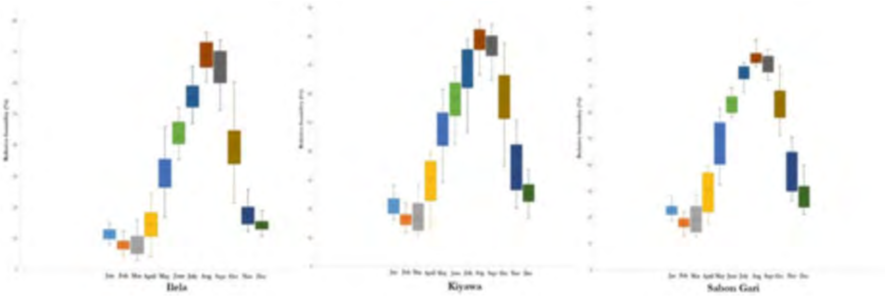

Fig. 4 Weighted average of relative humidity for Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria for 1982 to 2019

However, there was a recovery to positive anomalies in 1991–2000, 2001–2010, and 2011–2018. The dry years were more than the wet years during the 38 years study period. The result shows the region recorded 22 dry years and 15 wet years which corresponds to IPCC projection stating that the region will experience more of wetness as a result of increase in the total precipitation. This is an indication of increased rainfall pattern in the Guinea Savannah region of Nigeria.

Figure 3 shows the rainfall trend over Guinea Savannah of Nigeria for 1971–2018. In the first decade (1971–1980) and the second decade (1981–1990), it was observed that rainfall was below normal (1971–2000) in the region. During the third (1991–2000), fourth (2001–2010), and current decade (2011–2018) it shows a steady increase in rainfall amount in the region above normal. This result is in line with the work of Nicholson and Palao (1993), who reported that rainfall in West Africa generally decreased with latitude with essentially zonal isohyets.

Relative Humidity

The variations of relative humidity for the zones being considered in this chapter are depicted in Fig. 4. The highest proportions of relative humidity were record in August in the three zones being considered in this chapter. However, the amount of water in the atmosphere was lowest in March of every year across the three regions as shown in Fig. 4. The highest values for relative humidity were 81.11%, 85.55%, and 88.06% in Sahel, Sudan, and Northern Guinea savannah zones, respectively. The lowest value also follows similar trend of decreasing northward the zones with 7.77%, 10.09%, and 12.53%, respectively, for Sahel, Sudan, and Northern Guinea savannah zones.

Atmospheric Temperature

Figures 5 and 6 show the minimum and maximum temperature in the Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria as represented by Ilela, Kiyawa, and Sabon Gari. The highest value for minimum temperature was observed in May

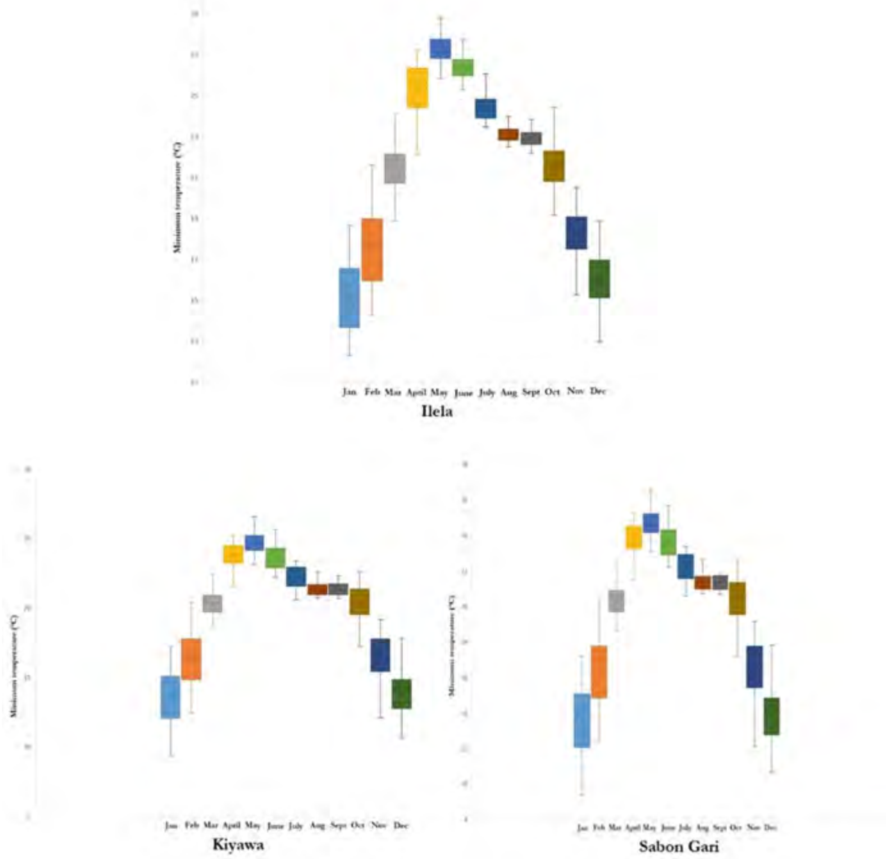

Fig. 5: Weighted average of minimum temperature for Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria for 1982 to 2019

and the coldest temperature was in January. While the coldest temperature at Ilela, the Sahel climate, is 12.29 °C; the other two climate zones had similar values of 9.34 °C. Ilela had the highest value for the minimum temperature which was 28.76 °C which was followed by 26.55 °C recorded for Sabon Gari and the least among the three climate zones was 25.19 °C recorded by Kiyawa. The hottest average temperature recorded in all the three zones for the period under consideration in this chapter was 42.55 °C which was recorded at Ilela in the Sahel climate.

The Concept of Temperature Humidity Index

Figures 7 and 8 show the temperature humidity index as calculated using minimum and maximum temperatures, respectively. Animals, especially cattle, start having mild stress from index of 72 to 78. Severe stress starts from 79 to 88 (Table 1). Using the minimum temperatures as reference, the animals in Sahel ecoclimate were mildly

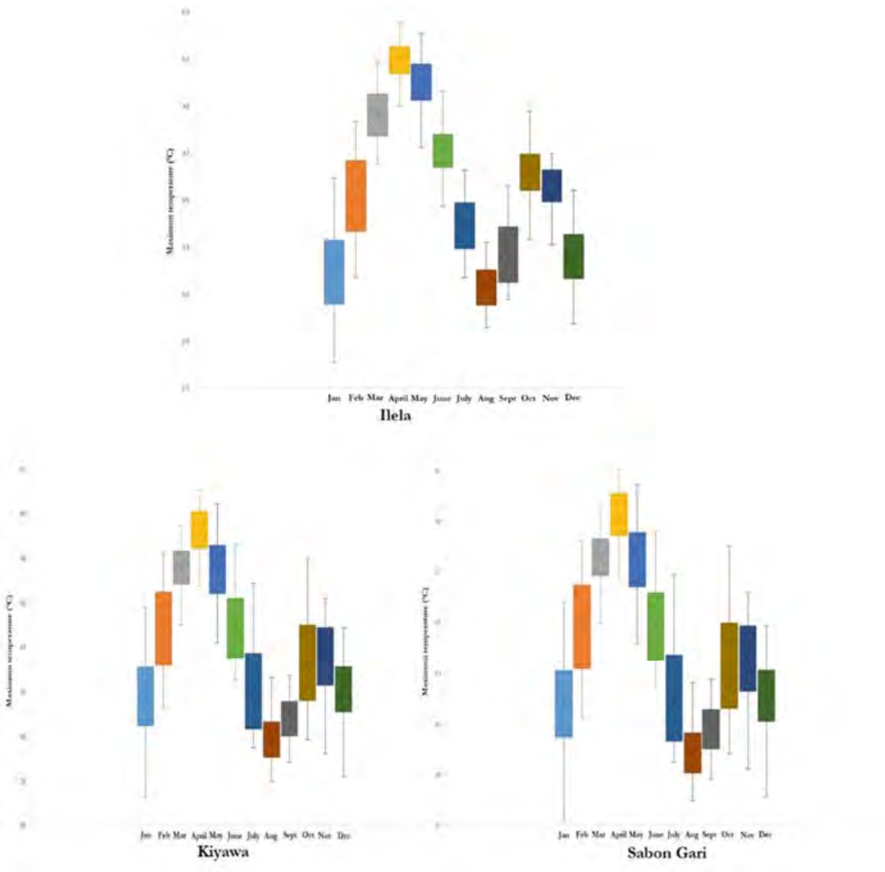

Fig. 6 Weighted average of maximum temperature for Sahel, Sudan, and Northern Guinea Savannah zones of Nigeria for 1982 to 2019

stressed due to heat and relative humidity interactions in May, June, and some days of July. Considering the animals during the maximum temperatures; they were mildly stressed in January, February, and December. That is the period of *harmattan* in the region. However, the animals are severely stressed for most of the other periods of the year. There were occasions of very severe stress on the animals during some parts of May and June (Fig. 8).

Livestock Production Characteristics in Sahel, Sudan, and Guinea Savannah Zones of Nigeria

Table 2 shows the production characteristics of livestock stakeholders in the Savannah and *Sudano-Sahelian* zones of Nigeria. Majority of the respondents were livestock farmers (62.3%). Substantial proportions of the respondents were research

Fig. 7 Temperature humidity index using minimum temperature at Ilela, Sokoto State, as reference point for Sahel ecoclimate zone

Fig. 8 Temperature humidity index using maximum temperature at Ilela, Sokoto State, as reference point for Sahel ecoclimate zone. According to the information in Table 1

scientists (28.2%) that are dealing with livestock production in the various agro-ecological zones covered in this chapter. About 10% of the respondents were dealing in buying and selling of livestock and poultry. Half the number of the stakeholders interviewed about the interrelationships between climate change and livestock

production preferred intensive management system of production. This can be explained because more than 40% of them are into commercial poultry production. Semi-intensive is a system of choice for ruminant animal production and it is preferred by 40.8% of the stakeholders interviewed in this chapter. Umunna et al. (2014) reported 56.3% of small ruminant producers rearing their stock through semi-intensive system.

The distribution of respondents was also shown in Table 3. The largest proportion of respondents (32.5%) was from Derived Savannah zone of Nigeria. This is commensurate to the very large land area of this zone when compared with some of the other zones (Fig. 1). The least population of respondents (6.7%) was from the Sahel zone. The Sahel zone in Nigeria is found at the uppermost portion of the country. Suleiman (2017) described the Sahel region of Africa as a 3,860-kilometer

Table 3 Features of Savannah and *Sudano-Sahelian* zones being experienced by respondents

Feature	Sahel N=22	Sudan $N = 57$	Northern Guinea Savannah $N = 61$	Southern Guinea Savannah $N = 80$	Derived Savannah $N = 106$	Total $N = 326$

Mostly flat plane topography	5 (22.7)	11 (19.3)	16 (26.2)	20 (25.0)	21 (19.8)	73 (22.4)

N is the number of respondents; values in parenthesis are the percentages of their respective frequencies

arc-like land mass lying to the immediate South of the Sahara Desert and stretching East-West across the breadth of the African continent. He further stated that the region stretches from Senegal on the Atlantic coast, through parts of Mauritania, Mali, Burkina Faso, Niger, Nigeria, Chad, and Sudan to Eritrea on the Red Sea coast.

Almost all the respondents (92%) were aware of the concept of climate change and its other attribute of global warming. Very high awareness level of climate change (88%) was reported by Adebayo and Oruonye (2012) among farmers in Northern Taraba State.

The features that best describe Savannah and *Sudano-Sahelian* zones of Nigeria were presented in Table 3. Seasonal variation in availability of natural forage was reported by all the respondents interviewed in Sahel and Sudan zones. About 95% of the respondents in Northern Guinea Savannah zones corroborated the scarcity or non-availability of natural forages during the dry seasons. Life-threatening high temperature during dry season was also reported as 63.8% by 326 respondents. Low temperatures during *Harmattan* period were reported as 95.5%, 80.7%, 39.3%, 22.5%, and 17.0% by respondents from Sahel, Sudan, Northern Guinea Savannah, Southern Guinea Savannah, and Derived Savannah, respectively.

The *Harmattan* is a season in the West African subcontinent starting from November to mid-March. The season is highly dependent on air pressure variability in the Mediterranean area. The Harmattan period is dust laden and also characterized by low temperatures (Schwanghart and Schutt 2008). In Sahelian parts of Africa, Aeolian dust transport is made possible by several wind systems (Jäkel 2004; Engelstaedter et al. 2006). One of the wind system is *Harmattan* (Schwanghart and Schutt 2008).

Low precipitation was also reported in Table 3. The proportions of the respondents that stated low precipitation as a prominent feature of the climate system were highest for Sahel (86.4%) and lowest for Derived Savannah (21.7%). This is an indication that there is more aridity in the Sahel and less in the Derived Savannah. Variability in Sahel rainfall is inextricably connected with the variability of the atmospheric circulation. Annual mean rainfall in the Sahel of Nigeria is less than 200 mm (Biasutti 2019). The author opined that across the zones, abundance or scarcity of rainfall and its distribution over the rainy season and the associated maximum temperature extremes determines the success or failure of farming system with its antecedent effects on livestock production. Desert encroachments were reported as a feature of Sahel (59.1%) and Sudan (45.6%) zones. Nigeria is faced with rapid desert encroachment affecting 15 states in the North. Most of the States covered in this chapter were described as desertification frontline States by Olagunju (2015).

Livestock Population in Nigeria

The total population of cattle in Nigeria was 20,407,607 in 2019 as against 20,231,589 in 2018. The distribution of cattle in States within Nigeria was illustrated through Fig. 9. Zamfara tops the list of States with 3,432,486 heads of cattle. The goat population in Nigeria was totaled at 46,757,458 in 2019. The highest population of goats (5,488,904) in 2019 was recorded in Katsina State (Fig. 10). Like as it is for cattle, Zamfara State tops the list of states for sheep production with the population size of 7,314,023 sheep (Fig. 11). These populations were reported in the Executive summary of Annual Performance Survey of National Agricultural Extension and Research Liaison Services in Nigeria (NAERLS 2019).

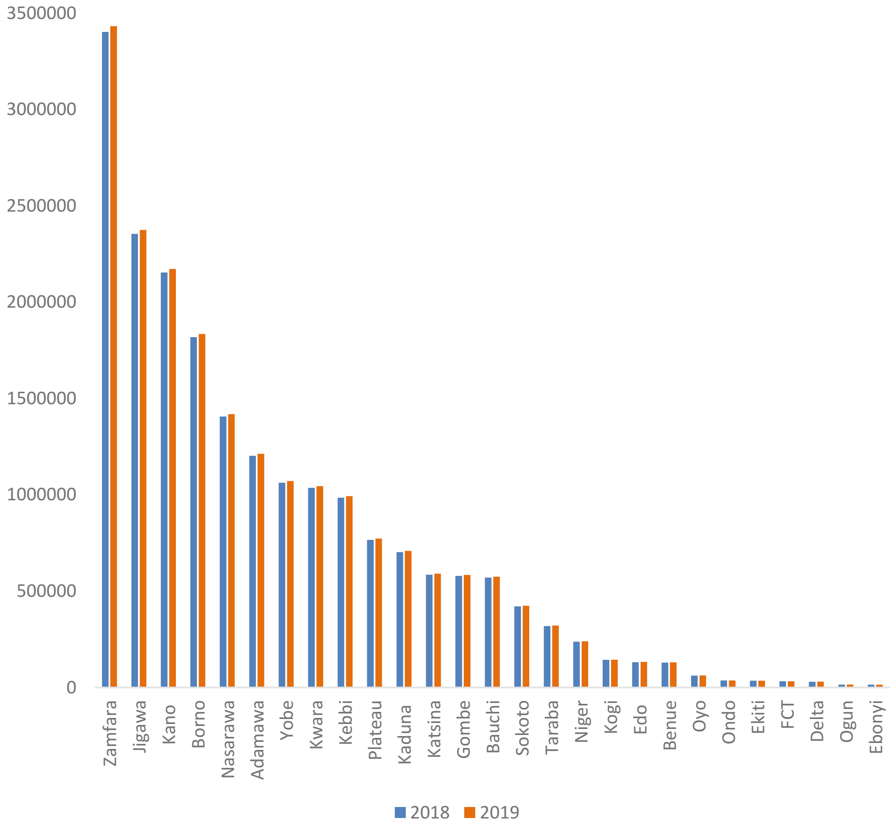

Fig. 9 Cattle population in Nigeria. (Source: Federal Department of Animal Production and Husbandry Services, FMARD, Abuja (Reported by NAERLS 2019))

The total populations of donkeys in Nigeria were 978,402 and 979,380 for 2018 and 2019, respectively (NAERLS 2019). The beast of burden (donkey), a very resilient animal is found mostly in about 11 states of the country (all within Sahel, Sudan, and Northern Guinea Savannah Zone of Nigeria) with the highest population found in Zamfara State (331,641) in 2019. Other states with prominent populations of donkeys in 2019 were Sokoto (153,657), Borno (143,707), Kano (135,962), Kebbi (82,870), Jigawa (25,135), and Gombe (14,241). Some other states like Bauchi and Yobe had populations of donkeys that are less than 1,500.

Camel is another livestock used as beast of burden in Nigeria. The total populations of camels in the country were 279,956 and 280,235 for 2018 and 2019, respectively. Almost half of all the camel population in Nigeria was found in Kano State with 128,104 heads of camel. Other states with some populations of camel in 2019 were Sokoto (60,346), Kebbi (50,483), Jigawa (12,851), Katsina (9,581), Bauchi (9,475), Niger (3,270), and Yobe (501). It was of note that the rate of increase in population of camel and donkey is very negligible. These animals (camel and donkey) are reported to

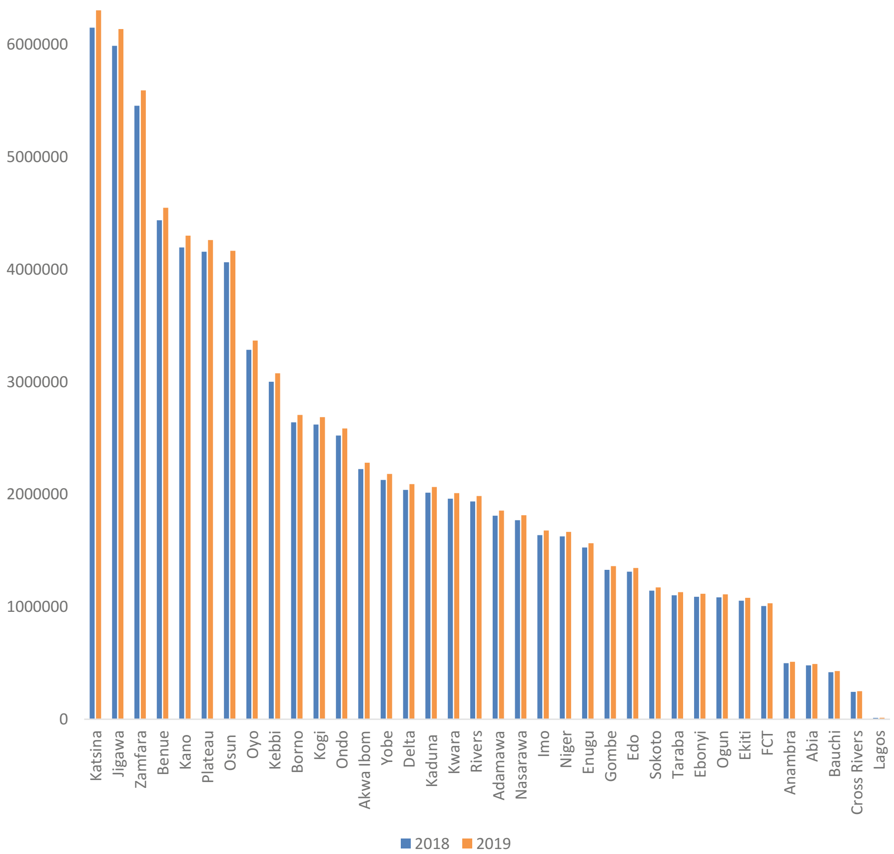

Fig. 10 Goat population in Nigeria. (Source: Federal Department of Animal Production and Husbandry Services, FMARD, Abuja (Reported by NAERLS 2019))

be dwindling in number as there is increased consumption and less production, therefore ways of increasing the population of this animal should be scientifically exploited to avoid the extinction of the species (Nelson et al. 2015).

The possible factors responsible for large population of livestock in the Savannah and *Sudano – Sahelian* zones of Nigeria were presented in Table 3. On the top of the list of such factors is the abundance of grasses, legumes, and other fodder crops as indicated by 59.8% of the respondents. Large expanse of grassland was also said to be a prominent factor enabling large population of livestock on the semiarid zone of Sahel, Sudan, and the Guinea Savannahs. Other factors being reported in favor of the large population of livestock in the zones being considered in this chapter were low infestation of pathogens during wet and dry seasons with 33.7% and 32.2%, respectively. About 22% of the respondents stated that the flat plane topography in the zones might have contributed to the enormous populations of livestock being found in the zones. Lawal-Adebowale (2012) stated that the concentration of

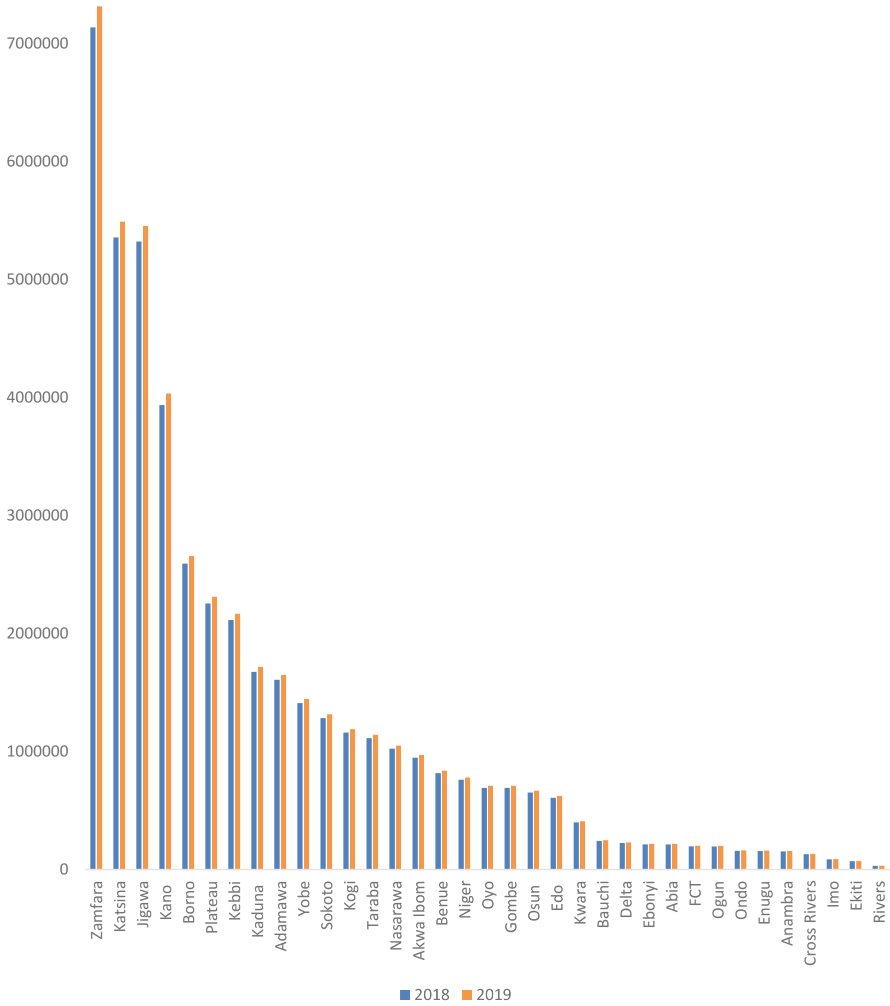

Fig. 11 Sheep population in Nigeria. (Source: Federal Department of Animal Production and Husbandry Services, FMARD, Abuja (Reported by NAERLS 2019))

Nigeria's livestock-base in the northern region is most likely to have been influenced by the ecological condition of the region which is characterized by low rainfall duration, lighter sandy soils, and longer dry season. This submission was predicated by the fact that drier tropics or semi-arid regions are more favorable to the ruminants. However, concerted efforts need to be made at retaining the large population of livestock in these regions (Savannah and *Sudano-Sahelian*) because livestock production will be possibly limited in the future by climate variability as animal's water consumption is expected to increase. There will be more demand for agricultural lands because of increase due to need for 70% growth in production, and food security concern since about one-third of the global cereal harvest will be needed for livestock feed (Rojas-Downing et al. 2017).

Table 4 showed the stakeholders perception of the effect of changes on climatic elements of livestock production in the Savannah and *Sudano-Sahelian* zone of Nigeria. About 77% of all the respondents agreed to the fact that changes in climatic

N is the number of respondents; values in parenthesis are the percentages of their respective frequencies elements affect livestock productivity. Kebede (2016) related the foremost reaction of animals under thermal weather as increase in respiration rate, rectal temperature, and heart rate. He further stated that the anticipated rise in temperature due to climate change is likely to aggravate the heat stress in livestock, adversely affecting their productive and reproductive performance and even death in extreme cases. The respondents observed that the climatic elements with most variations are atmospheric temperature (50.0%), rainfall (36.8%), and sunshine hour (5.8%). The climatic element with the least variation as being reported by the respondents is solar radiation (0.3%). Atmospheric temperature was also implicated by 69.9% of the respondents as a climatic element with the most debilitating effect on livestock when its variation is in the extreme. This was followed by relative humidity with 24.5% of the respondents stating that its effect can really affect livestock productivity.

Adaptive Measures Against the Effect of Climate Change on Livestock Production

Useable adaptive measures toward reducing the effects of climate change on livestock production are presented in Table 5. About 55% of the respondents agreed that the use of adaptive measures in alleviating the effect of climate change on livestock is capable of reducing its debilitating effect on livestock. The rest of the respondents, about 45%, were either neutral or disagreed with the fact that adaptive measures can mitigate the effect of climate change. It will be necessary to educate those that disagree on this very important fact. To guide the evolution of livestock production systems under the increase of temperature and extreme events, better information is needed regarding biophysical and social vulnerability, and this must be integrated with agriculture and livestock components (Nardone et al. 2010). The specific adaptive measures used by livestock farmers in the study locations are shown in Table 5 as well. At the top of the adaptive features of choice by respondents is provision of housing facilities for animals which was indicated by about 60% of the respondents. Provision of abundant water and supplements feeding were also indicated as adaptive measures by 45.4% and 44.2% of the respondents, respectively. Planting of tress to provide shades for livestock was of great interest because of the sustainable effect of this adaptive measure to livestock production. Trees are known to absorb carbon dioxide produced by man and animals that is apart from their primary function of shades as intended by livestock farmers. Development of superabsorbent fake leaves was proposed by scientists (Vince 2012) as a means of modulating the global temperature. This method was proposed as capable of removal of greenhouse gas from the atmosphere. The benefits of the introduction of artificial plants will be centered on geoengineering the planet which will be beyond its cooling effects.

Timely control of internal and external parasites was a choice of adaptive measure by a third of the respondents (31.3%). This is expected to eliminate the stress on health status of the animals which will go a long way in stabilizing the internal physiological equilibrium of the animals. If properly done, the animals will have enough energy to

N is the number of respondents; values in parenthesis are the percentages of their respective frequencies

combat stress from the environment. Storage of excess feed, especially during harvest, was stated as an adaptive measure by 32.5% of the respondents. This adaptive measure can be linked with another one that was also stated by the stakeholders, storage of crop residues obtainable during harvest (26.4%). These two measures are some of the important components of crop-livestock integration systems as discussed by Iyiola-Tunji et al. (2015). Feeding livestock with crop residues in a well-planned basis on the nutrient requirements and biomass needs of these animals will ensure adequate usage of the crop residues. Establishment of ranch, irrigation of pasture during dry season, making of multi-nutrient blocks, feeding of livestock with multi-nutrient blocks and seasonal migration of animals were of the other adaptive measures being carried out to combat the effect of climate change as reported by substantial proportion of the respondents. Integrating livestock and crop production will serve as a form of conservation, which will enable shifting from the traditional systems which is focused exclusively on livestock or crop to a new approach which sustainably combines both. Agroforestry (establishing trees alongside crops and pastures in a mix) as a land management approach can help maintain the balance between agricultural production, environmental protection, and carbon sequestration to offset emissions from the sector. Agroforestry may increase productivity and improve quality of air, soil, and water, biodiversity, pests and diseases, and improves nutrient cycling (Jose 2009; Smith et al. 2012).

Contribution of Livestock Production Activities Toward Climate Change

Table 6 showed the contribution of livestock production activities toward climate change. A lot of the stakeholders interviewed (62.3%) were aware of the

N is the number of respondents; values in parenthesis are the percentages of their respective frequencies contribution of livestock production to climate change. Generations of substantial proportions of global greenhouse gases that are very bad for the environment were on the knowledge of more than half of the respondents (53.4%). Just about the third (35%) of the respondents were aware that livestock and their by-products account for several million tons of carbon dioxide production per year. Very large proportions (73.6%) of respondents were aware that extensive system of livestock production plays a critical role in land degradation, climate change, water, and biodiversity loss. About 90% of the respondents however believed that economic, social, health, and environment perspectives are critical to solving the problems of the contributions of livestock production to climate change and global warning. In 2006, an FAO publication entitled “Livestock’s long shadow – Environmental issues and options” indicated that the influence of livestock on the environment was much greater than it was considered. This provided detailed perspectives on the impact of livestock on water, biodiversity, and climate change. The issue on climate change and 18% estimated contribution of livestock to overall GHG emissions is the concern that attracted the most attention. The FAO (2006) estimated 18% anthropogenic GHG emissions from livestock industry is disapproved by Goodland and Anhang (2009) who noted that the figure under-tallies emissions from certain production activities, underestimates demand, and absolutely omits some categories of emissions. They estimated that livestock production is contributing about 51% of anthropogenic GHG emissions. Goodland and Anhang (2009) revealed that CO_2 from livestock respiration was ignored as a source of the GHGs from the FAO study (2006). Both manure and enteric fermentation contribute some 80% of methane emissions from agricultural activities and about 30–40% of the overall anthropogenic methane emissions (FAO 2006). The 62–89% of greenhouse emission recorded in this chapter was similar to the findings of FAO (2006). Similarly, there is an increasing awareness within the policy and research communities that fast growth in consumption and production of livestock commodities is contributing to variety of environmental problems. The main notable issue is livestock’s significant contribution to anthropogenic emissions. Majority of the revenue is generated by pigs, chickens, sheep, goats, beef, and dairy cattle. These five species of livestock generate 92% of the overall revenue from livestock in Africa. In most rural communities, livestock is the only property of the poor, but it is highly susceptible to climate changes and extremes (Easterling and Aggarwal 2007; FAO 2007; Calvasa et al. 2009). The influence of climate change is anticipated to increase the susceptibility of livestock industry and reinforce current factors that are having impact on livestock farming systems (Gill and Smith 2008). The overall GHG emissions from livestock supply chains are approximately 7.1 gigatons CO_2-equivalent annually for the 2005 reference point forming about 14.5 % of all emissions induced by humans (IPCC 2007a). About 44 % of the livestock industry emissions are in the form of CH_4. Nitrous oxide and carbon dioxide represent 29% and 27%, respectively. Livestock supply chains emit 9.2 gigatons CO_2-eq of CO_2 annually or 5% of anthropogenic CO_2 emissions (IPCC 2007b). According to IPCC (2007b), 44% of anthropogenic CH_4 emissions or 3.1 gigatons CO_2-eq of CH_4 every year and 53% of anthropogenic N_2O emissions or 2 gigatons CO_2-eq of N_2O are produced annually. Similar results were observed in this chapter, which reported that livestock products account for 88–93% (Table 6) of the carbon dioxide production per year.

Adaptive Measures Toward Mitigation of Effect of Climate Change on Livestock

An adaptation such as the modification of production and management systems involves diversification of livestock animals and crops, integration of livestock systems with forestry and crop production, and changing the timing and locations of farm operations (IFAD 2010). Diversification of livestock and crop varieties can increase drought and heat wave tolerance, and may increase livestock production when animals are exposed to temperature and precipitation stresses. In addition, this diversity of crops and livestock animals is effective in fighting against climate change-related diseases and pest outbreaks (Kurukulasuriya and Rosenthal 2003; Batima et al. 2005; IFAD 2010). Changes in breeding strategies can help animals increase their tolerance to heat stress and diseases and improve their reproduction and growth development (Rowlinson et al. 2008; Henry et al. 2012). Adjusting animal diets can also be used as a mitigation measure, by changing the volume and composition of manure. GHG emissions can be reduced by balancing dietary proteins and feed supplements. If protein intake is reduced, the nitrogen excreted by animals can also be reduced. Supplements such as tannins are also known to have the potential to reduce emissions. Tannins are able to displace the nitrogen excretion from urine to feces to produce an overall reduction in emissions (Hess et al. 2006; Dickie et al. 2014). Some of the adaptable technologies for reducing the effect of livestock production activities on climate change and vice versa are also presented in Table 7 and discussions on each of them are presented below.

Proper Livestock Health Management and Welfare

On the top of the list of technologies as dictated by the respondents (63.2%) is proper livestock health management and welfare. Reducing greenhouse gas (GHG) emissions may seem like extra work that can hurt business, but in reality, best management practices for reducing GHG emissions can be economical (Lindgren 2019). Animals that are maintained in optimum health conditions and given adequate welfare will have improved production efficiency and reduction of methane production from digestion of feeds.

Adequate Waste Management and Utilization

Almost equally important technology is adequate waste management and utilization as proposed by 59.2% of the respondents. The major contribution to greenhouse gas emissions is methane (CH_4) from ruminant animals through belching when the animals digest their feeds (Plate I). The other sources of the deleterious gases are from fecal waste excretion and storage. Adequate waste management and utilization is capable of reducing the quantity of the greenhouse gases

Table 7 Adaptable technologies for reducing the effect of livestock production activities on climate change

emissions. Livestock farmers in the Sahel, Sudan, and the Guinea Savannah zones of Nigeria use the fecal waste as organic fertilizers for crop production. There were occasions where the litter materials from poultry production are fed to cattle (Lamidi 2005).

Crop-Livestock Integration Systems

A lot of the effect of livestock production on climate change can be eliminated if the farmers can engage in crop-livestock integration systems. About half of the respondents (50.3%) agreed to this fact. Ickowicz et al. (2012) presented three variants of CLIS in

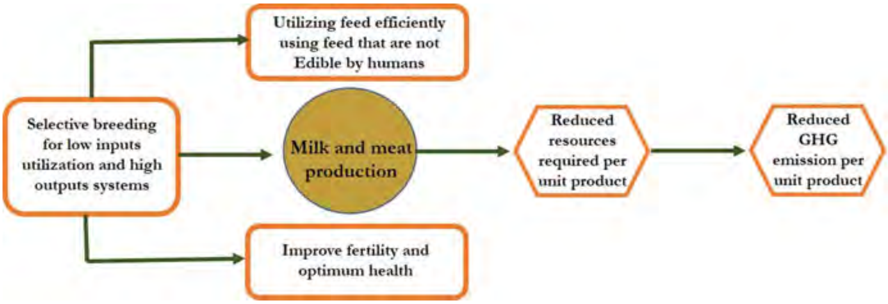

Fig. 12 Production efficiencies using management that can reduce GHG emissions beginning with selective breeding of a genotype for a particular system. (Adapted from Bell et al. (2012); modified by Iyiola-Tunji, A.O.) © 2012 Bell MJ,. Eckard RJ, Pryce JE. Published in [short citation] under CC BY 3.0 license. Available from: http://dx.doi.org/10.5772/50395

arid and semiarid areas: (i) livestock only grazing systems, (ii) rainfed mixed crop-livestock systems, and (iii) irrigated mixed crop-livestock systems. CLIS combine cereal crops (mainly millet, cowpea, sorghum, cotton and groundnut) and majorly ruminant animal production activities in different proportions. Crop-livestock integration systems (CLIS) enable recycling of products and wastes between crop production and livestock production. These methods are capable of increasing feed resources availability during the dry season and also replenish the soil for crop production through the use of fecal wastes from livestock. The major engagement of agro-pastoralists in Nigeria involves CLIS in a way though biomass inputs and outputs recycling are not scientifically calculated by the farmers (Iyiola-Tunji et al. 2017).

Breeding for More Productive Animals

Breeding for more productive animals was suggested by 50% of the respondents as an adaptive measure for reduction of greenhouse gas emissions. Selective breeding that is aimed at improving production efficiencies had been reported to result into increase productivity and gross efficiency by optimize the cost of production and reduce the number of animals that are needed to produce the same quantity of products (Bell et al. 2012). Reports from van de Haar and St. Pierr (2006) and Chagunda et al. (2009) related that more energy-efficient animals produce less waste in the form of methane and nitrogen excretion per unit product. The path toward reduced emission of greenhouse gases through selective breeding is depicted in Fig. 12. Animals that are selectively bred to utilize low inputs and give high outputs are expected to produce milk and meat (as the case may be) efficiently. The quantity of GHG emissions will be reduced once the number of animals put into productive is reduced.

Use of Methane-Reducing Feed Additives

The use of methane reducing feed additives was stated by 26.4% of the respondents as being capable of reducing the effect of livestock production activities on GHG emissions. Kataria (2015) observed that the practice of using feed additives to mitigate enteric methane production is more prominent in developed countries of the world where ruminant livestock are kept in well-managed production systems and generally fed diets that are very high in digestibility and nutrients. The results of this practice according to the author are an efficient production (milk or meat) relative to the amount of methane emitted. Klop (2016) expressed the advantage of using feed additives to mitigate GHG emissions as they are supplied in such amounts that the basal diet composition will not be largely affected by the feed additives (Klop 2016). Methane-reducing feed additives and supplements inhibit methanogens in the rumen, and subsequently reduce enteric methane emissions (Curnow 2019). Methane-reducing feed additives and supplements can be synthetic chemicals, natural supplements and compounds, such as tannins, and seaweed fats and oils (Curnow 2019). van Zijderveld et al. (2010) had experimented with lauric acid, myristic acid, linseed oil, and calcium fumarate as additives and obtained favorable results in the reduction of GHG emissions. Sunflower oil and monensin offer the greatest reductions in methane without substantial reductions in diet digestibility (Beauchemin and McGinn 2006). It is of note that the practice of using feed additives as an adaptive measure to reduce GHG emissions in developing countries like Nigeria is almost nonexistent.

Ranching

To further reduce livestock's greenhouse gas emissions while continuing to provide meat for a growing world population, beef cattle ranchers are proactively implementing methane-reducing methods to manage manure, improve soil health, and enhance herd efficiency. Ranching will enable farmers to consciously engage in practices that are capable of mitigating the effect of climate change on their livestock and also make attempt at GHG emissions from their livestock.

Pathway of Responses

The dual pathways of responses between climate change and livestock production activities are depicted in Fig. 13. Activities from livestock have very high tendencies to impact negatively on the environment and eventually causing unfavorable variability of climate and its elements, which is indicated by the blue big (fat) arrow that goes away from livestock to the environment and climate. The major component of the activities of livestock that is known to cause injury to the environment as depicted in Fig. 13 is the production of greenhouse gases (shown in an orange box on the right-hand side of the pathway). From the respondents in this study, some adaptive measures were stated as having controlling and mitigating effect at reducing the effect of activities of livestock on the climate and the environment. When these measures such as planting of trees to absorb CO_2, adequate waste management and utilization, feeding of livestock with methane reducing feed additives, and breeding of animals with faster growth rate are effectively deployed, the destruction of the environment will be reduced. Key breeding traits associated with climate change

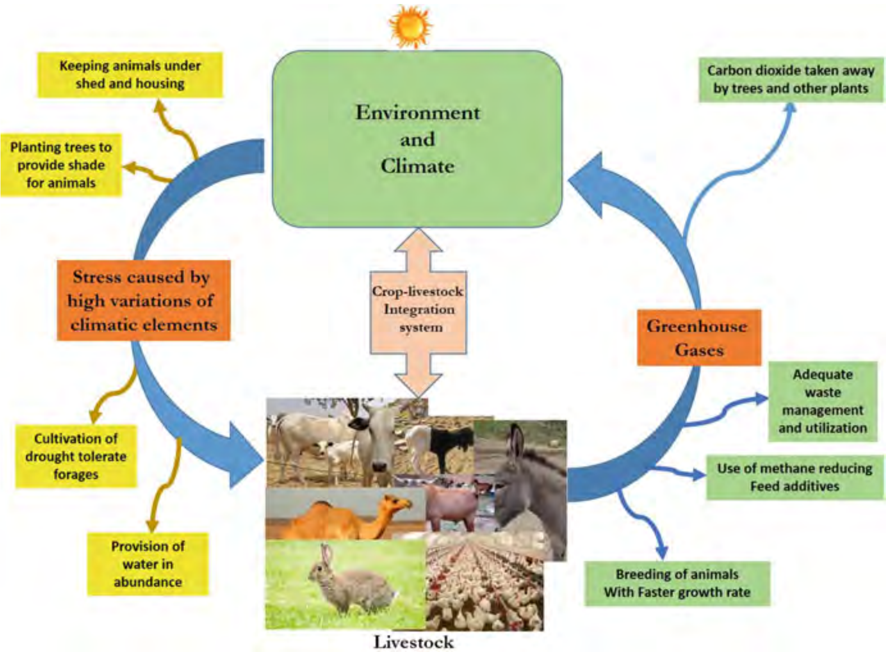

Fig. 13 Dual pathways of responses between climate and livestock

resilience and adaptation include thermal tolerance, low quality feed, high survival rate, disease resistance, good body condition, and animal morphology (Hoffmann 2008; Oseni and Bebe 2008). In general, developing countries have a weak capacity for high-tech breeding programs toward livestock improvement (IFAD 2002). Therefore, programs based on controlled mating methods are likely to be more appropriate. These programs usually do not produce immediate improvements. Improvements are usually not seen for at least one growing season, so a livestock producer must be able to incorporate long-term planning into production management strategies. Such measures could include:

- Identifying and strengthening local breeds that have adapted to local climatic stress and feed sources
- Improving local genetics through cross-breeding with heat and disease tolerant breeds

The environment and climate on the other side of the dual pathway is also known to induce stress on livestock. The respondents in this chapter stated that the components of the pathway that are in yellow boxes are capable of limiting the stress caused by high variations of climatic elements. The concept of crop-livestock integration system is advocated in this chapter as beneficial to livestock and environment in the short and long run.

Predicting Climatic Conditions Using Machine Learning Approach

The ability to forecast climatic conditions is essential for proper planning in livestock production. Machine learning (ML) approach leverages on past data to predict future events. Three (3) ML model were built to predict the monthly minimum temperature, maximum temperature, and relatively respectively based on information from the previous 11 months.

The methodology adopted is to treat each prediction task as a supervised learning problem. This involves transforming the time series data (Fig. 14) into a feature-target dataset using auto regressive (AR) technique.

The parameter (temp_min or temp_max or relative humidity) to be predicted is set as the target (dependent) variable and in each case be defined by

$$T\min(t)|T\max(t)|RH(t) = f[T\min(t-n), T\max(t-n), RH(t-n)] \qquad (1)$$

t is the prediction date.
t-n denotes the time lags, n is an integer between 1 and 11
*T*min*(t), T*max*(t), RH(t)* are temperatures and relative humidity to be predicted.
*T*min*(t-n), T*max*(t-n)*, and *RH(t-n)* are minimum, maximum temperatures, and relative humidity, respectively, each time lag.

The transformation resulted in a dataset with 445 samples, each with 34 new features. In order to build an ML model, the samples were divided into 361 train

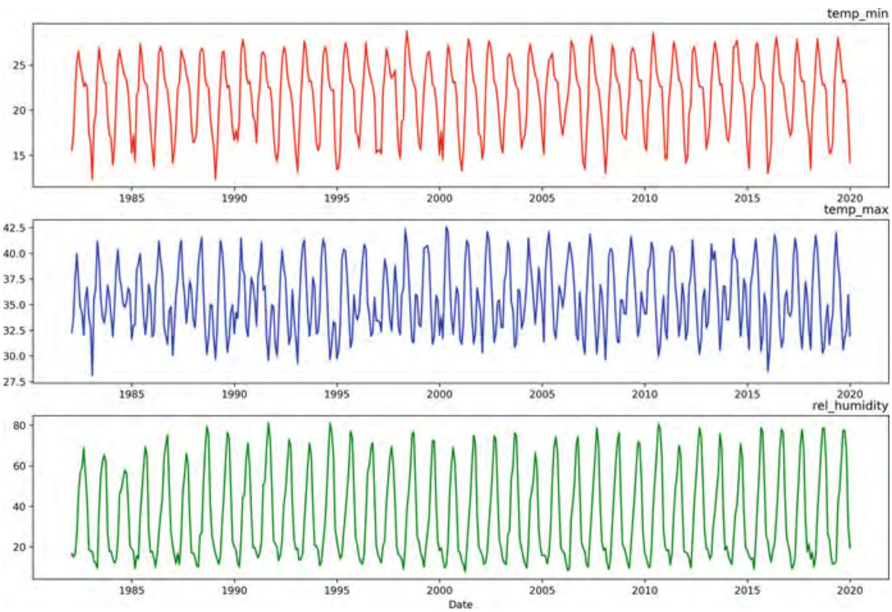

Fig. 14 Time Series of Temperature and Relative Humidity (1982–2019)

(samples from 1982 to 2012) and 84 validations (samples from 2013 to 2019) sets. The Ensemble machine learning methods which are a stack of multiple learning algorithms were used to train our model. The choice of ensemble algorithm is to obtain better predictive performance than could be obtained from any of the constituent learning algorithms. For the three models that were built, the predictive accuracy measured by the R^2 for minimum temperature, maximum temperature, and relative humidity are 0.9353, 0.8772, and 0.9569 respectively. The plots of the actual prediction and the ground truth for minimum and maximum temperatures and relative humidity are shown in Figs. 15, 16, and 17, respectively.

The usefulness of the model developed can be successfully used to predict minimum and maximum temperature as well as relative humidity of Ilela, Sokoto State (representative of Sahel ecoclimate zone). If these predictions are done appropriately, livestock farmers can use the predicted values to calculate temperature humidity index which is indication of level of stress to livestock. Farmers can in essence adjust their management practices accordingly to ensure adequate adaptation in reducing the anticipated stress that may come to their farm animals.

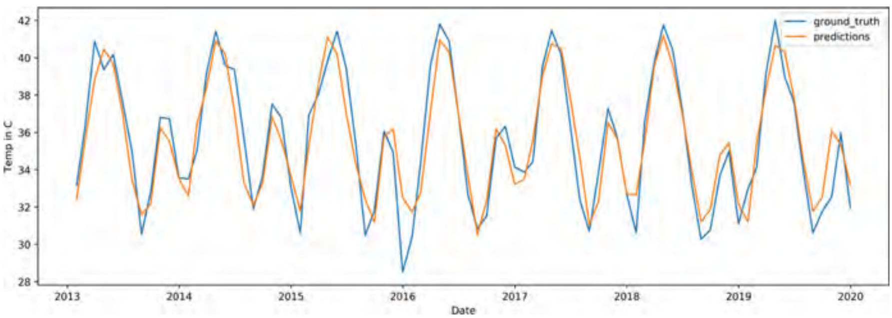

Fig. 16 Plot of predicted and actual values for maximum temperature for Sahel

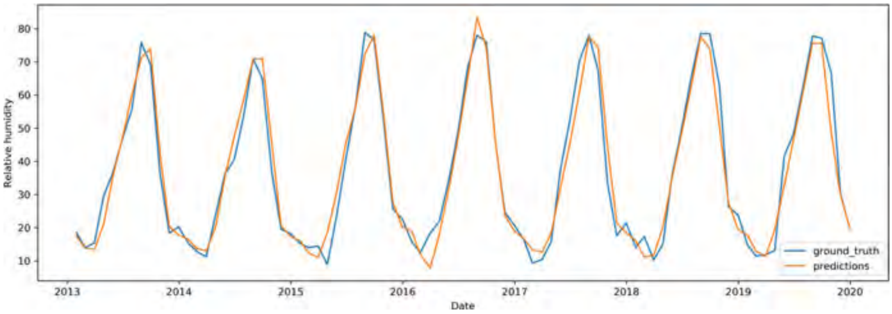

Fig. 17 Plot of predicted and actual values for relative humidity for Sahel

Conclusion and Recommendations

Large proportions of livestock stakeholders in Nigeria are aware of the effect of climate change on livestock production as well as the contributions of livestock production activities to climate change through GHG emissions. About 55% of the respondents agreed that the use of adaptive measures in alleviating the effect of climate change on livestock is capable of reducing its debilitating effect on livestock. The rest of the respondents, about 45%, were either neutral or disagreed with the fact that adaptive measures can mitigate the effect of climate change. It will be necessary to educate those that disagree on this very important fact. About 90% of the respondents however believed that economic, social, health, and environment perspectives are critical to solving the problems of the contributions of livestock production to climate change and global warning. Based on the predictive model developed for temperature and relative humidity in a sample location (Ilela) using Machine Learning in this chapter, there is need for development of a web or standalone application that will be useable by Nigerian farmers, meteorological agencies, and extension organizations as climate fluctuation early warning system. Development of this predictive model needs to be expanded and made functional.

Abstract

Coronavirus disease of 2019 (COVID-19) is a current pandemic causing lockdown of cities and countries. The nature of this disease and the global cases are still considered as deadly all over the world. Analogous was drawn between the current COVID-19 pandemic and some of the other contemporary crises of the world as regards to climate change in addition to food shortage. Also, Survey Monkey instrument was used to generate emperical evidences from 514 respondents on covid-19 awareness and the effect on food security. Effects of diseases on climate change, such as the increasing frequency and strength of extreme weather events or the expanding range and spread of diseases was considered. Then, the relationship between the COVID-19 pandemic and climate change was investigated. Prior to the pandemic, climate change already had adverse effects on agriculture and vice versa, which led to food insecurity. The need for fruits as well as leafy and root vegetables in peri-urban and urban areas is increasing, as well as the food shortage. A drop in agricultural production will be expected in the future if the pandemic continues for a few more months. The perception and adherence to the preventive measures for this pandemic were determined to reduce its spread and lessen its effect on agricultural production as well as to improve food security.

Keywords

Covid-19 · Climate outcomes · Consequences · Agriculture · Food insecurity

Introduction

A total of 17 sustainable development goals (SDGs) have been set to transform our world, namely: no poverty, zero hunger, good health and well-being, quality education, gender equality, clean water and sanitation, affordable and clean energy, decent work and economic growth, industry, innovation and infrastucture, reduced inequality, sustainable cities and communities, responsible consumption and production, climate action, life below water, life on land, peace and justice strong institutions, partinership to achieve the goals (United Nations Department of Economic and Social Affairs (UNDESA) 2015).

SDGs are the organized principles for addressing environmental improvement objectives and sustaining the capacity of the usual structure to offer natural resources, flora and fauna services upon which the economy and humanity depends is crucial.

This chapter identified some of the issues influencing climate change and the effect of climate change on food security. It also discussed coronavirus disease 2019 (COVID-19), which is the current pandemic causing lockdown of the entire economy due to its global occurrence (World Health Organisation (WHO) 2020). Some emperical evidences were determined with the use of "Suervey Monkey" Instrument that generated responses from respondents from different parts different of Nigeria at the peak of the pandemic. This chapter highlighted the pandemic nature of COVID-19 and other hidden evidences in litreature. Essentially, some of the health constraints on climate change include the increasing occurrence of extreme weather events and the growing rate and spread of illnesses, such as malaria.

COVID-19, a persistent respiratory disease caused by corona virus is transmitted chiefly by contact with human and infected surfaces and the individual shows symptom of fever, cough, and shortness of breath and may advance to pneumonia, respiratory failure and death.

Furthermore, the relationship between pandemic and climate change was investigated, although climate change already had adverse effects on agricultural production, which led to food insecurity, especially in under developed countries. It is expected that agricultural production will drop in the subsequent years if COVID-19 pandemic persists for more months. The vulnerable groups include small-scale farmers, migrants, labourers/workers, nomads, and fisher folks who have been prevented from working on their farms and from taking care of their animals/fisheries will fell the effect. These groups also face difficulty in obtaining access to proper marketplaces to retail their produces and processed goods as a result of increased food prices and inadequate purchasing resources. Informal laborers are also affected leading to hike in labor cost and income losses because of delayed harvesting of the produce.

Conceptualizing the Pandemic Nature of Coronavirus

COVID-19 could be described as a respiration set of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (World Health Organization (2020). This virus spreads primarily between people during close contact, often through small drops of discharge from the nostrils once an infested individual sneezes or coughs into the air. The droplets usually drop to the ground/surfaces without being suspended in the air moving 2-m distances (Nigerian Centre for Disease Control (NCDC) 2020). People may contract the virus by touching polluted surfaces and then touching their faces (mouth, nose, and eyes). The first case of COVID-19 occurred in December 2019 in Wuhan, China's Hubei Province. Then, it subsequently spread globally, which resulted in the ongoing 2019–2020 coronavirus pandemic (Hui et al. 2020; World Health Organization (WHO) 2020). COVID-19 has an incubation period of usually 2–14 days for people who develop symptoms; however, some people who are infected do not develop any form of symptoms and are thus called asymptomatic. While it is easy to isolate and treat infected people that develop symptoms, the asymptomatic patients cannot be easily identified, isolated, and treated, thus posing a great risk of spreading of the virus. This brings fear to the people and also has crippled many economies worldwide, affecting agricultural production, thus causing food scarcity, hunger, and food insecurity. Interestingly, researchers worldwide are working tirelessly to develop vaccines/drugs and treatment regimes of the disease.

Symptoms Associated with COVID-19 (NCDC and Hopkins University 2020; WHO 2020)

1. Cough – Coughing is a common impulse action that clears the throat of mucus or foreign irritants. While an individual coughs to free the throat at intervals, some amount of situations can lead more frequent coughing, which could be as a result of Covid-19.
2. Loss of appetite – This is referred to as anorexia and could be caused by a diversity of conditions and diseases. Some of these conditions could be temporal and rescindable, such as defeat of appetite or a side effect of medicine. Majority of the situations could be very severe, for instance, the consequences of disease causation (could be covid-19). Continuous absence of hunger should be evaluated by a healthcare professional.
3. Difficulty in breathing – This could be described as uneasiness and could be related to numerous diverse conditions. It is important to note that frequent incidents of shortness of breath could be a symptom of a severe illness (such as Corona virus) that needs attention.
4. High temperature/fever – The common body temperature is different for many people and changes during the day. If the body temperature is 38 °C, it is considered as a high fever. Several conditions could lead to fever, but it is usually caused by the body fighting an infection (may be covid-19).
5. Sneezing – This is a sudden reflex discharge of air from the nose and mouth due to irritation of the nostrils, which is caused by exasperation to the mucous membranes of the nose or throat. It may be very inconvenient and could be symptom of Corona virus.
6. Headache – Pain which occurs along the nerves, blood vessels, and muscles that is felt in the head. However, if it persists for 3 days, the doctor should be contacted because it could be an indication of an underlying disease.
7. Fatigue – This could be bodily, mental, or both, an indication which could be difficult to describe; however, words like tired, exhausted, and worn-out may be used.
8. Joint pains – This refers to the uneasiness and pain felt in some joints of the body, such as those of the shoulders, hips, elbows, and knees. Occasionally, joint pain is a result of an illness or injury.
9. Runny nose – This is an indication of several health situations resulting in the flow of secretion from the nostrils. This secretion protects material generated from the slimy tissue that lines the nasal cavity, which mixes with the saliva and drips down the back of the throat.

10. Sore throat – This is caused by a virus-related contamination, such as cold or influenza. It is also very important that symptoms are appropriately observed.

Preventive Measures of COVID-19

There are preventive measures recommended to prevent COVID-19 infection, such as self-isolation when feeling sick; avoiding busy spaces; practicing good hygiene; proper handwashing; using alcohol-based sanitizers; maintaining social and physical distancing from others, especially those with symptoms; covering mouth while coughing and sneezing with tissues, which should be thrown properly in a closed dustbin; and preventing from touching the face with unwashed hands. Furthermore, mask should be used outdoor, where additional non-pharmaceutical techniques cannot be adhered, to reduce the rate of transmission (NCDC 2020; WHO 2020).

Strategies Implemented by the Government Globally to Control and Prevent the Spread of COVID-19

1. Total and partial lockdown for weeks or months of states/regions affected by COVID-19
2. Enforcement of curfew between certain hours of the day to prevent people from going out and contracting the disease
3. Closure of the country/state borders (land, air, and waterways) to prevent further spread of the disease
4. Banning of the interstate movement
5. Fumigation of public places with disinfectants (marketplaces, parking areas, hospitals, congested areas, roads, etc.)
6. Enforcement of the use of surgical gloves, medical masks for healthcare givers, and fabric masks for non-medical personnel
7. Restriction of people's movements to only essential services (healthcare workers, security personnel, and journalists)
8. Opening of markets for some days of the week
9. Distribution of palliatives to the poorest of the poor in the country to enable citizens to fully comply with the total lockdown

However, some of the measures implemented to prevent the spread of the virus, such as fumigation of public spaces with chemicals and the use of personal protective equipment (PPE), which are not properly disposed, can lead to land, water, and air pollution, which will later negatively affect the environment, possibly resulting in environmental challenges and food insecurity and these could be worst in less-developed countries.

Diagnosis of COVID-19

The seriousness of the pandemic differs from person to person. COVID-19 infection could show minor sypmtoms, such as ordinary flue or common cold, or no symptoms at all. As the infection progresses, the symptoms change based on gender, generational, and the type of underlying illness. People with mild symptoms of COVID-19 infection usually get better in 14 days or less, although it takes 21 to 30 days to achieve full recovery (NCDC 2020; WHO 2020). Older people or those with underlying diseases, such as hypertension, diabetes, cardiovascular diseases, chronic respiratory diseases, and cancers of any type, are susceptible to this infection (NCDC 2020), while children experience less severe symptoms. The mortality rate of adults less than 50 years who were infected with COVID-19 is less than 0.5%. Conversely, those older than 70 years had the highest mortality rate from the disease. The major problems related with COVID-19 include sepsis, excessive clotting, and damage to the vital organs in the body. Up to 30% of the individuals infected with COVID-19 exhibited elevated liver enzymes, known as *transaminases* (Sanders et al. 2020), resulting in organ failiure and eventually death.

Transformation of Situations Causing Typical Climate Change

Climate change is described as variation on usual climate conditions of an area across periods due to natural circumstances or artificial activities causing degradation of the environment (Nwosu 2012). Climate change is considered as a long-term shift in the average weather situation of a region, such as its typical temperature, rainfall, and wind patterns. This variation in weather indicates that the consequences estimated in a lot of countries will vary over the coming decades.

> Weather variations are global phenomenon of climate transformation characterized through fluctuations observed on weather of the planet regarding temperature and precipitation, which are especially instigated through human activities (Food and Agriculture Organisation (FAO) 2002). The balancing of the weather condition to sustain ecosystems is under threat, as well as the future of humanity and the steadiness of the world economy.

In other words, climate change refers to the deviation in the geometric distribution of the average weather circumstances over a prolonged period of time. Climate change induces an increase in the occurrence of extreme weather events. The characteristics of weather variation poses risks to agricultural sustainability and results in food shortage, high level of poverty, and low level of human and physical development. Uninterestingly, weather variations negatively affect human health, water resources, land use, coastal infrastructure, and the environment (International Fund for Agricultural Development (IFAD) 2010), particularly in developing countries, such as Nigeria, where irrigation is not often practiced, as well as in regions that experience heavy rainfall, thus causing extreme flooding and leaching.

Thus, the apprehension of weather variation cannot be overemphasized which is based on the biggest problem facing the world, affecting everything and everyone, due to the fact that it plays an important environmental influence on ecosystem. Climate change affects the ecosystems in numerous ways, and intermingles with poor growth. The cumulative impacts could lead to intense environmental variations (United States Global Change Research Program (USGCRP) 2009). The severity and frequency of diseases are often related with unfavorable weather conditions and unpredicted health concerns spreading in regions where they have not occurred before.

> The consequences of weather variation on the availability, accessibility and stability of food supplies can cause major alterations in people's diet choices, which in turn have consequences on the health of the households and low recovery rate from the pandemic.

Nelson et al. (2018) has reported that climate change is expected to alter global nutrient availability, thereby exerting aftermath effects on malnutrition. The increasing CO_2 levels are also expected to reduce the levels of proteins, iron, zinc, and vitamins B1, B2, B5, and B9 in staple foods and docosahexaenoic acid content of fish, which will cause malnutrition to millions of people worldwide after the COVID-19 pandemic (Colombo et al. 2019). COVID-19 pandemic and devastating consequences, and how to stop its spread have become the focus of the world. The greenhouse gases (GHGs) that significantly contribute to climate change, include carbon dioxide, methane, nitrous oxide, ammonia, and other trace gases (Intergovernmental Panel on Climate Change (IPCC) 2007). The other factors causing weather variations are natural causes and human activities. Human activities, such as fumigation and disinfection of public places and improper disposal of used PPEs during the COVID-19 pandemic, also immensely contribute to climate change. The scorching of fossil fuels and the conversion of land for forestry to other uses, including agriculture, are also examples of human activities. Conversely, the natural causes of climate change include variations in ocean currents and atmospheric circulation.

Effects of Weather Variation on the Environment and Agriculture in Nigeria

The effects of weather variation on food production differ from one country to another which is dependent on the current climate condition affecting agricultural productivity differently. Nigeria, like all the other countries in the sub-Saharan Africa, is highly vulnerable to the impact of climate change. Climate change variations from 1960 and 1999 in parts of Nigeria presented visible incidences of deficiency for a cumulative period of approximately 8–18 years in some parts of Nigeria (Obioha 2009; Muhammed et al. 2011). Uncertainties about the farming season due to the changes in rainfall pattern resulted in crop failure, thus leading to food shortages because of poor harvests. An increase in rainfall is also favorable for the outbreak of pests and crop diseases, which is detrimental to crop production. Specifically, pests and crop diseases are visible in response to weather variation, which hypothetically threaten livestock in the drier northern states of Nigeria (Food and Agriculture Organisation (FAO) 2002). Small-scale farmers face the problem of flooding, which destroys the infrastructure used to store or transport food from production areas to markets, thereby discouraging the farmers to produce more food (Aluko et al. 2008). Global warming also negatively affects the seafood and aquatic lives that are important to humans. In addition, climate change affects not only food security but also the livelihood of the people, thus obstructing the advancement of many developing and underdeveloped countries. It is quite obvious that the most serious challenge to agricultural production and mankind worldwide, especially in Africa, is climate change.

Effects of Climate Change on Food Security

African countries that rely solely on natural resources and rainfed agriculture are more vulnerable to the risks of climate change (IFAD 2010). The consequences of climate change effects are irreversible, potentially disastrous to the entire nation, most especially the developing and underdeveloped nations. For example, it was estimated that by 2020, agricultural production would decline by 50% in some countries with rainfed agriculture (Nanki et al. 2010), and this will be worsened by the COVID-19 pandemic. The Intergovernmental Panel on Climate Change (IPCC) in 2008 analyzed that a temperature increase of 2.5 °C would result in a loss of 1.0–1.5% of the gross domestic product (GDP) in developed countries and 2–9% in developing countries. Generally, climate change causes floods, droughts, or tropical storms, which can take a major toll on a country’s economy if a significant part of economic activity is sensitive to the weather and climate. Therefore, if the current trend of GHG emissions continues, the per capita GDP loss by 2022 will be as much as 3–35% (Tamirisa 2008; Harris et al. 2017). Africa is a good example of the influence of climate variability on a developing country’s economy (USAID 2010; Zenebe et al. 2011). Boko et al. (2007) and IFAD (2010) reported that the rainfed agriculture and pastoral communities in Africa are dependent on annual rain and were identified to be more susceptible to the effects of climate change. Climate change have negative impacts on food production, especially livestock, in terms of CO_2 and methane emissions. Livestock uses about 32% of arable land, and cattle rearing causes up to 70% of land degradation and pollution. Therefore, if forests are lost, it will be difficult to fight climate change (Meludu 2019). The sheer quantity of animals being raised for human consumption is a threat to climate sustainability. Another scenario is that 1 ha of land for beef production will feed one person, the same hectare for rice production will feed 19 persons, and the same hectare for potato production will feed 22 persons. This competition is too high to achieve food security and eradicate poverty due to degradation and pollution.

Concepts of Food Security

Food security exists at all periods with individuals having financial access to necessary, harmless, and nutritious food that provides adequate requirement for sustainable life expectancy (FAO 2002; Meludu 2009; Meludu and Ewebiyi 2010). Food security and food insecurity are considered to be dynamics that depend solely on causes of not having enough food and the management. However, the partial and total lockdown implemented worldwide due to the COVID-19 pandemic has affected numerous economic activities, such as food distribution, restaurants, hospitality industries, and transportation activities. During the COVID-19 pandemic, many countries closed their borders, preventing the free flow of goods in to different countries and even within the cities. This restriction caused constraints in food distribution and food hoarding, which posed great challenges to food security. This is especially to the vulnerable population including; aged people (senior citizens), children, pregnant women and those with immune-compromised status. Due to the pandemic, food prices have increased worldwide; staple foods such as wheat, *garri*, rice and beans, tubers, meats, fruits, and vegetables became expensive. Adequate and effective support to encourage unhindered transportation of food items from source locations to various destinations, home deliveries became necessary to reduce human interactions and prevent the possibility of getting infected. When food security is compromised, the consequence is food insecurity.

Food accessibility is affected by the production, distribution, and stability of food (Fig. 1). Food accessibility refers to the easy access to food that is essential to combat hunger and overcome food insecurity. An individual or household's access to food can be influenced by their income and health conditions. Consumers must be able to have the purchasing power in order to have access to food. Due to the COVID-19 pandemic, the rate of unemployment has increased, which resulted in food insecurity. Individuals need to eat sufficiently to develop strong immunity against the virus and to be physically healthy to be able to digest and utilize the nutrients in the food consumed. Food utilization can also be influenced by nutritional values, health status of an individual, safety of the food, and how it is prepared before consumption. Food will be well utilized when people strictly adhere to the important safety precautions against COVID-19. Food stability is guaranteed if the governments worldwide make adequate preparations to reduce the rate of

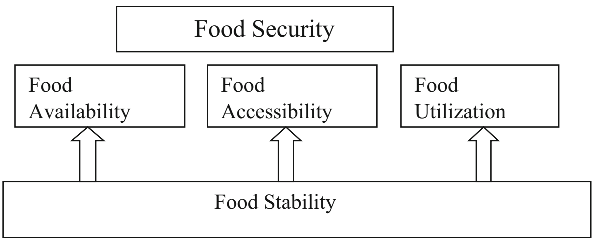

Fig. 1 Dimension of food security. (Source: Francesco et al. (2011))

postharvest losses to make food available during this pandemic so that people will remain healthy and safe.

Therefore, to achieve all the highlighted dimensions of food insecurity, the pandemic should be dealt with accordingly to reduce its impacts on climate change so as to avoid food shortage. If adequately managed, the resultant effects will reduce the occurrence of food insecurity globally.

Food Insecurity

Food insecurity could be considered as deficiency in access to adequate food amount in terms of quality and quantity. Inadequate diet and reduced immune system amplify vulnerability to diseases (Meludu 2011). Low diet is correlated with the increasing development of non-communicable diseases (NCDs) (Velmurugan et al. 2017).

Climate change-related incidents recurring everyday requires immediate action (Solly 2019). Therefore, a scientific innovation strategy for mitigating the impacts of climate chnage on agricultural systems is important. Increased food traceability aimed at preventing food loss due to contamination issues, prediction of extreme events is very germain at this period of pendemic (Dhaliwal and Williams 2019; Fabregas et al. 2018; Nkurunziza et al. 2019).

Food contamination caused by climate change also threatens the achievement of the SDGs, namely SDG 2 (zero hunger), SDG 3 (good health and well-being), SDG 8 (decent work and economic growth), SDG 12 (responsible consumption and production), and SDG 13 (climate action) and indirect effect on the other SDGs. Labor scarcities impacted producers, processors, traders, and distribution companies in food distribution chains necessitate workforces to be in near vicinity. The United Nations World Food Programme (UNWFP) predicted that approximately 265 million people will experience increased food insecurity by the end of 2020.

> Food insecurity can be illustrated by durations such as; chronic food insecurity is a long-standing food scarcity. Temporary food insecurity is a momentary circumstance of food insecurity where a populace agonizes from food insecurity transition at the time there is an unexpected drop in the capability to produce food for adequate nutritional status and lastly, Seasonal food insecurity is a condition that could happen from time to time.

Food insecurity “hot spots” according to the UNWFP include the following:

- Substantial conflict-affected states, where food supplies are problematic due to the pandemic. The Fulani nomads are also moving due to climate change which is destroying crops and agricultural land. Uninterestingly, many farmers and their families are displaced from their communities and killed
- Countries experiencing numerous emergencies due to climate change consequences that affect food production worldwide, accompanied by the high incidence of flood preventing farmers from going to their farms to plant

- Vulnerable individuals constantly experiencing food insecurity even before the pandemic
- Countries with significant currency depreciation and other product price failure (dropping the volume to import food)

Effects of the Coronavirus 2019 (COVID-19) Pandemic and Climate Change on Food Security

The COVID-19 pandemic has negative effects on climate change which lead to food insecurity. The process of fumigating public places (markets, churches, parking areas, offices, and the entire environment) pollutes the air which eventually affects the weather condition (Fig. 2).

COVID-19 has caused a dramatic loss of human lives worldwide. It also presented an unprecedented challenge with deep social and economic consequences, including food insecurity and malnutrition. An impact on the crusade of labor force and the distribution of inputs has also caused unacceptable constraint to food production. However, agriculture and food-related logistic services was considered to be among the important concerns during the COVID-19 pandemic; thus, food production and distribution should not be compromised.

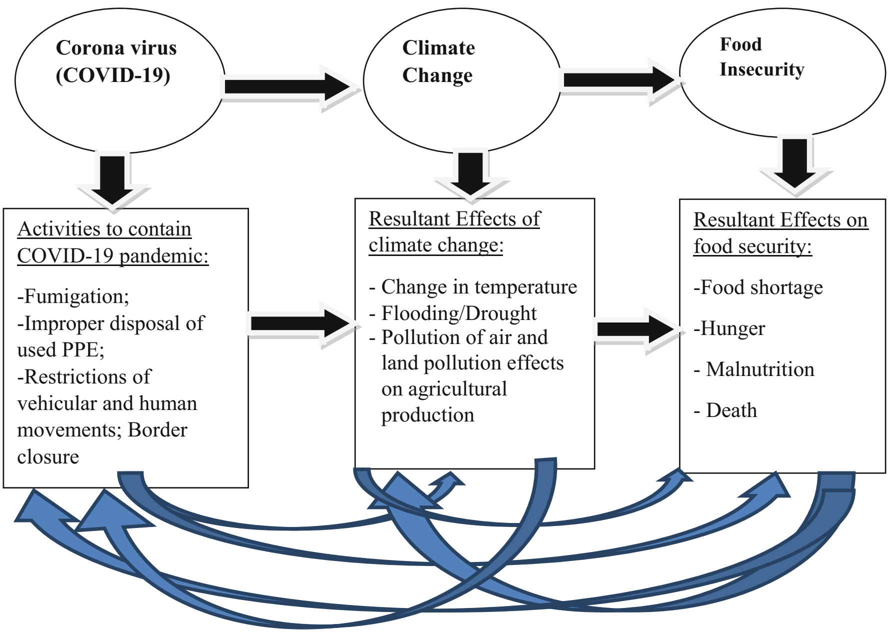

Fig. 2 Conceptual framework of the interface between COVID-19, climate change, and food security

The government in every country adopted the idea of lockdown as part of the precautionary measures to stop the spread of COVID-19 among its citizens. On the contrary, this lockdown resulted in food shortage in that farmers, marketers, processors, and other stakeholders in the value/supply chain were unable to carry out their enterprise characteristics and the global food system has been destroyed.

Empirical Evidences Obtained Through Online Survey on COVID-19 Awareness and the Effect on Food Security

This study used SurveyMonkey (Monkey Survey 2020) to obtain answers to selected questions that were raised with regard to the effects of the COVID-19 pandemic on farming and food security. This study included 514 agricultural stakeholders as participants, of which 55.6% are male and 44.4% are female. It is so disappointing to note that many of these participants (45%) were not taking COVID-19 very seriously, and some were even unsure whether this disease is real or not. They considered it as politicians or rich man disease. This resulted in non-adherence to the safety measures implemented by the government, thereby causing the rapid spread of the disease. About 60% of the respondents learned of this pandemic through radio, television, and Internet, 15% from healthcare workers, 15% from family members, 5% from market places, and 5% from workplaces. This implies that many farmers did not have access to information and communications technologies (Fig. 3) or regular power supply. Thus, only a few people who had sufficient information were able to take adequate measures. This will cause many people to contract the virus, thereby leading to death and affecting agricultural activities which causes food insecurity.

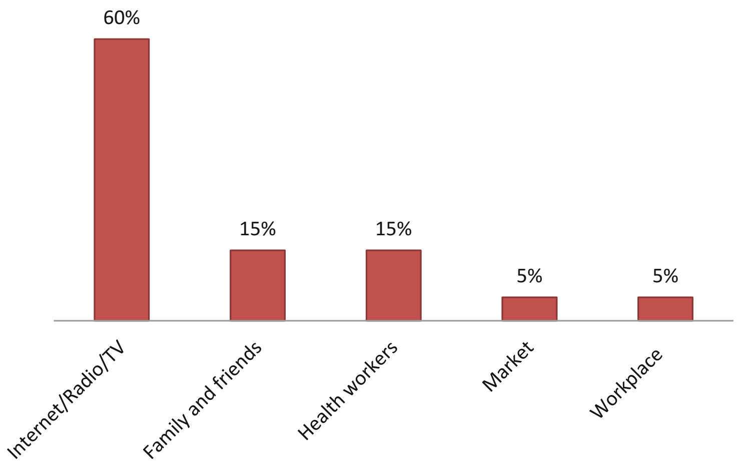

Fig. 3 Channel of information on the COVID-19 pandemic

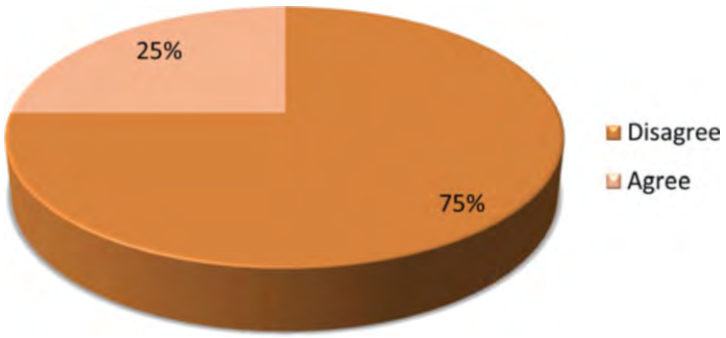

Fig. 4 Farmers' access to palliatives

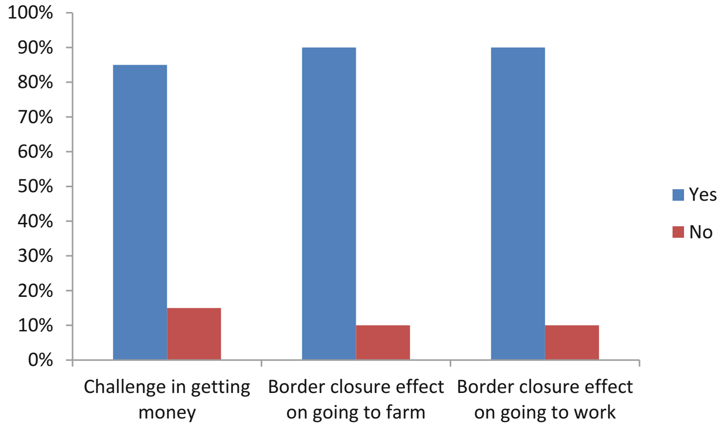

Fig. 5 Effect of COVID-19 on access to money, farm, and office work

During the period of the lockdown to contain COVID-19, when all economic activities were put on hold, many industries could not pay the salaries of their workers; thus, there was either a pay cut or staff layoff. Due to this, the purchasing power was affected and food accessibility became difficult to achieve. Majority (75%) of the respondents disagreed with the way the government handled the palliative distribution as not everyone was given, especially the farmers, whereas less than average (25%) agreed (Fig. 4).

Farmers that were supposed to be on the farm working were asked to stay home as one of the measures to prevent them from contracting the disease. Almost all (90%) the farmers adhered to this, and 85% did not have access to money (Fig. 5). Most crop and livestock farmers in the developing countries rely solely on rainfed agriculture, whereas only few depend on irrigation. Unfortunately, the peak of COVID-19 occurred at the beginning of the rainy season, which is in April. The farmers were unable to perform their seasonal farming activities. Eventually, this will result in food shortage and food insecurity. Transport route blockage hinders the

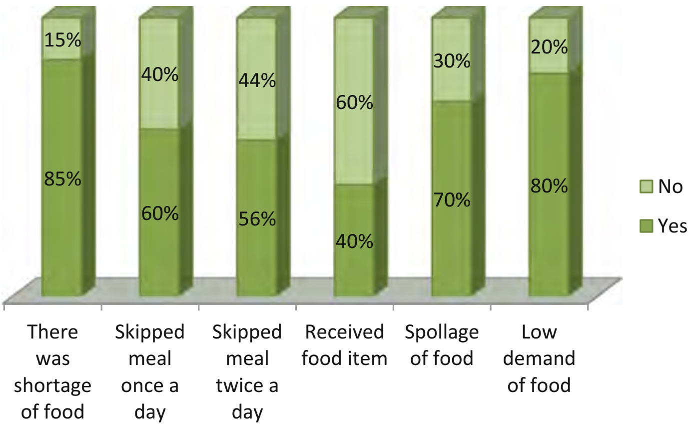

Fig. 6 Distribution of the shortage of food, skipping of meals, food gift, spoilage of agricultural produce, and low demand for food

distribution of fresh goods; thus, high levels of postharvest loss and waste may be experienced.

Marketers play significant roles in ensuring adequate distribution of food products. During the pandemic, marketers were also asked to stay home for a period of weeks or months, depending on the number of index cases recorded in the region. During this period, marketing activities were disrupted as marketers could not buy or sell food as expected. Moreover, there were no available buses/trucks to transport goods and services; interstate borders were also closed. During this, food accessibility was a major challenge for households, thus, eventually leading to food insecurity. Processors are another category of people involve in food distribution. Due to lockdown, the raw materials used for food processing were not available. Therefore, much of foods processing/income were not achieved. This invariably resulted in food shortage and food insecurity and resulted in many (85%) households not having access to food. A high percentage of households reported skipping food once (60%) or twice (56%) a day (Fig. 6). Some crops are supposed to be harvested before the rain in flood-prone areas. However, due to the pandemic, they were left on the ground to spoil (70%). These measures also resulted in labor shortage which disrupted the production and processing of food, most especially for labor-intensive crops. Migrant workers left to their states, and those who stayed were not allowed to come out, which led to high labor cost even after the relaxation of some measures.

Conclusion

Climate variation causes events that affect many economies and has been linked to poor food production even before the pandemic. Thus, more effects were felt as part of the pandemic consequences, which led to food shortages. Lockdown and closure of borders led to farm labor shortage and increase in food prices. In addition, the amount of food that would have been produced by farmers reduced. Crops harvested by the farmers and ready for sale got wasted on the farm due to the movement restrictions. There were also few trucks available for transporting produces and food products, which led to an increase in transportation costs. Many low-income households, especially in the rural areas, could not afford to buy enough food to sustain the family, thereby causing hunger and malnutrition and lowering their immunity, which made them susceptible to diseases. This pandemic has affected the sustainable development goals toward achieving food security, namely, goal 1: no poverty, goal 2: zero hunger, goal 3: good health and well-being, goal 4: quality education, goal 5: gender equality, goal 6: clean water and sanitation, and goal 7: achieving human development goals and sustaining the ability of natural system to provide natural resources and ecosystem services by 2030.

Recommendation

Timely and effective policies should be implemented to prevent more effects on climate variations and also to reduce the consequences of COVID-19 so that extreme poverty and hunger can be avoided. To overcome challenges on food price, an adequate price control mechanism and a price monitoring system for food produce must be in place to evaluate the actions. Quality supervision of food items by the appropriate organs of the government is very important in ensuring food safety and quality, especially during and after the pandemic. Countries are encouraged to produce their own agricultural products. People are now advised to engage in agriculture to reduce the effect of the pandemic on food security.

Abstract

Climate change has become one of the most profound threats to smallholder agriculture in semi-arid and arid areas. Farmers in this sector are especially vulnerable to climate change due to reliance on rain-fed agriculture, limited access to capital and technology among other challenges. While several potential adaptation options exist, many barriers hinder effective adoption of these practices, hence production in marginal areas remains very low. This chapter discusses crop adaptation through the adoption of small grains in Zvishavane rural, a semi-arid area in Zimbabwe. Small grains are conducive in hot areas; their drought-tolerant nature enables them to thrive in marginal areas making them an appropriate strategy in responding to climate change. However, several production and policy challenges associated with small grain production hinder their adoption by farmers. In view of this, this chapter discusses the potential of small grains as an adaptation strategy to climate change in Zvishavane District, Zimbabwe, and addresses potential challenges and opportunities for increased adoption and future research. The review showed that farmers in Zvishavane have perceived climate change due to noticeable changes in rainfall and temperature patterns in the past years. Despite small grain production being the best strategy due to drought and high temperature tolerance, an insignificant number of Zvishavane farmers is involved in small grain production. This is due to numerous barriers such as high labor demand associated with small grain production, the challenge posed by the quelea birds, food preferences, low markets, and low extension services and government support. It is therefore necessary to encourage adoption of small grains by developing improved varieties, adoption of climate smart agricultural practices, improved technical support, and access to markets among other interventions.

Adaptation · Climate change · Mitigation semi-arid areas · Small grain production · Smallholder farmers · Vulnerability

Introduction

Climate change has become one of the major threats to rain-fed agriculture resulting in major drawbacks in agricultural production and food security. IPCC (2007) notes that climate change has significantly modified rainfall and temperature patterns in many parts of the world. There is strong evidence of erratic rainfall and a noticeable shortening of the agricultural seasons worsened by higher ambient temperatures resulting in perennial crop failure and frequent droughts across the world (Jerie and

Ndabaningi 2011). The adverse effects of climate change are more pronounced within the smallholder agricultural sector in Africa, including Zimbabwe, compared to the more technologically advanced and high resource input commercial sector. Generally, smallholder agriculture is practiced by families or households using only, or mostly, family labor and deriving from that work a large but variable share of their income, in kind or in cash (HLPE 2013). It therefore follows that the livelihoods of smallholder farmers largely depend on agriculture and are particularly vulnerable to several hazards. Consequently, if changing climatic conditions continue unabated, traditional rain-fed agricultural systems will become increasingly unsustainable with severe food security implications.

Temperature in the sub-Saharan Africa region is predicted to increase by between 1 °C and 2.5 °C by 2030, which will ultimately result in yield losses of up to 20% by the 2050s depending on region (IPCC 2007). Consistent with regional data, Zimbabwe's annual mean surface temperature has warmed by about 0.4 °C from 1900 to 2000 with the period from 1980 to date being the warmest on record. Moreover, the timing and amount of rainfall received are becoming increasingly uncertain, with current data showing that during the last 30 years there has been frequent droughts and rainfall has significantly decreased with shorter seasons (GoZ 2014). Consequently, the Food and Agriculture Organization (FAO 2007) observed that the crop failures have been a result of early termination of the rains in most seasons or low rainfalls in Zimbabwe, especially in semi-arid areas. Gukurume (2013) perceived that climate change in countries like Zimbabwe has presented insurmountable challenges to the agricultural sector as well as agricultural sustainability. Droughts, floods, increased temperature, increased rainfall variability, and declining precipitation negatively affected agriculture in Zimbabwe, with other districts recording almost nothing in terms of output (Zimbabwe Agricultural Sector survey 2019). The 2018/19 cropping season was marked by a late onset of rains, which resulted in abnormally dry conditions, affecting agricultural activities such as land preparation and planting (IPC Zimbabwe 2019).

The effects of climate change in Zimbabwe are exacerbated by the concentration of most smallholder farmers in marginal soils in semi-arid and arid areas located in the natural region IV and V, which makes them more vulnerable to climate change due to their low adaptive capacity. High temperature and erratic rainfall have resulted in constant low yields of the preferred maize staple in the country. Maize is not a drought-tolerant crop; hence, it is highly sensitive to harsh environmental conditions, which negatively affect the yield (Muzerengi and Tirivangasi 2019). There is therefore a need to implement adaptation and mitigation strategies that will ensure resilience to climate change. Adaptation has the potential to reduce adverse impacts of climate change and to enhance beneficial impacts and hence reduce vulnerability both in the short and long term (IPCC 2001). There are several adaptation interventions that have been suggested for smallholder farmers including but not limited to crop relocation, adjustment of planting dates, and crop variety; improved land management, e.g., erosion control and soil protection incorporating agroforestry (IPCC 2007). However, due to the vulnerability of maize to drought, there is the need to move away from the production of maize and look for alternative crops that thrive under changing climatic conditions. Sharma et al. (2002) highlighted that there is an urgent need to focus on improving crops relevant to the smallholder farmers and poor consumers in the semi-arid areas. This chapter focuses on the adoption of small grain crops, which have been shown to thrive under harsh conditions, as one of the most viable strategies that must be consistently implemented in such semi-arid and arid areas as Zvishavane District in Zimbabwe, which are facing significant production challenges due to climate change. Zvishavane District has experienced recurrent droughts, inconsistence rainfall, and is consequently one of the districts that constantly faces food insecurity in the country. According to Mawere et al. (2013), for the past two decades, Zvishavane, among others in Zimbabwe and beyond, has witnessed pronounced increases in temperature, recurrent droughts, and unpredictable rainfall patterns, yet people mainly depend on rain-fed agriculture and natural resources for their livelihoods. This chapter discusses the potential of small grains as an adaptation strategy to climate change in Zvishavane District, Zimbabwe, and addresses potential challenges and opportunities for increased adoption and future research. The chapter will answer the following questions:

(i) What are the Zvishavane farmers' perceptions on climate change?
(ii) To what extent are farmers in Zvishavane adopting small grains?
(iii) What are potential barriers/challenges and opportunities for increased adoption of small grain crops in Zvishavane District?

Smallholder Farming in Zimbabwe

The smallholder sector is known for its small farms, mostly less than 2 hectares that are labor-intensive, uses traditional production techniques, and often lack institutional capacity and support (Louw 2013). The definition of smallholder farmer depends on the country; for instance, in Zimbabwe, smallholder farmers are typically farmers who are food insecure, predominantly in low rainfall areas who depend on rain-fed agriculture. Their reliance on rainfall for agricultural production exposes them to the risks posed by climate change. Smallholder farmers face challenges such as lack of infrastructure, reliance on rain-fed systems, highly degraded soils, a variety of chronic crop-affecting diseases, tough economic conditions due to poorly functioning markets, and limited access to credit, knowledge, and lack of farming skills (Mutekwa 2009). Lack of assets, information, and access to services deters smallholder farmers' involvement in possibly profitable markets. Moreover, most smallholder farmers are confronted with labor limitations as a result of HIV/AIDS, chronic illness, poverty, and illiteracy. Furthermore, smallholder farmers lack adequate knowledge, which leads to poor selection of cultivars, fertilizer application, and delayed planting of crops. As a result, the crop yields are negatively impacted. Worse still they are far from road networks to transport inputs, produce, and also access information and have a tendency to use inefficient modes of transport such as animals. In Zimbabwe there is nonexistence of investment in infrastructure, for instance, roads, storage, and market facilities and this handicap the potential role of smallholder farmers. This problem is not only common in Zimbabwe but the rest of Africa as well as most African government policies are unsuitable and inconsistent, and do not provide an enabling environment for the development of the small grains sector.

Mutasa (2011) highlighted the reasons below as challenges or factors that farmers are faced with that also increase farmers' vulnerability to climate change.

(a) Poor soil moisture holding capacity
(b) Lack of necessary farming knowledge
(c) Lack of draught power
(d) Difficulties accessing the appropriate inputs on time
(e) Inadequate farming space
(f) Poor rains and/poor rainfall distribution
(g) Communities' failure to fully recover from previous drought disasters
(h) Poor fiscal policies resulting in hyperinflation and inaccessibility to cash especially after the dollarization of the economy
(i) Poor governance evidenced by the suspension of humanitarian organizations' operations when they were greatly needed
(j) Politicization of food assistance and input schemes (benefitting only supporters of a particular party)
(k) Corruption associated with input facilities
(l) Communities' focus on maize production at the expense of other traditional crops
(m) Depletion of human resources and sources of income due to brain drain, HIV, and AIDS and other epidemics

All the above mentioned challenges affect their competitiveness and it leads to them having high transport costs to sell their products in the market and buy inputs. In addition, smallholder farmers face challenges in accessing markets due to inadequate infrastructure, low productivity levels, inconsistencies in supply, and low quality owing to poor post-harvest practices (FAO). Smallholder farmers do not make much income as they lack a reliable market and as a result sell their produce at their farm gates or local market where they sell below market value (Aaron 2012). They tend to be inconsistent in production due to lack of bargaining power and inability to reliably supply their products fresh to markets (Aaron 2012). Harvested crops are threatened by insects such as weevils, larvae, termites, and rodents such as rats; these insects may be present in the grains making it less marketable. Some of the pests are attributed to lack of storage facilities as some smallholder farmers store grain in their sleeping quarters whereas those who have structures tend to be in very poor conditions and hence cannot hinder pest attack.

Changing climatic conditions have become one of the major challenges affecting smallholder farmers in Zimbabwe and the rest of the world. In 2016 and 2017, Zimbabwe had a drought, which was aggravated by the impact of El Niño. Smallholder farmers tend to suffer from these disasters due to their low adaptive capacity, which increase their vulnerability, hence they have no means of recovering from the effect this has on their livelihoods. Most smallholder farmers have a tendency to recover by selling their productive assets, such as their livestock or land. Moreover, these persistent droughts, which have taken place over the past few years due to changes in climate, continue to erode maize yields. For instance, maize yields have been reduced to less than 1.5 ton ha^{-1} against a potential yield of more than 5 tons ha^{-1} (de Jager et al. 2001).

Semi-arid and arid regions like Zvishavane district have some of the worst affected farmers in Zimbabwe. Zvishavane is a district in Zimbabwe bordered by Mberengwa, Chivi, and Shurugwi districts. The mean annual temperature is 20 °C although high temperatures of up to 30 °C have been recorded during the hot months from October to December (Nciizah 2014). The area receives an annual rainfall of about 450–600 mm placing it in region IV but during droughts there can be just 250 mm of rain (Oakland Institute Undated). According to the OCHA report (2012), region IV is subject to periodic seasonal droughts and severe dry spells during the rainy seasons, and crops can only be intensified by growing of drought-tolerant crops. Natural farming regions are a classification of the agricultural potential of the country, from natural region 1(>1000 mm per annum), which represents high altitude wet areas to natural farming region V, which receives low and erratic rainfall averaging 550 mm per annum (Mugabe et al. 2007). The table below shows the agroecological regions in Zimbabwe and their characteristics.

Rainfall in Zvishavane has been erratic such that in some areas like Mazvihwa, rain-fed agriculture has become unreliable, worsened by droughts that have gripped the country (Nciizah 2014). Despite the hot climatic condition of the district, agriculture remains the main source of livelihoods (Mugiya and Hofisi 2017). Just like all areas in Zimbabwe, the main crop grown by smallholder farmers in Zvishavane is maize. Droughts and little rainfall in the district have led to low maize crop yields leading to food insecurity to be high in the area. According to ZimVac (2015), Zvishavane was one of the districts with the highest food insecurity levels with 42.2%. In 2016, the level went up with 50% households being food insecure, hence the need for adaptation and mitigation measures in smallholder farming areas (ZimVac 2016). Adaptation measures include adjustment of planting dates and crop variety, crop relocation among others. However, one of the most recommended approach is the growing of drought-tolerant crops such as small grains (Gukurume 2013; Muzerengi and Tirivangasi 2019; Musara et al. 2019). Adoption of small grains becomes a crucial necessity that must be embraced by households in the area. Small grains grown in the area are sorghum and millet, with finger millet being more common than pearl millet (Nciizah 2014).

Farmers' Perceptions on Climate Change in Zvishavane

Smallholder farmers in Zvishavane perceive climate change using two variables, which are temperature and precipitation paying attention to events that have been occurring in the area for the past 10 to 20 years. Perceiving that climate is changing is crucial as it leads to adaptation. According to Jiri et al. (2015), perceptions help to shape smallholder farmers' coping and adaptation strategies. Adaptation is a two-step process, which requires that farmers first notice that the climate has changed and then secondly, implement adaptation strategies. Farmers' ability to acknowledge the importance of adapting therefore largely depends on whether they have observed that there is climate change in the first place (Nciizah 2019). Most studies have shown that farmers who perceive that the climate is changing in line with the actual climate change records are most likely to adapt to climate change (Jiri et al. 2015). Simba et al. (2012) concurs that the most crucial element in spearheading adaptation options is for farmers to perceive climate change. Such farmers who perceive that the climate has changed, for instance, will be able to realize a sharp decrease in maize yields. Numerous studies have been done on farmers' awareness on climate change (Gbetibouo 2009). A study by Okonya et al. (2013) in Uganda showed that 99% of all households interviewed had observed a change in the climate in the last 10 years.

The greatest concern for farmers in Zvishavane is the drastic changes in rainfall patterns and temperature. This is confirmed by the records from meteorological centers. A study by Jiri et al. (2015) also confirmed the decline in rainfall and an increase in temperatures over the years. Similarly, Mutekwa (2009) showed that farmers in Zvishavane were mainly concerned with precipitation and temperature-related weather events, as the ones that are a real concern in relation to their agricultural activities. There are now more experiences in dry spells and cold spells. Murowa ward in Zvishavane is already a drought prone area and farmers indicated that dry spells have become more frequent and devastating in recent years (Mutekwa 2009). Farmers in the area now experience extremely high temperatures and very low rainfall. Maddison (2006) also reported a similar trend of increasing temperatures in his study in 11 African countries. Another concern for smallholder farmers in Zvishavane is the changing onset of the rainfall season, which was confirmed by a study done by Mawere et al. (2013) in Zvishavane and Chivi. The study revealed that the climatic conditions that have prevailed for the past 5 years or so in agro ecological regions IV and V were very hot with dry conditions. There was rainfall below average (300 mm per annum) with poor distribution giving high chances of dry spells. In the past, the area used to receive three groups of rainfall, which are Bumharitsva (August), Hukurahundi (September), and Munakamwe (November) per year. Now they only receive one rainy season (munakamwe), which is also not predictable (Mawere et al. 2013). In addition, the farmers used to receive the last rains in March but this is no longer the case. The rains are no longer predictable as they can come very late and end early, something that has proved to be challenging to the farmers.

In the same study by Mawere et al. (2013), it was discovered that 96% of the respondents acknowledged their awareness of the changes in their local weather pattern and climate change. Many smallolder farmers in the study perceived the following as indicators: less and less rainfall leading to droughts, dwindling farming seasons, unpredictable weather patterns, high temperatures, decrease in livestock and crop production, low fruit production of wild fruit trees, and extinction of some area-specific species. Many smallholder farmers in Zvishavane have noted that although the coldest month of the year in Zimbabwe is June, it has been becoming less cold and the hottest month and October has become hotter than the previous years. It has also become apparent for most farmers that precipitation has been declining for years with more frequent drought occurrences. Drought occurrences have largely contributed to low yields and drastic effects on livestock production (Jiri et al. 2015). Farmers in Zvishavane have perceived inconsistent rainfall patterns and arid conditions in the area, which have led to the perennial flop of maize production (The Chronicle 2020). A survey done by International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) noted that most farmers in Mberengwa and Zvishavane have been realizing very low yields from maize and other crops because of the effects of climate change (The Chronicle 2020).

Wetlands in Zvishavane have also declined over the years. Farmers in Zvishavane pointed out that their cattle used to drink water at wells and wetlands around the area but the wetlands are no longer there and they have to fetch water from distant places (Mawere et al. 2013). They also add that mountains in the area used to have wind storms signifying coming of heavy rains. This however no longer happens. Storms used to signify rainfall as well as animals such as ducks, baboons, rain bird-blue bird. Such animals are no longer existent as they have moved to other areas in search of food (Mawere et al. 2013).

Smallholder Solutions for Climate Change

Climate change has rendered Zimbabwe's region IV a non-maize producing zone due to climate shocks, a situation that promotes food insecurity (Mugiya and Hofisi 2017). This has left the majority of people in semi-arid areas food insecure, which calls for the need for adaptation. Given the reliance of most people in Zimbabwe on rain-fed agriculture, it becomes pertinent to identify solutions that can be implemented in order to deal with the insurmountable challenges posed by climate change. There are a couple of solutions that have been identified in some studies inclusive of conservation agriculture, irrigation, and gardening. A study by Mutasa (2011) showed that farmers in Buhera and Chikomba districts have incorporated certain strategies to address droughts that are prevalent in the area. The strategies are inclusive of early cropping, staggered cropping, dry planting, and planting crops with a short maturity life. This study recommends the production of small grains in semi-arid areas like Zvishavane. Small grain production will likely curtail the numerous challenges faced by farmers in Zvishavane given the advantages posed by small grains. Small grains have always been there and are not new as they were there before the introduction of maize; they are an indigenous African crop with more nutritional benefits than maize.

Several studies have looked at how small grains can lead to food security especially in semi-arid areas (Leuschner and Manthe 1996; FAO 2006; Mukarumbwa and Mushunje 2010). They highlight the numerous advantages associated with small grain production. Among such advantages are their nutritious value, drought resistance, and how they can be stored for longer periods as compared to maize. Leuschner and Manthe (1996) pointed out that sorghum and millet are some of the most important cereal crops for communal farmers in Natural Regions

1 V and V of Zimbabwe. Their study showed that in regions with low and erratic rainfall like Zimbabwe's Natural Regions 1 V and V, small grains have the potential of stabilizing household food security. In a study by Taylor (2003), sorghum and millet are vitally important cereals for the maintenance of food security in Africa. FAO (2006) also supports that small grains are the answer to chronic food shortages to rural communities who reside in semi-arid regions, especially of the sub Saharan region.

Characteristics and Impact of Small Grain Production on Climate Change Adaptation in Zvishavane District

As alluded to earlier, more than 475 million smallholder farmers across the globe cultivate less than 2 ha of land each (Lowder et al. 2016) on poor and marginal land with lack of access to technical or financial support that could help them invest in more climate-resilient agriculture (Morton 2007). These challenges are exacerbated by the effects of climate change, hence the need for appropriate adaptive and mitigation measure. Due to these challenges, smallholder farmers in semi-arid to arid areas continue to achieve very low yields. Growing small grains becomes an adaptation measure that smallholder farmers in areas prone to water and heat stress need to implement instead of maize, which is highly susceptible to water stress. Although maize is the preferred grain crop in Zvishavane and the rest of Zimbabwe, it is frequently written-off due to frequent droughts (Nciizah 2014) resulting in maize yields below 1 ton/ha. Consequently, small grain crops like millet and sorghum, which can better withstand drought conditions and offer more stable yields in the long term, are a better choice (Nciizah 2014; ICRISAT 2015). Small grains, particularly sorghum, adapt well to harsh climates and thus can grow in dry conditions due to their ability to tolerate heat, salt, and water stress, which makes them an ideal crop for semi-arid and arid areas (ICRISAT 2015).

There has been a conscious drive by the Government of Zimbabwe (GoZ) to urge farmers in arid and semi-arid to opt for small grain as a coping mechanism to climate change as evidenced by the increase in programs promoting sorghum production (GoZ 2014). The government of Zimbabwe has been working with international organizations such as FAO and ICRISAT to assist farmers in the country's marginal areas to focus more on the production of small grains such as sorghum and millet in order to counter poor yield and hence hunger. In Zimbabwe, small grains (sorghum, pearl, and finger millet) rank second after maize and consequently play a vital role in ensuring food security and nutrition (UNDP 2018b).

Droughts and dry spells have made smallholder farmers in Zvishavane to be expected to rely on irrigation schemes if they want to produce good maize yields. Unfortunately most of these farmers do not have the financial capacity to purchase the required equipment and the much needed fertilizers (Nciizah 2014). It is therefore vital for these farmers to concentrate more on small grain production compared to maize. Most of the farmers in the area are still concentrating on maize production with only a few household producing small grains. They still follow the norm of the country whereby maize is the mainstay crop even in drier areas where small grains can be produced economically and sustainably (Rukuni et al. 2006). However, this needs to change as maize production is no longer conducive for semi-arid areas that are constantly facing droughts and erratic rainfall. Recently, Zvishavane faced a drought in the 2019/2020 season leading to crop failure. In such circumstances, full adoption of small grain adoption becomes a necessity if the area is to avoid zero crop yields. This is mainly because small grains have characteristics and properties that allow them to thrive in areas like Zvishavane.

Sorghum and millet are important traditional cereal crops in Africa (Chisi Undated). Notably these cereals are indigenous to the African continent (Musara et al. 2019), making them well adapted to the African semi-arid areas (Taylor 2003). These small grains have become favored because of their good adaptation to hard environments and their good yield of production. The grains are drought resistant as compared to maize, making them to thrive in areas that are hot and have limited rainfall. Water requirements over the growing period average 400 mm for sorghum and 300–350 mm for millet as compared to 500 mm that is required for maize (Orr et al. 2016). Hence, they are genetically adapted to drylands that face little and irregular rainfall, drought, and high temperatures than other cereals like maize. This makes them to be able to give some yields in years of low rainfall, especially when grown in a multi-cropped system, whereas maize will be a complete failure (Muzerengi and Tirivangasi 2019).

Sorghum and millet also have deeper roots than maize and can withstand higher temperatures without damage to the crop (Orr et al. 2016). Bang and Sitango (2003) point out that small grains are generally the most drought-tolerant cereal grain crops as they require little input during growth. They bring more nutritional value to people's diet compared to cereals like maize. Dube (2008) posits that some of the advantages of small grains like sorghum and millet over maize include the following: a smaller amount of flour is needed to cook the main meal compared to maize, and a meal cooked from small grains satisfies hunger for a longer period and gives more energy (which is especially important for persons who do heavy manual labor like farmers).

Specifically, looking at finger millet, it can be observed that the crop has valuable properties that make it more beneficial to grow in the semi-arid of Zvishavane. The cereal is drought resistance in nature, has high nutritional content and has the ability to produce with few inputs. Finger millet is a nutritious crop providing proteins, carbohydrates, minerals, and amino acids, especially methionine, which is lacking in the diets of numerous poor people who live on starchy foods (Bhatt et al. 2003). This goes the same with sorghum, which remains important for sustainability of smallholder farmers' subsistence, social and economic livelihoods in semi-arid areas (Musara et al. 2019). Sorghum grain contains 11.3% protein, 3.3% fat, and 56–73% starch (National Research Council, 1996). It is relatively rich in iron, zinc, phosphorus, and B-complex vitamins. Tannins, found particularly in red-grained types, contain antioxidants that protect against cell damage, a major cause of diseases and aging (National Research Council, 1996). Thus, sorghum and millet have the capability of providing the nutritional value that can boost the immune system of people particularly poor families. They both have more health nutrients compared to maize, wheat, and rice and they improve the physical health of the elderly, the sick, children, and pregnant and nursing women. Another advantage of sorghum and finger millet maize is that they have a long shelf storage life as they can be stored for about 5 years compared to maize, which is only stored for about 2 years. Hence, they become conducive in Zvishavane, a place that is facing consistence drought and erratic rainfalls.

Although small grains are mostly suitable for Zvishavane, research conducted in the area shows that most smallholder farmers are still reluctant to fully adopt the grains. Mawere et al. (2013) in a study in Zvishavane stated that in as much as farmers reported that small grain crops performed much better than maize, most farmers still preferred growing maize. Similarly, Nciizah (2014) observed that an insignificant number of farmers were cultivating small grains in the area. Mugiya and Hofisi (2017) reported that while small grain crops prove to be a viable option to boost production in the background of climate change vulnerability, people in Zvishavane were not adopting such varieties enthusiastically, as adopting such varieties threatened their food preference. Hence, in Zvishavane, a significant number of households still prefer maize over small grain production. There are a number of barriers that have affected small grain production in Zvishavane. This has made the area to be consistently food insecure as smallholder farmers still grapple with inadequate yields.

Perceived Barriers to Small Grain Production in Zvishavane

Despite the advantages associated with small grains, small grain production remains low with only a few farmers producing these around Zimbabwe and specifically in Zvishavane. Studies done in Zimbabwe have shown that small grain production continue to decline (Gukurume 2013). The production of small grains has been very low in Zvishavane and the decline in small grain production is due to a number of barriers, which are central to this chapter. As indicated by smallholder famers in Zvishavane the major barriers to small holder production are labor constraints associated with small grain production, the challenge of birds (quelea birds), lack of inputs, and challenges associated with storage among other aspects. Studies have shown that small grain production is a good adaptive strategy, but is difficult to implement given the problems associated with the production of the crops. All barriers central to small grain production in Zvishavane are discussed below:

Lack of Inputs

UNDP (2018a) carried out a study on the barriers to small grain production. Their study showed that there are constraints in accessing inputs that limits the uptake of small grains. Overall, the results of the study showed that there is overreliance of farmers on untreated seed, evidencing inefficiency of the formal market. The study confirmed that treated and packed seed is not readily available in local markets or alternatively, if available, farmers do not afford the improved seed. This is the same case as what is transpiring in Zvishavane. There is limited access to small grain seeds, which reduces its production. In most cases, farmers end up using untreated seed, which largely contributes to poor yields.

While improved varieties of seeds have been released by NGOs in Zvishavane District, the seeds of these small grains are not readily available from the various seed producers (Nciizah 2014). Whether farmers in Zvishavane want to produce small grains or not, their choices are affected by limited seeds. Christian Care, a non-governmental organization (NGO) operating in Zvishavane, has distributed seeds to farmers but with limited stock, which has resulted in few farmers accessing it. In addition, given the limited seed stock of small grains and the easier accessibility of maize seeds most farmers end up preferring maize. Mugiya and Hofisi (2017) cited that in Zvishavane there is too much politicization of programs geared to boost productivity among small-scale farmers. Farmers in the area revealed that farm inputs (inclusive of seeds), which are meant to benefit smallholder farmers, are usually diverted for political initiatives impacting negatively on small grain production. In most cases farmers in Zvishavane end up planting sorghum seeds that they saved from their yield (Mugiya and Hofisi 2017). Most of these seeds are of very low quality, which impacts heavily yield.

Labor Intensiveness

The cultivation of small grains is extremely laborious, from land preparation, weeding, bird scaring to harvesting and grain processing. Most farmers in the area rely on manual production methods, which explains why labor intensiveness is a major concern. Nciizah (2014) noted that 95% of farmers in Zvishavane pointed to the labor intensiveness associated with small grain production as a very significant challenge. The study also showed how weeding is made more challenging by the similarities that exist between the weed “*Eleusine Indica*” and finger millet. The two are so similar that in most cases one might end up removing the crop and leaving the weed. There is also so much labor associated with harvesting the small grains given that the seeds are too small to handle and so much is done manually. Because the seeds are small it takes skill and much effort to mill finger millet (Nciizah 2014; UNDP 2018a). Farmers also mentioned the labor demands associated with processing of small grains as one of the limiting factors. Farmers in the study mentioned how processing of small grains is laborious as it involves threshing and winnowing, which is also done manually.

The Challenge of Quela Birds

Even though small grains are generally tolerant to diseases there is a huge challenge of damage by quela birds. Like in most studies (Nciizah 2014; UNDP 2018a), birds and animals are the major challenges in small grain production. According to

Nciizah (2019), the birds are attracted by the grain of the crops as the grains are exposed unlike those of maize, which is covered by leaves. Chasing birds is highly regarded as a strenuous activity that most farmers cannot embark on. Farmers in Zvishavane prefer producing maize as maize is prone to attacks by baboons and wild pigs, which are easier to scare away than birds which attack the crop in large numbers and are difficult to chase away (Nciizah 2014).

Low Yields

In Zimbabwe, production of maize continues to dominate in the country's semi-arid regions as compared to small grains (Sukume et al. 2000). The lower productivity associated with small grains makes them very unattractive to communal farmers in semi-arid areas. Small grains also require large farm size, which is out of the reach for most farmers in Zvishavane. Given the limited farm size in most places in Zvishavane, most farmers then prefer producing maize. A few of those who produce small grains have large land size and can also provide labor required to produce these. Some studies have also discovered that small grains do not yield much crop residue as compared to maize, resulting in most farmers preferring maize production. According to Mapfumo et al. (2005), maize production provides crop residue for livestock, which the livestock largely depend on for survival during winter.

Lack of Knowledge

Despite the evidently dismal performance of maize in the area as a result of the effects of climate change, most farmers have for years been disregarding and fiercely resisting advice from agricultural experts to plant small grains (The Chronicle 2020). Research has shown that people tend to be largely ill-informed about small grain production. Many farmers in Zvishavane ignored the calls to adopt small grain production and in many instances continued to produce maize despite the realization that they are likely to get very low yields due to drought (Nciizah 2014). This is largely attributed to taste preferences and the low yields associated with small grains. Due to unawareness and lack of prioritization of small grains, most farmers end up cultivating small grains in their worst part of arable land, which heavily impacts production yields.

Lack of Markets

It has been found out that when it comes to selling small grains, it has a very low market as people prefer other agricultural produce like maize. This is also confirmed by a study done by FAO (1996), which explains that as incomes rise, consumers tend to purchase wheat, rice, and, in some cases, maize, rather than traditional coarse grains. This has resulted in farmers viewing small grains as having lower earnings than other crops. Nciizah (2014) showed that one major disadvantage of small grains cited by Zvishavane farmers is the limited marketing opportunities. In the study farmers complained about the absence of a ready market for small grains. Farmers in Zvishavane do not rely on the Zimbabwe Grain Marketing Board (GMB) to buy small grains. According to Mugiya and Hofisi (2017), farmers complained that the GMB normally delays to pay farmers, a situation which further complicates their adaptation, as their purchasing power remains poor.

Low Extension Services and Government Support

Mukarumbwa and Mushunje (2010), show that small grain production has been negatively affected by inadequate government support. Research has shown that sorghum and millet are the most drought-tolerant cereal grain crops suitable in semi-arid regions (Taylor et al. 2006). The agricultural extension services department (AGRITEX) and the Department of Meteorological Services have extensively been incapacitated as a result of the country's economic and political challenges over the past decades that resulted in brain drain of skilled staff (Mutasa 2011). This has had a negative impact on farmers' production capacity and delivery of information about appropriate seeds and production technology. Mukarumbwa and Mushunje (2010) in their study indicated that inadequate government support to promote small grain production has led to low productivity of these small grains. Mugiya and Hofisi (2017) indicated that NGOs in Zvishavane are allegedly accused of imposing programs on small-scale farmers. The study also revealed that this also applies to government officials like extension officers. Extension officers believe that small-scale farmers are rigid and thus end up forcing farmers to adopt small grains. The farmers end up facing a challenge as their perceptions end up being ignored.

Food Preferences

A significant production constraint toward small grain production is food preferences. Most Zvishavane farmers significantly prefer maize due to taste preferences as compared to small grains. Mugiya and Hofisi (2017) reported that while small grain crops prove to be a viable option to boost production in Zvishavane in light of climate change, most farmers are not adopting small grains enthusiastically as it threatens their food preference. Such preferences affect the overall production of small grains. There remains a strong inclination to maize production as compared to small grain production. Maize is easily processed compared to small grains, which makes maize widely accepted. Jones (2011) pointed out food taste, media, and education as influential to people's food preference. Mugiya and Hofisi (2017) also indicated that children prefer maize to millet and sorghum. Food security in Zvishavane has been hindered due to farmers' rejection to produce small grains.

Interventions to Overcome the Barriers to Small Grains Adoption

Despite the huge potential of small grain crops to provide a viable adaptation mechanism to climate change, adoption among smallholder farmers remains disappointingly low due to the barriers addressed above. There is need for practical solutions from all stakeholders that will make the crop attractive for smallholder farmers in drought prone regions such as Zvishavane District. A comprehensive review by UNDP (2018b) on emerging solutions to small grains value chains in Zimbabwe identified the following interventions;

(i) Availing improved varieties
(ii) Improved processing methods and equipment
(iii) Improved post-harvest management
(iv) Improved access to markets for both inputs and outputs

These interventions are likely to make small grain crops more attractive for smallholder farmers. For instance, Musara and Musemwa (2020) showed that the allocation of more land toward improved sorghum varieties by smallholder farmers resulted in improved food diversity and food access. Moreover, improved varieties are likely to be more resilient to elevated temperature and low rainfall conditions due to climate change. However, it is necessary for stakeholders to increase funding for the development of improved small grains varieties, which currently lags behind of maize. Nevertheless, it is important that breeders, seed companies, seeds suppliers, processors, and retailers work closely with smallholder farmers to effectively understand and incorporate farmers' preferences as the end users.

It is also important to note that while small grains like sorghum perform comparatively better than maize under harsh conditions, unfavorable soil conditions, extremes in weather, pests, and poor management practices negatively affect yield. Consequently, it is important to complement improved varieties with sustainable cropping practices. One of the most widely recommended approaches is climate smart agriculture (CSA), which entails agricultural practices that concurrently increase productivity, strengthens resilience to climate change (adaptation), reduces/removes GHGs (mitigation), and contributes to achieving food security and development objectives (FAO 2010). Examples of such practices include conservation agriculture, legume intercropping, agroforestry, organic agriculture, and improved pest, water, and nutrient management. These practices significantly improve soil health, which ultimately improves crop productivity. Improved cropping practices have a potential to improve yields, which may in turn increase adoption of small grains. An increase in the adoption of the crop may in turn make seed production more attractive for established seed companies, who currently do not see the benefit of producing small grain seed due to low sales. However, for farmers to adopt these sustainable agricultural practices, there is a need to strengthen technical support services. Poor technology as well is generally one of the most prevalent challenges to agricultural production and uptake of new technology in smallholder farming areas.

Conclusions

The Chapter examined the role played by small grains in adapting to climate change in Zvishavane. Farmers in Zvishavane have perceived climate change as they have noticed changes in rainfall and temperature patterns in the past years. Such perceptions have been helpful in assisting many farmers to realize the need to adapt to climate change. The most appropriate way to adapt to climate change in the area as shown in this chapter is small grain production. Small grain production is the best strategy given that small grains are drought resistant and can withstand the hot temperatures in Zvishavane. However, despite this realization, an insignificant number of Zvishavane farmers are involved in small grain production. This is due to numerous barriers that have affected the smooth implementation of small grains. Such barriers are inclusive of the labor associated with small grain production, the challenge posed by the quelea birds, food preferences, low markets, and low extension services and government support. If nothing is done to mitigate these barriers, Zvishavane will continue to be a food insecure area. In this regard, the chapter highlighted possible interventions that can assist in helping farmers adopt small grains, which include the development of improved varieties, adoption of CSA practices, improved technical support, and access to markets. The labor intensiveness associated with small grain production requires technology and machinery that help in reducing manual labor. There is also need for policies promoting small grain production and processing to add value to small grains.

is crucial for farmers to adapt to the never ending climate change. However, there are constraints to adaptation strategies used by the farmers. This study therefore identified some of the constraints to the farmers' choice of climate change adaptation strategies in Ondo State, Nigeria. A multistage sampling procedure was used in selecting one hundred and sixty respondents for the study. Data collected with a well-structured interview schedule were analyzed using frequency, percentage, and mean statistic, while Pearson Product Moment Correlation was used to test hypothesis. Crops competing for nutrient, inadequate access to climate information, inadequate finance, scarcity of labor, and inadequate farm input supplies were among the major constraints to choice of climate change adaptation strategies used by the respondents. The study recommended that weather forecast information should be published and made available to the farmers through agricultural extension agents. Training on how to improve mixed cropping technique and avoid vulnerability should be pursued.

Introduction

Background

Climate change is one of the major sources of risk in agriculture (De and Badosa 2015). In sub-Saharan Africa, it is set to hit the sector severely and cause suffering, particularly for smallholder farmers. The potential of agriculture to generate a more pro-poor growth process depends on the creation of new market opportunities that most benefit the rural poor (Culas and Hanjra 2011). This could be attributed to the fact that climate change affects the two most important direct agricultural production inputs: precipitation and rainfall (Deschenes and Greenstone 2006). Climate change also indirectly affects agriculture by influencing emergence and distribution of crop pests and livestock diseases, exacerbating the frequency and distribution of adverse weather conditions, reducing water supplies for irrigation, and enhancing severity of soil erosion (IPCC 1998).

Nigeria, which is dependent on rain-fed agriculture together with low level of socio economic development, is highly affected and vulnerable to climate change. Thus, a better understanding of farmers' concerns and their perception of climate change is crucial to design effective policies for supporting successful adaptation of the agricultural sector (Kumar and Sidana 2018). Adaptation helps farmers achieve their food, income, and livelihood security objectives in the face of changing climatic and socioeconomic conditions, including climate variability, extreme weather conditions such as droughts and floods, and volatile short-term changes in local and large-scale markets (Kandlinkar and Risbey 2000). Farmers can reduce the potential damage by making tactical responses to these changes.

Adaptation strategies which are applicable to climate change are not exhaustive. These strategies vary with scope, approach, purpose, use, application, and timing. The choice of adaptation methods by farmers depends on various social, economic, and environmental factors (Bryan et al. 2013). Adaptation is therefore important for finding ways to help farmers adapt in the rural economies of Africa by providing effective adaptation strategies such as the use of irrigation facilities, improved and resistant crop varieties, modern farm mechanization among others in combating the adverse effect of climate change.

However, there are constraints to adaptation strategies of the farmers, which vary across countries. Satishkumar et al. (2013) categorized constraints faced by farmers in India into personal, institutional, and technical constraints. Small scale fragmented land holdings, low literacy level, inadequate knowledge of how to cope or build resilience, and traditional beliefs were categorized as personal constraints; poor access to extension services, poor access to information sources, and nonavailability of institutional credit were categorized as institutional constraints, while non-availability of drought tolerant varieties, lack of access to weather forecasting information, dependent on monsoon irrigation, high cost of irrigation facilities, shifting of cropping pattern, and lack of technical know-how were categorized as technical constraints.

Fagariba et al. (2018) ranked the constraints affecting farmers' efforts to curb the impact of climate change in Northern Ghana. The study reported unpredictable weather conditions to be the most serious constraint to climate change adaptation strategies. Inadequate government support, lack of access to weather information, land tenure issues, high cost of input, inadequate extension officers, lack of formal education, and poor soil fertility were the other constraints. Otitoju and Enete (2016) grouped the constraints to the use of adaptation strategies among food crop farmers in South-western Nigeria into four. The groups include public, institutional, and labor constraints; land, neighborhood norms, and religious beliefs constraints; high cost of inputs, technological and poor information on early warning systems constraints; and far farm distance, poor access to climate change adaptation information, off-farm job, and credit constraints. Evers and Pathirana (2018) submit that greater communication, cooperation, and coordination of both policy and scientific work that cut across both disciplinary and geographical boundaries are needed to help reduce uncertainties in future climate projections and inform adaptation decisions.

As site-specific issues require site-specific knowledge, it is very important, therefore, to clearly understand what is happening at community level, because farmers are the most climate vulnerable group. In the absence of such location specific studies, it is difficult to fine tune interventions geared towards alleviating the constraints faced by the local farmers. It is on this note that this study seeks to know the socio economic characteristics of the farmers' and also identify the constraints to farmers' choices of climate change adaptation strategies in the study area.

Description of the Study Area and Methodology

Study Area

The study was carried out in Ondo State, one of the 36 states in Nigeria, and a member of the Niger Delta commission (NDDC) in Nigeria. Ondo State was created on third of February 1976 from the former western state. It originally included what is now Ekiti state, before the separation in 1996 (ODGS 2016). It is bounded in the North West by Ekiti State, west central by Osun State, South East by Ogun State, South East by Edo and Delta states, and the South by the Atlantic Ocean. The state lies between latitude 5° 45 and 8° 15^{1} north and longitude 4° 45^{1} and 6° 05 ^{1} east. Its land area is about 15,500 square kilometers (ODGS 2016).

Ondo State's climate is of two distinct seasons (wet and dry season). In the south, the mean monthly temperature is 27 °C with a mean monthly range of 2 °C, while mean relative humidity is over 75%. However, in the northern part of the state, the mean monthly temperature and its range are about 30 °C and 6 °C, respectively. The mean monthly relative humidity is less than 70%. Also, the mean annual total rain fall exceed 2000 mm. However, in the northern part, there is marked dry season from November to march when little or no rain fall, hence, the total annual rain fall in the North drops considerably to about 1800 mm (Fasina et al. 2016; ODSG 2016).

The natural vegetation is the high forest, composed of many varieties of hardwood timber such as *Melicia excelsa, Antaris toxicaria, Lophira alata, Terminalia superba*, *and Symphonia globulinfera.* An important aspect of vegetation of the state is the prevalence of tree crops. The major tree crops include cocoa, kola, rubber, coffee, oil palms, fruits, and citrus (Institute of Food Security, Environmental Resource and Agricultural Research (IFSERAR) 2010). Ondo state is predominantly an agricultural state with over 60% of its labor force deriving their income from farming. It is the leading Cocoa producing state in Nigeria. Other agricultural products include yam, cassava, cocoyam, plantain; thus, the state can support the cultivation of a large variety of crops. It also has the longest coastline in the Country which favor fishing activities in the riverine areas (IFSERAR 2010). The population of the study includes all arable crop farmers in Ondo State, Nigeria.

Research Methods

Study Site Selection and Sampling Methods

A multistage sampling procedure was used in selecting the respondents for this study. In the first stage, two out of the three senatorial districts in the state were randomly selected. The selected senatorial districts are Ondo Central and Ondo North. The second stage involved a random selection of two (2) Local Government Areas (LGAs) from each of the two selected senatorial districts. The selected LGAs are: Akure South, Ifedore, Ose, and Owo LGAs. The third stage involved purposive selection of four (4) villages, based on the predominance of arable crop farming in the LGAs, making a total of sixteen (16) villages. In the final stage, ten arable crop farmers were randomly selected. Thus, a total of one hundred and sixty (160) respondents constituted the sample size for the study. Data were collected with the aid of a well-structured interview schedule.

Data Source and Collection Method

Data Analysis

Data analytical techniques that were used in achieving the objectives for this study are descriptive statistics. They include frequency counts, percentage and mean.

The socio-economic characteristics of the farmers were analyzed using frequency, percentage, and mean statistic. To identify the constraints to choice of adaptation strategies used by the respondents, a list of possible constraints were made available for the farmers to tick on a three-point Likert- type scale of major constraint, minor constraint, and not a constraint, with the value of 2, 1, and 0, respectively. These values were added up to 3 and divided by 3 to get a mean value of 1. Any variables with mean value greater than or equals to 1 imply that they are constraints to climate change adaptation, while mean value of less than 1 implies that they are not a constraint. Any variable with a mean value of greater than or equals to 1.5 are major constraints. The responses were analyzed using mean statistic.

Hypothesis H_0: There is no significant relationship between some socio economic characteristics of the respondents and constraints to choice of adaptation strategies used by the respondents. This was tested using the Pearson Product Moment Correlation (PPMC).

Limitations of the Study

The study covered only four (4) LGAs out of the eighteen (18) LGAs in the state. Only one hundred and sixty respondents out of several hundred thousands of arable crop farmers in the state were included in the study. This was due to the paucity of funds to carry out the study. A funded research can cover a larger sample for a similar study in the future. Furthermore, access to some farmers was very difficult due to bad access roads, which is a feature of many rural communities in Nigeria. Responses gotten from the respondents were based on memory recall which may not be perfectly and correctly stated. The effects of this limitation were minimized by repeating some questions but reframed, so as to confirm the response to the previous question. Uncooperative attitude of some farmers in terms of giving accurate information about themselves was another limitation. These limitations propelled the researchers to put extra effort to collect reliable data, which will be affected by the identified limiting factors.

Results and Discussion

Socio-Economic Characteristics of the Respondent

The distribution of respondents by their socio-economic characteristics is presented in Table 1. It was revealed that 38.8% were between 50 and 59 years of age, 24.5% were between 40 and 49 years, 20.7% were between 60 and 69 years, while 10.5% of the respondents were above 70 years of age. Also, 4.9% of the respondents were between 30 and 39 years, while only 0.6% of the respondents were less than 30 years of age. It was further revealed that the average age of the respondents was 54.6 years. This is an indication that arable crop farmers in the study area are fairly old, although they are still within the active age with the strength and vigor to carry out all the laborious activities involved in agricultural production. This agreed with the findings of Oluwasusi and Tijani (2013), who reported an average age of 53.9 years in a study conducted in Ekiti State, Nigeria.

Farming in the study area was dominated by the males (62.5%), while the female respondents accounted for 37.5% of the respondents. This might be attributed to the laborious nature of all the activities involved in arable crop production/farming in the study area. However, the females were believed to be more involved in the processing and marketing of farm by-products. This agreed with the findings of Ibitoye et al. (2014) who reported that the males dominated agricultural production in a study on the constraints to climate variability adaption among arable crop farmers in Ekiti State, Nigeria.

It was further revealed that majority (87.5%) of the respondents were married, while only 1.9% of them were still single, 6.3% of the respondents were divorced, while 4.4% of them were separated. The fact that majority of the farmers in the study area were married might be a reflection of the strong moral values attached to marriage institution in the study area. This also agreed with the findings of Ibitoye (2012) and Oguntade et al. (2014) who reported in their separate studies that arable crop farmers that are married dominated arable crop farming activities in Nigeria. Majority (62.5%) of the arable crop farmers in the study area were Christians, 32.5% of the respondents were Muslims, while 5.0% of the respondents practiced traditional religion.

Average household size of the respondents was 7 people. It was revealed that majority (71.2%) of the farming households had between 5 and 9 people, while 16.3% had less than 5 people in their household. However, 12.5% of the respondents had 10 people and above in their respective households. The average household size of about 7 people implied that the household size among farming households in the study area is fairly large. However, this is expected to be a very good source of labor (family labor) for their farming activities and it is expected to enhance their level of productivity.

It was observed that 28.1% of the respondents had no formal education, 21.9% completed primary school education, while 15.6% of them completed secondary school education. It was also revealed that 11.3% attempted primary school education, 8.1% of the respondents acquired adult education, 8.1% of the respondents

Source: Field Survey, 2017

attempted secondary school education, while 6.3% of them completed tertiary education. However, 0.6% of the respondents attempted education at tertiary level, without completing it. The fact that only 15.6% of the total respondents completed secondary school education and that only 6.3% of them completed tertiary education is an indication that the level of education among the farmers in the study area is low, in agreement with the findings of Oluwasusi and Tijani (2013). This is believed to have an effect on their level of awareness about climate change effects and also on their level of adoption on strategies in mitigating its effects.

It was further revealed that respondents that had farming experience of 30 years and above constituted 46.3% of the total respondents sampled for this study. However, 25.5% of the respondents were reported to have between 20 and 29 years of farming experience, 18.1% had between 10 and 19 years of farming experience, while only 10.1% of the total respondents had less than 10 years of farming experience. It was also revealed that the average years of farming experience among the arable crop farmers in the study area was 27.5 years. This is an indication that respondents are well experienced in farming activities in the study area. This is expected to enhance the knowledge of the farmers in how to select the appropriate measures to mitigate and cope with the effect of climate change in the study area, in agreement with the findings of Oguntade et al. (2014).

Majority (71.4%) of the respondents had less than one hectare of farm land, 17.5% have between 1–1.99 ha, while 10.0% of the respondents had a farm size of between 2 and 4.99 ha. However, 1.1% of the respondents had a farm size of five hectares and above. The average farm size was approximately one hectare. This suggests that respondents in the study area are small holder arable crop farmers, who practice farming on subsistence basis. This finding is in agreement with the findings of Babatunde (2008), who reported that majority of arable crop farmers in Nigeria are small holder farmers who practice subsistence farming on a small piece of land.

Majority of the respondents (70.6%) earned between ₦100,000 and ₦499,999 per annum, 17.5% of them earned between ₦500,000 and ₦999,999 per annum, while 8.7% of the respondents earned less than ₦100,000 per annum. However, 3.2% of the respondents earned above ₦1,000,000 per annum. The average annual income of the respondents was also revealed to be ₦318,595.91. This suggests that the average annual income of the respondents was fairly low. This could, however, be attributed to the fact that the arable crop farmers in the study are operating on a subsistence scale, with majority of them farming on less than one hectare of land as reported earlier. The low income earned by the arable crop farmers might equally be due to low output that usually occurs as a result of the adverse effects of climate change. This is in agreement with the findings of Falola et al. (2012); also, low income earned by the arable crop farmers may also be as a result of extra costs incurred by the arable crop farmers in an attempt to mitigate the adverse effects of climate change.

Constraints to Choice of Adaptation Strategies Used by the Respondents

Table 2 presents the constraints to choice of adaptation strategies used by the respondents in the study area. It was revealed that inadequate finance ($\overline{X} = 1.8$), scarcity of labor ($\overline{X} = 1.8$), and inadequate technical know-how knowledge ($\overline{X} = 1.7$) were the major constraints militating against the choice of irrigation as a coping strategy to the effect of climate change in the study area. The problems of inadequate finance would not enable the arable crop farmers to acquire the necessary irrigation equipment and facilities which might be too expensive for them to acquire from the proceeds from their farming activities. Also, inadequate knowledge and technical know-how in operating the modern irrigation equipment will to a greater extent limit the farmers use of irrigation as an adaptation strategy to the effect of climate change in the study area.

It was further revealed that poor agricultural extension services ($\overline{X} = 1.6$), high cost of fertilizer and other inputs ($\overline{X} = 1.5$), as well as pest and diseases ($\overline{X} = 1.6$) were the major constraints militating against the choice of planting of cover crops as a coping strategy to combat the effect of climate change in the study area. This implied that inadequate dissemination of information as a result of poor extension services limits the level of awareness of the farmers on the potentials the planting of cover crops has in reducing the effect of adverse climatic condition (e.g., drought) on arable crops in the study area. This is in conformity with the findings of Satishkumar et al. (2013) Also, high cost of fertilizer and other inputs required in planting and maintaining cover crops constrained some of the arable crop farmers to use the planting of cover crops to combat the adverse effect of climate change in the study area. This is in line with the findings of Otitoju and Enete (2016). High possible incidence of pest and disease infestation associated with the use of cover crops can also be a constraint to the use of cover crop in mitigating the effects of climate change in the study area.

It was further revealed that the major constraints militating against the use of weather forecasting as an adaptation strategy against the effects of climate change included inadequate access to climate information ($\overline{X} = 1.8$). This corroborates the findings of Fagariba et al. (2018). This suggests that inadequacy of climatic information available to the arable crop farmers in terms of accuracy and consistency of metrological information greatly constrained them from choosing weather forecasting as an adaptation strategy against the effects of climate change. Also, the high cost of accessing the weather forecast information as well as the incompatibility of such information constrained the farmers in adopting weather forecasting as a reliable means of coping with the effect of climate change in the study area.

Table 2 Constraints to choice of adaptation strategies used by the respondents

Constraints to adaptation strategies	Major constraints (2)	Minor constraints (1)	Not a constraint (0)	Mean ($\overline{X}$)	Std. dev.
Irrigation					
Inadequate finance	38 (86.4)	4 (9.1)	2 (4.5)	1.8*	0.5

Key: 0–0.9 = Not a Constraint; 1.0–1.4 = Minor Constraint; 1.5 and above = Major Constraint
*denotes major constraints
Note: Values in parenthesis are Percentages

It was further revealed in this study that the major factors militating against the use of resistant crop varieties as an adaptation strategy against the effects of climate change in the study area included nonavailability of the disease resistant varieties ($\overline{X} = 1.8$), high cost of the varieties ($\overline{X} = 1.7$), as well as off farm job and credits of the farmer ($\overline{X} = 1.5$). The high cost, coupled with the unavailability of improved varieties of arable crops that are resistant to pest and diseases, is a major constraint preventing the arable crop farmers from adopting the use of resistant crop varieties to cope with the effect of climate change in the study area. Otitoju and Enete (2016) reported a similar finding.

Poor agricultural program and service delivery ($\overline{X} = 1.7$), inadequate access to hybrid seeds ($\overline{X} = 1.7$), and reduction in output ($\overline{X} = 1.5$) were the major constraints militating against the use of change in planting date as an adaptation strategy against the effects of climate change in the study area. Also, inaccurate agro-metrological information ($\overline{X} = 1.6$), time of dissemination of agro-metrological information ($X = 1.5$), and poor storage and processing facilities ($\overline{X} = 1.4$) were the major constraints militating against the use of change in harvest date as an adaptation strategy to the effects of climate change in the study area. This implied that inaccurate and unseemliness of agro-metrological information greatly constrains the arable crop farmers in the adoption of both change in planting and harvest dates as a coping strategy in combating the effects of climate change in the study area.

It was also observed that major constraints that militated against the use of sand bags by river banks as an adaptation strategy to the effects of climate change in the study area included high cost of labor ($\overline{X} = 2.0$), inadequate finance and credit facilities ($\overline{X} = 2.0$), and drudgery of making the sand bags ($\overline{X} = 1.9$). This implied that the use of sand bags as an adaptation strategy might be very expensive for the arable crop farmers to adopt. Therefore, with the limited finance available to the arable crop farmers, it might be difficult to adopt the use of sand bags as an adaptation strategy to combat the effect of climate change in the study area. Also, drudgery of making the sand bags might be a discouraging factor preventing the farmers from adopting the use of sand bags as an adaptation strategy to combat the effect of climate change in the study area.

Furthermore, high cost of labor in applying the mulching material ($\overline{X} = 1.7$) and the durability of the mulching materials ($\overline{X} = 1.2$) were the major constraining factors militating against the use of mulching materials as an adaptation strategy against the effects of climate change in the study area. This suggests that the higher the cost of labor in applying the mulching materials, the lesser the adoption of mulching materials as an adaptation strategy in combating the effect of climate change in the study area. It was further observed that the constraints militating against the use of mixed cropping system as an adaptation strategy in the study area were minor ones. They included crops competing for nutrient ($\overline{X} = 1.4$), vulnerability to pest and diseases ($\overline{X} = 1.2$), and depletion of the soil nutrient ($\overline{X} = 1.2$). This might be attributed to the fact that the practice of mixed cropping increase the vulnerability of the crops planted to different pests and diseases. Also, practicing mixed cropping will make the different crops compete for the limited available nutrients, and ultimately this will lead to quick depletion of soil nutrients.

Table 3 PPMC Correlation between some socioeconomic characteristic of the respondent and constraints to choice of adaptation strategies

Variable	r-value	p-value	Decision
Age	−0.028	0.729	Not significant
Household size	0.122	0.128	Not significant
Level of education	−0.074	0.354	Not significant
Farming experience (years)	0.126	0.116	Not significant
Farm size (plots)	0.170[a]	0.034	Significant

[a]Correlation is significant at the 0.05 level (2-tailed)

Furthermore, the major constraining factor against the use of crop rotation as an adaptation strategy to the effects of climate change was observed to be inadequate farm input supplies ($\overline{X} = 1.6$), while the life span of the crop grown ($\overline{X} = 1.2$) was a minor constraint. Moreover, there were only minor constraining factors against the use of intercropping as an adaptation strategy to the effects of climate change in the study area. They include complication of crop management and harvesting ($\overline{X} = 1.3$) and problem of separating seed crop yield ($\overline{X} = 1.0$). However, inadequate finance and credit ($\overline{X} = 1.5$), poor skills ($\overline{X} = 1.5$), and low wages and poor condition of work ($\overline{X} = 1.5$) were the major constraints preventing the arable crop farmers from choosing nonfarm income diversification as an adaptation strategy against the effects of climate change in the study area.

Relationship Between Some Socioeconomic Characteristic of the Respondents and Constraints to Choice of Adaptation Strategies

Table 3 presents the result of the null hypothesis which states that "There is no significant relationship between some socioeconomic characteristic of the respondent and the constraints to choice of adaptation strategies used by the respondent." It was revealed that the farm size of the respondent was the only socioeconomic characteristic that had a strong positive correlation (r = 0.170; p = 0.034) with the constraints to choice of climate change adaptation strategies used by the respondent in the study area. This suggests that constraints to choice of climate change adaptation strategies increases with increase in the farm size, implying that respondents with larger arable crop farms were faced with more constraints to choice of climate change adaptation strategies in the study area compared with those with smaller farm size.

Conclusions

From the findings, it can be concluded that many of the farmers, who happened to be males, fairly old, and are arable crop farmers. The major constraints to the various adaptation strategies were inadequate finance, scarcity of labor, poor agricultural extension services, inadequate access to climate information, nonavailability of resistant varieties, poor agricultural program, inaccurate agro-meteorological information, high cost of labor, low wages and poor condition of work, complication of crop management and harvesting, inadequate farm input supplies, and crops competing for nutrient. These constraints have hindered arable crop farmers in their choice of the identified adaptation strategies in coping with the adverse effect of climate change; it is also reduced farmers level of food production in a bid to ensure food security in the society and also elevate their own economic standard. Hence, respondents with larger arable crop farms were faced with more constraints to choice of climate change adaptation strategies in the study area compared with those with smaller farm size.

It is recommended that weather forecast information should be published and be made available to the farmers for them to be aware of situations to be prepared for at the beginning of each production season through agricultural extension agents. Also, training on how to improve the mixed cropping technique and avoid vulnerability should be pursued. This could also avert crop failure.

Maize, Cassava, and Sweet Potato Yield on Monthly Climate in Malawi

33

Floney P. Kawaye and Michael F. Hutchinson

Contents

Abstract

Climate change and climate variability in Malawi have negatively affected the production of maize, a staple food crop. This has adversely affected food security. On the other hand, there have been increases in growing area, production, yield, consumption, and commercialization of both cassava and sweet potato. Factors behind these increases include the adaptive capacity of these crops in relation to climate change and variability, structural adjustment programs, population growth and urbanization, new farming technologies, and economic development. Cassava and sweet potato are seen to have the potential to contribute to food security and alleviate poverty among rural communities.

This study used a simple generic growth index model called GROWEST to model observed yields of maize, cassava, and sweet potato across Malawi between 2001 and 2012. The method can be viewed as a hybrid approach between complex process-based crop models and typical statistical models. For each food crop, the GROWEST model was able to provide a robust correlation between observed yields and spatially interpolated monthly climate. The model parameters, which included optimum growing temperatures and growing seasons, were well determined and agreed with known values. This indicated that these models could be used with reasonable confidence to project the impacts of climate change on crop yield. These projections could help assess the future of food security in Malawi under the changing climate and assist in planning for this future.

Climate change · Food security · Maize · Cassava · Sweet potato · Crop yield modelling

Introduction

Process-based simulation models and statistical models are commonly used to assess the impact of climate variability and climate change on food crop yields (Lobell and Asseng 2017). The former typically have complex plant and environmental data requirements, while the latter can have large uncertainties in fitted parameters that make application to climate change assessment difficult (Schlenker and Lobell 2010; Ray et al. 2019). This chapter examines a hybrid approach that statistically calibrates a simple generic plant growth model, called GROWEST, using spatially distributed yield and monthly climate data. The model parameters are robustly determined and hence able to provide baseline models suitable for assessing the potential yields of maize, cassava, and sweet potato in relation to projected climate change. The GROWEST plant growth index model was originally developed by Fitzpatrick and Nix (1970) and Nix (1981) and has been implemented by Hutchinson et al. (2002). It has been used to develop a global agroclimatic classification that has identified agroclimatic classes for Australia (Hutchinson et al. 2005) that have been used to support a wide variety of ecosystem assessments.

The model is applied to annual yield data for the eight Agricultural Development Divisions (ADDs) across Malawi and corresponding spatially distributed monthly climate data. Spatial climate data were available from 1981 to 2012. The maize analyses were restricted to the years 2006–2012 after the introduction of the Farm Input Subsidy Program (FISP) in 2005/06 which had a significant impact on maize yields. Reliable annual yield data were available for cassava for the period 2001–2011 and for sweet potato for the period 2006–2012. The yield model is based on regressing the logarithms of the observed crop yields on average weekly growth indices of the GROWEST model, with the average taken over the respective growing season for each crop. Three key parameters of the GROWEST model, the optimum growth temperature and the starting and finishing weeks of the growth season, are tuned to the observed yield data for each crop. The regressions take into account variations in site and management conditions across different ADDs and are extended to take into account systematic increases in yields over time due to plant breeding programs, improvements in growing practice, and carbon dioxide fertilization. Robustly calibrated models are obtained for local, composite, and hybrid maize varieties and for cassava and sweet potato.

Maize, Cassava, and Sweet Potato Growth

As noted by Kawaye and Hutchinson (2018), maize is a staple food crop in Malawi that is grown under both irrigation and rainfed farming systems. However, rainfed farming dominates as it covers about 99% of Malawi's agriculture, mainly on smallholder farms. Kawaye and Hutchinson (2018) further noted that rainfed maize is normally planted between November and December (the start of the rainy season). It grows rapidly during the high rainfall months of January and February and matures by early April. It is harvested in late April or early May. Maize yields in Malawi range from less than 1000 kg to over 4000 kg per hectare, depending on various factors including climate, location, seed variety, fertilizer use, labor, and policy-related factors including access to credit, input and output markets and extension services.

Cassava (*Manihot esculenta* Crantz) is a perennial woody shrub with an edible starchy tuberous root (Mathieu-Colas et al. 2009). Cassava grows under diverse ecological and agronomical conditions. It favors a warm moist climate with mean temperature of 24–30 °C (Nassar 2004; Mkumbira 2002). It can tolerate temperatures from 16 °C to 38 °C (Cock 1984). It does not favor excess soil moisture nor high salt concentrations nor pH above 8 (Nassar 2004; Mkumbira 2002). Cassava is normally planted early in the wet season, usually around mid-November. As a perennial crop, cassava has no definite lifetime or maturation period. After full development of the canopy, root growth slowly decreases and finally stops. This is the maturation point of cassava when maximum or near maximum yield is obtained. Cassava is harvested when the returns for production and utilization are maximized. Thus harvesting can be delayed to well after when the tubers have matured. The optimum time to harvest is 9–12 months (Mathias and Kabambe 2015) depending on various ecological factors such as rainfall, temperature, and soil fertility (Mathieu-Colas et al. 2009; Benesi 2005).

Sweet potato (*Ipomoea batatas* Lam) is an annual crop (Mathieu-Colas et al. 2009). It is widely grown in tropical, subtropical, and temperate areas between 40°N and 32°S. It grows best with air temperatures between 20 °C and 25 °C, and growth is restricted below 15 °C (Ramirez 1992). It can be cultivated across a wide variety of soil types and prefers lightly acid or neutral soils with a pH between 5.5 and 6.5 (Ramirez 1992). Sweet potato is commonly grown as an intercrop with maize and planted early in the calendar year (FAO 2005). It can also be planted toward the end of the wet season in late April and grown on residual soil moisture. Like cassava, the growth period of sweet potato depends on various ecological factors, but it generally takes 4–5 months to mature (Mathieu-Colas et al. 2009).

Methodology

This study modelled the dependence of observed maize, cassava, and sweet potato yields on spatially distributed monthly climate to provide a basis for assessing the impact of projected climate change. The models were constructed by performing multilinear regressions of the logarithms of the observed yields on accumulated outputs from the GROWEST growth index model. The GROWEST model generates a generic, process-based, growth index that depends on weekly or monthly climate with a minimal number of parameters. The growth index varies between 0 (climate totally limiting for growth) and 1 (climate optimal for growth). It is normally assumed to be proportional to the rate of relative increase in plant biomass over time. The growth index is calculated as the product of three separate indices that incorporate the impact of temperature, solar radiation, and modelled soil moisture. The simplicity of the model, and its underlying process basis, makes it well suited to deriving robust calibrations of yield response to climate using yield data limited in quantity or quality. The modelling approach can be seen as a hybrid between complex crop simulation models and statistical analysis of growing season weather variables (Lobell et al. 2011). The critical parameters of the GROWEST model are able to be determined by maximizing the alignment of the GROWEST outputs with the observed crop yields using standard multilinear regression. These regression analyses are extended to take account of observed systematic increases in crop yields over time due to crop breeding programs, improvements in crop management, and possible carbon dioxide fertilization.

GROWEST Analysis

The models were calibrated on yield data for each ADD over the periods for which both climate and reliable yield data were available, namely, 2006–2012 for the three main varieties of maize, 2001–2011 for cassava, and 2006–2012 for sweet potato. The GROWEST model was applied to monthly climate across all eight ADDs using interpolated monthly climate values at 74 points that approximately equi-sampled the cropping areas across the eight ADDs of Malawi as shown in Fig. 1. The interpolated climate values were obtained using thin plate smoothing splines as provided by the ANUSPLIN Version 4.4 package (Hutchinson and Xu 2013). The output growth indices (GIs) were averaged across each ADD to match the average yields reported for each ADD. The GROWEST model runs on a weekly time step but can be applied to monthly climate data by interpolating monthly data to weekly

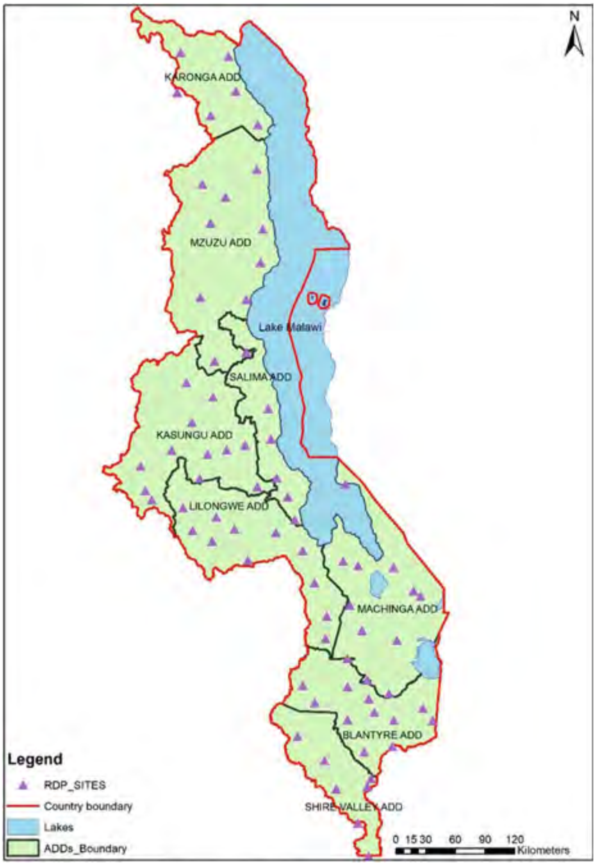

Fig. 1 Seventy-four sites sampling crop growing areas across the eight Agricultural Development Divisions (ADDs) of Malawi

data "on the fly." It can provide weekly or monthly outputs. Weekly GROWEST outputs were used to obtain finer-scale demarcations of the fitted growing seasons.

A robust regression model was used to determine critical GROWEST parameters for all five crop varieties. Since the GROWEST model describes a relative growth rate, it is natural to formulate the regression model in terms of the natural logarithm of the observed yields. The log formulation has been used in other yield studies (Lobell et al. 2011) and appears to offer a natural separation between site and climatic effects on observed crop yields. A similar approach, but not applying the log transformation, was described by Kawaye and Hutchinson (2018). The regression model for the observed yields Z_{ij} for year Y_i and ADD_j ($j = 1,..,8$) was defined by:

$$\log\left(Z_{ij}\right) = a_j + b\, G_{ij} + cY_i + \varepsilon_{ij}$$

where G_{ij} denotes the accumulated growth index for year Y_i and ADD_j and ε_{ij} denotes a zero-mean random error. The model parameters a_j and b were initially fitted by least squares regression while setting c = 0. Three additional critical GROWEST parameters were optimized during this initial fitting of the model. These parameters were the optimum temperature of the temperature index, used in calculating the weekly growth index, and the first and last weeks of the fitted growing season, used to define the growing season period. The soil water balance parameters of the GROWEST model were set to default values with the soil water holding capacity set to 150 mm and the soil drying rate set to that of a clay loam soil. The soil water balance is an important component of the growth index, but it is not very sensitive to departures from these default parameter values.

For the three maize varieties, parameter c was fitted by refitting all parameters using least squares regression. For cassava and sweet potato, parameter c was fitted by least squares regression on year of the residuals of the data from the initial model. This removed instabilities when all parameters were fitted directly to the cassava and sweet potato data.

The model is robust with just ten parameters. It has a constant dependence of log (yield) on the climate-based accumulated growth index but has a site varying intercept to allow for different site and management conditions across different ADDs. The linear dependence on year via parameter c allows for underlying improvements in yield due to crop breeding programs, improvements in crop management, and possible carbon dioxide fertilization.

As in Kawaye and Hutchinson (2018), the GROWEST parameters were optimized by automating GROWEST runs and initial regressions using FORTRAN code and standard LINPACK numerical analysis software (Dongarra et al. 1979). Comprehensive analyses of the fitted models were computed using the standard regression package within Excel software. These analyses permitted the identification and removal of a small number of yield data outliers with large standardized residuals. These were associated with anomalies and accounting errors evident in the supporting yield data.

Once outliers were removed and GROWEST optimizations were complete, final comprehensive statistical analyses were computed, making due allowance for the three degrees of freedom associated with estimating the three GROWEST parameters. Standard errors of the fitted GROWEST parameters for the initial regressions were calculated from the diagonal elements of the inverse of the associated Hessian matrix. The Hessian matrix was estimated by calculating second-order finite differences of the residual sums of squares of the model with respect to the three fitted GROWEST parameters.

The final fitted models were applied to the associated growing areas for each ADD and each year. These outputs were aggregated across all ADDs to obtain modelled national yield and production for all crops analyzed. These values were compared with the tabulated national yield and production values to assess the performance of the models at the national scale.

With a view to assessing the potential impacts of climate change, the domains of the fitted temperature indices for each crop were compared with the distributions of the weekly temperatures that occurred across the ADDs over the fitted growing seasons.

Results

Trends in Production and Yield of Maize, Cassava, and Sweet Potato

Three main varieties of maize are cultivated in Malawi. These are (i) local (traditional) varieties, (ii) composite varieties, and (iii) hybrid varieties. There are major differences between the yield potentials of these varieties (Giertz et al. 2015; Pauw et al. 2010; Denning et al. 2009; JICAF 2008; Heisey and Smale 1995; Ngwira and Sibale 1986). Local varieties have the lowest yield. They are not subject to yield improvement programs, and harvested seed is recycled from year to year. Composite varieties have higher yields and are often more drought tolerant. They are subject to yield improvement programs but seed can be recycled. Hybrid varieties are the highest yielding and most expensive. They are subject to strictly controlled yield improvement programs, and harvested seed cannot be recycled.

Figure 2 compares growing areas and yields of these three maize varieties from 1984 to 2015. There has only been significant composite maize production since the late 1990s. There has been a steady increase in the area devoted to composite and hybrid varieties and a simultaneous reduction in local maize growing area. This shift has been encouraged by increasing climate stress, such as increasing temperatures, and poor access to farm inputs for local maize production. There is significant year-to-year variation in maize yields, with composite and hybrid yields particularly low from 2001 to 2005. This could be attributed in part to poor climate including low rainfall. The generally higher yields of composite and hybrid maize after 2005 coincide with the introduction of the Farm Input Subsidy Program (FISP). Kawaye and Hutchinson (2018) have presented evidence that FISP has made a significant improvement in composite and hybrid yields since 2006. The analysis of maize yields presented below is therefore restricted to the post FISP years.

Figure 3 shows that cassava and sweet potato production has been generally increasing. There was an abrupt increase in cassava yield in the year 2000 followed by a steady increase, while sweet potato yield has been steadily increasing since the mid-1990s. The abrupt increases in yields in earlier years suggest there have been major improvements in crop-growing practice, and perhaps recording practice, during the 1990s. The steady increase in yields since 2000 reflects increased policy and institutional support, such as the introduction of higher yielding varieties, and improved management practices to diversify the food security basket. The general increase in area under cultivation cassava and sweet potato since 2005 indicates that more farmers have been planting these crops on new land or on land withdrawn from or shared with maize. As noted above, this is due to an increasing reliance on cassava and sweet potato for food security, especially in maize deficit (drought) years.

There was a sharp drop in both yield and production for all crops (maize, cassava, and sweet potato) in the drought year of 2005. For the other years, major variations in production are largely explained by major variations in growing areas as shown in Figs. 2 and 3. On the other hand, minor year-to-year variations in yield are likely to be attributable to year-to-year climatic variations. The differing year-to-year

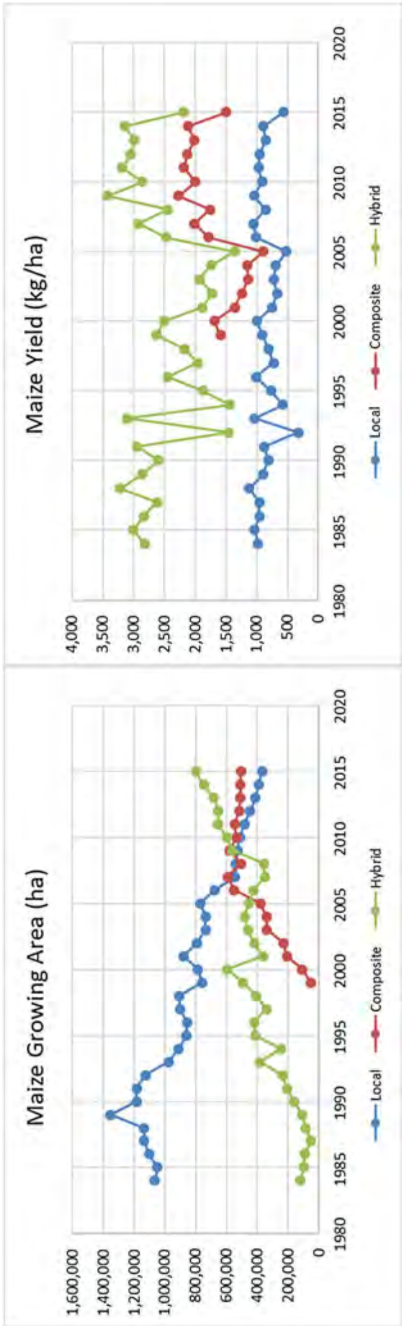

Fig. 2 Growing areas and total yield for local, composite, and hybrid maize from 1984 to 2015

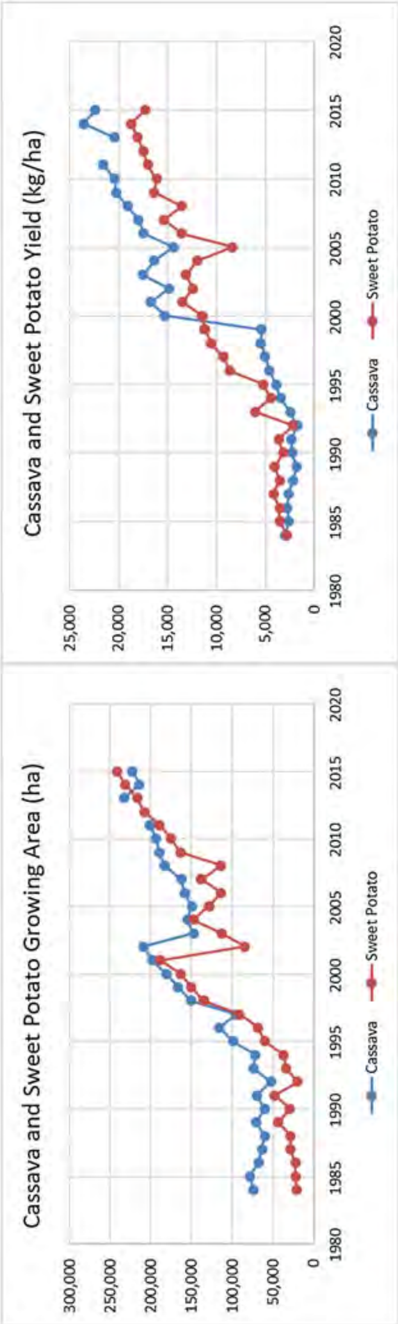

Fig. 3 Growing areas and total yield of cassava and sweet potato from 1984 to 2015

variations in yield and climate by ADD enable the calibration of the yield responses to monthly climate using the models described here.

GROWEST Analyses

For each crop the model was initially fitted to the available yield data values with the optimum GROWEST temperature set to a commonly accepted value for each crop. The automated model fitting code was used to adjust the growing season to minimize the standard error of the fitted model. A small number of large standardized residuals for each model were found to correspond to anomalous growing areas or yields for particular RDPs making up the ADD yield data. These large outliers were removed from the analysis, and the three key GROWEST parameters, the optimum growing temperature and the beginning and end of the growing season, were finally optimized by minimizing the residual sum of squares of the fitted model. There were two outliers for each of the three maize analyses, none for the cassava analysis and four for the sweet potato analysis. The values of the three key GROWEST parameters were found to be quite critical to the overall performance of the model. This is in keeping with the finding of Wang et al. (2017) who similarly found that the shape and location of the temperature response function in process-based crop models are critical to their performance. The fitted GROWEST parameters are listed in Table 1.

The fitted starting weeks for the three maize varieties were remarkably similar. Allowing for a period of around 2 weeks from sowing to emergence when the maize plants begin to interact with the atmosphere, the fitted starting weeks corresponded to planting in early December when the wet season is underway. Composite and hybrid maize had fitted growing seasons lasting 13 and 12 weeks, while local maize had a somewhat longer fitted growing season of 15 weeks. These values are all in reasonable agreement with standard management practice. There is systematic variation in the fitted optimum growing temperatures. The fitted temperature for local maize is consistent with documented optimum temperatures of around 26 °C

Table 1 Optimized GROWEST parameters and mean yield for each crop. Standard errors for each parameter value are provided in parentheses. Weeks are numbered sequentially 1–52 for each year

Crop	Number of data points	Optimum growing temperature (°C)	First week of growing season	Last week of growing season	Mean crop yield (kg/ha)
Local maize	54	24.5 (0.9)	52 (1.0)	15 (1.7)	928
Composite maize	54	28.9 (0.4)	52 (0.8)	13 (1.3)	1,981
Hybrid maize	54	30.2 (0.6)	51 (1.4)	12 (1.5)	2,883
Cassava	88	27.3 (0.6)	47 (2.0)	26 (2.9)	17,984
Sweet potato	52	23.4 (0.7)	7 (2.9)	22 (2.0)	15,920

for maize root growth and grain filling (Sánchez et al. 2014). The fitted temperature for composite maize is consistent with documented optimum temperatures of around 28 °C to 30 °C for maize growth from sowing to anthesis. The slightly higher fitted temperature for hybrid maize is consistent with documented optimum temperatures of around 31 °C for whole plant maize growth. The fitted parameter values indicate that hybrid and composite maize are better adapted to higher temperatures and have shorter growing seasons than the traditional local maize varieties. These are both accepted aims of maize breeding programs.

The fitted growing season for cassava corresponded to planting cassava in mid-November and effective growth terminating by around the end of June. This agrees with the usual growing practice for cassava reported above, with planting time somewhat variable from year to year depending on the arrival of rain and harvesting time variable according to a range of conditions. The latter is consistent with the larger standard error for the finishing week. The fitted optimum growing temperature for cassava is in good agreement with accepted values (Nassar 2004; Mkumbira 2002; Cock 1984).

The fitted growing season for sweet potato corresponded to planting sweet potato in early February and effective growth terminating by around the beginning of June. This is consistent with sweet potato being mainly grown as an intercrop with maize and planted after the maize crop is in place. The fitted optimum growing temperature for sweet potato is also in good agreement with accepted values (Ramirez 1992).

Statistics and key model parameter estimates for each crop are provided in Table 2. All of the model fits were highly statistically significant well beyond the 0.001% level. The performance of the model, with a single coefficient of the accumulated growth index and a different model intercept for each ADD, is remarkably consistent across all crops. Allowing the coefficient of the accumulated growth index to vary from ADD to ADD gave unstable behavior and did not improve the standard error of any model. This confirmed that the relative dependence of crop yield on climate via the accumulated growth index was effectively constant across all sites, justifying the use of a single parameter b across all ADDs.

Table 2 Critical parameter estimates and the percent of yearly variance accounted for the fitted models for all five crops. Standard errors of the fitted parameter values are provided in parentheses

Crop	Number of data points	Model standard error	Parameter b	Parameter c	Percent yearly variance accounted for (%)
Local maize	54	0.141	2.79 (0.55)	0.000 (0.009)	38
Composite maize	54	0.141	3.33 (0.71)	0.013 (0.010)	36
Hybrid maize	54	0.150	2.61 (0.69)	0.032 (0.011)	34
Cassava	88	0.132	2.16 (0.34)	0.025 (0.004)	54
Sweet potato	52	0.070	0.85 (0.17)	0.016 (0.005)	47

The standard errors of the fitted models are generally no more than 15%, and the fitted values of parameter b are mostly between 2 and 3 with relatively small standard errors of around 20%. The percent of yearly variation in crop yields explained by the model, after removing variation between sites, ranged from 34% for hybrid maize to 54% for cassava. These values are consistent with the finding of Ray et al. (2015) that climate variation explains around a third or more of crop yield variability.

The smaller value of parameter b for sweet potato suggests that the model has been less successful in calibrating the full impact of climate on tuber growth. This may have been contributed to by the relatively short data record available for sweet potato and the larger number of apparent accounting errors in the yield data. The variation in planting dates between the traditional early planting date in February and the less common late planting date at the end of the wet season may have also contributed to the less strong fitted dependence on climate via parameter b. On the other hand, the small model standard error suggests that sweet potato yields may be more stable in relation to climatic variability than cassava. Analysis of yield data over a larger number of years would help to resolve this question.

The underlying rates of increase in crop yields are well determined for all crops. The fitted rate of zero for local maize is consistent with no breeding program in place for local maize. The marginally statistically significant rate of increase for composite maize of 1.3% per year is consistent with the modest breeding program in place for composite maize, and the statistically significant rate for hybrid maize of 3.2% per year is consistent with the strong breeding program in place for hybrid maize. The fitted rates of increase of around 2% per year for sweet potato and cassava are consistent with breeding programs being in place for both crops.

Plots of the log (yield) data values versus modelled values are shown in Fig. 4. Individual plots (not shown) of the fitted model, as a function of accumulated GI for each ADD, show considerable scatter of the observed yield data about the fitted model, but the constant slope b of the fitted line across all ADDs is estimated with reasonable precision, as described above. Likely contributors to the scatter about the fitted model include changes in management practice from year to year, including variations in planting dates, inaccuracies in recording crop yields, and possible misalignments between the locations of the sites sampling climate across the ADDs and the main locations of crop growth. The monthly time scale of the supporting climate data is likely to have made only a small contribution to the scatter about the fitted model given that the largest departures from the fitted model are in every case attributable to clear accounting errors in particular resource development districts (RDDs) within each ADD rather than systematic climate-related anomalies across all RDDs in any ADD.

The smallest observed and modelled values in the plot for cassava are for the drought year 2005 in Shire Valley ADD. The drought was severe in the other southern Machinga and Blantyre ADDs but particularly severe for the Shire Valley ADD (FAO 2005). The plots in Fig. 4 show that the model is able to recognize most drought conditions with reasonable accuracy but somewhat overestimates cassava yield during particularly severe droughts.

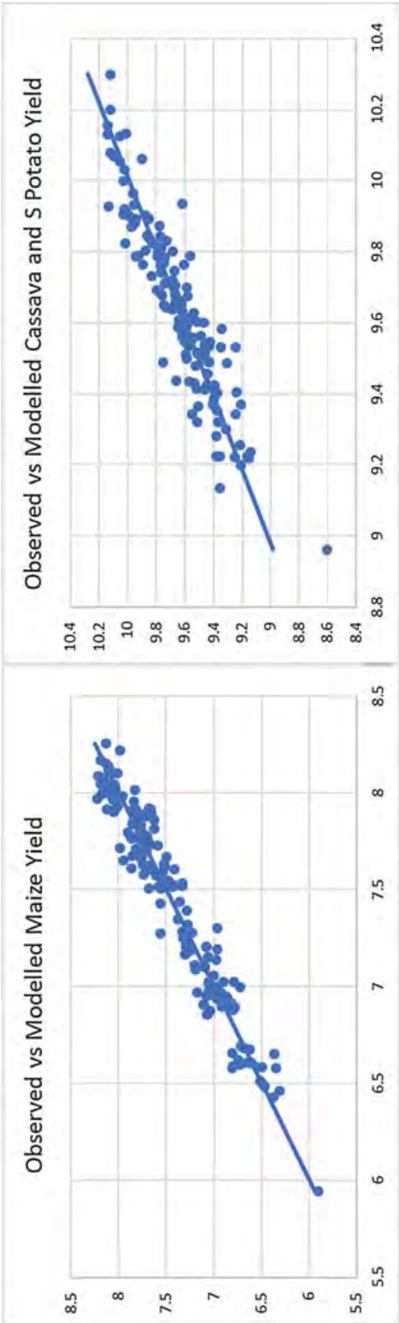

Fig. 4 Log (ADD yield) versus log (modelled ADD yield) for maize, cassava, and sweet potato

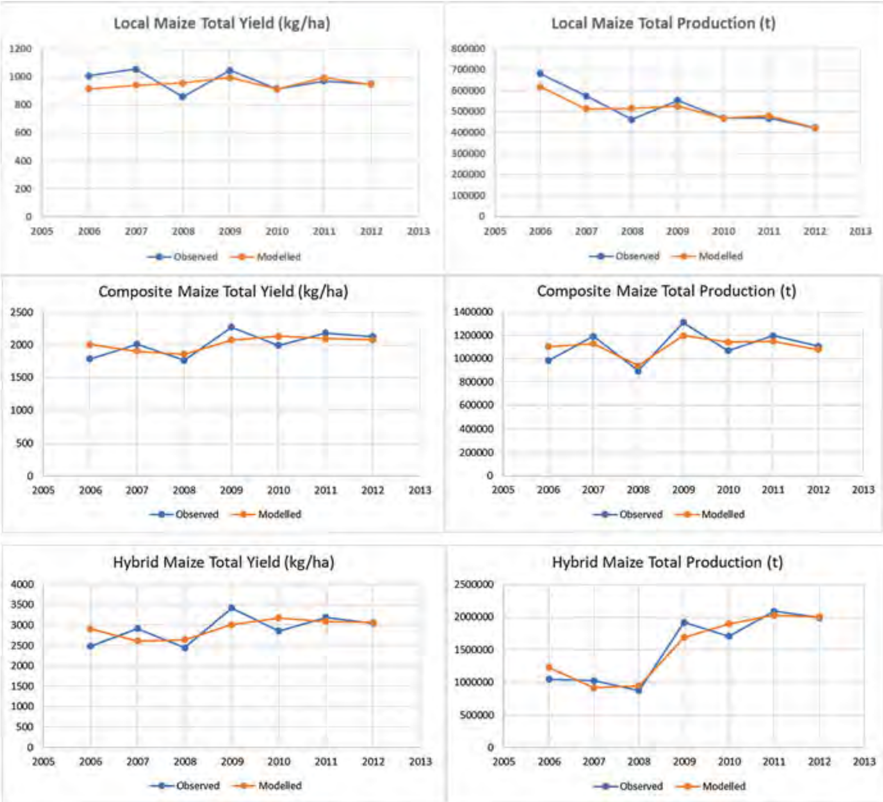

Fig. 5 Modelled and actual total yield and production for all three maize varieties

The models were finally assessed by their ability to explain the total yield and production across Malawi. The observed and modelled yield data were aggregated across all ADDs and plotted in Figs. 5 and 6. The spatially aggregated models provide accurate explanations of the observed values with average percentage differences from the actual annual values around 7% for the three maize varieties and less than 5% for cassava and sweet potato. The larger departures in these plots generally correspond with known accounting errors in the supporting yield data.

The fitted temperature index curves and the corresponding relative histogram of weekly temperatures observed over the fitted growing season for the 74 sites representing the eight ADDs across Malawi are plotted for local maize, hybrid maize, cassava, and sweet potato in Fig. 7. The plots show that the apparent temperature constraints on local maize and sweet potato are well matched to the observed weekly temperatures across Malawi, while the optimum temperatures of hybrid maize and cassava are somewhat larger than the mode of the observed weekly average temperatures. This suggests that projected future increases in temperature of

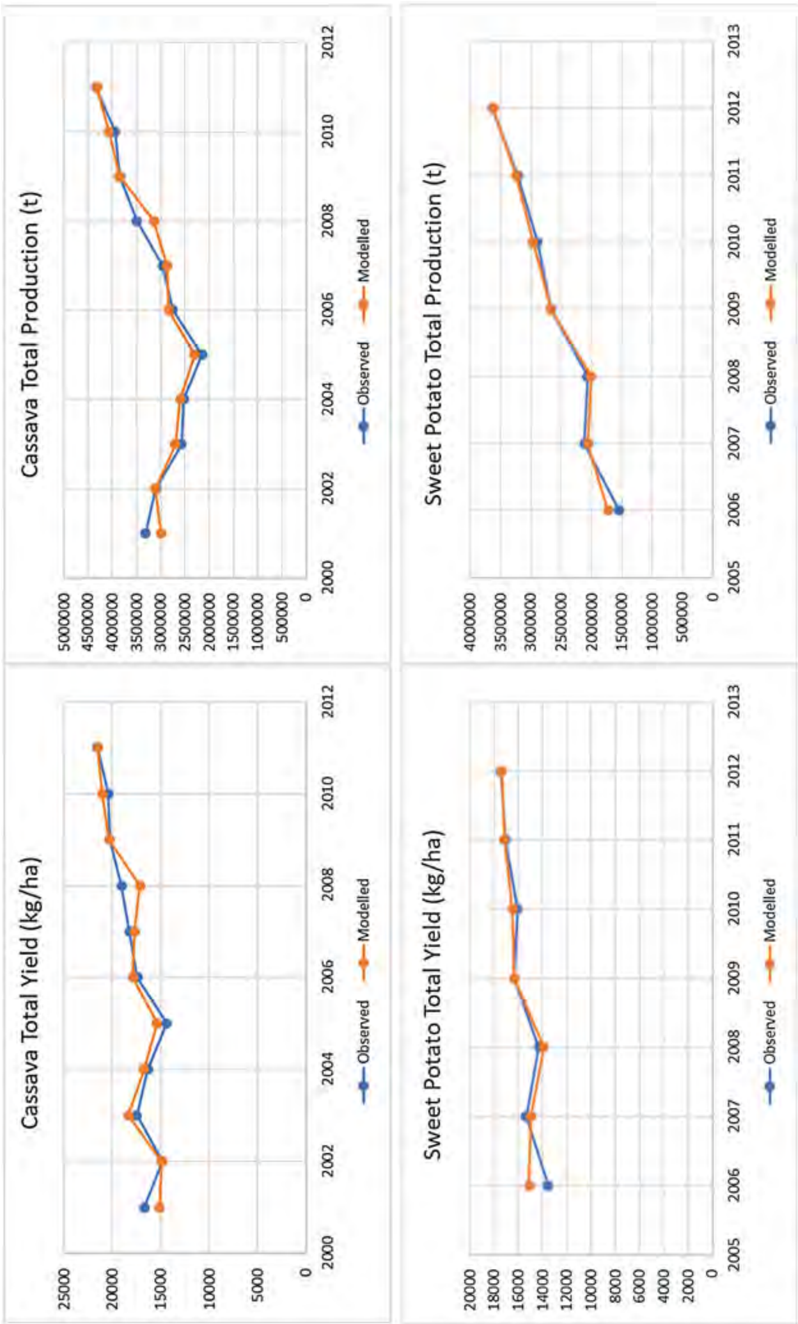

Fig. 6 Modelled and actual total yield and production for cassava and sweet potato

around 2 °C would have minimal impact on local maize yield, perhaps slightly reduce sweet potato yield and moderately enhance yields of higher temperature adapted hybrid maize and cassava. Possible changes in soil moisture regimes also need to be taken into account to obtain a more complete estimate of the likely impact of projected future climate. Soil moisture status is particularly important in the grain filling stage of maize (Li et al. 2018).

Discussion

The fitted regressions on accumulated GI have provided reasonably accurate models of observed maize, cassava, and sweet potato yields for each ADD and are more accurate when aggregated to the national level. The model formulation is robust and able to fit well-determined trends on accumulated growth index, despite the uncertainty associated with the supporting data, including some imprecision in the location of actual crop growing areas and year-to-year variations in planting times and growing practice. Schlenker and Lobell (2010) have noted the particular difficulties in modelling cassava that this model has appeared to overcome.

The fitted growing seasons agree well with known practice. The fitted optimum temperatures also agree with generally accepted values for all five crops, with hybrid maize better adapted to higher temperatures than traditional local maize varieties. This close agreement with known values provides strong support for the adequacy of the fitted models in calibrating the climate dependencies of maize, cassava, and sweet potato yields. The formulation of the regression model has permitted an effective separation between site-specific effects (such as soil fertility and particular crop management practices) and climatic effects on relative plant growth. The site-specific effects are accounted for by a separate intercept for each ADD in the regression model, while the relative climatic effects appear to operate independently of different site conditions and can be effectively calibrated by a single factor across all ADDs. Allowing this factor to vary across the ADDs did not improve the fit of the model for any crop. The model formulation is similar to that employed by Lobell et al. (2011) but uses a specifically tuned nonlinear plant growth index instead of various growing season weather variables. The effectiveness of this modelling approach reflects the finding of Wang et al. (2017) that the form of the temperature response function is quite critical in the accuracy of crop simulation models. The functional form of the temperature indexes plotted in Fig. 7 is similar to the preferred functional forms described by Wang et al. (2017).

The single parameter for the climatic effects was an important factor in the robustness of the regression growth models. On the other hand, allowing a separate site-specific intercept for each ADD was an important factor in incorporating different conditions modifying yields across the different ADDs. The resulting robust statistical model could reliably detect data outliers, as confirmed by inspection of the supporting data for the contributing RDPs. The robustness of the spatial analyses of the supporting monthly climate data has also contributed to the robustness of the fitted growth models. The net result has been well-determined

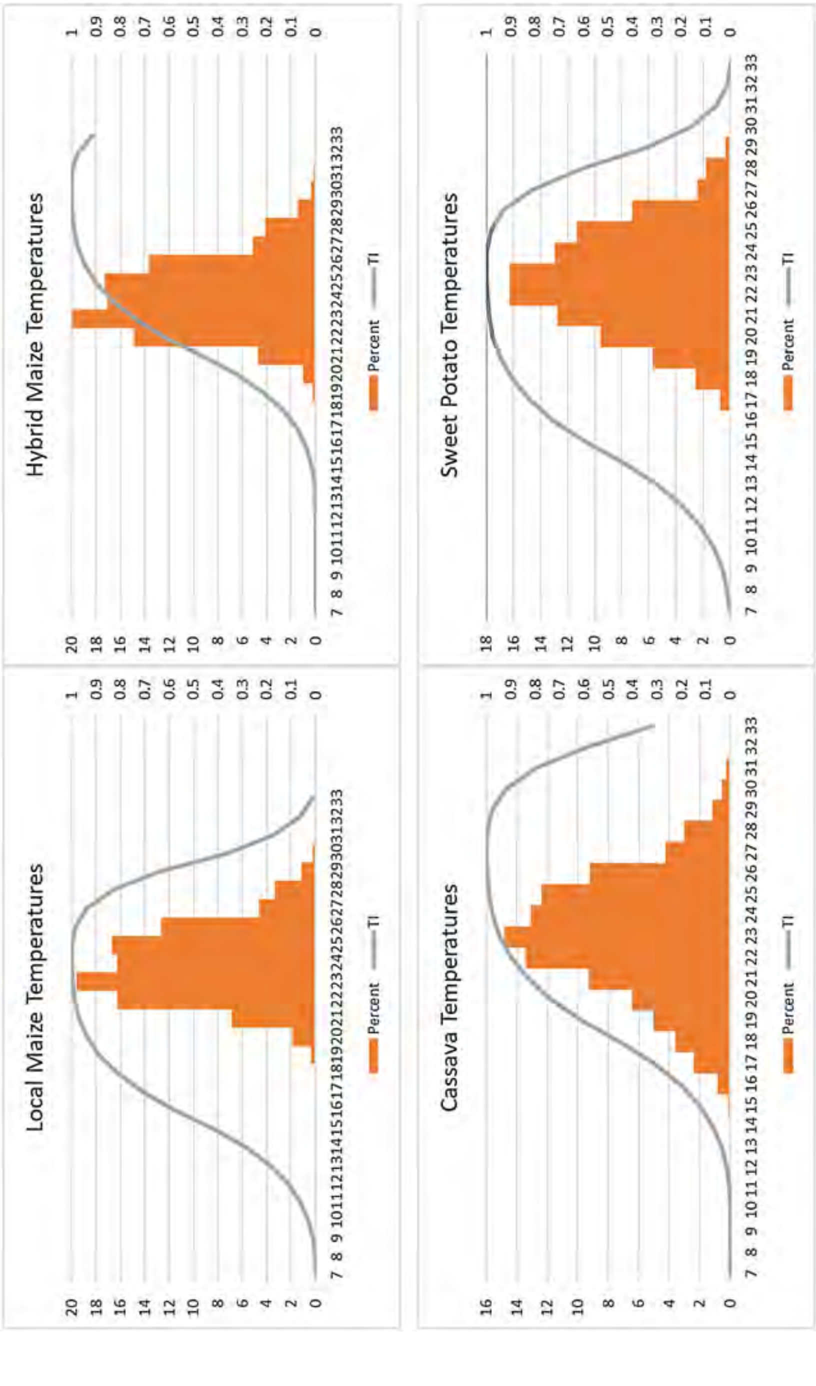

Fig. 7 Fitted temperature index curves (line) and observed monthly average temperatures (relative histogram) over the fitted growing season for local maize, hybrid maize, cassava, and sweet potato

coefficients calibrating the dependence of the three maize varieties and cassava and sweet potato yields on monthly climate via appropriately accumulated GI.

The models have simultaneously calibrated significant underlying increasing trends in yield over time that can be ascribed to improvements in plant breeding, crop management, and carbon dioxide fertilization. The fitted underlying trends of around 2% increase in yield per year for cassava and sweet potato may have been augmented by carbon dioxide fertilization. For such tubers there is around a 15% increase in tuber yield per 100 parts per million increase in atmospheric carbon dioxide concentration (Kimball 1983; Miglietta et al. 1998). In view of the prevailing rate of an increase in carbon dioxide concentration of two parts per million per year, this would give rise to an increase in tuber yield of around 0.3% per year over the analysis period. This is similar to the standard error of the fitted annual percentage increases in crop yield, making it difficult to discriminate from other increases in crop yield. It is not clear whether the fitted underlying percentage increases in crop yields will be maintained indefinitely. The impacts of improved production and reporting methods are likely to plateau in the future. However, ongoing improvements due to plant breeding and carbon dioxide fertilization are likely to continue, and the fitted trends of around 2% per year are remarkably consistent with the documented increase in world average cereal yields over the 50 years from 1961 to 2009 (Prohens 2011). It is unlikely that conventional crop breeding methods are able to maintain this rate of progress into the future, but Prohens (2011) argues that recent progress in molecular biology and genetic engineering offers great promise to further increase crop yields. Thus the fitted models should be able to be used, with appropriate qualifications, in assessing the impact of projected climate change.

Conclusion

This study analyzed the impact of monthly climate on the observed yields of maize, cassava, and sweet potato across the eight ADD crop production regions of Malawi via a robust yield regression model that can be viewed as a hybrid approach between complex process-based models and statistical modelling using selected weather variables. It offers progress toward the eventual dissolution of the differences between these approaches as suggested by Lobell and Asseng (2017). A particular strength of the GROWEST model used here is its incorporation of a process-based temperature response function that could be readily tuned to maximize model performance. This reflects the finding of Wang et al. (2017) that appropriate parameterization of the temperature response function is critical to crop model performance. The tuning of the period of the effective growing season was similarly critical. An additional important contribution to the accuracy and robustness of the regressed GROWEST models is their effective separation of site-specific and climatic effects. This aspect is shared by the statistical modelling approach described by Lobell et al. (2011). Finally, the calibration of the model in terms of monthly, instead of daily, climate data offers robustness in delivering spatially distributed climate data from limited point sources and in generating projected future climate data. Projecting daily precipitation data in particular is problematic with many approaches simply adjusting positive daily rainfall amounts but leaving daily rainfall occurrence structure unchanged. Such changes in daily precipitation structure can be subsumed within simple changes in monthly precipitation totals, although at the expense of losing some precision in the timing of precipitation within the month.

The main limitation of the modelling approach described here, and many others, is an assumption that management practice does not change significantly from year to year. This can be violated in periods of extreme drought or flooding when planting dates can be significantly delayed or disrupted. This assumption could also be violated in future scenarios when there could be a systematic shift in planting times in response to systematic changes in seasonal climate. Changes in planting density due to changes in intercropping practice are also possible. There is also an assumption that a fixed temperature response function applies over the entire growing season. The differing temperature optima over different stages of maize growth cited by Sánchez et al. (2014) suggest that the model could be usefully elaborated to reflect this, although at the expense of fitting additional model parameters. Despite these limitations, the GROWEST plant growth index model applied to spatially distributed monthly climate data has provided robust correlations between modelled and actual yields for all five crops examined. These correlations have yielded process-based parameter values that agree with known values, and the dependence on accumulated growth index has been fitted with enough precision for the models to be able to be used with reasonable confidence in projecting the impacts of climate change on future yields. The comparisons of the fitted temperature index curves with observed monthly average temperatures in Fig. 7 show that projected increases in temperature are likely to have minimal impact on local maize and sweet potato yield while yields of high temperature adapted hybrid maize and cassava are likely to be enhanced. Such projections need to be coordinated with projected changes in soil moisture levels.

Abstract

Livestock rearing is a popular climate change adaptation strategy among farmers in Matobo District, Zimbabwe. In this chapter we reveal how farmers in Matobo District have benefited immensely from rearing small livestock in response to climate change. Although the descriptor "small livestock" generically refers to different types of livestock, in this chapter we limit it to goat and sheep rearing. The purpose of the chapter is (1) to discuss the efficacy of small livestock rearing as a response to climate change and (2) to use smallholder farmer's narratives to evaluate the success of government interventions in enhancing small livestock production. Utilizing an inductive approach, data was gathered through five (5) key informants, five (5) focus group discussions, and 50 in-depth semi-structured interviews. Our study reveals that small livestock are suitable and adaptable to climate change impacts in Matobo. We recommend that government and its development partners prioritize and avail funds for the increased uptake of small livestock rearing among smallholder farmers in Matobo District and beyond.

Keywords

Adaptation · Climate change · Small livestock · Smallholder farmers · Matobo · Zimbabwe

Introduction

Small-scale communal livestock rearing plays an essential role in sustaining livelihoods in developing countries. Livestock is central to food security, nutrition, organic fertilizer (manure) production, non-mechanized ploughing, and income generation initiatives (Nandhini and Suganthi 2018). However, as climate change impacts are increasingly being felt across the world, poor countries are most affected owing to poor adaptive capacity and budgetary constraints compared to more developed countries in the global North (Chaudhury 2017). Developing countries' vulnerability is worsened by their strong dependence on rain-fed agriculture and free range pasture-fed livestock, which are susceptible to the negative effects of changing climate (Dube and Phiri 2013; Brazier 2015; Apraku et al. 2018a). Livestock plays an essential role in sustaining the fragile economies of most developing countries, with more than half of the rural population being sustained by livestock production (Kaasschieter et al. 1992; Assan and Kumar 2009; Assan 2014). Kaasschieter et al. (1992) note that "the largest share of the world's livestock population is found in developing countries: 61% cattle, 43% sheep, 79% goats, and 57% pigs." Of the stated livestock, "the production of small livestock like goats and pigs strengthens the capacity of communities to adapt to climate change" (Ndlovu 2010; Girum et al. 2008). Small livestock have higher chances of surviving under climate change conditions like increased droughts compared to bigger livestock since they require smaller grazing land and less amount of water and are less affected by the depletion of pastures. Assan (2014) argues that livelihoods sustainability in rural areas can be achieved through livestock production in the face of rapidly changing climate that weakens crop production especially in arid climates like Zimbabwe. It is against this backdrop that the International Union for Conservation of Nature and Natural Resources (2010) observes that rural livelihood systems in Southern Africa are converting from mixed crop-livestock to pure rangeland systems. Although livestock production in arid agroecological regions of Zimbabwe is yet to be endorsed as an agricultural policy, there is increased support for the uptake of livestock rearing from the government's Livestock Production Department (LPD).

Given the foregoing, the research thus examined the efficacy of small livestock production as a climate change adaptation strategy in Matobo District compared to the much traditionally desired cattle rearing. This switch is being pioneered by Khulasizwe which is a nongovernmental organization (NGO) operating in Matobo wards 3, 4, 10, and 19 with the aim of enhancing household livelihood security. Khulasizwe has thus far distributed goats to 380 households in the targeted wards (World Vision 2015). It is crucial to investigate community narratives (and experiences) about the effectiveness of this technical adaptation strategy. The study sought to answer the following research questions: What benefits (if any) are Matobo community members deriving from the switch to small livestock production? What has been the uptake of this strategy in the broader Matobo community over and above the project beneficiaries?

The Impact of Climate Change in Zimbabwe

There is consensus that climate change is causing more socioeconomic, health, and environmental harm in developing countries (Van Aelst and Holvoet 2016; Kahsay and Hansen 2016; Apraku et al. 2018a, b). The harm is exacerbated by the fact that most of the population these countries is heavily reliant on the natural environment for survival, both of which are highly susceptible to climatic changes. Consequently, climate change is negatively impacting the livelihoods of the poor as well as deepening poverty in many developing countries (Africa Partnership Forum 2008; Nyong 2009; Phiri et al. 2014, 2019). In Zimbabwe, the adverse impacts of climate change are particularly felt in the rural areas where the majority of the population (67%) lives and mostly depend on agriculture-based livelihoods (ZIMSTAT 2013). Within the context of the unfolding adverse effects of climate change, vulnerable communities are adapting to these conditions by "rearing small drought resistant livestock such as goats" (Zimbabwe's National Climate Change Response Strategy 2014).

Climate Change and Vulnerability

Climate-induced variability increases the vulnerability of rural livelihoods and reduces the ability of households to deal with risks, shocks, and stresses (Prowse and Scott 2008). Dulal et al. (2010) and Ndlovu et al. (2019) concur with the above argument that, since households typically have limited assets, they are at increased risk (exposure) and their ability to cope is restricted. Cutter et al. (2000) and Dube et al. (2017) point out that livelihood vulnerability to climate change can be usefully understood as an outcome of biophysical and social factors. Firstly, biophysical climate change vulnerability refers to the level of exposure communities' physical impacts of sea level rise, increase in sea surface, or atmospheric temperatures. Secondly, social vulnerability is explained as partially the product of those factors that shape the susceptibility of communities to harm and those that govern their ability to respond. It also includes "place inequalities" – those characteristics of communities and the built environment, such as the level of urbanization, growth rates, and economic vitality – that contribute to the social vulnerability of particular places (Cutter et al. 2000; Shah et al. 2013).

Moss et al. (2001) add a third dimension as an external assistance, which is defined as "the degree to which a region may be assisted in its attempts to adapt to change through its allies and trading partners, diasporic communities in other regions, and international arrangements to provide aid." In contrast to the United Nations (2004), this conceptualization of vulnerability includes factors outside the vulnerable system, such as characteristics of the stressor and the expected level of external assistance.

Four dimensions have been identified as defining a vulnerable situation within the literature. The first dimension consists of human-environment system, population group, economic sector, geographical region, or natural system (Downing and Patwardhan 2004). They note that other researches limit vulnerability to social systems coupled with human-environment systems (Turner et al. 2003) whereas others apply it to any system that is potentially threatened by a hazard (Mcbean 2012). The second dimension is the attribute of concern. Examples of attributes of concern include human lives and health; the existence, income, and cultural identity of a community; and biodiversity, carbon sequestration potential, and timber productivity of a forest ecosystem (Downing and Patwardhan 2004).

The third dimension is the hazard. United Nations (2004) defines a hazard broadly as "a potentially damaging physical event, phenomenon or human activity that may cause the loss of life or injury, property damage, social and economic disruption or environmental degradation." Hence, a hazard is understood as some influence that may adversely affect a valued attribute of a system. A hazard is generally but not always external to the system under consideration. For instance, a community may also be threatened by hazardous business activities or by unsustainable land management practices within this community. Hazards are often distinguished into discrete hazards, denoted as perturbations, and continuous hazards, denoted as stress or stressor (Turner et al. 2003).

Finally, the fourth dimension is the temporal reference which denotes the point in time or time period of interest. Specifying a temporal reference is particularly important when the risk to a system is expected to change significantly during the time horizon of a vulnerability assessment, such as for long-term assessments of anthropogenic climate change (Downing and Patwardhan 2004).

Adaptation Strategies in Zimbabwe

Adaptation strategies need to be understood using the concept of "adaptive capacity." Adaptive capacity has been defined as the ability or potential of a system to respond successfully to climate variability and change, and this includes adjustments in both behavior and in resources and technologies (IPCC 2007). Other scholars define it as the potential of a system to adjust itself to change (Watts and Bohle 1993; Smit et al. 2000; Turner et al. 2003; Fussel and Klein 2006). According to Armitage and Plummer (2010: 6), adaptive capacity is:

> generally referred to as the capability of a social-ecological system to be robust to disturbance, and to adapt to actual or anticipated changes (whether exogenous or endogenous). From a social systems vantage point adaptive capacity is determined by the suite of resources (technical, financial, social, institutional, political) held, and the social processes and structures through which they are mediated (i.e. governance).

From the perspective of the social sciences, adaptive capacity does not just explain how people cope with change but reflects an ability to learn, experiment, and foster innovative solutions in complex social-ecological circumstances (Cutter et al. 2003; Armitage and Plummer 2010). Therefore, the capacity of households and communities to adapt to climate change cannot be under emphasized. In response to the negative climate change impacts, smallholder farmers are adopting a variety of adaptation strategies in Zimbabwe. There is consensus that rural communities in Zimbabwe have not been mere passive victims of climate change but have been action oriented in adapting to climate variability (Gukurume 2013; Dube et al. 2018; Kahsay and Hansen 2016). Crop diversification, mixed crop livestock systems, changing planting times, and conservation farming are some of the strategies that have been adopted by communal farmers in Zimbabwe (Munhande et al. 2013; Musarurwa and Lunga 2012; Makuvaro et al. 2014).

In addition, Mano and Nhemachena (2006) argue that climate change has severely reduced chances of rain-fed crop farming in arid regions of the country such that they suggest livestock production as the most suitable strategy that can drive communities out of food insecurity and poverty. Gukurume (2013) notes that livestock production was on the increase in Bikita and other places in dry regions, indicating that farmers are replacing crops with livestock production in order to promote livelihood sustainability. The government through its departments is also encouraging farmers in areas prone to increased dry spells to invest more on livestock, because they can withstand the harsh weather conditions induced by climate change. Small stock like goats, sheep, and indigenous poultry are becoming dominant as people try to cope with drought in areas continuously receiving little rainfall (Gukurume 2013). However, Munhande et al. (2013) observed that climate change hugely contributes to extreme temperatures, severe water scarcity, and reduced fodder for livestock, especially large stock leading to poor animal production.

Water harvesting techniques (WHTs) are another climate change adaptation strategy available to communities. Rain-water harvesting (RWH) technologies are a range of techniques used for collecting, storing, and conserving rainfall and surface runoff in arid and semiarid regions (Mutekwa and Kusangaya 2006). WHTs are more amenable to “small livestock” because they consume less water compared to “large livestock” like cattle.

A very traditional and significant adaptation strategy that had been practiced particularly for rural communities is livestock herding. According to Leichenko and O’Brien (2002) livestock herding, including nomadic pastoralism, remains one of the indigenous strategies best adapted to frequent droughts in dry land areas such as in Namibia and Botswana. Seasonal movement of livestock, splitting up of herds, changing herd composition, and distributing livestock among relatives and friends in different areas minimize risk from droughts, floods, or diseases. Appropriation of the wetter areas and water sources for cultivation and fencing inhibits these crucial strategies, however.

Study Site and Context

The study was conducted in Matobo Rural District of Zimbabwe which lies in ecological regions IV and V characterized by low and erratic rainfall (450–650 mm/year) with very high temperatures. Of the 27 wards in Matobo District, the study wards were (Gwezha, ward 3; Marko, ward 4; Makhasa, ward 10; and Zamanyoni, ward 19). Climate change has worsened the already extreme weather patterns in the district. Drought is an example of this phenomenon that has affected Matobo District in a negative way. Data emerging from the interviewed farmers shows that the prolonged droughts have dried up natural water points such as streams, rivers, and swampy areas (Fig. 1). Consequently, their pastures and grazing lands for their livestock have been depleted. **The study was conducted from March to September 2017**.

Materials and Methods

The research employed a qualitative methodology which was more suitable for capturing community narratives and experiences about the appropriateness and effectiveness of small livestock production within the context of a changing climate in Zimbabwe. As highlighted by Turner et al. (2003), the primary strength of the qualitative approach to cultural assessment is the ability to probe for underlying values, beliefs, and assumptions. Data collection tools employed included the use of in-depth semi-structured interviews (50 households), 5 focus group discussions, and 5 key informants conducted using purposive sampling in 4 selected wards of Matobo District of Zimbabwe. The limitations of the study are that findings on how small-holder farmers adapt to climate change through small livestock in Matobo District cannot be generalized to other districts in Zimbabwe and beyond. Success of these

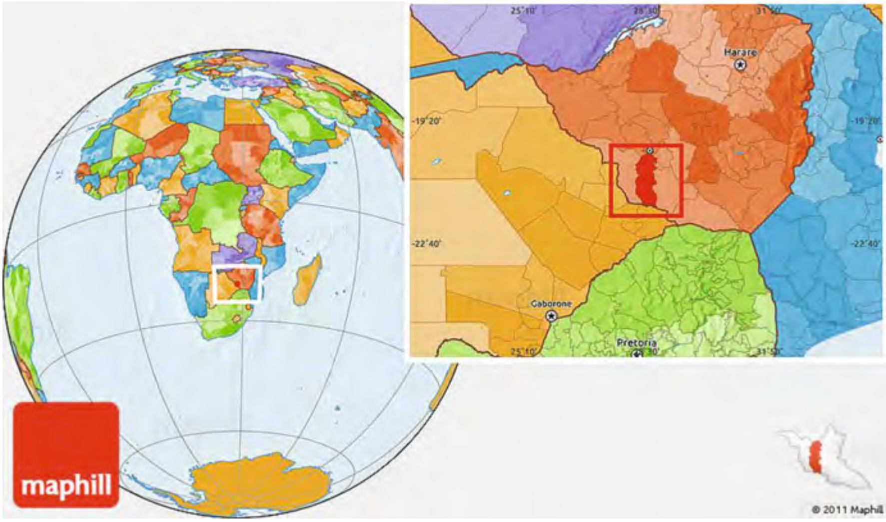

Fig. 1 Map of Zimbabwe (showing Matobo District)

technical climate change adaptation strategies is location specific. However, important lessons can be drawn from the narratives of the smallholder farmers in semiarid districts and go on to influence policy.

Results and Discussions

Small Livestock and Climate Change Nexus in Matobo

Small livestock, namely, sheep and goats, are relatively more adaptive to negative changing climatic conditions compared to cattle. Goats are both grazers and browsers, while cattle are limited to the latter (Girum et al. 2008). The chances of survival for small livestock are higher compared to cattle in the context of a changing climate. Moreover, on the basis of their size, the goats consume less from the pastures in a specified area in comparison to cattle that demand more feed due to their sheer size. The amount of water drunk by goats and sheep is far less than that of cattle. Small livestock have a comparative risk aversion advantage in that respect. The suitability and appropriateness of small livestock in a climate change environment are premised on the aforementioned characteristics.

Goat Production

In the context of the study area, a key informant justified the rearing of small livestock when he explained that:

> Even in times of drought, small stock (goats) herd will multiply because they reproduce at two to three times the rate of cattle. A goat may produce one to four kids in a year as opposed to one birth every one and a half years to two years for cattle. The farmers in Matobo can attest to that. It is a known fact in Matobo that goatherders fare well in comparison to cattle herders in general. (Key Informant 4, Khulasizwe Trust)

Furthermore, another important statement was made in respect to small livestock rearing in Matobo. Key informants 1 and 3 indicated that:

> Small livestock are particularly important and useful during and after a drought or disaster period. It is easy for farmers who are keeping goats for instance, to sell the goats for cash, give goats as a gift, or slaughter for food or traditional ceremony. This is because the amount of money and food generated by a single goat is optimal for day to day transactions. (Key Informant 3, AGRITEX)
>
> The most popular small livestock that the farmers keep are goats. Pigs are shunned because of religious reasons…and generally because they need to be fed a lot which is highly cost ineffective and therefore not sustainable particularly for rural communities who are already struggling enough to meet household needs. The sheep herd is relatively small as well because there is too much work involved in rearing them. Sheep need special care. (Key informant 1, World Vision)

Similarly, the views raised by interviewed smallholder farmers were in tandem with what was also raised by the key informants.

Three of the respondents from different wards commented that:

> Small livestock are a good insurance against crop failure. When our harvest is low– we have an easy alternative that is of slaughtering a goat. We value our goats because they give us meat, milk and manure for our gardens. We also use the goat skin as a carpet and sell to obtain cash for petty trading. (Household Respondent 26, Marko)
>
> Goats are doing very well for me despite the heavy rainfalls and hot temperatures this year. I started with 5 goats but I now have 27 goats in less than 3 years. They multiply faster compared to cattle provided that they are dosed regularly. I love rearing goats because they do not demand stock feed like cattle. Moreover, they can even feed on groundnuts and round nuts leaves. Goats are basically easy to maintain in a climate change environment. (Household Respondent 33, Makhasa)
>
> I do not have a lot of goats myself but I have friends who are rearing a lot of them. I know of one farmer who possesses over 50 goats. From my observation, these small livestock don't collapse and die due to high temperatures and drought. They survive unlike cattle. They feed close to the homestead and can easily be watered by the owners. In times of crisis, goats can be exchanged for money or grains for food or feeding the community during a funeral wake. (Household Respondent 21, Zamanyoni)

A key informant from AGRITEX emphasized that even those who do not have cattle perceive goats and sheep as a symbol of wealth. One of the commentators in a focus group discussion indicated that there is a lot of contempt in society for one that does not have any kind of livestock and few villagers are likely to attend his funeral. For most farmers who do not have cattle, goats are a good source of relish during funerals when villagers gather in the bereaved homestead. The key informant added that small livestock are also kept for security reasons. They are likely to cushion the farmers during times of drought when the harvest from their fields is very low. They can be eaten or exchanged for grain or sold for cash to buy other household consumables during hard times. This point was also raised by interviewed smallholder farmers earlier in the discussion. It is clear from the above comments that small livestock, specifically goats, play a pivotal role as a livelihood strategy in Matobo District.

The smallholder farmers are aware of the competitive advantage of rearing goats over cattle in their specific area of habitation. Firstly, as a source of food, goats are easily slaughtered to obtain meat to meet food needs at the household level or feeding community members in funeral wakes and traditional and cultural rituals like weddings. Goat milk is also a preferred source of food in selected households specifically for children. Secondly, goats are acknowledged to be easy to keep and maintain in a harsh climatic environment compared to cattle because they consume less food and are more drought resistant compared to cattle. Thirdly, goats are utilized by farmers as a medium of exchange to pay school fees, hospital bills, and other urgent needs of the households. Interviewed farmers unanimously indicated that it is easier to sell goats than cattle.

It emerged from the sampled respondents that the Matabele goat is common in Matobo District because it is an indigenous breed that has been kept there since time immemorial. However, the key informant from AGRITEX indicated other breeds like the Boer goat and Kalahari red are common in areas like Gwanda and Beitbridge. This is so on account of farmers' cross-breeding them due to the proximity and accessibility of South Africa at the Limpopo province. The Mashona goat is mainly confined to Mashonaland province of Zimbabwe (Table 1).

Experts in the field of small livestock rearing concur that goats are an effective strategy for adapting to climate change in the study area. Their views go beyond the perception of interviewed farmers who are yet to fully appreciate this knowledge beyond merely keeping goats as a tradition. The key informant from Khulasizwe justified the rearing of small livestock like goats over cattle for a number of reasons. He noted that:

> Goats can withstand the harsh climatic changes and are not prone to collapsing like cattle. They feed on vegetation not used by other domestic species of animals since they are browsers. Goats do not easily succumb to diseases. Farmers living in marginal agricultural areas can keep them. Moreover, they are easy to handle and can be looked after by children and women. (Key Informant 4, Khulasizwe)

Another key informant from the Department of Livestock Production and Development gave a lengthy response in showing the viability and effectiveness of goats' production over cattle production. He narrated that:

> Goats multiply very easily and flocks expand in a relatively short time forming a major part of the family asset base in a harsh changing climate. Goats have an economic advantage over large ruminants because they are cheap to buy hence they provide an opportunity for vulnerable people to own them. They can quickly and easily be sold off for cash to meet family emergency needs like health costs, educational needs, in times of death and therefore are an easily disposable asset during times of poverty and calamities. With goat rearing, there are none or few social, religious and cultural taboos associated with keeping them in Zimbabwe. (Key Informant 5, DLPD)

Table 1 Common goat breeds in Zimbabwe

Goat breed	Characteristics
Matabele goat	This breed is found mostly in the southern part of the country. It is large framed animal
	Mature weight can reach up to 50 kg plus for males and between 35 and 40 kg females
	It is a dual-purpose breed (meat and milk production)
	Has multiple colors ranging from white through brown, mixed to black
	Can give birth to singles, twins, and triplets
	Adapted to local conditions
	Gestation period is between 145 and 154 days
	Can be mated for the first time at 18 months of age
Mashona goat	It is small-framed breed
	It is highly prolific
	Tolerant to local diseases
	Found in the northern parts of the country
	Mature weight is 30 and 35 kg for females and males, respectively
	Color ranges from white, mixed to black
	Edible and saleable proportion after dressing is 48% of the live body weight (equivalent to 12–14.5 kg)
	Sexual maturity is 7 months but a relatively slow growth rate. Goats are mainly kept for meat
	They have good potential for selection to increase productivity
Boer goat	It originates from South Africa and is well adapted to the southern parts of the country
	This is a large framed breed, with white body and a brown neck and head
	Adult female can grow up to 60–70 kg and males up to 70–90 kg
	It is mainly for meat production
	Very stocky body, well-muscled, strong bones
	Ears are pendulous and horns are prominent
	Very prolific breed, kidding rate of 1, 5 (three times in 2 years)
	50% twins and 7% triplets
	Valuable for meat, milk, and skin but has been promoted for its meat potential
Saanen goat	Originated from Switzerland or France
	Large size, white color with black spots on the nose, ears, and udder
	Hair coat is short; ears are erect and forward and upward
	Face is straight, slightly dished
	Good body conformation

Source: Khulasizwe File Report (2018)

From a technical point of view, it was evident that small livestock especially goats are a viable adaptation strategy to climate change effects. Key issues raised in support of their breeding were by virtue of their size in comparison to cattle; the risk of loss is small. It was suggested that for every cow one has an equivalent of six goats. The land size for communal farmers is small, and therefore keeping goats rather than cattle enables them to reach economies of scale. The eating habits of goats (grazers and browsers) mean they have a more varied diet and can survive in drier areas. They basically can survive in any terrain that can either be hilly or flat terrain. In addition, it was revealed by the key informants that where water is scarce, goats can survive without drinking water for 2 days. However, the conscious decision to rear small livestock for the purpose of responding to climate change is yet to be understood by the smallholder farmers depending on efforts by government and its partners to spread that knowledge and the willingness of the respondents to accept that reality.

Sheep Production

Data gathered from the study area also revealed that 20% of the interviewed farmers rear sheep. However, despite their resilience to the impact of climate change, they are not produced en masse in Matobo District in comparison to goats and chickens. The reasons given by two interviewed households were that:

> Sheep easily get lost because they can hardly re-track their way back if they feed a distance away from home. Due to that fact, sheep demand more labour than other livestock since they require close attendance almost all the time. (Household Respondent 24, Gwezha)
>
> Keeping sheep is hard work and not ideal for these reasons. When thieves and predatory animals like jackals and hyenas pounce in the night, they do not make any noise. We are not alerted that there is impending danger the same way goats make a loud noise when disturbed. As a result, we have lost quite a number of sheep due to this problem. We are therefore, reluctant to rear them in our village. (Household Respondent 40, Zamanyoni)

On a different note, the interviewed farmers who are rearing sheep had other reasons that they gave for doing so besides their adaptability to climate change. The reasons are purely religious beliefs. The following views confirm that:

> We keep sheep for the purpose of enterprising especially with white garment churches known as apostolic sects. They believe that the tail of the sheep on which they extract fat brings good luck. Whether that is true or not is not an issue for me. As long as I can make money out of them, I do not care. I am keeping 53 sheep. It’s a big market for me and my household. (Household Respondent 3, Marko)
>
> Most of those households that keep sheep are superstitious. They believe that if you rear sheep your homestead can never be struck by lightning. Climate change has also come about with lightning and terrifying thunder. As a protection measure, sheep are kept to ward off that risk. For sure, I know no household in the village that has been struck by lightning that kept sheep. (Household Respondent 19, Makhasa)

The key informants acknowledged that specific farmers in the district held such indigenous knowledge beliefs about sheep being said to prevent lightning and the supernatural powers they possess to ward off bad luck and bring good fortune. Their belief system primarily informs their choice of rearing sheep. The production of sheep for the purpose of adapting to climate change is secondary under those circumstances. In this instance, small livestock keeping is a tradition passed on through generations and is not intended as a direct response to climate change. All household respondents kept one form of small livestock or another. However, it should be noted that it is not attributed to responding to climate change per se but a continuation of what has always been the norm in the district since time immemorial. The findings also show that because of the traditional inclination to goat rearing, farmers' knowledge on which types of goats are reared is lacking and immaterial. Farmers in Matobo are not really concerned about the types of breeds that they are rearing; they keep whatever breed that they can access or obtain. This lack of knowledge on breed types has however an implication on the effectiveness of small livestock as adaptation options to climate change. Sustained and successful adaptation strategies demand a level of knowledge and understanding about livestock breeds and their resilience to the adverse effects of climate change.

Feminization of Small Livestock Rearing in Matobo

In Matobo, rearing of sheep and goats is mostly relegated to women. While men do keep small livestock in Matobo, it is understood that it is a feminine exercise. On that basis, men play a peripheral role in small livestock rearing and would prefer to focus on owning cattle. It is an unwritten law that women (especially those that are married) may not slaughter a beast under any circumstances without prior approval of their husbands. This points to a strong patriarchal culture that is predominant even in climate change adaptation strategies.

Constraints to Small Livestock Rearing

Despite the fact that small livestock have a comparative advantage in adapting to climate change over cattle in the study area, the production is beset by subtle challenges that threaten its viability and effectiveness. For instance, the key informant from the DLPD commented that:

> While goats' production is a good option for adapting to climate change in Matobo, they have their own share of problems. Goats can be destructive animals only if overgrazing in areas occurs, resulting in reduced or loss of tree regeneration. Moreover, goats have a tendency to stray and eat neighbours' crops. Therefore, goats should be herded properly. (Key Informant 5, DLPD)

The respondents in the study area were more concerned about the security of their livestock more than anything else. Thieves and predatory animals like hyenas and jackals threatened the viability of their small livestock. The following comments were made during a focus group discussion:

> Jackals are a big problem in our village. Four jackals can chase one goat till they catch and kill it. Sometimes we see the jackals during the day. They are so daring these days. I recently lost 3 of my goats as a result of jackals. Unless, one devises a mechanism of herding them throughout the day– they will get eaten. I am actually better off– my neighbor lost 12 goats within a month. Jackals are really a menace. (Marko Focus Group Discussion, Participant 2)
>
> Stock theft is a common occurrence in our village. The incidences are rampant probably because of hunger perpetuated by what you call climate change. Crop yields are no longer enough to feed the communities throughout the year. Sadly, some people in the village resort

to stealing chickens and goats to make ends meet. I own 65 goats. I lost 13 just last year to thieves. It's not acceptable. (Zamanyoni Focus Group Discussion, Participant 9)

Hyenas have cost me a great deal of my goats. They target the kid goats especially. Twenty-one of my goats got eaten by hyenas. We cannot even hunt them down because it is a criminal offence. The government is not doing anything to protect our goats from the menacing hyenas. (Gwezha Focus Group Discussion, Participant 5)

The interviewed farmers also narrated that thieves are so daring in certain instances. It was noted that thieves can even drive goats in broad daylight when they have observed that they are not herded by any one. The villagers suspect that they sell them in nearby urban areas like Bulawayo where there is a ready meat market. The key informants from World Vision, Khulasizwe, AGRITEX, and DLPD confirmed the issues raised by farmers on losses of their small livestock as a result of thieves and predatory animals. As a result, some livestock security strategies have been developed by community members. Plate 1a, b is a new idea of goat and sheep kraals in Matobo District.

Plate 1 (**a** and **b**) Goat and sheep kraals

The key informant from DLPD commented that they are encouraging the construction of these kraals because:

> . . .they are constructed in an elevated manner to prevent hyenas and jackals from killing the sheep and goats. They also serve the purpose of protecting the sheep from harsh weather conditions like intense heat and heavy rainfall. Traditional kraals which are constructed at ground level were not as secure as this new model. Thus, farmers are able to protect their livestock from being attacked and also prevent diseases caused by exposure from the heat and intense precipitation. (Key Informant 5, DLPD)

The Department of Livestock Production and Development in conjunction with local NGOs has been instrumental in encouraging farmers in the study area to construct these new kraals to preserve and protect their small livestock.

Another very important challenge that negatively affects the interviewed farmers is the diseases that reduce the number of their small livestock. Diseases like liver fluke, round worms, aching eyes, lump skin, pulp kidney, and heart water have affected livestock in the study area in varying degrees. In the face of these challenges, interviewed farmers seem to be helpless. There is little that they have done to treat their animals despite the few trainings received from the veterinary department. Farmers do not seem to understand the kind of diseases that are affecting their livestock. When asked about what kind of diseases affect their livestock, the farmers usually respond by describing what happened; they fail to state the disease that has led to the mortality of their livestock either in vernacular or in English. They just refer to them as *igazi* (*blood*), *or* any other terms that describe the symptoms not the disease. Three interviewed farmers commented that:

> Out of 35 goats, I lost all 16 in a single year through a strange disease, but could do nothing about it. I just watched helplessly. Some of us don't believe that drinking stagnant water can affect our livestock. Our goats used to drink from the same rivers and dams which are said to be causing their death. We don't understand why. We don't have money to buy the chemicals to treat our animals. (Household Respondent 41, Makhasa)
>
> We have received training on how to identify diseases and cure them from the Veterinary Department. The medication for dosing and injecting our goats are both expensive and not accessible in Maphisa. Bulawayo is too far where we are referred to. We end up resorting to traditional medicines to cure our livestock. The Veterinary Department discourages us from doing so. But what other options do we have? (Household Respondent 27, Zamanyoni)
>
> Goats and sheep are affected by liver fluke and bowels due to drinking stagnant water. There are no signs or symptoms for these two diseases, one just discovers after the death of the animal. I have lost three goats because of liver fluke. (Household Respondent 15, Gwezha)

Over and above the lack of disease knowledge, the expensive medication from the veterinary department is also responsible for the high mortality rate of goats and sheep. The farmers are too poor to purchase the recommended medication to cure their animals. Consequently, they suffer heavy losses due to diseases like liver fluke, round worms, aching eyes, lump skin, pulp kidney, and heart water. Farmers were clueless on how some of those diseases could be dealt with. Moreover, there is some resistance on dipping goats which solves the tick problem. Farmers are used to dipping cattle. They are reluctant to dip goats and sheep. That attitude allows their livestock to easily succumb to tick borne diseases.

The views of the respondents concur with other studies which also show that communities in Africa grapple with what are called multiple stressors (Adger et al. 2003; Osbahr et al. 2008; Drimie and Gillespie 2010). Multiple stressors (in this case predatory animals and thieves) are other challenges that come about or are in existence when communities are attempting to adapt to climate change. These multiple stressors complicate the ability of farmers to adapt to climate change smoothly. The AGRITEX official summarized the challenges faced by interviewed farmers when he remarked that:

> There are a number of challenges faced by the small livestock farmers ranging from diseases, thieves, predators and lack of finance to buy treatment for their livestock. For most of the constraints that they face, nothing has been done much to help them. For fear of retribution through current legislation, they watch as their livestock are mauled by the hyenas and jackals. They have not taken meaningful steps to address the diseases that affect their livestock. Thieves sometimes help themselves to their livestock and for those that are able to keep significant numbers they find themselves with a dilemma of markets to sell their livestock. (Key Informant 1, AGRITEX)

He however further suggested that the attitude of farmers also needs to be worked on. They do not classify themselves as goat farmers. They do not keep records. Livestock production is something to invest time and resources on. Few are taking steps to exploit the huge potential that lies with small livestock production. It was also apparent that interviewed farmers rear goats without an awareness of the type of breed which they keep. For all the interviewed farmers, a goat is appreciated just because it is a goat, what breed it is does not matter.

Institutional Mandate Response on Small Livestock Production

The Livestock Veterinary Department in partnership with AGRITEX has been very instrumental in the study area in promoting small livestock rearing. The Livestock Veterinary Department offers technical support to the smallholder farmers at no charge to assist them to improve on small livestock production. Two household respondents from different wards remarked that:

> The veterinary department has been very helpful to us as farmers in our village. They conduct training and workshops to teach us on small livestock breeding. We have been taught that are goats must be dosed and well-sheltered so that they are not exposed to too much heat and precipitation. Our goats are now dipping although some farmers still find it strange to do that because we grew up knowing it is cattle that dip. They respond fast even when there is an outbreak of a disease that affects our chickens as well. (Household Respondent 34, Makhasa)
>
> I am one of the few farmers that have benefited from teachings facilitated by the Veterinary Department. I was trained at Maphisa to be a paravet for a week. Because of my passion in goat rearing I have over 50 goats now from the mere 14 I had before I was

> trained. All my goats go for dipping every month. I dose them regularly. I have thus constructed this new kraal to prevent them from being mauled by hyenas and jackals. (Household Respondent 50, Zamanyoni)

However, another research participant in the study area had a different view on the role of the veterinary department. He exclaimed that:

> Our Veterinary personnel are not well capacitated in our district in terms of resources to serve the farmers. They have lots of literature in their office but they have no transport to go around distributing the literature and equipping farmers as they should. They do not even have up to date statistics because they don't have the means to get to where the people are. (Household Respondent 22, Gwezha)

It was clear from the 67% interviewed farmers that the Livestock Veterinary Department is making great strides in capacitating smallholder farmers to enhance the production of small livestock in the study area. They acknowledged that they have received information through field visits on issues relating to small livestock dipping, dosing, climate friendly shelter, and dealing with diseases. However, 33% of the interviewed farmers felt that the department is limited by resource constraints from the central government. They argued that the technical experts from the veterinary rarely do field visits and that they only avail themselves during emergency situations such as disease outbreaks threatening small livestock. They also claimed that they occasionally come when they have a joint program with NGOs like World Vision. Given such a scenario, smallholder farmers are forced to be initiative and deal with some diseases using traditional medicine or fork out money to travel from their village to Maphisa Centre to get technical advice. There was also a concern that even if one travels to Maphisa, medicine is not readily available, and therefore farmers are compelled to further go to Bulawayo which is difficult due to financial constraints.

Khulasizwe (local NGO) which used to operate in the study area from 2009 to 2013 played a crucial role in the promotion of goat production. They mainly distributed three female goats per household to promote food security and create a market for Bulawayo butcheries where the demand for goat meat was high. The researcher identified two beneficiaries who had benefited from the Khulasizwe project. They commented that:

> Khulasizwe gave me 3 goats in 2009. They also gave me and other beneficiaries cement, asbestos to build shelter for goats. Khulasizwe offered a 50/50 deal where you also paid half prize of stock and they paid the other half. They offered vaccines. This has improved livestock production in Matobo. I currently own 27 goats from the original 3 I received from Khulasizwe. (Household Respondent 49, Makhasa)
>
> Goats have a huge potential of saving not only Matobo farmers but the whole nation from a potential disaster caused by climate change. There is therefore need for the government to help the small livestock farmers to go commercially and to produce for the nation. A little more of the government presence on the ground can make a huge difference. (Household Respondent 50, Makhasa)

Conclusions

Farmers in the study area are agreed that goats and sheep have increased their adaptive potential in the face of adverse climatic condition. Unlike cattle, the survival rates of small livestock is high in the drought prone areas like Matobo District and have proved more viable and effective. Most households from the sample kept one form of small livestock irrespective of the knowledge on the breeds that they kept. The success and viability of small livestock production largely depend on the input of government and other stakeholders like the Department of Livestock Production and Development, Jairos Jiri, World Vision, and Khulasizwe working closely with farmers. Their contribution to farmers through expert training and provision of small livestock is key to successful adaptation. Therefore, that working relationship should be strengthened and maintained.

Recommendations

Based on the above findings, this study recommends the following:

The government, at local and national level, can facilitate and implement adaptation strategies through policies that support farmers and make resources available. The government has documented action plans and strategies to tackle the challenges of climate change through the Ministry of Environment, Water and Climate. However, there is need for government to "walk the talk" and implement what is documented on paper and implement it on the ground. There is a discrepancy over what the government intends to do and what communities experience in their environment.

There is need for government and NGOs like AGRITEX, EMA, Department of Livestock Production and Development, World Vision, Khulasizwe, and Jairos Jiri to coordinate their activities. Research participants noted overlaps in how such programs are implemented. Coordination among them assists in avoiding or at least reduces overlap of activities. Climate change adaptation strategies if coordinated well can help in discovering of existing gaps in need of implementation.

Adoption of technical adaptation strategies like small livestock rearing should be broadened through knowledge dissemination and awareness in all wards. The challenge currently is that interventions target a few farmers and leave out others. Going forward, knowledge and training should be emphasized until communities fully appreciate the adaptation options suitable and appropriate for their areas. Raising awareness of climate change issues can be done through the local media and extension staff. Dissemination of climate change information from national and local meteorological stations to farmers through extension agents is also very critical.

Abstract

This chapter discusses the barriers to climate change adaptation among pastoralists in the Rwenzori region in Western Uganda. Despite the implementation of adaptation programs by public and private agencies, pastoralists still have impediments to adapting to climate change. Data was collected using a household survey involving 269 pastoralists. The results revealed that the main barriers were poor access to climate change information, poor access to extension services, high cost of adaptation measures, poor access to credit, and insecure land tenure. There is need to improve capacity building of extension workers and other stakeholders in the dissemination of climate change information. Land tenure and land rights issues should be given high consideration in climate change adaptation policies and programs. Climate finance programs should be made more effective in addressing the high cost of adaptation.

Introduction

Climate change is one of the greatest threats to achieving the sustainable development goals related to eradicating poverty and hunger and ensuring clean water and life on land in Africa (IPCC 2018c). Despite the increased efforts at both national and international levels in the form of climate finance and programs, pastoralists still have barriers to adapting to climate change. Failure to adapt to climate change has resulted into high livestock mortality leading to a poor quality of life among pastoral households (IPCC 2014b). The impacts of global warming of 1.5 °C above pre-industrial levels are likely to lead to an increase in droughts and floods in Africa, especially in pastoral areas (IPCC 2018a). This could result in a failure to achieve sustainable development goals (IPCC 2018c). Pastoralists have adapted to climate change with various strategies that include livestock diversification, destocking, livestock migration, and engagement in nonfarm enterprises (Greenough 2018; IPCC 2014b). However, some pastoral households have been more vulnerable than others to climate change, resulting in loss of livestock (Greenough 2018). This implies that there are hindrances to adaptation.

Developing countries such as those in Africa still have challenges in addressing the hindrances, leading to an adaptation deficit when compared to developed countries in Europe (IPCC 2014a; Shackleton et al. 2015). These hindrances are categorized as limits and barriers. Barriers refer to impediments that can be easily overcome, while limits refer to impediments that cannot be easily overcome (IPCC 2014a). Many scholars have written about the barriers to adaptation without scrutinizing their causes (Filho and Nalau 2018; Shackleton et al. 2015). Moser and Ekstrom (2010) argue that barriers have various causes which have to be addressed for successful adaptation to be achieved. The issues of concern include the context of the pastoral household, type of pastoral household, and the governance system of the natural resource. This suggests that smallholder pastoralists experience different barriers compared to large-scale pastoralists. Rangeland policies that promote sedentary pastoralism have different barriers compared to those that promote mobile pastoralism (Löf 2013; Shackleton et al. 2015). These policies have strong implications for the governance system and context of pastoralism. For example, sedentary policies in pastoralism have a detrimental effect on the land tenure system that does not promote herd mobility as a coping mechanism for droughts (Little et al. 2008). This then becomes a barrier.

The barriers that have been identified include economic, biophysical, financial, informational, sociocultural, governmental, and institutional (Alam et al. 2018; Antwi-Agyei et al. 2015; IPCC 2014a; Shackleton et al. 2015). Juana et al. (2016) reported that barriers identified among livestock farmers in Botswana included poor access to improved technology; lack of land, extension workers, credit, and markets; and government restrictions on land use. Muller and Shackleton (2014) showed that the main barriers to commercial livestock farmers in semiarid East Cape in South Africa were poor access to finance, lack information on climate change adaptation and climate information, and lack of government support. This shows that there are barriers that are unique to livestock farmers and pastoralists.

The "barrier to adaptations" diagnostic framework was used to analyze the causes of the barriers (Moser and Ekstrom 2010). This was in order to have a robust investigation of the causes of the barriers, leading to measures of overcoming them. The analysis took into account the sources of the barriers that include the pastoralists (actors), context (governance and economic setting), and socio-ecological system in the rangelands (system of concern) (Moser and Ekstrom 2010). The larger context refers to the level of socioeconomic development and the control of information flow at national and local government level associated with climate change adaptation. Governance refers to the laws, policies, implementation frameworks, and resource allocation at national and local government levels that are associated with the socio-ecological system. The socio-ecological system refers to rangelands, herdsmen, and pastoral households. The socio-ecological system produces signals of environmental change (Moser and Ekstrom 2010) in terms of floods and droughts, although droughts have slow onset and may not be easily detected by the pastoralists. Early warning systems such as seasonal climate forecasts that are disseminated via mass media are not usually observed (Luseno et al. 2003). Pastoralists tend to use indigenous forecasts in their adaptation to extreme weather events despite their reliability and accuracy being affected by climate change (Speranza et al. 2010). Some pastoralists use both indigenous and scientific forecasts (Lybbert et al. 2007). The analysis also took into consideration the temporal dimension of the barrier sources, which include recent occurrence (contemporary issue) or occurrence over a long time (legacy issue) (Moser and Ekstrom 2012). The purpose was to find out when the barriers came into play. The spatial jurisdiction origin of the barrier in relation to pastoralists includes proximate, referring to the origin of the barrier being within pastoralists' cycle of influence, and remote, referring to the origin of the barrier being outside the pastoralists' cycle of influence, for example, government policies (Moser and Ekstrom 2010). The idea was to examine which barriers were within the cycle of influence of the pastoralists.

This chapter examines the barriers to adaptation among pastoralists in the Rwenzori region in Western Uganda. The key question is what are barriers to adaptation among pastoralists? The sources and origins of the barriers are examined to provide strategies for overcoming them. The objective is to generate empirical evidence that could be used by policymakers, development partners, extension workers, and nongovernmental organizations to address the barriers among pastoralists to improve their adaptation to climate related risks. The chapter contributes to pastoral literature that relates to barriers to climate change adaptation in Africa. The scope of this chapter addresses barriers among pastoralists in the tropical equatorial region in Western Uganda and does not cover arable farmers and pastoralists in semiarid areas.

Methods

Study Area

The study on barriers to adaptation among pastoralists was conducted in Kasese and Ntoroko districts found in the Rwenzori region in Western Uganda (Fig. 1). There are a few weather stations used to provide the climate data of the region. The rangelands in the study area are conducive to pastoralism and wildlife conservation, and wildlife protected areas (WPAs) exist in the area. WPAs include Queen Elisabeth National Park in Kasese district and Tooro-Semiliki Game Reserve in Ntoroko district (Fig. 1). As an adaptation strategy for climate change, pastoralists migrate to the eastern part of the Democratic Republic of Congo. Political instability in Eastern DR Congo tends to cause large numbers of pastoralists to migrate back to Uganda (KRC and RFPJ 2012). However, some pastoralists illegally graze in WPAs. The Uganda Wildlife Authority imposes heavy penalties on pastoralists who illegally graze in WPAs. The emphasis on sedentary pastoralism in government rangeland policies has led to a reduction in mobile pastoralism in Uganda (Wurzinger et al. 2006, 2009). The region has a bimodal rainfall distribution and experiences droughts and floods with increased frequency (NAPA 2007).

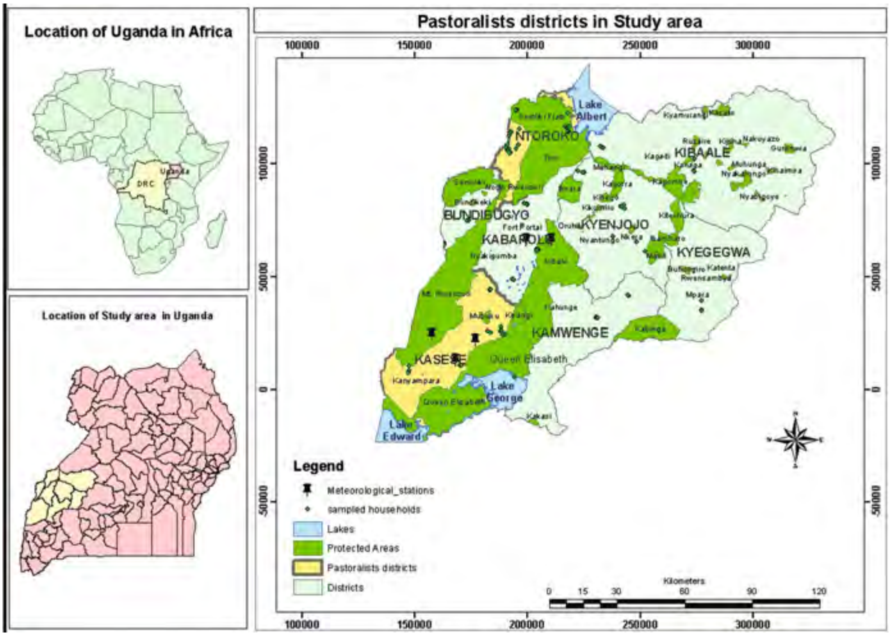

Fig. 1 Location map of study area. (Source: Michael Robert Nkuba)

Data Collection Methods and Sample Size

Data collection took place from August to October 2015 in the Rwenzori region. Household surveys gathered data on barriers to adaptations, socioeconomic characteristics, and use of indigenous forecasts (IFs) and/or scientific forecasts (SFs). A two-stage stratified sampling design was used (Cochran 1963), in which the strata were the districts and the second stage units were households. Stratified sampling was based on farming systems and agro-ecosystems in the Rwenzori region. Random sampling was used to select the respondents for the survey. The sample size was 778 households, with a 95% confidence level and a margin of error of 3.5%, based on the total population of the study area (the Rwenzori region and the Kibale district) of 102,496 households, according to Uganda population census report 2014. However, to allow for replacement in the sample of those who might back out of the study, and have good sizes for subsamples for those who use IF and SF and IF only, 19% of the statistically selected sample was included, giving a total study sample of 924. This was also to ensure a good sample size for subsamples (for those who use IF and SF and IF only). After data cleaning, 17 questionnaires were excluded from the analysis due to incomplete responses. Of the remaining 907 respondents, 580 were arable farmers, 269 pastoralists, and 57 agro-pastoralists. For this chapter, the sample size is 269 from pastoral areas in Kasese and Ntoroko districts. Data was analyzed using Stata 12. The scope of this chapter addresses barriers among pastoralists in the tropical equatorial region in Western Uganda and does not cover arable farmers and pastoralists in semiarid areas.

Results and Discussion

Socioeconomic Characteristics

The descriptive characteristics show that respondents were mostly male (59%) (Table 1) with an average number of local cows produced in the previous last 12 months being 70 per pastoral household. Pastoralists mainly used both IFs and SFs (59%) or IFs only (41%) in their adaptation to climate-related risks (Table 2). The use of indigenous forecasts has enhanced climate change adaptation and disaster

Table 1 Socioeconomic characteristics of respondents

Variable	Variable definition	Full sample ($N = 269$)
Female	Gender of the respondent (1 if female)	0.41
Male	Gender of the respondent (1 if male)	0.59
No school	Respondent had no formal school education (1 if yes)	0.38(0.50)
Primary	Respondent attained primary education (1 if yes)	0.47(0.50)
Secondary education	Respondent attained ordinary or advanced secondary education (1 if yes)	0.12(0.33)
Farm experience	Farming experience of the respondent in completed years	27.72(13.84)
Age	Age of the respondent in completed years	44.26(13.25)
Kasese	Respondent resides in Kasese district (1 if yes)	0.17(0.38)
Ntoroko	Respondent resides in Ntoroko district (1 if yes)	0.81(0.40)
Drought experience	Respondent has had drought experience (1 if yes)	0.96(0.20)
Flood experience	Respondent has had flood experience (1 if yes)	0.82(0.39)
Herd mobility	Respondent practices herd mobility (1 if yes)	0.55(0.50)
Livestock diversification	Respondent practices livestock diversification (1 if yes)	0.54(0.50)
Livestock migration	Respondent practices livestock migration (1 if yes)	0.83(0.38)
Selling livestock	Respondent practices selling livestock (1 if yes)	0.51(0.50)
Well construction	Respondent practices well construction (1 if yes)	0.31(0.46)
Nonfarm	Respondent engages in nonfarm enterprises (1 if yes)	0.08(0.27)

management in Africa and South America (IPCC 2018b). Climate-related risks experienced were floods and droughts. The majority (47%) had attained primary education, and 38% had no formal education. The common adaptation methods were livestock migration, herd mobility, livestock diversification and livestock sales. Enablers to adaptation included access to land through purchasing (suggesting that functional land markets existed) and inheritance (Table 3). Pastoralists diversified their livelihoods to include other natural resources such as fisheries resources, which were demonstrated by ownership of boats and fishnets (Table 1).

Barriers to Climate Change Adaptation among Pastoralists

The high cost of adaptation is a major barrier in wealthy pastoral households (Table 4). According to a key informant, it costs $800 to construct a private dam, and sinking a borehole would cost $5400 in the study area. These costs are high for smallholder pastoralists. The key informant also said that the government program, National Agricultural Advisory Services (NAADS), used to provide fence materials to a few model pastoralists. The NAADS program ended in 2014, and the cost of infrastructure development in pastoral areas is high. The fencing materials were provided to a few pasture demonstration farmers (Dalipagic and Elepu 2014; GoU 2018). The government also provided tractors for pasture improvement but not water for pastoralists (NAADS 2017). Climate finance should address such barriers. The Uganda government provided support for the construction of over 650 communal valley dams and 135 private dams for ranches in the rangelands (Nema 2001). Some of these dams dried up during droughts resulting in livestock mortality and an increase in herd mobility (Zziwa et al. 2012). Lack of hydrographic surveys for communal valley dams, poor designing of water sources without taking into account the rangeland dynamics and context, poor maintenance, and lack of community ownership were the main factors that led to the poor performance of communal valley dams (Mugerwa et al. 2014; Nema 2001). Community involvement in the management of micro-dams is higher in the Southwest and Central regions of Uganda (40–50%) than in the North and Northwest regions, where it is very low (less than 10%) (Bashar et al. 2004).

The poor performance of valley dams has increased water scarcity in the rangelands, resulting in an increase of mobile pastoralism and sociopolitical conflicts (Nema 2007), yet the government built the water sources to promote sedentary pastoralism. Even in situations where there was good performance and management of the dams, there was land degradation of the rangelands surrounding the water source (Egeru et al. 2015). Individual pastoralists tend to manage their private water sources better than they manage communal ones. The Botswana government provides support to livestock farmers with infrastructural development assistance, such as for fencing materials, and construction of boreholes to improve their adaptive capacity against droughts (Pauw 2013). Climate finance should support pastoral initiatives toward adaptation by providing fencing materials and sustainable water sources in communal rangelands and paddocks (Denton 2010).

Poor access to climate change information and poor access to extension services were also important barriers to adaptation among pastoral households. Extension workers have not mainstreamed climate change information in their dissemination of extension messages, but emphasis has been put on livestock production (AfranaaKwapong and Nkonya 2015; GoU 2016; Nkonya et al. 2015). Furthermore, in Uganda (as elsewhere in Africa) the extension system has gone through many changes from a unified extension system (1981–2000) to a demand-driven extension under the NAADS (2001–2014), to the current single-spine extension system (2015 to date) (Barungi et al. 2016; GoU 2016; Rwamigisa et al. 2018). The extension services have been tailored to sedentary but not mobile pastoralism. The demand-driven extension system under NAADS was relevant not to mobile pastoralists but to sedentary pastoralists. The extension did not serve all the pastoralists but concentrated on a few, especially model farmers (AfranaaKwapong and Nkonya 2015; GoU 2016). Furthermore, pastoralists in remote areas did not access extension services (AfranaaKwapong and Nkonya 2015). There were also a limited number of qualified service providers in rural areas, resulting in services engaging unskilled and poor quality providers (Feder et al. 2011; GoU 2016). Most of the service providers had such a narrow scope of the subject matter that they were incompetent and lacked capacity to handle other aspects such as plant and animal diseases (GoU 2016; Rwamigisa et al. 2018). There was reportedly much political interference with the implementation of demand-driven extension service (Joughin and Kjær 2010;

Rwamigisa et al. 2018). This included the use of members of the Uganda Peoples Defence Forces in the distribution of inputs and various presidential directives on the implementation of the extension services, especially during election periods (Rwamigisa et al. 2018).

Poor access to credit facilities as a barrier mostly applied to small-scale sedentary pastoralists. Large-scale pastoralists tended to finance their livestock enterprises through destocking, using rural livestock markets (Bryan et al. 2013). Furthermore, these pastoralists diversified into fishing and other nonfarm enterprises (Nkuba and Sinha 2014). The large-scale pastoralists were much more involved in livestock migration to the DR Congo as a means of adapting to climate-related risk. During severe droughts, large-scale pastoralists incur losses but recover much more quickly than small-scale pastoralists (Little et al. 2001). According to key informants, about 10,000 cattle were lost in the Ntoroko district during the severe drought of 2011. In some cases, smallholders tend to resort to agro-pastoralism in a sedentary life after high livestock mortality due to severe drought (Berhanu and Beyene 2015).

Insecure land tenure or property rights (Table 4) was another barrier to climate change adaptation in pastoralism. The rangeland policy in Uganda supports sedentary pastoralism (Byakagaba et al. 2018), while pastoralists with land enjoy dual grazing rights. During the rainy season, they graze their livestock in the paddocks. However, during pasture and water scarcity periods, such as during long dry spells and droughts, they graze communally. The areas that used to be grazed communally have been taken up by crop farmers and wealthy pastoralists who have paddocks. Over the years, “the commons” have therefore shrunk in the Rwenzori region, yet the cattle population has not decreased substantially (GoU 2006). During political instability in the DR Congo, the livestock population in rangelands of Ntotoko is much higher than its carrying capacity. The debate concerning having titled land in rangelands and communal grazing land in the cattle corridor continues. Dual grazing rights of wealthy livestock farmers who have access to large acreages have also been reported in Botswana as a coping mechanism during severe droughts (Perkins 1996).

Labor shortages and the associated high cost of labor for pastoralism (Table 4) have been caused by the labor dynamics in the study region. Most herdsmen are youth, many of whom have resorted to nonfarm activities such as motorcycle hire services (commonly called *bodaboda*) in rural areas. Furthermore, there has been a mass migration of the youth from pastoral households to urban centers and towns in search of so-called greener pastures. Thus, the high demand for herdsmen in the face of a diminished labor supply in rangelands has led to the high cost of labor. The labor of herdsmen is in high demand for such adaptation strategies as livestock migration to the DR Congo, herd mobility to River Semiliki, and pasture lands in the neighborhood of the protected areas.

Sources of the Barriers

The question that remains is whether pastoralists can overcome these barriers. As noted earlier, to answer this question, the sources of barriers needed to be identified using the barriers to adaptations diagnostic framework. The sources were then analyzed using the three structural elements in the framework, namely, the actors (referring to pastoralists), governance (referring to policies, implementation frameworks, and laws that govern adaptation or hinder it), and socio-ecological system (life in the rangeland, sometimes referred to as system of concern) (Moser and Ekstrom 2010). The three structural elements were used to examine strategies of overcoming the barriers, as is reflected in the following discussion.

The high cost of adaptation was due to the poor performance of valley dams, an insufficient number of water sources in the rangelands, policy emphasis on support for communal water sources at the expense of individual pastoralists, and equity concerns where support was only given to a few model pastoralists. This suggests that the sources of barriers were principally governance (institutional), technological, and human resource concerns. As a solution, pastoralists could be supported in infrastructure development such as fencing and construction of dams (in communal rangelands) and of boreholes in paddocks for sedentary pastoralists using climate finance from both national and international agencies. The recent change in extension policy from demand-driven extension to single-spine may also help mainstream climate change in its implementation and take into account cost of adaptation (GoU 2016). This implies an increase in allocation of resources related to climate change adaptation. The poor performance of valley dams had a bearing on the hydrological dynamics in rangelands, implying that the socio-ecological system was also a source of barrier. This can be overcome by making good use of the available expertise in hydrology to carry out feasibility studies before the water sources are constructed. Human resources in hydrology and appropriate technology for the various agro-ecological zones from the Ministry of Water and Environment should be utilized to good effect, both in monitoring and in program design of water for agricultural production facilities (GoU 1999).

The source of barriers such as poor access to climate change information and poor access to extension services was governance (institutional concerns). From a governance perspective, rangeland and extension policies were not relevant to the context. Past extension policies, both the unified extension policy, which used the training and visit system, and the demand-driven policy under NAADS, did not meet the expected outcomes (Rwamigisa et al. 2018; World Bank 2007). This has been mitigated through the new extension policy based on the single-spine extension system, which also has mainstreamed climate change information in the extension messages (GoU 2016). However, the new rangeland policy is not compatible with the socio-ecological system (Byakagaba et al. 2018). Mobile pastoralism makes good use of fragile ecosystems in the rangelands under changing climate conditions (Bailey and Brown 2011; Weber and Horst 2011). Instead, the ultimate goal of the new policy is to convert hitherto mobile pastoralists into agro-pastoralists and sedentary farmers (Wurzinger et al. 2009). There is therefore need to lobby the policy-makers to take into account both mobile and sedentary pastoralism in the rangeland policy. There is also the problem of inadequate human resources in terms of extension officers to serve the entire country. Only 35% of the technical positions in local governments had been filled in 2016 (GoU 2016). This can be overcome through increased supply and recruitment of qualified labor from tertiary agricultural institutions in the country, such as Makerere University and Bukalasa Agricultural College. Provision of incentives to extension staff is also critical to achieving sustainable outcomes.

Poor access to credit facilities is an actor-centric barrier. This can be overcome with pastoralists joining savings and credit organizations dedicated to pastoralists (Mpiira et al. 2014), probably supported by climate finance arrangements.

Insecure land tenure or property rights are governance-related barriers arising from concern related to the contradictory rangelands and land-use policies. The land policy promotes mobile pastoralism (GoU 2013) while land-use and rangeland policies discourage mobile pastoralism (GoU 2006); hence there is lack of policy coherence. This is another reason to lobby for change in the land-use and rangeland policies to take into account mobile pastoralism concerns.

The high cost of labor and labor shortages are governance-related and actor-centric barriers. From the governance perspective, there is a need for government policies that attract youth in rural areas of rangelands. The Ugandan government has passed a minimum wage law, but it is unclear how effective it will be in rangelands. From the actor perspective, pastoralists need to increase the amount of wages paid to herdsmen to attract more youth in the socio-ecological system.

Origins of the Barriers

The origins of the barriers were investigated using temporal and spatial analysis (Table 5).

Lack of credit is a contemporary and proximate barrier, implying that it is within the cycle of influence of pastoralists and a more recent barrier that can be overcome. Wealthy pastoralists finance their enterprises from destocking using rural livestock markets. Destocking is also a climate change adaptation strategy. Thus, poor access to credit mostly applies to the poor sedentary pastoralists. There has been prevalence of savings and credit organizations (SACOs) in rural areas even among pastoralists (Mpiira et al. 2014).

The high cost of hired labor is a contemporary and legacy barrier, implying it is within the cycle of influence of pastoralists and has been in play over a long time. The rural-urban migration of youth in the socio-ecological system has led to an

Table 5 Opportunities for influence and intervention to overcome the barriers

		Temporal	
Spatial Jurisdictional		Contemporary	Legacy
	Proximate	Lack of access to credit	High cost of hired labor
	Remote	Insecure land tenure, high cost of adaptation	Inadequate or no access to extension services Inadequate or no information on climate, labor shortages

Source survey data 2015. Adapted from Moser and Ekstrom (2010) increase in the cost of labor. The youth nowadays prefer to engage in nonfarm activities such as the motorcycle hire business (popularly known locally as *bodaboda*), and move to urban centers. The promotion and implementation of universal primary education (UPE) even in pastoral areas has improved the skills of youth and provided opportunities outside the rangelands (Appleton 2001). Before the implementation of UPE, the cost of labor was very low as the supply of labor was high because many youth did not go to school. This barrier can be overcome by encouraging pastoralists to destock and by enabling them to obtain credit to finance their labor needs.

Insecure land tenure or property rights and the high cost of adaptation are contemporary and remote barriers, implying that they are a recent occurrence but outside the cycle of influence among the pastoralists due to change in government policies. Mobile pastoralism was commonly practiced in the cattle corridor in Uganda. The increase in human and livestock populations and conflicts among pastoralists and with pastoralists in the neighboring arable farming communities resulted in a change of government support, from mobile pastoralism to sedentary pastoralism. The change in rangeland land policy from mobile pastoralism to sedentary pastoralism is a result of armed conflict between arable farmers (from Teso) and pastoralists (the Karamanjong) in northeastern parts of Uganda. Before 1980, mobile pastoralism thrived in Uganda, until the Karamanjong got access to arms, which led to armed conflict in the rangelands (USAID 2011). The change in the land policy and act, with an emphasis on titling land, resulted in the shrinking of the commons in the rangelands, in turn resulting in an increase in insecure land tenure among the commoners (GoU 2013). This barrier could be mitigated through amending the land policy to provide for common grazing lands in land policy in the rangelands and to avoid titling every piece of land in Uganda. This debate has been ongoing among the various nonstate actors since the enactment of the land act in 2004 (Byakagaba et al. 2018). Blanket policy recommendations did not take into account the local setting in different parts of the cattle corridor.

The high cost of adaptation can be overcome through an increase in climate finance to include support to more pastoralists who are not model farmers, as is the current practice under the NAADS implementation framework. There has been a change in the national extension policy from the demand-driven to the single-spine NAADS, which is more inclusive and has taken into account equity concerns (GoU 2016).

Poor access to extension services and climate change information and labor shortages are legacy and remote barriers, implying that they lie outside the cycle of influence of pastoralists and have been in existence over a long period of time. Extension services should have provided the climate change information to the pastoralists, but the ineffective demand-driven extension policy had detrimental outcomes on both. This has fortunately been mitigated through the change in extension policy from the demand-driven to single-spine model (GoU 2016). The new policy promotes mainstreaming climate change information and providing services to all pastoralists.

Labor shortages are due to the failure of a minimum wage law and effective rural development strategies to address the rural–urban migration in Uganda. As observed earlier, educated youth will no longer work for very low incomes as herdsmen in pastoral areas. Recently government passed a minimum wage law whose outcomes are yet to be evaluated in rangelands. It is hoped that this will serve to retain youth in rangelands and promote urban-rural migration among the youth that have already left for urban areas. There is need for government to implement effective rural development strategies that would make rural areas more attractive to the youth. So far, strategies such as the Plan for Modernisation of Agriculture have not been effective in reversing the rural-urban migration of the youth.

It is noteworthy that the remote barriers are due to national policies such as extension and land policies that were heavily influenced by donors such the World Bank (Deininger 2003; Deinlnger and Binswanger 1999; Rwamigisa et al. 2018). Local ownership, support to home-grown initiatives, and bottom-up approaches to climate change adaptation would enhance and facilitate the development of the adaptive capacity of pastoralists against these barriers (World Bank 2007) .

Enablers of Adaptation in Uganda

Alongside barriers to climate change adaptation, studies have also identified adaptation enablers (Azhoni et al. 2018), such as human resource, institutional, governance, and economic enablers (Moser and Ekstrom 2012). In Uganda, climate change adaptation enablers include the following:

- *Human resources*, such as extension staff and climate change adaptation researchers, pastoralists with indigenous knowledge of climate change adaptation and forecasts.
- *Institutions*, such as climate change units and climate change policy, research centers for agricultural innovations, the Uganda National Meteorological Authority that provides early warning information and seasonal climate forecasts, mass media that disseminates climate and climate change information (GoU 2015).
- *Economic*, such as national and local government resource allocations to climate change adaptation initiatives, donor support from Denmark, the United States, Ireland, the United Kingdom, Belgium, Norway, the World Bank, the United Nations Development Programme, support for climate-smart agriculture from the Food and Agricultural Organisation of the United Nations, nonstate actors such as nongovernment organizations implementing climate change adaptation initiatives at local government level such as Oxfam, World Vision, Care, Volunteer Effort for Development Concerns (GoU 2015).
- *Political will* both at national and local government levels and parliamentary fora on climate change. The government provides mechanisms for flexible and negotiated cross-border access to pastoral resources under the land policy, such as access to rangelands in Eastern DR Congo (GoU 2013).

Conclusion

The study has established that the barriers to pastoralism are mainly actor-centric and governance concerns. The main barriers were poor access to climate change information, poor access to extension services, high cost of adaptation measures, poor access to credit, and insecure land tenure. Some of the policies under which pastoralism is practiced hinder adaptation to climate change. A change in the policies will enhance adaptation; for example, the recent change from the unified extension system and demand-driven extension system to the single-spine system will help in overcoming poor access to extension services and climate change information. Climate finance programs should be made more effective in addressing the high cost of adaptation. Enhancing social capital can help in overcoming poor access to credit. A change in land-use and rangeland policies will help in mitigating insecure land tenure. Coherence of land, land-use, extension, and rangeland policies will enhance pastoral adaptive capacity. It is noteworthy that there are several enablers for climate change adaptation in Uganda, which could be exploited to good effect.

The key lessons learned are that policies associated with climate change adaptation either hinder or enhance the adaptive capacity of pastoral households. Enhancing social capital such as pastoralists' savings and credit groups facilitates access to credit, which improves the capacity to overcome some barriers. Climate finance should be administered in an equitable manner to improve the adaptive capacity for both wealthy and poor households in rural areas.

Future prospects for overcoming barriers in developing countries lie in the identification of the origins and sources of the barriers for effective policy interventions. Policy coherence in climate change adaptation implementation is critical to achieving sustainable development goals, especially Goals 13 and 15, which address the problems of climate change and terrestrial ecosystems, respectively. Mainstreaming climate change in, and effective implementation of, rural development policies will improve the ability of pastoralists to overcome the barriers to climate change adaptation. Rangeland policies should promote both mobile and sedentary pastoralism.

Acknowledgments The authors are grateful for the support during the research from research assistants and the respondents who made this research a reality through their favorable cooperation. This research was self-financed by the lead author for data collection, and special thanks to Nassali Mercy Nkuba for moral support. We are grateful to Kabarole Research and Resource Centre for their collaboration during the field work and the Government of Uganda for permission to carry out the study. Special thanks to Susane Moser and Julia Ekstrom for the insights in the diagnostic framework. This research is part of PhD work for Michael Robert Nkuba, who wishes to thank the University of Botswana for waiving tuition costs.

Abstract

This study identifies the need for holistic understanding of gender-differentiated climate-smart agriculture (CSA) adoption by smallholder farmers who are at the frontline of climate-related hazards and disasters in Africa. CSA adoption is predominantly informed by a parochial linear approach to farmers' decision-making processes. Resilience-building and adaptation, which forms the second pillar of CSA and can enhance understanding of the CSA adoption nuances at farmer level, often receives less attention in adoption investigations. To appreciate CSA adoption from a resilience perspective, this study focused on resilience-building based on the interlinkage between CSA and disaster risk reduction and applied a resilience perspective in a gendered approach to CSA adoption by smallholder farmers. Through primary data collected in an exploratory sequential mixed method design, the study presents a proposed normative gender-sensitive CSA adoption framework to guide CSA implementation strategies and policies. The framework is anchored in resilience thinking, and some of its key components include gender-sensitive CSA technology development, risk-informed decision-making by heterogeneous smallholder farmers, gender-sensitive enabling factors, resilience strategies, gender equitable and equal ownership, and control of and access to resilience capitals. The proposed framework can be used to improve CSA adoption by smallholder farmers by addressing gendered vulnerability and inequality that influence low adoption.

Climate-smart agriculture · Disaster risk reduction · Gender · Adoption · Resilience · Framework

Introduction

Climate change threatens the achievement of sustainable development, undeniably presenting complex developmental challenges in less developed regions. The impetus is to find solutions to the dilemmas that disasters related to climate change present, especially in regions such as Southern Africa, which are categorized as climate change hotspots (Müller et al. 2014). In recent agricultural seasons, Southern Africa has faced devastating and unprecedented climate change-related disasters, often resulting in Member States declaring a state of disaster. Some climate-related disasters affect only one country, such as the floods in Malawi in the 2014–2015 agricultural season that caused the country to declare a state of disaster due to floods (Murray et al. 2016). Others transcend national boundaries, for example, the El Niño-Southern Oscillation-induced drought of 2015–2016 that caused Eswatini, Lesotho, Malawi, Namibia, and Zimbabwe to declare state of drought emergency (Nhamo et al. 2019). Other examples include the fall armyworm *Spodoptera frugiperda* infestation of 2017–2018 and cyclones Idai and Kenneth in the

2018–2019 season. The result of these disasters is that the food security, poverty alleviation, and sustainable development ambitions of individual countries and the affected regions are hampered (Lipper et al. 2018). One of the chief concerns is the effect of climate-related disasters on smallholder farming, which in most developing countries is estimated to constitute at least 70% of the population, with the agriculture sector contributing at least a third of gross domestic product (Diao et al. 2010).

Consequently, current development discourse in Africa is concerned with exploring resilience-building strategies for smallholder farming households so that they may become resilient in the face of climate-related disasters (Speranza et al. 2014; Lipper et al. 2018). With each climate-related disaster, there is a growing need to change from conventional agricultural farming toward new, unfamiliar, and uncommon farming technologies perceived to contribute toward resilience-building. It is for this reason that climate-smart agriculture (CSA) has gained prominence as a possible panacea to the developmental challenges presented by climate change, specifically in relation to smallholder farming in Africa (Arslan et al. 2018). CSA recognizes that climate change amplifies developmental challenges, hence its conceptualization based on three pillars, viz., (1) improved food and agricultural productivity, (2) resilience-building and adaptation, and (3) mitigation through the reduction of greenhouse gas emissions from agricultural activities (Asfaw et al. 2015; Chandra et al. 2017a). CSA is a livelihood-oriented integration of the triple wins of sustainable intensification, resilience-building, and climate mitigation (Taylor 2018). The adoption of CSA technologies and strategies provides one option for resilience-building. Consequently, there is growing focus on adoption of CSA technologies by smallholder farmers (Kpadonou et al. 2017; Nyasimi et al. 2017), although there are still some shortcomings in the understanding of CSA adoption. This chapter seeks to offer an in-depth understanding of the tensions between gender inequality and CSA adoption and of the existing limitations to resilience-building through CSA. The research departed from a resilience perspective applied on the CSA pillar that seeks to build resilience and promote the adaptation of smallholder farmers. It was conducted in two regions sharing almost similar disaster profiles, namely, Malawi and Zambia.

Findings show that low CSA adoption can be attributed to gender disparities in ownership of resilience capitals, inadequate provision for equal participation of smallholder farmers in CSA technology development, a lack of diverse CSA options that farmers could adopt, and the failure to sustain household food security, income generation, and improved quality of life through CSA. This chapter accentuates that increasing climate risk compels an exploration of measures to address these shortcomings of CSA. Furthermore, the paper emphasizes heightened need to pursue alternative gender-sensitive pathways that may help address gender disparities. Such disparities in smallholder farming societies continue to be a barrier not only to CSA adoption but also to resilience-building in the face of climate change. In pursuit of alternative approaches to addressing barriers to CSA adoption and increasing its uptake by smallholder farmers, this chapter presents a normative gender-sensitive CSA adoption framework that can be adapted and used in developing regions, ultimately contributing to resilience-building.

Criticism Directed at CSA

The conceptualization of CSA envisions that humanity could address some of its developmental challenges, such as the negative effects of climate change, population growth, and the corresponding increases in food demand, poverty, and sustainable development (Williams et al. 2015). Unfortunately, despite its positive attributes, CSA has also been met with some skepticism that cannot be ignored in a gendered approach to CSA adoption. The main criticism is insufficient consideration of power relations and inequalities (Chandra et al. 2017b). While Taylor (2018) considers power disparities at a global level between countries of the North and the South, this study considers these aspects at a farmer level. Further dissentions over CSA emanate from its failure to promote participation of local communities, with technologies and research dominantly unidirectional and top-down (Chandra et al. 2017a). Other scholars caution that when CSA fails to pay attention to social issues, its implementation may actually magnify preexisting social imbalances such as gender inequality (Murray et al. 2016; Collins 2017). When considered within the context of the pivotal role women play in smallholder farming, current CSA scholarship has insufficiencies when it comes to the appreciation of the gender dimensions in the CSA adoption decision-making process. Yet, for many African societies, the gender composition in the smallholder farming sector validates the relevance of gender as an investigative element.

Previous work by Khoza et al. (2019) shows that underlying gender inequality, patriarchy, and other social imbalances manifest as gender-differentiated, sociocultural, sociopsychological, and gendered vulnerability drivers that shape decisions on whether to adopt, dis-adopt, or not adopt CSA technologies. This emanates from a focus on CSA as solving the dilemma of climate change through technical fixes to increase food production. The provision of technological solutions for resilience requires consideration of their social implications, the absence of which has resulted in growing concern over the observed adoption paradox. Failure to address the underlying gender inequalities and vulnerabilities may have ramifications for resilience-building for smallholder farmers. Additionally, an existing understanding of CSA adoption is framed within a simplistic linear approach, which is insufficient when gender and resilience-building dimensions are brought into consideration. Thus, this study was conducted with the aim to explore the application of a resilience perspective to CSA to address the underlying gender inequality and gendered vulnerability in order to improve CSA adoption by diverse men and women smallholder farmers.

The shortcomings of CSA have also been linked to the issue of a conceptual misnomer, arising from a general conceptualization of CSA that includes policies, technologies, and practices at farmer, landscape, and ecosystem levels (Lipper et al. 2014). While some literature labels CSA as an already compromised concept pushing a hegemonic agenda for the developed countries (Taylor 2018), the concept has the potential to address some of the challenges African societies face with climate change. Having considered the concerns, this study situates CSA adoption assessment at a farmer level and with a deliberate focus on technologies and practices that farmers have to adopt. Some scholars highlight the need for alternative frameworks to address the shortcomings of CSA (Taylor 2018; Glover et al. 2019). This gives currency to the application of resilience thinking in CSA adoption, and a reconnaissance of CSA that leverages on its relationship with disaster risk reduction (DRR) can help address some of the highlighted shortcomings.

The Concept of CSA in a DRR Context

The second pillar of CSA is "resilience-building and adaptation," which underpins the interconnectedness of CSA and DRR (FAO 2013). This relationship paves the way for the application of a DRR lens to CSA in order to explore opportunities for improving CSA adoption by smallholder farmers. The climate-related risks and disasters affecting smallholder farming as already outlined in the introduction of this chapter give credence to such an approach. Moreover, at a farmer level, the demarcations between adaptation, resilience-building, and DRR are indistinct, as farmers are more concerned with surviving each disaster event.

A DRR approach to CSA draws attention to issues of vulnerability reduction, while CSA implementation in smallholder farming provides a vehicle to deliver both risk reduction and adaptation simultaneously (FAO 2013). A DRR approach to CSA could help resolve some of the shortcomings of CSA as highlighted in the preceding section. Greater strides have been made in DRR than in CSA, for example, in terms of the appreciation of resilience-building, indigenous knowledge systems, and the application of socio-ecological system concept to understand resilience-building and community-based participation (FAO 2013; Coetzee et al. 2016). Therefore, CSA could draw from progress made in DRR this far as a way of resolving the adoption challenges. Unfortunately, there has been minimal scholarly interrogation of CSA from a DRR perspective. Yet, at a time when increased climate risk threatens to wipe out the development gains made in agriculture so far, such a consolidated approach could better cross-examine CSA adoption. Furthermore, the relationship of DRR and resilience provides basis to interrogate CSA adoption from a disaster resilience perspective.

Disaster resilience is framed as an *ability*, where a system and its units are able to anticipate, absorb, accommodate, and recover from a disturbance by bouncing back or bouncing forward timeously and efficiently (Manyena et al. 2011). The system and its units may have the ability to change without loss of basic structure and functions, or self-organize, attaining incremental capacity to learn, adapt, and change through absorptive, adaptive, or transformative capacities (Béné et al. 2016). When smallholder farmers make decisions to adopt CSA technologies and practices, that is essentially indicative of their aspirations to be resilient to climate vagaries. Resilience of a system or its units, which in this study were individual farming households in a farming system, is better appreciated by considering resilience principles. This includes maintenance of redundancy and diversity, management of intra-system connectivity, feedbacks, promotion of social learning, participation and inclusion, embracing polycentricity, and understanding that agricultural systems are complex adaptive systems (Carpenter et al. 2012; Coetzee et al. 2016). Therefore, in assessing CSA adoption challenges from a resilience perspective, we argue that these resilience principles can be applied to assess barriers to CSA adoption and may help identify required improvements to build the resilience of farming households and communities.

Absorptive resilience is when households are able to contend with the negative effects of climate disasters through persistent coping and resistance, without any distinct changes to function or structure (Bennett et al. 2014), for example, when households cope with a drought through humanitarian interventions such as food aid distribution. Adaptive resilience is when the agricultural system or its units have the ability to learn from acquired or experiential knowledge and to make adjustments in response to disasters (Walker et al. 2004). In adaptive resilience, the aim is to make adjustments for continued functioning within a household or system. Transformative resilience refers to the capacity for change in structure and function of the system or households owing to disturbance. Transformation is more concerned with changes made in behaviors, cultural ethos, stereotypes, institutions, and policy direction (Walker et al. 2004). Thus, transformation depends on interrogation of the status quo and advocating for pragmatic changes in structure or function to be instituted. Adaptation and transformation are long-term and essential dimensions of resilience from a development standpoint. It is important to bear in mind that the three dimensions should not be pursued separately in linear fashion. It is important to harness the existing synergies among them (Béné et al. 2016).

Accordingly, for the majority at-risk rural smallholder farmers, CSA offers a pragmatic relevant conduit to pursue resilience. The assorted CSA options (see Table 1) contribute or have the potential to contribute to the three resilience dimensions, so it is worth mentioning that CSA implementation and policies should not elevate any one dimension and subordinate the others. Rather, in building on the synergistic relationships of absorption, adaptation, and transformation, CSA can help smallholder farmers and their systems become resilient.

In the context of smallholder farming in developing regions where CSA is promoted, it is key to recognize the heterogeneity of the farmers (Khoza et al. 2019).

The diversity among smallholder farmers draws attention to existing inequalities that relate to vulnerability and shape power, agency, ownership and control of resources, decision-making, and participation within farming systems (Ensor et al. 2018). This magnifies the need for resilience-building in CSA to pay attention to the skewed landscape within which CSA adoption decisions have to be made by different farmers. Ultimately, this mandates that over and above absorptive and adaptive resilience, transformation is required in CSA. This compels the interrogation of existing social imbalances that determine whether a smallholder farmer will adopt, dis-adopt, or not adopt CSA.

Methodology

An exploratory sequential mixed method design (Teddlie and Tashakkori 2009) was applied in Chikwawa, Malawi, and Gwembe, Zambia, to gather empirical data at a local level where smallholder farmers interface with climate-related disasters and

Table 1 Climate-smart agriculture options

CSA options	Examples
Crop management	Intercropping
	Crop rotation
	Crop diversification
	Improved seed varieties
	Value chains and marketing
	Improved postharvest storage
	Agro-processing
Livestock management	Fodder crops
	Feedlots
	Improved breed
	Rotational grazing
	Grassland restoration and conservation
Soil and water management	Basin/mechanized conservation farming
	Solar-powered irrigation
	Rehabilitation of degraded landscapes
Agroforestry	Woodlots
	Fruit trees
	Nitrogen-fixing trees
	Multipurpose trees
Integrated food-energy systems	Biogas stoves
	Energy-saving stoves
Infrastructure	Roads
	Housing
	Mobile network
Access to climate information	ICT platforms/information hubs
Fisheries	Aquaculture
	Capture fisheries

Adapted from FAO (2013)

where resilience-building is essential. The study was conducted between 2017 and 2019, with data collection in February and March 2018. The initial phase entailed qualitative data collection through semi-structured face-to-face interviews from purposively selected key informants at district level and focus group discussions (FGDs) at ward level. A total of 16 interviews and 6 FGDs were conducted (3 in each country: men only, women only, and mixed men and women). Thematic qualitative data analysis informed the design of an instrument used in quantitative cross-sectional data collection. In the quantitative cross-sectional survey, a total of 102 smallholder farmers were interviewed, 51 from each study site. The cross-sectional survey served to explore the generalizability of the themes established from the qualitative findings. In order to capture the perspectives and contexts of the gender dimensions in CSA adoption, the study placed emphasis on qualitative findings. This is in line with the methodological provisions of a mixed method research design (Teddlie and Tashakkori 2009). The quantitative data was analyzed with SPSS version 26 for descriptive statistics that established the distribution and trends.

Findings

Ownership of Land

The findings revealed that in Chikwawa, the average land owned by men household heads was 1.4 ha, while for women, it was 0.7 ha. In Gwembe, 40% of women-headed households who indicated they rented land did so for CSA purposes. While men household heads generally rented land in addition to what they owned, the women rented land because they were landless. Land ownership by women in Africa is a contentious issue (Doss et al. 2015), and these findings call for renewed effort to address the issue. Land ownership influences the adoption of agricultural technologies and practices; therefore, if CSA is to contribute to resilience-building, there is a need for equal distribution of land as a starting point toward equitable resilience (Matin et al. 2018).

Participation in CSA Technology Development

The qualitative findings established that CSA technology development occurred in a top-down manner, with smallholder farmers not engaged in technology development as they are generally considered as recipients "who receive your technology you have developed for them" (NGO respondent, Chikwawa). In both study sites, field days and demonstration plots were identified as opportunities for farmer participation in technology development. However, respondents acknowledged that even these events were top-down as they mainly showcased technologies that had been developed *for* the farmer, and technologies developed *with* the farmers' involvement were rare, if any. Currently, no mixed approach to CSA technology development that comprises technologies developed *for* and *with* the farmers is being considered. This may be due to the perception that farmers are technology recipients, as reflected by some interviewees: "they cannot contribute anything in technology development... what do farmers know that they can contribute in CSA?" (Government Department Respondent, Gwembe).

These sentiments were corroborated by quantitative findings that established that there was minimal participation among farmers in technology development irrespective of gender. In Chikwawa, 25% of the households, with over 70% of these being male household heads, stated that they had been involved in meetings when conservation farming and irrigation schemes were first brought to their communities. In Gwembe, 11% of the farmers acknowledged participation in similar meetings. At both study sites, those who participated in meetings went on to become adopters as they benefited from the respective CSA projects.

However, this is insufficient as participation should also include problem identification, evaluation of options, and eventual selection of technologies that farmers know will address their problems. This would leave room for the consideration of indigenous knowledge systems, which can also be considered as alternatives to solve the problems farmers face. For example, in Chikwawa, farmers shared how they used a fish broth to control the fall armyworm before pesticides were available. Scientific research could be incorporated to explore how indigenous knowledge can be harnessed in CSA.

CSA Options Available for Farmers

The qualitative findings established that conservation farming was the major form of CSA that farmers have adopted, and confirmation from quantitative findings revealed that 100% of farmers practicing CSA at both sites stated that they used improved seed varieties (ISVs) and soil moisture conservation techniques. At both study sites, less than 40% of sampled households were engaged in more than one form of CSA. In Chikwawa, other forms of CSA included small-scale irrigation schemes, while in Gwembe, a new aquaculture project was at inception stage at the time of data collection. In Gwembe, less than 20% of interviewed farmers had also been previously involved in improved livestock breed projects. However, the qualitative findings showed that there were concerns that conservation farming alone was insufficient in addressing farmers' needs as explained by practitioners:

> ...we know that crop production is always vulnerable, we also need to bring in livestock for the farmers, to help them when crops fail...especially goats which they can sell when crops fail. (Respondent from Government Department, Chikwawa)

The quantitative findings showed that livestock ownership differed between male and female heads of households. At both sites, married men owned the most cattle, with average cattle ownership in Chikwawa being two heads, while in Gwembe, it was eight. More female household heads owned cattle in Gwembe than in Chikwawa, 16% and 7%, respectively. When these trends are viewed from an intersectionality perspective, intersection of gender with education and wealth status can be noted as the women who owned cattle in Gwembe were predominantly retired professionals who were categorized as better-off in the community wealth rankings.

CSA Goals for Farmers

In Chikwawa, qualitative findings established that the intended CSA outcomes of improved agricultural productivity and resilience-building were not being achieved by means of the CSA options available to farmers. Evidence of these shortcomings of CSA was linked to humanitarian food assistance. Qualitative findings indicated that there was no major difference in terms of food security between CSA farmers and those who were not involved in any form of CSA because "we see it when it comes to food aid, they all need assistance because they will be all food insecure" (Respondent from Government Department, Chikwawa). More concerning were sentiments from non-adopters who indicated a lack of motivation to adopt available CSA options because "we are all the same, CSA does not make them any better than us" (Discussants in mixed gender FGD, Chikwawa). These findings were confirmed by the quantitative survey where 100% of farmers who adopted conservation farming also reiterated that they benefited from food aid each year because of low crop yields. Farmers using ISVs raised concerns about their susceptibility to the fall armyworm, claiming that their traditional open-pollinated varieties (OPVs) were better resistant.

In Gwembe, a different scenario emerged when assessing whether CSA options were able to contribute to food security and resilience-building. Qualitative findings established that while yields increased through conservation farming, there were postharvest crop losses as farmers could not sell their surplus anywhere. Quantitative findings confirmed these sentiments as 100% of the farmers who were practicing conservation farming techniques were utilizing less than half of their arable land for CSA to "avoid high yields that they would still lose through spoilage," as farmers concurred during household survey in Gwembe.

Discussion

Gender-Equitable Resilience in CSA Adoption

The findings presented in this chapter show that men and women farmers may not be realizing benefits of the CSA activities they are involved in. Findings further show that currently, CSA is not contributing toward the resilience of farmers as they are still prone to food insecurity, often relying on food aid to see them through to the next season. This creates a dependency syndrome and demotivation farmers in CSA adoption. Moreover, dominance of conservation farming leaves farmers vulnerable to climate hazards that have a negative effect on crop production. Findings illuminate the insufficiencies of current CSA and gaps that continue to hinder CSA adoption, especially among women farmers. This chapter accentuates that a resilience framing of CSA leaves room for broader consideration of the decision-making context within which smallholder farmers live. On that basis, a normative gender-sensitive CSA adoption model (Fig. 1) is proposed.

The aim of the framework is to provide a normative approach to improve CSA adoption, especially by diverse women smallholder farmers in developing regions, considering their central role in farming activities. The framework is conceptualized from a resilience viewpoint, enabling a more holistic approach to the issues that may enhance decision-making by different groups of farmers, especially diverse women smallholder farmers. There is a need for gender transformation at various CSA implementation levels, starting at household level up to national and global levels. Transformation requires various strategies and enablers to be put in place to create

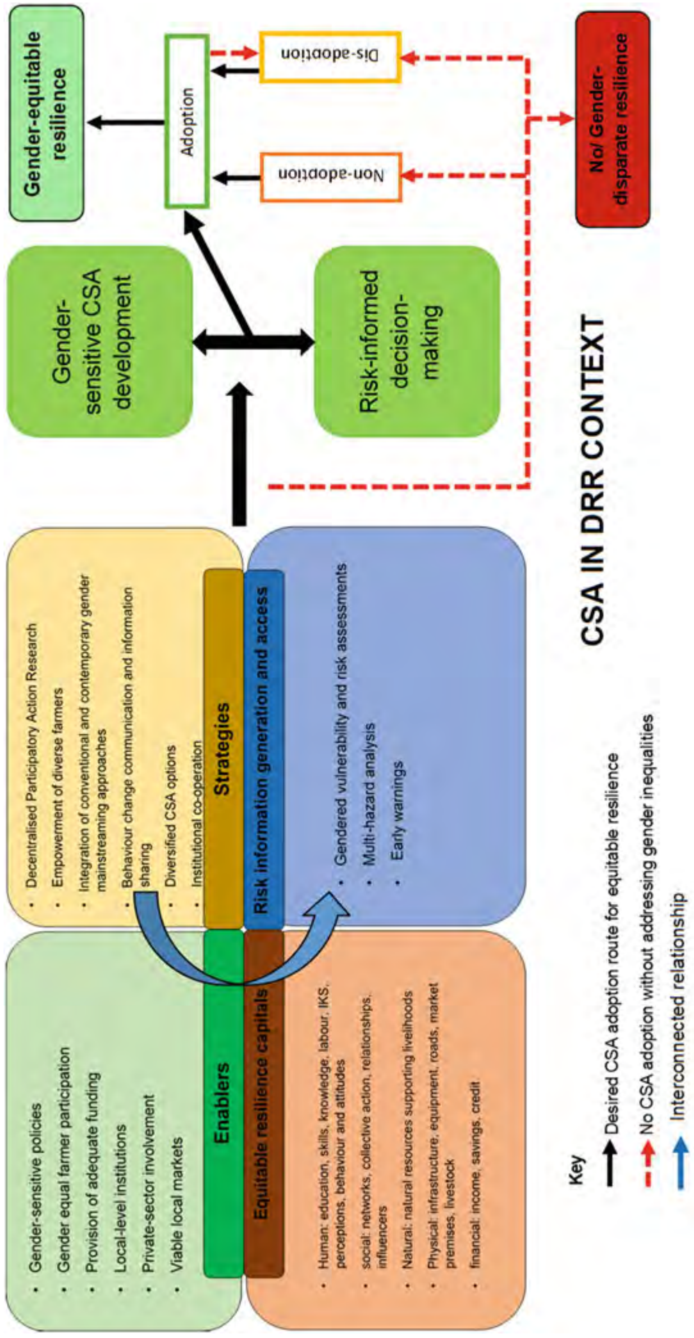

Fig. 1 Proposed gender-sensitive CSA adoption framework

equality and address gendered vulnerability, which should potentially result in improved CSA adoption at household level. The gender-sensitive CSA adoption framework comprises various interconnected components that should be used from a gender perspective throughout, aimed at transformation toward more egalitarian-resilient societies. In the proposed framework, the desired adoption route likely to help achieve gender-equitable resilience is illustrated with black arrows, and the undesired route likely to result if gender disparities are not addressed is shown with red dotted arrows. The blue curved arrow shows that the enablers, strategies, gender equality, and risk information are all interconnected, interacting to inform gender-sensitive technology development and risk-informed decision-making. The framework components are discussed in the following subsections.

Enablers for CSA Adoption

Gender-Sensitive Policies

The findings of this study show that there are preexisting gender inequalities at household level which may be perpetuated by gender-blind CSA implementation. This chapter suggests that an improvement in CSA adoption by women farmers would require gender-sensitive policies to ensure that issues of gender inequality are addressed to achieve gender parity. This requires a holistic assessment of CSA that will consider implementation strategies and resilience capitals, not just limited to the technological benefits of CSA. There is need for policies directly or indirectly linked to CSA to be assessed for their implications on different genders. This should include land tenure systems, marriage and property inheritance laws, technology development, as well as economic empowerment, which all affect CSA adoption decisions (Doss et al. 2015; Khoza et al. 2019).

Gender-Equal Farmer Participation

CSA presents various opportunities where farmers should be engaged for active participation in CSA technology development. However, study findings showed that currently, farmers' participation in CSA is mainly as recipients of already developed technologies and CSA information. CSA is characterized by top-down approaches which may fail to pay attention to critical gender issues that hinder adoption. This study reiterates the need for CSA implementation to ensure equal participation of farmers in technology development and identification of CSA options to adequately meet the resilience needs of diverse farmer categories. There should also be gender-equal participation in the co-creation of knowledge through research in gendered risk assessments, vulnerability assessments, and multi-hazard analysis. Gender-equal participation of farmers will likely assist with the identification of gender-differentiated barriers of CSA adoption and opportunities that can be harnessed to improve adoption across different genders.

When smallholder farmers are given equal opportunities to participate in various aspects of CSA, this is likely to also bring to the fore critical contextual gender issues and to facilitate transformation. Gender-equal participation may potentially enable bottom-up engagement in CSA, where farmers can also contribute their knowledge and experiences. This is especially important when considering the role of indigenous knowledge systems in CSA. Ultimately, equal participation of farmers allows CSA to engage with their various realities, ensuring farmers have a voice in the design and ownership of CSA projects and technologies. When farmers are given the space to participate in various components of CSA, not just as recipients, they are more likely to adopt CSA. This will also enhance sustainability of CSA in communities.

Provision of Adequate Funding

There is no doubt that technological requirements of CSA are likely to be costly and beyond the reach of many individual farming households. For instance, capital investment for some CSA options, such as irrigation schemes and aquaculture, may be costly. This means that at a higher national and global scale, there is a need to improve funding for CSA projects. This can be achieved through multiple funding streams. For example, at a national level, countries should fulfil commitments of the Malabo Declaration that states that African governments should allocate 10% of their public spending to agriculture (AU 2014). Other funding sources could be explored through other government sectors. For instance, on the basis of its relationship with DRR, disaster risk management (DRM) departments could also provide part of the funding required for CSA. Similarly, at a global level, multiple sources may be explored apart from specific CSA projects, such as resilience-building, climate change adaptation, or DRR funds.

Importantly, CSA funding should ensure that funds provided address the resource needs of local-level institutions, such as the provision of vehicles, information and communication technology equipment, and recruitment of more extension agents. This will likely improve quality of gender-specific contact extension services provided to the farmers. This may also compel strategic direction toward the integration of local-level institutions.

Local-Level Institutions

Strong operational relationships among local government and nongovernmental institutions are required to facilitate gender-sensitive CSA adoption. According to Carpenter et al. (2012), polycentricity is key to resilience, often helping to promote connectivity within systems and facilitating learning. This is key in CSA where diverse institutions need to work together. These institutions are the first-level responders to different hazards affecting smallholder farmers; hence, their cooperation is necessary to improve adoption of diverse CSA options. Local-level institutional cooperation and collective action remain essential in the provision of extension services, information dissemination, and facilitation of gender transformation in communities. Ultimately, a polycentric approach enhances the delivery of CSA with precision and efficiency to meet gender-specific farmer resilience needs.

Private Sector and Viable Markets

The findings reveal that one major drawback of CSA adoption by both men and women farmers is the lack of improved quality of life as a result. This was connected to a lack of economic opportunities, resulting in farmers failing to earn meaningful income from the sale of surplus produce. This chapter recommends that innovative strategies be implemented to involve the private sector in CSA to ensure win-win scenarios for farmers and business. CSA adoption is negatively affected by unviable local markets, and an enabling environment for CSA adoption should consider creation of viable local markets where farmers can buy and sell CSA inputs and outputs. This may help create a thriving local economy and increase the income earned from CSA to meet household needs.

Strategies to Improve CSA Adoption

Decentralized Participatory Action Research

The gender disparities identified in the study magnify the need for CSA adoption to be informed by participatory action research (PAR), which can be achieved with an enabling environment for gender-equal participation of smallholder farmers. PAR may facilitate engagement with farmers, giving them a platform to share their experiences in gender issues that demotivate them from adopting CSA or drive them to discontinue CSA. Furthermore, PAR should be decentralized, allowing research to be conducted at the local epicenter of climate disasters. The strength of PAR in driving CSA adoption is the recognition of farmers as both sources and consumers of knowledge, with their involvement in research tapping into local knowledge, perspectives, and realities. At the same time, they are able to use the information from PAR to inform their CSA adoption decisions. Decentralization of PAR to local level should be gender-sensitive, identifying best ways to examine challenges and opportunities for specific groups of farmers in CSA. Farmer participation will illuminate sociopsychological behaviors, attitudes, and perceptions of diverse groups, ensuring that precise and complete information equips farmers' decision-making. PAR is also essential in creating a platform for behavior change communication and information sharing.

Diversity of Livelihoods and CSA Options

Considering CSA from a resilience perspective magnifies the need for CSA to move beyond dominance of conservation farming as revealed in this study. If CSA is to contribute to resilience of diverse smallholder farmers, then there is a need to provide diversified CSA options in addition to conservation farming. Diversified CSA options ensure redundancy so that in the face of a climate-related disaster affecting one component of the farming systems, farmers have other alternatives to rely on (Carpenter et al. 2012). The dominant focus on conservation farming could help explain protracted food insecurity and vulnerability, with farmers often relying on food aid assistance. Therefore, a resilience lens in CSA advocates for transformation toward consideration of other livelihoods and CSA options. This may include income generation through sale of improved livestock breeds, honey from apiculture, or fish from aquaculture, among others. Diversity and redundancy should improve the resilience of farmers, and gender should be considered to assess which CSA options would be relevant to each category of farmers.

Empowerment of Diverse Women Farmers

In view of the study findings, this chapter accentuates the need for the empowerment of communities in general and women in particular to equip them to be able to articulate their resilience needs and to demand more space to participate in different aspects of CSA. The heterogeneity of women smallholder farmers is suggestive of their corresponding diverse resilience needs. This is essential when considering issues of economic empowerment in CSA. CSA adopters have not been able to derive tangible economic benefits, yet this is one of the goals of CSA. Empowerment of farmers means they will participate in technology development, contributing toward defining relevant CSA options they need, and they will participate in decision-making at various levels from intra-household level going up.

Empowerment in CSA should ensure that women farmers can share their experiences, practice autonomy and agency, and be able to collectively come together to tackle structural bottlenecks affecting their adoption decisions. However, this requires a transformation from traditional gender mainstreaming approaches that have shaped empowerment efforts in the past, toward an integrated approach that also considers contemporary approaches such as intersectionality, African feminisms, and positive masculinity (Arndt 2002; Davis 2008). Studies have shown insufficiencies of traditional gender mainstreaming approaches in addressing gender inequality and patriarchy in agriculture (Khoza et al. 2019). The integration of traditional and contemporary approaches may compensate for the weaknesses of each approach applied on its own. Empowerment should address practical gender needs while also ensuring that attention is paid to structural gender issues that may hinder especially women household heads from adoption of CSA. Empowerment should also pave way for participation and inclusion of farmers, especially women, in the various aspects of CSA as explained in earlier sections. This remains an essential vehicle of transformation.

Gender-Equitable Resilience Capitals

Based on the study findings, this chapter highlights that a resilience framing of CSA adoption compels consideration of gender inequality and gendered vulnerability with regard to access to and control and ownership of resilience capitals (Mayunga 2007). The gender constructions that determine who owns, has access, and controls resilience capitals should be assessed in CSA as they shape farmers' adoption decisions. In order to achieve resilience-building through CSA, there is a need for deliberate strategies aimed at establishing gender equality and equity in the ownership, control of, and access to social, natural, physical, financial, and human resilience capitals. This will require CSA to engage with disparities and to improve especially the ownership of resilience capitals such as farming equipment, livestock, land, and finance by women farmers. This will not only enable them to cope with climatic disturbances but will also ensure they are equipped to build back better or bounce forward from each disturbance. Paying attention to resilience capitals also helps illuminate key vulnerability issues that dispose farmers to either dis-adoption or non-adoption of CSA. Creating gender equality and equity in resilience capital ownership will require innovation in tackling the socioculturally entrenched patriarchal systems and women's subordination, and contemporary gender mainstreaming approaches may be useful in this regard.

While addressing identified gender inequality issues may not be the primary mandate of agricultural departments, a resilience framing emphasizes polycentricity and collective action. Other development actors need to be involved in CSA, such as gender, DRM and community development departments, NGOs, women's rights activists, and local leaders. These structures already exist at a local level, although agriculture departments may need to lead the integration to ensure that the expertise of various groups is channeled toward addressing inequality and vulnerability in pursuit of resilience.

Risk Information: Generation and Access

Any attempt to improve CSA adoption requires strategies to ensure supply of adequate information to aid farmers during decision-making. Collective action, participation, and inclusion are key to the generation of risk information. Processes to generate risk information are undertaken by governments, NGOs, and donor agencies in many countries. These are usually in the form of vulnerability and risk assessments, as well as hazard analysis. However, there is a need to move beyond simple gender-disaggregated data generated in these processes to critically engage with the gender implications of collected data in terms of resilience-building. Risk information is not only useful to technocrats and practitioners, but farmers should also have access to the information for decision-making. Knowledge is required to make informed decisions. Across different gender groups, its creation and acquisition is important in decision-making. The proposed framework advocates for the involvement of farmers in knowledge co-creation, which will harness valuable indigenous knowledge, especially with regard to climate hazards and early warnings. This means attention should be paid to access to gender-sensitive risk communication. Gender-sensitive risk information is also requisite in development of gender-sensitive CSA technologies.

A systemic approach helps appreciate that CSA adoption decisions are not only based on technological benefits of CSA options. Farmers consider other risks that affect their resilience capitals negatively or positively within the wider system context. For instance, for many communities, disease epidemics such as HIV/AIDS remain a health risk that threatens agricultural labor provision in households. Therefore, any adoption improvement strategy should engage farmers to identify what other risks they face in their contexts, and this may be achieved through gender vulnerability and risk assessments, as well as multi-hazard analyses that should endeavor to obtain in-depth qualitative perspectives on systemic risks.

Risk-Informed Decision-Making

Adoption decisions of men and women smallholder farmers are influenced by various factors depending on their gender roles (Khoza et al. 2019). Importantly, decision-making for men and women household heads should be viewed within the multifaceted context in which decisions are made and have to be risk-informed. There is a need to acknowledge different factors and drivers that shape decision-making for different genders. A resilience framing of CSA accommodates risk-informed decision-making (RIDM) even at smallholder farmer level (Weichselgartner and Pigeon 2015). RIDM acknowledges that decision-making is not in simple linear fashion as traditionally understood. It is a more comprehensive analytical approach that interrogates and seeks to understand complex interactions between people, risks, hazards, and systems. Risk-informed decisions pay attention to qualitative information from gender-differentiated risk assessments (Gardoni et al. 2016), narratives, and realities that shape decisions by different farmers. However, Apostolakis (2004) caution against the exclusive use of risk assessments to inform decisions, necessitating a more consolidated approach where gender vulnerability assessments and multi-hazard analyses can also feed into decision-making.

Gender-Sensitive CSA Technology Development

Findings of this study showed that smallholder farmers, irrespective of gender, were not directly involved in the development of CSA technologies. Rather, technology development was a top-down process where farmers were viewed as recipients. However, this chapter argues that if CSA adoption is to be improved, there is a need for farmers to participate in technology development. CSA technology development should be two-way, with provision for consideration and development of local farmer innovations for further scaling up. Development and dissemination of CSA technology should be participatory to generate and manage perspectives that may determine adoption decisions made especially by the women farmers. CSA technology development should therefore be informed by the gender analyses that recognize gender roles and interactions with technology in relation to culture, behaviors, attitudes, and social influences (Ngigi et al. 2018; Khoza et al. 2019). Development of CSA technology should appreciate and address any underlying disparate distribution of resilience capitals. Failure to consider these underlying factors and corresponding strategies to address them may manifest as low adoption of CSA by women farmers.

Additionally, through gender analyses, CSA technology development can consider existing and projected changes in gender roles. CSA technology may seek to improve current gender roles, or transform them, depending on identified inequalities and farmer needs (Nyasimi and Huyer 2017), where technologies can be developed to help bridge the gender productivity gap and contribute to equitable resilience across the heterogeneity of smallholder farmers. For instance, women in men-headed households and women who were household heads lamented labor demands of basin conservation farming which they felt increased their workload, while they have other reproductive and community roles too. Moreover, caution should be exercised to ensure that CSA does not reinforce gender stereotypes, for instance, when CSA projects target women only for energy-saving stove distribution.

Critical to gender-sensitive technology development is the cost of CSA technologies. Women who are already less economically empowered than men are less likely to be able to afford costly new CSA technologies. CSA focus should also be on women's economic empowerment. Ultimately, rural women need appropriate CSA technologies that can transform their contexts and realities where necessary, helping them to become more resilient. This can be achieved by engaging the diverse groups of women to establish their practical and structural gender needs. Gender-sensitive CSA technology development should be as pragmatic and transformative as possible in pursuit of resilience.

Operationalization of the Framework

This chapter suggests that utilitarian value of the framework lies in its ability to identify and confront issues of inequality and social disparities in a broader context, which may pave way for decision-making that favors CSA adoption by smallholder farmers. Operationalization of this framework should start at a district level and bring together communities and experts from diverse disciplines such as agriculture, DRM, climate change, gender, community development, local leaders, businesses, weather services, research institutions, and NGOs. Most of these disciplines are already represented at district level, although there is a need to transition toward collective integrated operations. The agriculture department may maintain the leadership and coordinating mandate, ensuring representation and multidirectional participatory engagement, communication, and information dissemination. The use of the framework can then feed into large-scale administrative processes at the provincial and national levels. Some components of the framework are already addressed by ongoing activities, such as vulnerability assessments and hazard and risk assessments. However, a gender lens should be applied in these processes, which should include smallholder farmers in their diversity, and findings from assessments should be used to inform all DRR components, not just for response through humanitarian food assistance.

The proposed framework is worth exploring as it derives value from the participatory nature of its formulation and has a strong focus on social dimensions in CSA adoption. As such, it addresses some of the gaps in current appreciation of CSA adoption, which seems to elevate the technological merits of CSA at the expense of the equally important social dimensions. This framework's ingenuity also lies in that it speaks to the insufficiencies of a linear approach to CSA. Challenges may arise in that the framework was developed independent of any existing CSA project, which means that its uptake by different institutions is not guaranteed. Nevertheless, it does present a normative approach to improving CSA adoption so that men and women smallholder farmers can be enabled to "build back better equally, leaving no-one behind," which should form the core of resilience and sustainable livelihood outcomes in Africa.

Key Lessons, Study Limitations, and Future Research Prospects for CSA

Several key lessons can be drawn from this study that applied a resilience framing to the interrogation of gender dimensions in CSA adoption. Firstly, at local level where loss and damage from each disaster event worsen food insecurity and poverty, there is an amplified urgency for gender-equitable resilience-building through CSA. This compels improvement of CSA adoption by at-risk smallholder farmers. Drawing on resilience principles may give strategy direction in CSA implementation at the local level. Resilience principles such as the maintenance of redundancy and diversity, management of intra-system connectivity, feedbacks, promotion of social learning, participation and inclusion, embracing polycentricity, and understanding that agricultural systems are complex adaptive systems all play an essential role in pursuit of gender-equitable resilience in CSA.

Secondly, there remains need to address gender inequality as it stands in the way of CSA adoption and inhibits the successful pursuit of resilience. Areas of focus should include the promotion of active and equal participation of smallholder farmers, especially vulnerable, at-risk women in CSA technology development. CSA technologies should not merely be developed *for* the smallholder farmers, but *with* them, creating space for consideration of their innovations and indigenous knowledge systems to suit their gender-specific resilience needs.

Lastly, it is essential to shift from risk-based decision-making toward risk-informed decision-making, starting at household level right up to institutional level where CSA support is provided. This is dependent on an appreciation of the fact that CSA adoption decision-making is not linear and only based on the technological benefits of CSA in the face of climate change, but rather occurs within a multifaceted decision-making context, which may differ along gender lines.

Further studies on CSA can adapt and replicate the study methodology in similar developmental contexts and disaster profiles. This study did not test the applicability of the proposed gender-sensitive CSA adoption framework. Future studies can test the applicability of the proposed framework in any of the Southern African countries or in other developing regions. The key is sensitivity to site-specific contexts on issues of gender, inequality, power, and agency. CSA adoption itself is a difficult variable to assess by means of a cross-sectional survey. Longitudinal studies can be considered in future research.

Conclusions

The assessment of the gender dimensions of CSA adoption by smallholder farmers anchored in resilience thinking enriches understanding of the inherent challenges specifically faced by women farmers. The study highlights several factors that drive gender-differentiated vulnerability and contribute to low CSA adoption by at-risk women farmers. These factors include gender disparities in ownership of resilience capitals, limited participation of farmers in CSA technology development, narrow CSA options that can be adopted by farmers, and the limited tangible benefits realized from CSA. There is a need to improve the adoption of CSA by diverse smallholder farmers and to meet their gender-specific resilience requirements in the face of climate-related disasters. This can be achieved through the creation of an enabling environment and implementation of strategies that can facilitate gender-sensitive CSA technology development and the equal participation of smallholder farmers. The farmers should be assisted to make risk-informed decisions by improving generation and access to risk information through participatory action research. Gender equity and equality in the ownership of resilience capitals can contribute to gender-equitable resilience in smallholder farming. In conclusion, this study reiterates the importance of a gendered approach to CSA to improve adoption by smallholder farmers who directly interface with inclement climate hazards.

Rainfall Variability and Adaptation of Tomatoes Farmers in Santa: Northwest Region of Cameroon

37

Majoumo Christelle Malyse

Contents

Abstract

The Santa agrarian basin being one of the main market gardening basins in Cameroon and one of the producers of tomatoes in the country is vulnerable to the impact of rainfall variability. The spatiotemporal variability of rainfall through the annual, monthly, and daily fluctuations has greatly affected the market gardening sector in general and tomatoes production in particular. Thus, given rise to the research topic "Rainfall variability and adaptation of tomatoes farmers in Santa North west region of Cameroon," its principal objective is to contribute to better understanding of the recent changes occurring in tomatoes production and productivity in Santa. To attain this objective, a principal hypothesis was formulated that rainfall variability instead of unnatural conditions or human constraints justifies changes observed in tomatoes production in Santa and resulting adaptation strategies developed by peasants and stakeholders.

Our study came out with several findings, among which includes rainfall events in Santa fluctuate in time and in space with reduction in the number of rainy day and increase in the intensity of rainfall events causing soil erosion, infertility, and frequent crop diseases, insects, and pests. Extreme events such as drought and flooding have equally become frequent in the area especially during the different cycles of tomatoes production disrupting the agricultural calendar and causing crop failure and decrease in yields with Pearson's correlation of 0.017. This positive value shows that there is a relationship between annual rainfall and tomatoes output in Santa. Tomatoes farmers in Santa are struggling to adapt locally to this situations, but their efforts are still limited especially due to their low level of education and poverty. Finally, it was seen that the output of tomatoes over the years in Santa has a strong correlation with rainfall. Based on the findings of this study, the government is called upon to assist farmers in their adaptation options.

Introduction

The change in global climate system is now undeniable, and it is human-induced as it has been concluded to a large extent by scientists during the past decade (IPCC 2007). Climate variability in general and rainfall variability in particular are very important environmental problems affecting mankind today with the highland areas being very sensitive to the change in rainfall pattern and its related impacts. Tsalefac (1999) in his work on climate variability in the western highlands of Cameroon brought out some aspects. He studied the relationship that exists between climate variability, land-use pattern, and the economic crisis that brings into question the sustainability of land use in the region. As such, this work explores the state of rainfall variability in Santa and some of the adaptation options adopted by tomatoes farmers in Santa. It's aim is to elucidate how changing rainfall pattern in space and in time as well as an increase in extreme weather events which includes dry spells, torrential rains, flooding, and droughts, which has greatly affected tomatoes yields, incidence of weeds, insects, pest and diseases, the economic cost of tomatoes production and how farmers are struggling to adapt to these changes?. This work analyzes tomatoes yields with production cost from 2001 to 2011 with efforts to understand how they have varied with the current rainfall changes. It focuses on extreme weather events on tomatoes production in Santa using examples from recent past such as severe drought of 1999 and 2004 that greatly disrupted the agricultural calendar. Finally, with the current rainfall and tomatoes scenarios serving as models, this work looks at better adaptation options that could limit the impact of rainfall variability on tomatoes production and boast tomatoes production in Santa.

The study of Zorom et al. (2013) and Rodriguez Solorzano (2014) on climate variability and adaptation practices by farmers shows the adoption of numerous adaptation strategies to cope with drought conditions. Some of the strategies adopted included the diversification of nonfarm activities such as selling of poultry and rearing of livestock as alternative measures as well as the reduction of food intake. Again, some farmers also engage in the cultivation of dry season irrigated vegetables. They further argued that these practices help farmers to distribute climate risk over different activities which strengthen their financial capacities to be able to raise their purchasing power.

These adaptation strategies adopted by tomatoes farmers in Santa range from changing production techniques to the adoption of improved tomatoes species, irrigation, and the use of agrochemicals and the diversification of activities. Stakeholders' adaptation ranges from the provision of agrochemicals to farmers finance to the provision of farm tools and farm equipment to farmers to help them improve on their production.

Tomatoes production which is a major market gardening crop in Santa has been witnessing a change in the daily, monthly, and annual rainfall in the area.

Variation in the date of onset, amounts, and the retreat of rainfall has affected the growth of tomatoes over the years.

However, the inability of tomatoes farmers to master and cope with rainfall especially the coming of rains has been a major setback to current and future tomatoes production as according to most of the peasants, rainy season during the past years has been very fluctuating and does not begin in mid-March as in the past years; rather, it begins in February and at times comes late and most of the time very is irregular, making the availability of water for irrigation very difficult. The few streams and watershed whose water up wells the water needed by plants are vast declining in quantity; this has been a natural occurrence, and these farmers and their crops have an average chance of survival. They loss income, time, and crops.

Dry spells as well as rainy days recorded on this area have been responsible for the outbreak of diseases such as septoria leaf spot, anthracnose, and *Verticillium* which leads to a fall in yields. This is particularly worrisome because farmers have very little strategies as they have resorted in the use of pesticides which has both negative and positive impacts on both the plant and the environment. Most of the time, pesticides are being washed away by heavy downpour due to the fact that most farmers do not know the best times to apply these pesticides. Heavy downpours have led to rapid depletion of the soils in some areas which have completely destroyed large portions of lands with crops. With all these, farmers in Santa have tried to make up for this loss by augmenting the dosage of fertilizers to beef up growth and productivity, but these fertilizers are very bad for the longevity of crops. Looking on the above explanations, the following question will guide us throughout this work: How does rainfall impact tomatoes farming in Santa? What are the farmers doing to remedy the situation?

Location of the Study and Research Methodology

Location of the Study Area

Santa is one of the 32 subdivisions in the northwest region located between latitude 5°42 N to 5°53 N of the equator and longitude 9°58 E to 10°18 E of the Greenwich meridian. It falls within the western highlands agroecological zone and covers a surface area of about 532,67 km^2. It covers some villages, namely, Akum, Baba II, Pinyin, Baligham, Matazem, and Santa (Njong, Ntarrah, and Mbei), which are our zone of study. This area lies some 20 km from Bamenda and is commonly called "the gateway into the northwest region" with an altitude from 1000 to 2600 m, making the area suitable for the cultivation of market garden crops especially tomatoes (Fig. 1).

Methodology

Data Collection

Primary data was collected from key informant such as tomatoes farmer, agricultural extension officers (MINADER and ACEFA), and field officers of research institutes (IRAD). This information was obtained through observations, interviews, and questionnaires. Field observation was very important in making a correlation of questionnaire response by the farmers to the actual remarkable activities in the farm. Field visits were made at different tomatoes farming sites in Santa where different farming, impacts of rainfall variability on tomatoes plants, and adaptation practice were applied with the help of some main tomatoes farmers. A total of 100 questionnaires were taken to the different selected villages, of which 39 were distributed in Ntarrah, 22 in Njong, and 39 in Mbei. Interviews were equally conducted with Farmers in the area who knew the area and had experience in tomatoes production. However, rainfall and output data was equally a secondary data of this study, of which the rainfall data here was obtained from two meteorological stations: Santa and Bamenda stations. The rainfall data used in the study ranged from 1963 to 2011 for the Bamenda station and from 1981 to 2006 for the Santa station. The different quantity of tomatoes harvested by farmers between the years 2001 and 2011 was obtained from the subdivisional delegation of agriculture for Santa and was used hand in globe with the rainfall data to show how rainfall variability has impacted on tomatoes production output over the years in Santa.

Presentation of Results and Discussions

The state of rainfall variability in Santa is analyzed based on the interannual and monthly anomalies as well as variability in rainfall intensity and rainy days which has really show evidence of rainfall variability in Santa this has greatly impacted

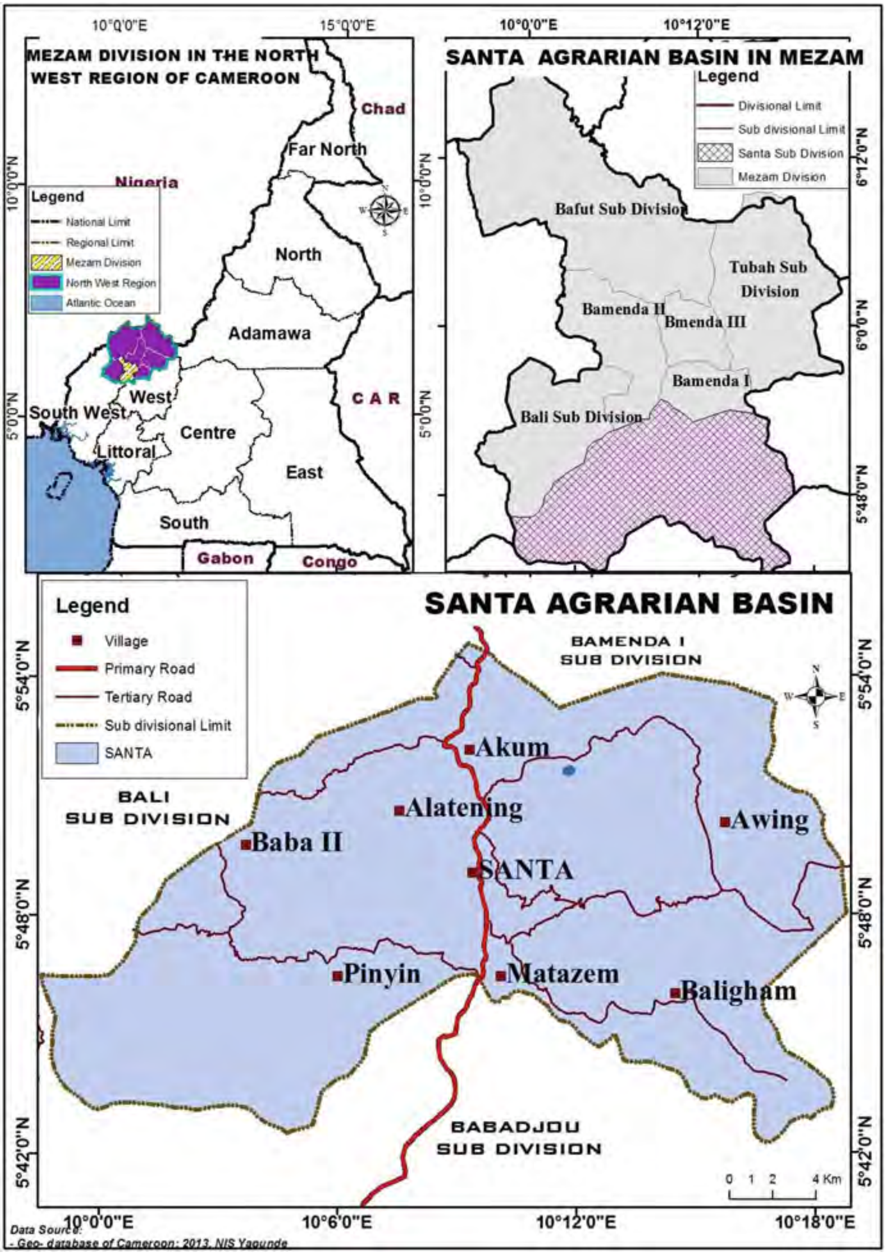

Fig. 1 Location and layout of the Santa agrarian Basin. (Source: Extracted from Fogwe and Zoum 2014)

tomatoes production in different ways which includes the attack of tomatoes crops by diseases, insects and pest, soil erosion causing infertility of soils, inaccessibility, water shortages most farmers have come out with several adaptation strategies to adapt to the impact of rainfall variability in Santa which has greatly decrease the yields of farmers.

State of Rainfall Variability in Santa

Interannual Anomalies in Santa

The situation in Santa demonstrates more negative anomalies than positive anomalies as seen.

Figure 2 shows rainfall anomalies in Santa. As already mentioned, years with positive anomalies are fewer than years with negative anomalies. The few years that registered rainfall over the annual average for the periods were 1990, 1992, 1997, 2001, 2002, and 2003. On the other hand, most years had rainfall lesser than the annual average such as the period from 1981 to 1989, 1993 to 1996, 1998 to 2000, and 2004 to 2006. Within these years of less rainfall, the period 2004 to 2006 stands out exceptionally and indicates dry periods.

Rainfall Variability in Santa

The variability of rainfall equally manifests on monthly basis. Generally, the monthly rainfall pattern affects the seasonal pattern. This area falls within the humid tropical climate with two distinct seasons, a short dry season and a long rainy season. Dry season months record lower rainfall amounts than rainy season months in both Santa and Bamenda stations. Tomatoes production in Santa depends on the pattern of rainfall as it provides water and moisture for plant growth.

Figures 3 and 4 indicate that rainfall is lower for the months of January, February, November, and December. These months are the dry season months. The amounts begin to rise from March which marks the beginning of the rainy season, and the

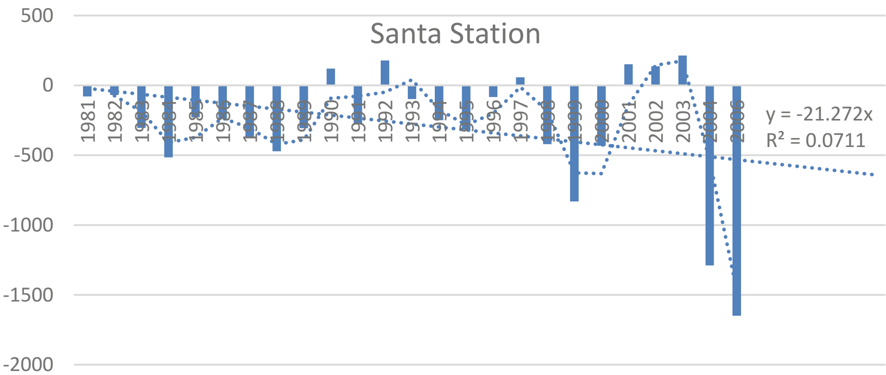

Fig. 2 Interannual anomalies

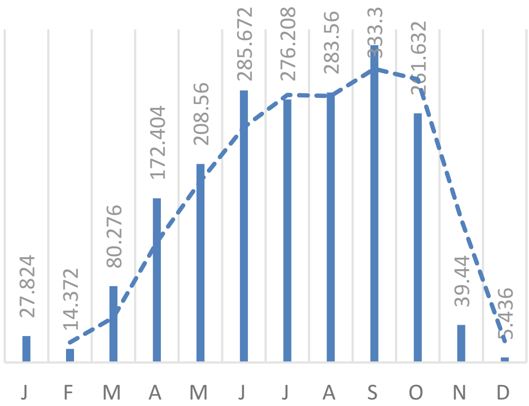

Fig. 3 Monthly rainfall variability in Santa station

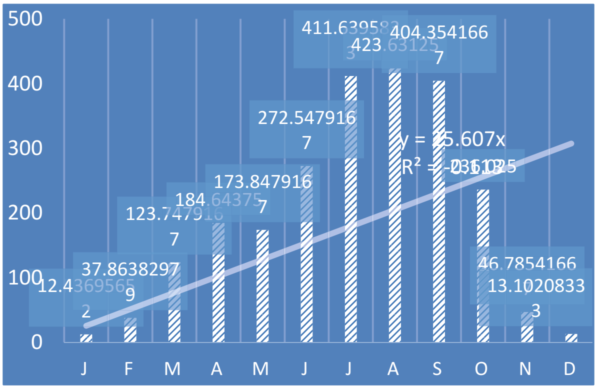

Fig. 4 Monthly rainfall variability in Bamenda station

highest amounts are registered in the months of June, July, and August. These months are at the mid of the rainy season.

This trend is the same for both stations, but there is an indication of spatial variability when referring to the two stations. It is observed that rainfall amounts vary within the same months in both stations.

Variability in the Number of Rainy Days and Rainfall Intensity

Variation in the number of rainy days and changes in rainfall intensity are some powerful indicators of rainfall variability. This change has a link with fluctuations in the dates of onset and departure of rains. Generally, a rainy day refers to a day that records at least 1 mm of rainfall. The number of rainy days varies according to seasons, but when observed annually, we noticed the days have been fluctuating over the past years in Santa.

Figure 5 shows variability in rainy days from 1963 to 2011 in Santa. The highest number of rainy days was recorded in 1999 (225 days), 1976 (222 days), and 2002

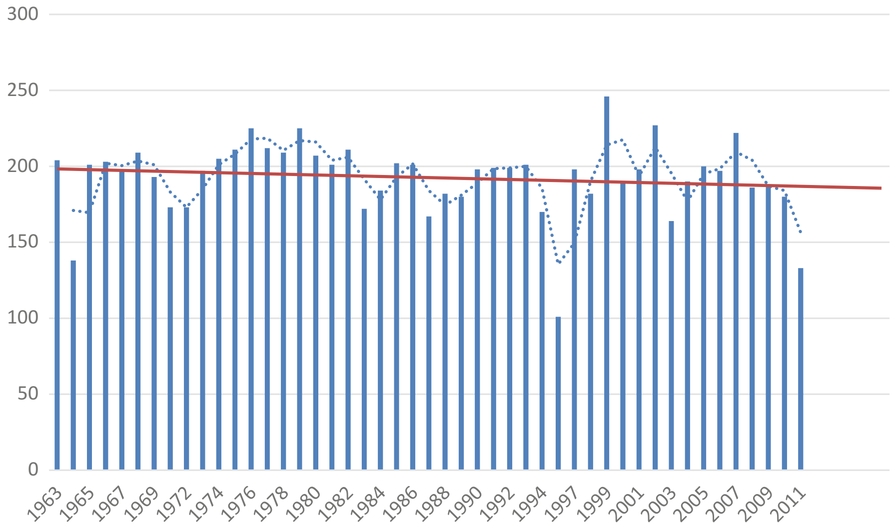

Fig. 5 Interannual fluctuation in rainy days in Santa. (Source: Fieldwork 2018)

Table 1 Farm-level adaptation strategies

	Variables	Frequency	Percentages
1	Crop diversification	17	17.34
2	Use of agrochemicals	54	55.10
3	Mixed cropping	4	4.08
4	Irrigation farming	13	13.26
5	Changing crop varieties	10	10.20
	Total	98	100

Source: Fieldwork 2018

(207 days). On the other hand, 1964, 1995, and 2011 had the least number of rainy days (138 days, 101 days, and 133 days, respectively). The annual difference in rainy days is about 124 days which is very large. This is an indicator of rainfall variability because it affects the frequency and intensity of rainfall.

Peasant Adaptation to Rainfall Variability on Tomatoes Production in Santa

Peasants in Santa have adopted several adaptation options to reduce the impact of rainfall variability on tomatoes production. These impacts are numerous, and the capacity to adopt varies according to farmers and the farm sizes. These adaptation options can be classified into two groups: the farm-level adaptation options and the nonfarm-level adaptation options (Table 1).

Tomatoes farmers in Santa use the farm-level adaptation options such as the use of new species of tomatoes, pesticides, and agrochemicals, changing farming

Photo 1 Improved variety of tomatoes (F-hybrid species). (Source: Photo by Majoumo 2018)

methods, and irrigation methods in order to reduce the impact of rainfall variability on their tomatoes farms.

Adaptation to Improved Varieties of Tomatoes

The use of improved varieties of tomatoes by most farmers in Santa has been a major response to drought and pest. The new variety used by farmers in this area is the F1-hybrid. According to one of the farmers interviewed (Photo 1):

> Hybrids are plants that are a result of cross pollination and they have advantages compared to open pollinated varieties they mature earlier and are uniformly than the other species and are resistant to change in seasons and diseases. (NGU 2018)

Adaptation Through Irrigation

Irrigation is one of the major adaptive strategies that could improve tomatoes yields in era of climate variability (Olwoch and Tshiala 2010). Tomatoes are not resistant to drought. Yields decrease considerably after the short period of water deficiency. It is important to water the plants regularly during flowering and fruit formation. The amount of water that is needed depends on the type of soils. Irrigation is one of the adaptive measures used by famers in Santa during periods of drought and low rainfall. Some of the different irrigation methods used by farmers in Santa on their farms includes the use of water pipes and watering canes to obtain water from wells to water farms, as can be seen in Plate 1.

From Plate 1, Photo 1 shows the sprinkler irrigation method used by tomatoes farmers in Santa to irrigate their farms during period of no rainfall or prolonged dry season, Photo 2 shows the water pipes used by farmers to connect water into their

Plate 1 The different methods of irrigation used by tomatoes farmers in Santa

farms, and Photo 3 shows another local way of irrigation where farmers dig holes where there is water and use watering canes to carry water to water their farms.

Cropping System and Change in the Technique of Production as an Adaptation Option

Most farmers in Santa use poor farming methods to cultivate their crops which has greatly reduced their yields and also makes the area vulnerable to extreme climatic conditions such as flooding, droughts, as well as soil erosion. Tomatoes farmers in Santa are moving from monoculture to mixed cropping, crop rotation, and intercropping to avoid the risk of reduction in yields as well as crop failure and to equally allow the soils to regain its fertility. It was observed that tomatoes farmers in Santa mix tomatoes with crops such as green beans and lettuce and most of them do carry out intercropping on tomatoes farms.

Adaptation Through the Use of Agrochemicals and Fertilizers

The application of agrochemicals and fertilizers is common to all tomatoes farmers in Santa. The application of agrochemicals and fertilizers improves soil fertility and eradicates crop diseases, insects, and pests. Also, the use of agrochemicals especially fertilizer is a good adaptation strategy that improves tomatoes yields (Tshiala and Olwoch 2010). Most of the farmers in this area apply the NPK 20:10:10 fertilizer in order to increase fertility of their soils especially soils that have been rendered fertile during heavy rainfall or changing rainfall. With the growth of diseases and pest in Santa that affect tomatoes crops, most farmers adapt to use agrochemicals for their crops. An example of pesticide used by farmers in Santa is the CLEANZEB BLUE.

Table 2 Nonfarm-level adaptation

	Variables	Frequency	Percentages
1	Diversification of nonfarm activities	45	45.91
2	Migration	53	54.08
	Total	98	100

Source: Fieldwork 2018

Diversification to Off-Farm and Nonfarm-Level Activity Adaptation Strategies Diversification to nonfarm and off-farm activities is one of the adaptive measures that is not popular to tomatoes farmers in Santa, but it was much preferred by most them as it was seen that most of the farmers in that area do carry out other activities such as trading, bike riding, and dress making, just to name a few. Some of these farmers even migrate to other areas in search of jobs especially in urban centers as shown in Table 2.

Table 2 shows the different off-farm adaptation options adopted by farmers in Santa. 54.08% of farmers say they diversify into nonfarm activities such as trading, teaching, and bike riding, just to name a few, while 45.91% migrate to other areas to obtain lands that are more fertile and to areas they think do not suffer from extreme weather conditions or in search for jobs. Respondent explained that the tomatoes business is the main source of livelihood bequeathed to them by their forefathers.

Conclusion and Future Prospects

This study has been able to come out with the state of rainfall variability on tomatoes production in Santa and some of the adaptation options adopted by farmers to remedy the situation. Rainfall events in Santa fluctuate seriously around the mean values. Data from two meteorological stations were analyzed and show yearly, monthly, and daily rainfall variability.

Spatial rainfall variability in the area shows that rainfall has become intense and fall over short duration varying from one area to another. This was analyzed in this work due to the fact that data for this study was obtained from two stations found on the same geographical locations. Temporally, as years goes by, rainfall is becoming very unreliable and varies greatly within the same months.

Extreme weather events such as heavy rains, drought, and flooding are increasingly becoming common in Santa, their occurrence determines the length of growing period, distorts the plants through diseases insects and pest during the plants life cycle, soil lost through flooding and erosion is one of the characteristics of rainy seasons in this area. Most of the farmers in the area are becoming aware of the situation as they have perceived the presence of rainfall variability in the area through the different ways in which it manifest.

In order to adapt to the situation, most of the farmers resorted in the use of irrigation, agrochemicals, mixed cropping, and diversification in nonfarm activities which have greatly helped them to improve on their productivity over the past years.

Future Prospects

The introduction of various adaptation strategies by the government and/or stakeholders, including the method of distribution of the agricultural inputs, was found to be very uncertain and partly unacceptable by most farmers in the study area. Thus, there is a need of further studies in this area to explore and develop the best method that will be efficient and effective.

Furthermore, an improvement in agricultural research will provide a backbone for adaptation measures. This is because research rapidly changing situations is different from research for stable conditions. Therefore, traditional knowledge is a suitable entry point but very insufficient in a changing situation. So tomatoes varieties need to be developed for future conditions as their applicability cannot be assessed at the location where they may be used in the future. The results of the research have to be published in an environment in which methods and crop varieties are accessible for use.

The analysis of the effect of rainfall variability on tomatoes production indicates that farmers do face production losses since the study area is vulnerable to rainfall and tomatoes production and tomatoes are one of the market gardening crops mostly cultivated by farmers in Santa. It is very important to develop a drought-resistant tomatoes variety that can withstand drought and extreme weather conditions and help to improve yields. It is therefore imperative that institutes such as crop research institutes like IRAD in the country develop more resistant drought varieties to withstand extreme weather conditions.

Rainfall Variability and Quantity of Water Supply in Bamenda I, Northwest Region of Cameroon

38

Zoyem Tedonfack Sedrique and Julius Tata Nfor

Contents

Abstract

Bamenda I municipality found in the humid tropic is endowed with a dense hydrological network which makes it a water catchment for the entire region. Paradoxically, the region still suffers problems of water shortage. This is due to the spatial and temporal variability in rainfall that greatly affects water supply

through its impacts on surface and groundwater. For this reason, we came up with the research topic **“Rainfall variability and quantity of water supply in Bamenda 1, Northwest Region of Cameroon.”** The objective of this study is to examine the manifestations of rainfall variability, and how it affects quantity of water supply in the humid tropics. Rainfall data use for this study comprised of annual, monthly, and daily rainfall over a period of 55 years. Water supply data was made of monthly and annual supply. With these data, a Pearson’s correlation was computed, and it gave a value of 0.701, with a rainfall proportion of 49.14% and 50.86% for other factors. The seasonality and the Standardized Precipitation Index were equally analyzed. At the end of the study, results showed that rainfall events in Bamenda I fluctuates with time and in space. It equally presented a reduction in the number of rainy days from 204 days in 1663 to 155 in 2018. This led to a reduction in length of rainy season and in rainfall amounts. In addition, the area has witnessed sedimentation of riverbeds and water reservoirs due to erosion and deposition during high rainfall peaks. Equally, floods observed during high rainfall episodes have become a potential threat to water infrastructures imposing exceptional water shortages during the rainy seasons. Due to these, actors in the water supply sector are putting in measures to remedy the situation.

Introduction

The Intergovernmental Panel on Climate Change (IPCC 2008) relates that there is a consensus that increases atmospheric greenhouse gases and will result in climate change which will cause: rise in sea levels, increased frequency of extreme climatic events including intense storms, heavy rainfall events, and droughts. This will increase the frequency of climate-related hazards on water resources. There is less consensus on the magnitude of change in climatic variables, but several studies have shown that climate change will affect the availability and demand for water resources. Tsalefac (2007) and Wilby et al. (2006) defended the idea that if global warming averagely increases, isotherms will be displaced, leading to a modification of ecosystems and hydrological cycle, and therefore consequent impacts on both surface and groundwater. Climate variability in general and rainfall variability in particular are ills that are affecting mankind today with highland areas being the most vulnerable to the changes in climatic patterns and its related impacts on water resources. As such, this work explores the state of rainfall variability in Bamenda I and its impacts on the quantity of water supply. Our aim is to show how changing rainfall pattern in space and in time as well as extreme weather events such as torrential rains, floods, and droughts have led to disastrous impacts on the water resource and on the water system.

This work analyzes rainfall data from 1963 to 2018 as well as water supply data from 2012 to 2018 with efforts to understand how quantity of water supply has varied with the past and current changes in rainfall patterns. It focuses on the impacts of extreme rainfall events on water supply in the Bamenda I municipality. According to the national plan of action for integrated water resource management (PANGIRE 2013), Cameroon has a dense river network and both surface and groundwater resources are available but not evenly distributed, and both physical and human factors influences the state and availability of its fresh water resources. These factors include climate change, sedimentation of riverbeds, floods, deforestation, physical and chemical contamination, as well as government policies on both waste management and fresh water management. The Bamenda I municipality, found in the humid tropics ought to have had abundant water due to its geographical, geomorphological, geological, and hydrological features. Paradoxically, this region suffers problems of water supply. This is due to the past and current episodes of seasonal droughts and floods caused by heavy and varying rainfall patterns that continue to affects discharge in river basins. The seasonal fluctuations in the quantity of water supply in this locality are equally attributed to the variations in daily, monthly, and annual rainfall variability. These variations have greatly affected the supply of water to the catchment (surface stores), as well as to reservoirs and consequently to different supply points despite the water potentials in the municipality. This work therefore considers rainfall variability as a major constraint to quantity of water supply in the Bamenda I municipality and aims at bringing the impacts of rainfall variability on water supply.

Literature Review

Climate Variability and Water Supply

Much has been said on rainfall (climate) variability and water supply, both in the long term and short term. The impacts of climate on water supply can therefore be seen below.

A group of researchers, Beniston (2003), Sadjin et al. (2005), and Martin Dahinden (2010), who studied mountain and climate change, stand for the idea that mountains are among the most sensitive regions to climate change and that some of the most visible indicators of climate change comes from mountain areas. Their ideas were that mountains are water towers of the world as they provide fresh water to more than half of the world's population, but these areas are also among the most sensitive and vulnerable to climate change.

According to Adefolalu (1993) in his study on precipitation, evapotranspiration, and the ecological zones in Nigeria, he explained the fact that during rainy season, it is not expected to have precipitation on daily basis. However, when breaks of equal or more than three pentads (15 days) occur, they are considered serious anomalies. Also, climate change (prolonged dryness) can lead to the drying up of springs, and it is projected to reduce renewable surface water and groundwater resources significantly in most dry subtropical regions. This will intend to increase the frequency of meteorological droughts (less rainfall) which is likely to increase the frequency of hydrological drought (less surface water and ground water).

Jiduana et al. (2011) explained the variations in the evolution of rainfall patterns and laid emphasis on the fact that the quantity of rainfall and its duration is experiencing a simultaneous decrease in Nigeria which is remarkable to about 78.6% while the intensity of the rainy days and rainy season decreased equally to 77.3%. The study equally permitted to analyze that there has been a regression in the stream flow data over the past years in Nigeria, and this is due to a fall in the quantity of rainfall of about 76.8% affecting the level of stream flow, the stream's transportation capacity, and time of annual recharge. Therefore, it is seen that changes in climate parameters has a potential impact on water supply.

Tsalefac et al. (2007), in their contributions to a book titled *Afrique Centrale, le Cameroun et les changements globaux*, prospected that a certain number of potential consequences of climate change can be seen in a more or less precise manner. If global warming averagely increases, isotherms will be displaced, leading to a modification of ecosystems, mutations in major vegetation types with a great reduction in the forest surface (wood). Drought will increase in the tropical latitudes and thereby increase the risks of extreme weather conditions. This will lead to a reduction in surface and groundwater. Also, certain ecosystems that are very fragile will be particularly sensible to climate change, notably the mountain and coastal ecosystems.

Adaptation to Climate Variability

In the phase of hydrological changes and fresh water-related impacts, vulnerability, and risk due to climate change, there is need for adaptation and for increasing resilience. Managing the changing risks due to the impact of climate change is the key to adaptation in the water sector and risk management should be part of decision-making and treatment of uncertainty (IPCC 2014). To exploit the impacts of climate change on fresh water, adaptation is generally required; there is growing agreement that an adaptive approach to water management can successfully address uncertainty due to climate change.

According to a group of scholars Mark et al. (2008), adaptation strategies to rainfall variability include household water treatment and safe storage (HWTS), water storage and conservation techniques, water reclamation and reuse technics, increasing use of water-efficient fixtures and appliances. These strategies are grouped in to six typology of adaption technologies which are diversification of water supply, groundwater recharge, preparation for extreme weather events, resilience to water quality degradation, storm water control and capture, and water conservation.

Another group of researchers, ML Parry et al. (2007), in water supply sanitation (WSS) propose sector-specific models, which included upgrading existing infrastructure to meet future challenges and cope with the risks associated with climate change. Example, installation of pre-sedimentation pond or riverbank filters for pretreatment, shifting from shallow wells to more reliable sources of water supply, such as surface water and confined aquifers. It was equally concerned with improving water supply through master plan and long-term investment plan including an inventory of groundwater resources. They equally implemented complementary measures, which included the introduction of disaster and climate risk assessment, and improving general framework for risk assessment and management, establishing system for managing floods and other climate and water-related disasters. According to them a proper adaptation could equally be done through protecting water intake facilities from flooding, protecting pumping stations and treatment plants or other facilities potentially exposed to flooding and encouraging the use of alternative water sources, such as (treated) wastewater reuse and rainwater harvesting, to minimize dependence on freshwater and secure access to stable sources of water. Recent experience in Moldova confirms that well properly designed and operated basic treatment plants can deliver even under extreme weather conditions.

Location of Study Area and Research Methodology

Location of the Study Area

Bamenda I subdivision is situated Southeast of Mezam division, one of the seven divisions of the Northwest region of Cameroon. It is located within latitude 5°51” to 5°58” north of the equator and longitude 10°8” to 10° 17” east of the Greenwich meridian, (Fig. 4). It falls within the humid tropical climatic zone and covers a total surface area of about 110 km^2 with one main village (Bamendakwe) comprising of about 13 quarters, namely, Abangoh, Achichum, Alahnting, Aningdoh, Banche, Nkar, Ayaba, Ntanche, Ntafebuh, Nta’afi, Moyo, Keneleri, and Abumuchi. This municipality is situated at the entry to Bamenda town, and it is oriented 366 km northwest of the Cameroon capital with an altitudinal range from about 1269 to 2606 m above sea level.

As seen on Fig. 1, the Bamenda I municipality is bounded to the north by Bamenda III subdivision, to the south by Santa, to the east by Tubah and Balikumbat, and to the west by Bamenda II subdivision (Flyer Bamenda I council 2018). It is connected to the national territory by the national road N°6. Its geographical location falls within the Guinean climate type. This climate varies from one area to another, and it equally varies with altitudes (thermal gradient) and seasons. The climate is marked by two distinct seasons which are the dry and rainy season. The rainy season is usually from around mid-March to mid-October and sometimes extends to November. The rainfall ranges between 2000 and 2500 mm per annum and highest amounts are recorded in July and August. Heavy torrential rainfall in this area usually results from strong Southwest Monsoon winds blowing into the country from the Atlantic Ocean. These rainfall amounts lead to a considerable recharge of the water table and consequently an increase in stream volume, thereby leading to adequate supply of water to the entire municipality.

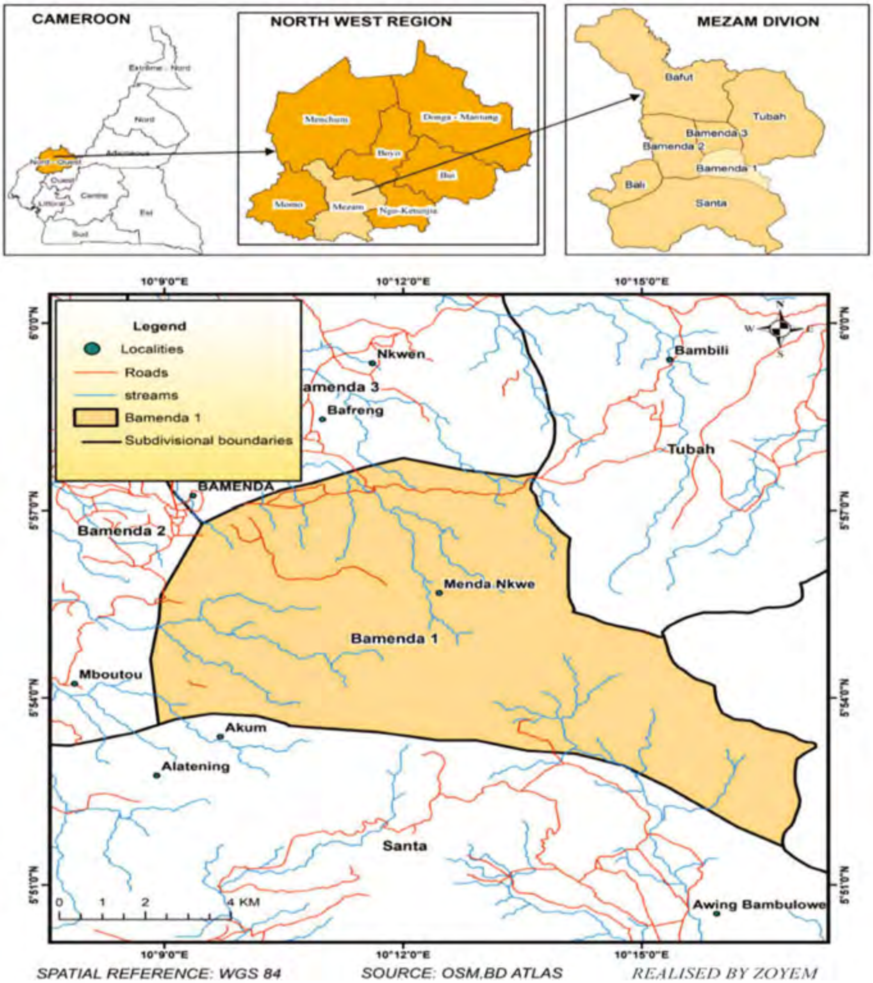

Fig. 1 Location of the study area

On the other hand, dry northeast trade winds from the Sahara Desert blow to the national territory through the northern part of the country, from November to January. The dry season is usually from mid-October and or November to around mid-March. Strong winds and heavy cloud cover characterize the area due to convectional heating. The altitudinal range gives it a highland average temperature of about 19.4 °C with about 18 °C around water catchments, confirming the reduction of temperatures with altitudes. Equally, this area registers average relative humidity of about 76.9%. These moderate temperatures are friendly to water conservation as very little is lost through evaporation. On the other hand, high humidity conditions the availability of moisture in the atmosphere. The area also receives insulations of about 6–8 h/day, reaching its peak in January when the northeast trade winds sweeps across the area. This leads to some cloud formations on the highlands of Mendankwe, and during such occurrences, potential cases of convectional rainfall are recorded. These climatic parameters are favorable for the natural supply of water to the catchments and subsequently to the water system there by qualifying this area as a watershed for the entire locality. It is clearly seen on Fig. 1, as most rivers take their rise from the municipality and flows to different areas.

The area is equally located on the western highland plateau, along the Cameroon dorsal, which runs from Mount Cameroon in the southwest passing through Mount Manengouba and Mount Bamboutos in the west, and stretching to Mount Oku in the northwest. High altitudes with series of mountain chains are common in this area. The locality therefore presents a wide range in its relief forms, with altitudes ranging from 1269 to 2606 m. This range permits an ample downflow of water to the rest of the municipality and beyond. The zone is therefore considered a watershed for the entire region since most rivers and streams draining the region take their rise from its highlands.

Research Methodology

Data Collection

Both qualitative and quantitative data were gotten from respondents in the zone of study, and the data was from primary as well as secondary sources. Primary data was mostly qualitative and comprised of observations made, interviews conducted, and questionnaires administered to both the water management committee and the local population. This information was obtained using questionnaires and interview guides, where 99 questionnaires were successfully administered to seven quarters and returned. Secondary data were both quantitative and qualitative. Quantitative secondary data comprised of the total quantity of water abstracted and supplied in Bamenda I from 2012 to 2018, collected from the Cameroon Water Utility Corporation (CAMWATER), and of rainfall data for Bamenda Station from 1963 to 2018, collected from the chief in charge of the meteorological station at the Northwest Regional Delegation of Transport. These data were used firstly to characterize rainfall events in the Bamenda I municipality, secondly to determine the Standardized Precipitation Index (SPI) and the rainfall seasonality index, and finally the Pearson's correlation coefficient.

Results and Discussions

Manifestations of rainfall variability in Bamenda I was evaluated through analyses of interannual rainfall variability and anomalies, analyses of monthly rainfall variability and anomalies, fluctuation in number of rainy days and in rainfall intensity, and through the application of climatic indices. Also, the Pearson's correlation coefficient was used to evaluate the extent to which manifestations in rainfall affect water supply quantity. These manifestations have consequent impacts on water resource availability or stream discharge in catchments, on riverbanks and on the water systems. This is due to heavy downpours that cause massive erosion in the drainage basin, landslides along river banks, and sedimentation in water reservoirs.

Interannual Rainfall Variability and Anomalies

Rainfall variability in Bamenda I manifest through fluctuations in annual rainfall amounts seen as some years registered more rainfall amounts than others. It equally manifest through annual rainfall anomalies as seen on Figs. 2 and 3, respectively.

As seen on Fig. 2, there have been great variations in annual rainfall amounts over the study period. This is seen as some years registered high rainfall amount (above the means of 2362 mm), while others registered low rainfall amounts (below the mean). High amounts of rainfall where registered in 1963 (2800 mm), in 1969 (2900 mm), in 1981 (2500 mm), and in 2018 (2400 mm), while low rainfall amounts were registered in 1972 (2200 mm), in 1973 (1800 mm), in 2014 (2000), and in 2016 (1600 mm). There have been a general fall in rainfall amount over the past 55 years, indicated by the depressing trend line. This is in line with global trends of falling rainfall with time due to changing climate, IPCC (2008).

On the other hand, Fig. 3 illustrates rainfall anomalies, and it is seen as some years registered positive rainfall anomalies and others negative rainfall anomalies. Example positive anomalies were recorded in years like 1963, 1969, 1976, 1979, and in 2002. They registered anomalies ranging between 300 and 500 mm, while negative anomalies were recorded in 1964, 1973, 2015, 2016, and 2017 with anomalies between 400 and 900 mm. Negative anomalies registered a frequency 60% against 40% for positive anomalies reason for the falling trends.

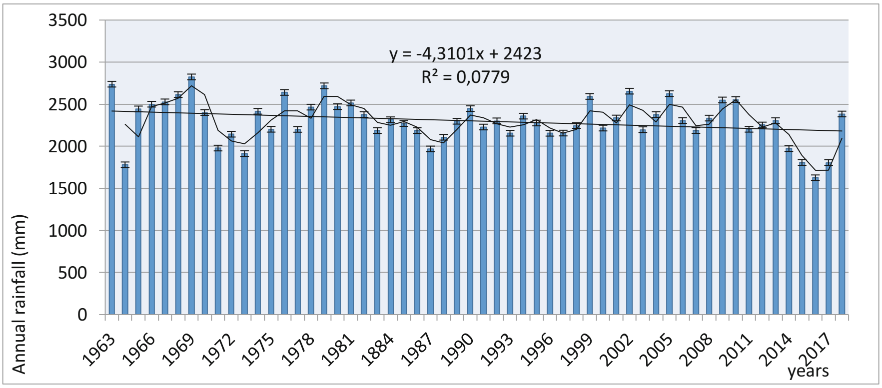

Fig. 2 Interannual rainfall variability in Bamenda up station. (Source: Author (2019))

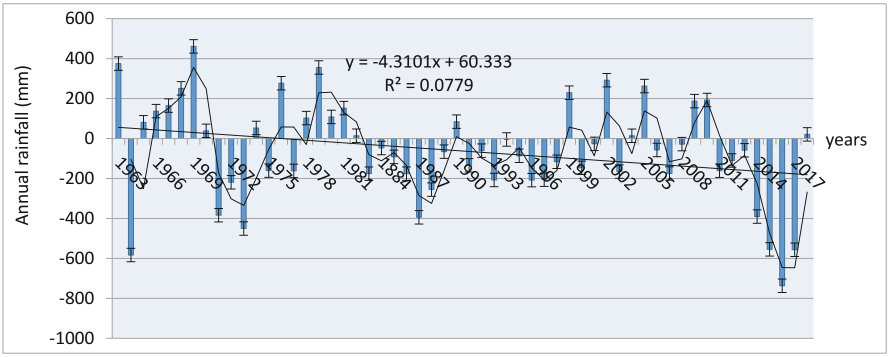

Fig. 3 Interannual rainfall anomalies in Bamenda up station. (Source: Author (2019))

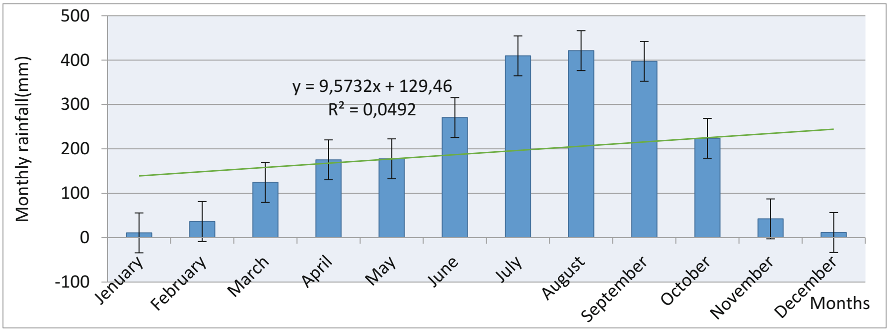

Fig. 4 Monthly rainfall variability. (Source: Author (2019))

Monthly Rainfall Variability and Anomalies

Rainfall variability equally manifests through fluctuations in monthly rainfall amounts and anomalies, but fluctuations follow a seasonal pattern. The mean monthly rainfall was calculated at 191.68 mm and fluctuations went both below and beyond the mean, indicating variations rainfall (Fig. 4).

As seen on Fig. 4, rainfall amounts are lower in months of January with about 10 mm, February with 35 mm, November (42 mm), and December with about 11 mm, as they all register rainfall below the mean of 191.68 mm. The rainfall begins to rise in the months of March (120 mm), which mark the beginning of the rainy season. Its reaches its peak in July (410 mm), and August (420 mm), and starts falling around October (220 mm).

Rainfall variability in the Bamenda I municipality is equally indicated by monthly rainfall anomalies. This is seen as some months record positive rainfall anomalies while others record negative anomalies (Fig. 5).

Figure 5 on the other hand illustrate monthly rainfall anomalies, and it is seen that negative anomalies were recorded in some rainy months (March, April and May).

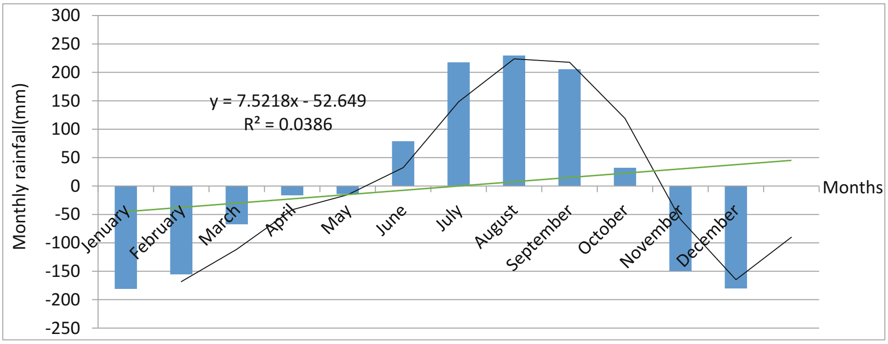

Fig. 5 Monthly rainfall anomalies. (Source: Author (2019))

This is paradoxical because negative anomalies are expected in months of the dry season, but they are instead recorded in rainy months. This may be accounted for by the late onset of rains leading to an increase of the length of the dry season. This will lead to a drop in the water table, thereby reducing water level in catchment and thus exacerbating water shortages. This confirms the results of Hayward et al. (1987) that "an increase in the length of time for recharge of ground water due to prolonged dry season will cause a drop in the water table and a drying up of some streams and springs on which people depend for survival."

Fluctuation in Number of Rainy Days and Rainfall Intensity

Variation in the number of rainy days and changes in rainfall intensity are other indicators of rainfall variability. This variation has a link with fluctuations in the dates of onset and retreat of rains. This link is seen as years with late onset and early retreat will have a higher tendency of registering less rainy days but with higher rainfall intensity while years with early onset and late retreat will have higher chances of recording many rainy days but less rainfall intensities.

Figure 6 shows variability in rainy days in Bamenda up station from 1963 to 2018. This study period has registered a lot fluctuation in number of rainy days as some years registered close to 250 rainy days annually and others about 130 rainy days. Highest number of rainy days were recorded in 1999 (249 days) and in 2007 (225 days). On the other hand, 1964 and 2011 had the least number of rainy days (135 days and 130 days, respectively). The annual difference in number of rainy days is about 119 days, which is much enough to attest that there have been variations in rainfall within the study area. This is because fluctuations in number of rainy days will obviously lead to fluctuations in frequency and intensity of rainfall. This is felt as years with less rainy days and more rainfall amount record high rainfall intensity, while those with more rainy days and less rainfall amount record less rainfall intensity. This is because less rainfall amount is rationed within

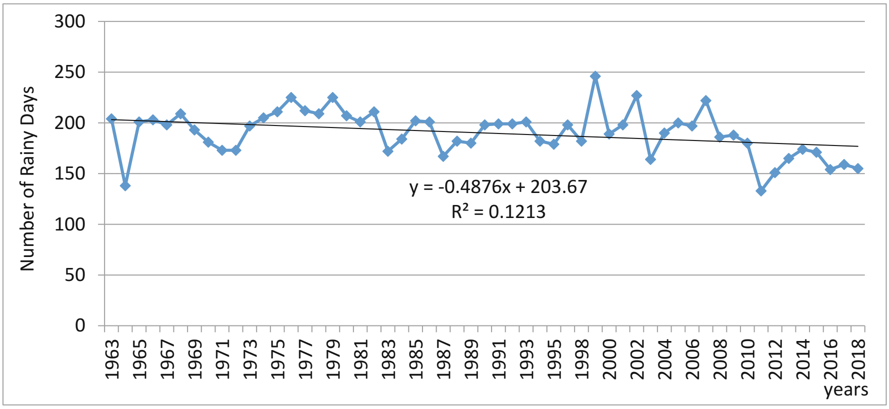

Fig. 6 Number of rainy days. (Source: Author (2019))

Table 1 Classification of SPI values, categories, and corresponding proportions

SPI value	Category	Probability (%)
2.00 or more	Extreme wet	0.3
1.5 to 1.99	Severely wet	2.4
1.00 to 1.49	Moderately wet	11.2
0 to 0.99	**Mildly wet**	**30.1**
0 to −0.99	**Mild drought**	**37.4**
−1.00 to −1.49	Moderate drought	14.2
−1.50 to −1.99	Severe drought	4.4
−2 or less	Extreme drought	0

Source: McKee et al. (1993)

the many rainy days and consequently, low rainfall intensity, whereas with the few rainy days, much rainfall amount is pouring per unit area, and hence high rainfall intensity.

Analyses of Rainfall Variability in Bamenda I Using Climatic Indices

Climatic indices were equally used to characterize rainfall variability in Bamenda I, and both the seasonality and the standardized precipitation index were used (Tables 1 and 2).

The Standardized Precipitation Index (SPI)

The Standardized Precipitation Index (SPI) is a tool used primarily for defining and monitoring drought and floods (rainfall situation). It equally serves as a method of assessing climatic variability. It was developed by McKee et al. in 1993. It was therefore used to access the situation of rainfall variability in Bamenda I (Table 1).

As seen on Table 1, 0.3% of the study period registered SPI values greater than or equal to 2.00 indicating extreme wet conditions. This implies that the probability of occurrence of extreme floods in Bamenda I is 0.3%. Equally, 2.4% of the study period registered values between 1.5% and 1.99% corresponding to severely wet conditions. Also, 11.2% recorded moderately wet and 30.1% recorded mildly wet conditions. To what concerns drought conditions, 37.4% lived mild drought, 14.2% lived moderate drought, and 4.4% lived severe drought conditions, but no situation of extreme drought was witnessed. The SPI therefore indicates that mild wet and mild drought conditions are most common in Bamenda I since they have the highest probability of occurrence.

The Seasonality Index

The seasonality of precipitation refers to the tendency for a place to have more rainfall in certain months than in others. It therefore determines the rainfall regime of a particular place (length of seasons). This makes use of the seasonality index (SI) of Walsh and Lawler (1981). Table 2 presents the seasonality index for Bamenda I.

Table 2 shows the scale (class limit) of the seasonality index and their corresponding seasonal regime. The seasonality index for Bamenda up station is calculated at an overall value of **0.901**, and as seen on the scale, this value falls within the limit **0.80 to 0.99**. This means that the rainfall regime for Bamenda station portrays a markedly seasonal with a long drier season instead of a seasonal regime. Instead of seasonal because humid tropics (Bamenda) are characterized by two distinct seasons, so we should normally have a "seasonal" rainfall regime with a well-defined rainy and dry season but instead of a seasonal regime, it shifted to a "markedly seasonal with long drier season." This is a clear indicator of a variation in rainfall, and it also indicates that rainfall in Bamenda I has been reducing gradually, leading to higher trends of drought occurrence. This result is in line with that of Jiduana et al. (2011), in Northern Nigeria, which emphasizes on the fact that "rainfall amounts and its duration is experiencing a general decrease." This explains why rainy months of March, April, and May portray negative anomalies, with rainfall

Table 2 Rainfall seasonality index and corresponding regimes

Seasonality index class limit	Rainfall regime
≤0.19	Very equable
0.20–0.39	Equable but with a definite wetter season
0.40–0.59	Rather seasonal with a short drier season
0.60–0.79	Seasonal
0.80–0.99	**Markedly seasonal with long drier season**
1.00–1.19	Most rain in 3 months or less
≥1.20	Extreme, almost all rain in 1–2 months

Source: Walsh and Lawler (1981)

below the normal. This fall in rainfall and occurrence of droughts will obviously lead to a fall in the general quantity of water supply in Bamenda I.

Impacts of Rainfall Variability on Water Supply

This section deals with the effects of variation in rainfall on water supply. These variations in rainfall pattern and amount have caused several impacts on the water system. They include intense erosion within river channel leading to occurrence of landslides, sedimentation in water collection chambers leading to its blockage, and erosion along pipeline network leading to breakage. Also, meteorological droughts lead to shrinking of rivers and springs. It equally shows the Pearson's correlation coefficient between monthly rainfall amount and water supply.

Pearson's Correlation Coefficient Between Rainfall Variability and Water Supply

The Pearson's correlation coefficient is a measure of the linear correlation between two variables. It is a tool for determining the strength of a relationship existing between two variables. It was therefore used to establish the relationship between rainfall and water supply in Bamenda I.

From Table 3, the Pearson's correlation coefficient is 0.701. This positive value shows a direct relationship between monthly rainfall and monthly water supply in Bamenda I. Meaning that an increase in rainfall amount will lead to an increase in quantity of water supply while a fall in rainfall will condition a fall in water supply quantity (in monthly or seasonal bases). This is because an increase in rainfall amount due to the outbreak of the rainy season will progressively recharge the water table and increase its level thereby increasing the volume and level of surface and groundwater, respectively, this will consequently increase quantity of water abstracted and supplied in the municipality.

Though the correlation coefficient indicates a strong positive relationship (+0.701), it is not up to a total positive relationship (+1), implying that other factors influence quantity of water supply in Bamenda I. To determine their contribution, the coefficient of determination was calculated, and the proportion of rainfall was determined. This coefficient gave an R^2 value of 0.49 and a rainfall proportion of 49.14%. This percentage shows the contribution of rainfall on the changes observed in quantity of water supply, therefore the remaining 50.86% indicates the contribution of other factors. These factors include demographic increase, urban expansion, infrastructural, and managerial factors.

Table 3 Pearson's correlation coefficient between monthly rainfall variability and water supply

Variables tested	Pearson's correlation coefficient (r)	Coefficient of determination (R^2)	Proportion of rainfall in the change
Rainfall (mm) and water supply (m^3)	0.701	0.49	49.14%

High Rainfall Intensity and the Water System

Occurrence of torrential rains in this area is usually accompanied by heavy downpours, which generally constitutes more of overland flow than infiltration. This is because the steep topography limits chances of infiltrate and rather permits runoff. These conditions will therefore lead to occurrence of surface runoffs, which flow into rivers and increase their volumes. This increase in river volume will increase its force and action within the channel, and this will lead to the occurrence of landslides along its banks. On the other hand, runoffs mostly transport sediments and debris, which ends up blocking water intakes and damaging transmission pipes, thereby preventing water input and output into and out of the system (Plate 1).

As seen on Plate 1, landslides occur due to intense erosive activities along the river course due to intense rainfall episodes (Photo 1). Equally, the transportation of sediments and deposition within the river channel leads to blockage of water collecting chambers and consequently, no inputs into the water system. Also, the occurrence of gully erosion will lead to the exposure of and further damage on pipelines and in such situations, outputting will be hindered, (Photo 3). When these phenomena take place, the entire water system is disrupted, and water crises are witnessed in the municipality.

Droughts and Natural Supply

When meteorological droughts persist, hydrological droughts develop. The term "drought" can have different meaning to different people, depending on how a water deficiency affects them (Moreland et al. 1993). To the people of Bamenda I, droughts are condition of persistent dryness that leads to a reduction in stream flow and groundwater levels, thereby causing water shortages. Prolonged occurrences of this drought therefore lead to shrinking of their water sources (streams, springs, and wells) and in some cases, it leads to the complete disappearance of some streams, (Plate 2).

As seen on Plate 2, there is a drastic fall in the volume of stream flow (Photo 1), shrinking of springs (Photo 2), and complete disappearance in stream flow as seen on Photo 3. These situations are found in Nkar, Ntanche, and Alahnting, respectively.

Plate 1 Impacts of heavy downpour on the water system

Plate 2 Impacts of drought on natural supply

Plate 3 Impacts of drought on supply points

This is caused by three main factors: firstly by lack of precipitations to recharge surface and groundwater, secondly by prolonged evaporation that lead to direct water lost, and lastly by uptake and transpiration from vegetation that reduce both ground- and surface water. Intense insulation and high temperatures often amplify this situation. This result supports the thesis of Adefolalu (1993). On the idea that "climate change can lead to drying up of springs and is projected to reduce surface and ground water resources significantly in most subtropical regions." This reduction in stream flow will reduce quantity of natural supply, thereby reducing input of water to the system, and this will lead to a drastic reduction in total quantity of water supplied within the municipality.

This fall in supply has led to the shutdown of most public supply spots since available water quantity is no longer sufficient to supply all points, (Plate 3).

Plate 3 illustrates shutdown of water supply points due to scarcity in water resource. This is the case of Akumbele and Ntafebuh on Photos 1 and 2, respectively. This occurs because a fall in natural supply due to meteorological drought will lead to a reduction in input to the water system. This reduced in input will lead to a reduction in the quantity of water abstracted and stored in reservoirs, consequently, there will be shutdown of most public supply points since water quantity is no longer enough to freely satisfy the population.

Adaptation Measures

Households and stakeholders have put in place a wide range of measures to adapt to rainfall variability and reduce its effects on water supply in Bamenda I. They range from drilling of boreholes and wells, spring source coverage, use of rainwater collection systems (during rainfall episodes), and through the application of water catchment protection and management measures such as construction of life fences, planting of water friendly trees, slanting and enlarging river banks, and engaging the local population in catchment protection.

Drilling of Boreholes Wells

Surface water sources have become exposed and vulnerable to climatic and environmental hazards such that people were forced to adapt through use of alternative water source. This change was from the use and dependence on surface water sources to groundwater source, which are less exposed and sensitive to the effects of climatic hazards. These surface water sources include boreholes and well.

Spring Source Coverage

To reduce the effects of runoffs, mudflow, and consequent pollution on spring source, the local population constructs protective layers on spring sources. These layers are locally constructed using cement and sand (Plate 4, Photo 2). This is done by joint contribution from the inhabitants of the quarters concerned.

Use of Rainwater Collection System

The use of rainwater over the years has gained its importance as a valuable alternative or supplementary water resource. This is due to the growing scarcity of

Plate 4 Adaptation to climate-induced effects on water sources

ground- and surface water caused by extreme weather conditions. Households therefore witness waters shortage and seizures in the dry season as well as in the rainy season. Seizures in the rainy season are often because of intense rainfall that creates damages around stream catchments preventing water inputs and limiting supply. To remedy water shortage during these periods, some households install rainwater collection systems to increase their water supply. Others use containers to collect water dripping directly from roofs. All these measures are clearly illustrated on Plate 4.

Plate 4 illustrates adaptation measures mainly by the local population to combat the effect of climate extreme on water sources in other to maintain and perhaps increase domestic supply quantity. Photos 1, 2, and 3 shows use of wells, spring source coverage, and rainwater collection system, respectively.

Photo 1 shows a domestic well, and it consists of a digged hole down to the water level. Its water is stored within the hole, and its depth is less compared to that of a borehole. This water source is less vulnerable to climatic extremes, and it ensures a steady supply regardless of seasons. Its steady supply is because it is alimented by aquifers, which are less vulnerable to extreme weather conditions. This water source is therefore used as an adaptive source.

The arrow in Photo 2 points out the protection chamber constructed on a spring outflow. This is to prevent the runoff and mudflow into spring sources. This preventive measure will ensure steady water supply without interruptions especially during and after rainy periods. This situation is common in Ntanche and Aningdoh, respectively. Photo 3 illustrates a household rainwater collection system and this system is used to harvest and store water from roofs during rainfall episodes. Rainwater harvesting and storage is done with pipes, which are connected to gutters permitting to link water from the roof to the storage containers. Water is harvested and stored for further use, especially when the stream supply system fails.

Other domestic measures of adapting to water shortage brought by extreme weather conditions includes: increase use of storage containers, buying mineral water from shops and from water vendors, regulating water use, use of stream water, and practicing of household water treatment and storage measures. Those with borehole at times use generators to pump water into reservoirs during periods of power failures. This is common in dry season due to a fall in dam discharge caused by excess meteorological drought that reduces water recharge in the dams. This reduction in water recharge reduces power supply to the electrical system, and this increases the rate of power failures. As such, those with electrical-based water systems are forced to use alternative power supply measures to electrify their systems. The frequency of implementation of adaptation measures depends on the extent to which rainfall variability affects their sources of supply.

Adaptation Through Catchment Protection and Water Management Measures

Water catchment management (WCM) refers to a range of measures and policies implemented on water catchment in other to reduce environmental, climatic, and anthropogenic actions. It equally involves the management of water catchment through taking precautionary measures to prevent or reduce environmental and climatic hazards on drainage basins and or catchment areas. It also concerns the sustainable use of water resource and land within the watershed. Actors involved in these activities include the Ministry of Water and Energy (MINEE), the Cameroon Water Utility Corporation (Camwater), and the Bamenda I sub divisional council. There is equally the role of the local community and anonymous individuals. These WCM measures are aimed at providing sustainable supply of water in terms of both quantity and quality of water. They include:

- **Construction of life fences.**
  To fight against erosion, there was the planting of life fences round the water catchment areas, both by the subdivisional council and the Camwater. These fences are made of wires and backed up by trees to prevent excess erosion from the surrounding into catchment and river channels. They equally help to prevent grazers from invading the catchment with their cattle. All these measures reduce the rate of damages by erosion on river channel as well as prevent the abuse of water resource by grazer.
- **Planting of water friendly trees.**
  To combat the problem of excess hydrological droughts in Bamenda I, there was a massive planting of water conservation trees (50,000 *Pygeum africanum* tree) around water catchments. This was done by both the Bamenda I subdivisional council and the Bamendakwe Development and Cultural Association (BAMEDCA). This tree has a little quantity of water uptake and disfavors transpiration. It equally has a large canopy that sheds the catchment and prevents evaporation. Its roots equally hold soil particles together, thereby limiting occurrence of landslides in water catchment. On the other hand, there is a strict restriction on the planting of eucalyptus trees around water catchments. This is due to their high water needs and uptake. All these reduce the level of water lost, thereby conserving water within catchments and ensuring sustainable supply.
- **Slanting and enlarging riverbanks.**
  Due to the occurrences of landslides along river courses, there was the need to dig along riverbanks in other to gentle the slopes and reduce the action of gravity, which often bring down landmasses along steep riverbanks. Slanting in most cases widens the riverbed, this reduces both the level and the strength of river flow, and this will therefore reduce the erosive action of the river on its banks. This activity is at times accompanied by the planting of trees along river banks which hold soil particles together and reduce the movement and land masses into river channels. This activity is mostly carried out by Camwater.
- **Engaging local population in catchment protection.**
  This involves giving scientific knowledge to the local population on how the catchment operates, thereby permitting them to protect the water catchment at the local level and ensuring a lasting supply of water in catchments. This includes sensitizing the local population (especially those around the catchment) on sustainable agricultural practices around the catchment, such as the importance of agroforestry and antislope wise cultivation in other to prevent and reduce

excess erosion and deposition of sediments in river channels. It equally concerns placing restrictions on practices such as grazing within water catchment, farming, and deforestation along river courses. It also involves restriction on waste disposal in river channels and around water catchments, since solid and liquid waste disposal in rivers and open space leads to diverse kind of health problems including water and airborne diseases (Achancheng et al. 2003). On the other hand, this is concerned with the massive participation of the entire community around water catchment during activities such as planting of trees and building of life fences. A reduction in these activities and participation of the local population will provide a friendly milieu for conservation of water in the catchments and hence to improve water resources while ensuring the productivity of any water body for the community that depends on it.

Adaptation measures are equally implemented on storage and distribution facilities. This was in a bit to increase water collection, storage, and hence distribution.

Adaptation on Storage Facilities

To address the problem of water lost to the environment by natural springs, amendments were made on spring sources and reservoirs constructed on them to collect and store flowing water. There was equally the construction of water tower to abstract and store water from aquifers, all these in a bit to store water and prepare for periods of high water demand. Doing so equally reduces the direct impacts of climate extremes on springs especially pollution from runoff and mudflow due to intense rains. This was done by the Bamenda I subdivision council and by the Cameroon-China cooperation. These reservoirs were constructed at Menka, Abangoh, and Mendankwe with a carrying capacity of 18 m^3 each.

Adaptation on Distribution Facilities

To limit the damaging action of erosion, floods, and other external factors on pipelines, the water management committee proceeded to the use of metallic pipes on strategic points (in highly vulnerable zones to erosive actions) on the distribution network. There was equally a considerable increase in depth of pipelines especially in areas with loosed soil particles. These were aimed at minimizing damages on pipe network in other to maintain supply. The water management committee equally puts in place distribution trucks (mobile reservoir) to ensure supply especially to extreme quarters on the distribution network. This is mostly common in the dry season were pressure is not enough to pump water to all localities due to low water levels in reservoirs. This service is common in Achichum, which is furthest on the distribution network, and sometimes in Ayaba, which is higher in altitude. In most cases, the trucks are recharged in areas with adequate water supply and distributed in those with limited supply. All these facilities will therefore increase supply in periods of shortages and in vulnerable zone, thereby increasing the total quantity of water supply in Bamenda I. In addition, during situations where available water cannot adequately satisfy the entire population, there is water rationing to ensure equitable supply to all subscribers.

Conclusion and Future Prospects

Rainfall is one of the climate parameters which affect water in the entire drainage basin, thereby leading to consequent effects on rivers and their tributaries. This study was based on the impact of rainfall variability on the quantity of water supply in the Bamenda I municipality. Rainfall amounts in the municipality fluctuate around the normal. Its variability is indicated through fluctuations in interannual rainfall variability and anomalies, and through monthly rainfall variability and anomalies. These anomalies are either positive or negative indicating periods of more or less rainfall amounts. Rainfall variability equally manifests through variations in number of rainy days and through fluctuations in rainfall intensity. The rainfall regime was gotten using climatic indices, and the Pearson's correlation coefficient was conducted to determine how quantity of water supply responds to rainfall variability. However, rainfall conditions seasonal variation in quantity of water supply to an extent, since supply is generally higher in rainy than dry seasons (direct relationship), though some cases occurred where periods of intense rainfall instead leads to a drastic reduction in supply (inverse relationship). Extreme weather events such as heavy rains, flooding, and drought are increasingly becoming common in the municipality. Their occurrence distorts the functioning of both the hydrological cycle and the water system, thereby affecting the quantity of water supply in the municipality.

Future Prospects

Since the study was carried out in the Bamenda I municipality (Bamenda highlands), there is need for further research to expand the geographical scope of the study, in other to do a comparative study of two different drainage basins or water catchments to assess the level of responsiveness of water resources to rainfall variability.

Result from the study showed that beside rainfall variability, there exist other factors, which greatly affect quantity of water supply in Bamenda I. Therefore, further research should be carried out in other to access the validity of these factors.

Equally, an improvement in hydrological research will provide a room for adaptation measures. This is because more research in the domain of water supply will identify more threat to the natural functioning of water catchments (drainage basins), and therefore more suggestion will come up to improve adaptation measures on water catchment.

Abstract

It is apparent that climate change affects every facet of life as no living organism lives outside of the universal environment (air, water, land), and all of these are affected by one or more climate or weather conditions. Climate affects agriculture and vice versa as they are deeply interconnected. The effect of climate change on agriculture goes a long way to increase or decrease food security and invariably food nutrition through its impacts on agricultural lands. This is because the more food insecurity there is, the more issues of undernutrition are observed.

This chapter studies the different ways climate and climate change affect crop production through the different sections of agriculture in terms of plant diseases and biocontrol, food production, livestock rearing, fish production, forestry, and microbial diversity. It goes further to look at the different ways nations and communities are adapting to climate change to mitigate the challenges of food insecurity and nutrition. Finally, some of the solutions that can be pilot tested at the community level, which can later be cascaded to national and regional levels, are also emphasized. Other recommendations that can become a research focus to forestall this threat are also highlighted and would be important in policy development.

Keywords

Climate change · Environment · Food availability · Food production · Food security · Nutrition · Soil · Weather

Introduction

Food security has been affected by a change in climate and weather conditions globally. Recently it is also obvious that food nutrition security needs to be addressed. Agriculture is important for food security in two ways: it produces the food people eat and (perhaps even more important) it provides the primary source of livelihood for 36% of the world's total workforce (ILO 2007). The Food and Agriculture Organization (FAO) of the United Nations (UN) defined food security at the World Food Summit in 1996 as "when all people, at all times have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active and healthy life" (Food and Agriculture Organization 1996). Food security transcends food availability (production, distribution, and exchange) but also include how food is accessed (affordability, allocation and preference), utilized (food safety, nutrition, and social value) and also how it is distributed in the supply chain (food stability) (Ziervogel and Frayne 2011). This also means that it is not just about food but how available food is. And even when it is available, communities and individuals might be food insecure if they are not able to access food either because of monetary incapacitation or because of lack of knowledge of where to acquire the food, based on their livelihoods and socioeconomic level. It could also be as a result of how safe the food is especially in terms of processes followed during food preparation (Ziervogel and Ericksen 2010).

Agriculture, forestry, and fisheries have all been affected by climate change, and they have contributed to the increase in greenhouse gas emissions, thus affecting climate change negatively. The solution to climate change also partly lies within this sector, if agriculture is able to mitigate climate change through reduction of greenhouse gas emission during sustainable agricultural practices (Al et al. 2008).

Adaptation to climate change can constitute a range of interventions across all levels from individuals to communities to regional and national level. As observed by Bierbaum et al. (2013), communities can initiate their climate adaptation efforts in numerous ways. For example, in the United States, some diverse strategies employed by different communities to combat the issue of climate change include:

- Focusing on internal operations
- Beginning with a sector that is particularly vulnerable to climate change
- Integrating climate change concerns into existing planning approaches
- Conducting a community-wide assessment

The results from these experiments with adaptation strategies demonstrate that there is no "one size fits all" adaptation process or adaptation action (Bierbaum and Stults 2013). This is quite important to note in adaptation plans; however, the information required and the approached to adaptation can be similar across regions and sectors. Therefore, strategies that encourage data and best practices sharing, practical approaches, collaborative, and integrative processes will be important in developing adaptation plans in different countries.

Climate Change and Reality

Climate change occurs when changes in the Earth's climate system result in new weather patterns that last for at least a few decades and maybe for millions of years. Effects of climate change are seen in the frequency and severity of extreme weather events including droughts, floods, new rainfall patterns, and heatwaves. Increases in temperature have led to an escalation in the distribution of weeds, pests, and diseases some of which are a threat to marine life, plants, animals, and humans. In the same vein, an increase in extreme weather events has led to soil erosion (by water and wind) and loss of arable land for forestry and agriculture.

Impact of climate change on food production cannot be overemphasized; it is enormous and felt more acutely in developing and the least developed nations (Fig. 1). Flooding and droughts have been observed to ruin crops and pastures already being cultivated on the fields. Losses due to floods and droughts between

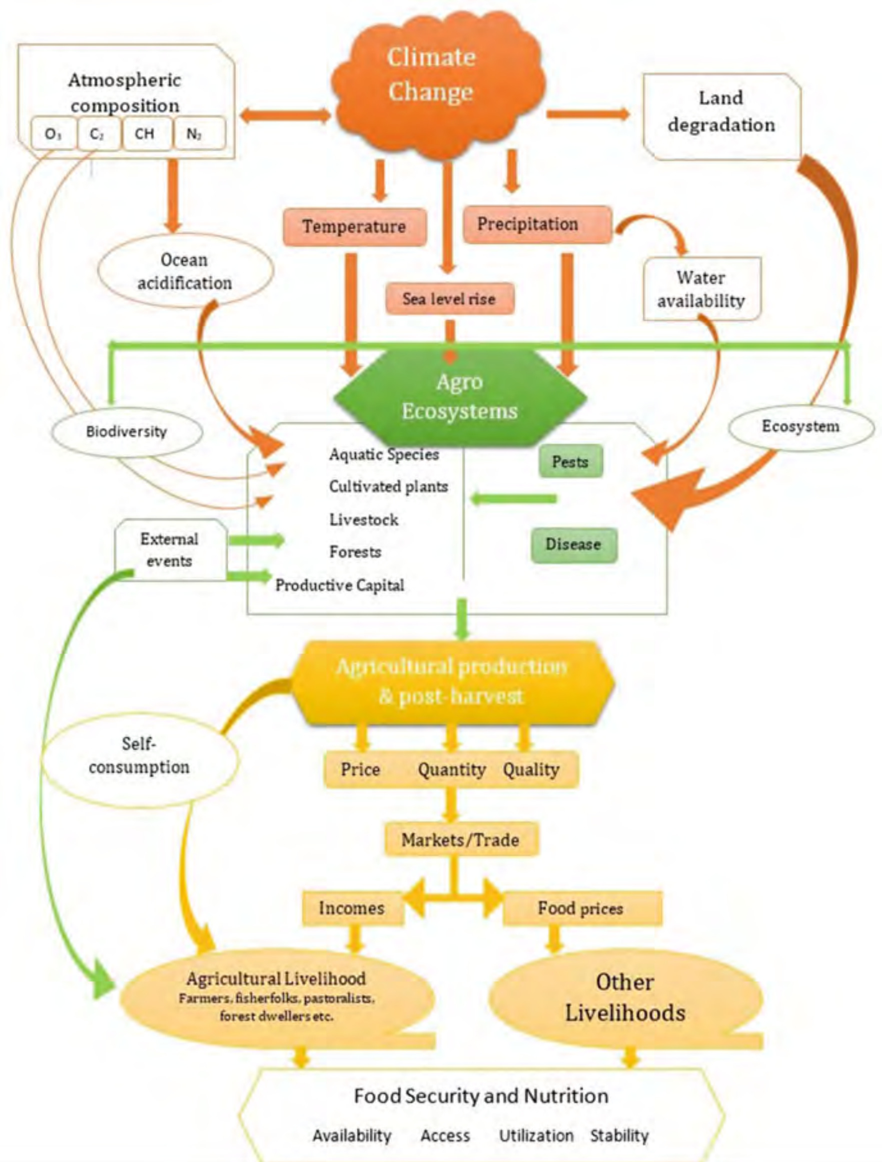

Fig. 1 The interrelatedness between climate change, food security and nutrition showing the impact of climate change on food security. (Adapted from FAO 2016)

2004 and 2014 have been estimated to be over 100 billion USD globally (Food and Agriculture Organization 2015; Brida et al. 2013).

Agriculture and fisheries are extremely climate dependent. Temperature and carbon dioxide (CO_2) increases in some areas can increase some agricultural productivity. Nevertheless, the higher demand for nutrients, soil moisture, water availability, and other requirements must also be met in order to realize these benefits. Changes in drought and flood frequency as well as intensity can present severe threats for farmers and ranchers and therefore threaten food safety (Ziska et al. 2016). In addition, warmer water temperatures are likely to trigger a change in the habitat ranges of many species of fish and shellfish, which may threaten ecosystems. Furthermore, climate change could make it harder to produce food and fish and raise livestock in the same way and in the same places as in the past (Chen 2015).

Climate Change Adaptation and Mitigation

Adaptation to climate change is a way of responding to global climate change (also called “climatic change” or “anthropogenic climate change”). According to The Intergovernmental Panel on Climate Change (IPCC), adaptation is sequence of modifications to actual or expected climate and the impacts of the modification. Adaptation is aimed at mitigating or preventing harm or manipulating beneficial possibilities within human systems. Sometimes, the contributions of human beings enhance adaptations to these modifications and its impacts (IPCC 2014). This requires intentional efforts in the human environmental system to adapt behavioral patterns, lifestyles, and perceptions that can lower the risk to human lives and livelihoods, while mitigation involves coordinated actions to reduce long-term emissions of greenhouse gases (Al et al. 2008). In contrast, climate change mitigation means reducing greenhouse gas emissions and short-term sequestration and processing of coal and even more significantly by making infrastructural decisions that will reduce risk by reducing long-term emissions. While the entire food system is a producer of greenhouse gas emissions, still the most important component is primary production. Incentives are required to encourage producers, agribusinesses, and managers of biodiversity to follow good practices to mitigate climate change.

Food Production and Climate Change

Climate change will affect food production and welfare of food animals (i.e., livestock, poultry, and fish) in several different ways. Consider the production of livestock that will probably be restricted by climate change as consumption of water by livestock is expected to increase by a factor of three. The need for arable land for pastures and feed production will increase because of a 70% increase in demand for agricultural products. Food safety issues also become important because around one-third of the world’s cereal harvest is used for animal feed (Rojas-Downing et al. 2017). Furthermore, 14.5% of global greenhouse gas (GHG) is produced by the livestock industry. The livestock sector will therefore be a key player in reducing GHG emissions and enhancing global food security in the future (Rojas-Downing et al. 2017; Gerber et al. 2013).

Climate change and competition for land together with water and food security are likely to adversely affect livestock production at a time when it is most wanted (Thornton 2010). The output efficiency of feed conversion ratios for food, dairy, and egg production could be felt as a result of losses due to climate change. Increasing temperatures can also lead to death of food animals, as was noted by the deaths of more than 30,000 dairy cows in California and also in reduction of the overall production of milk in 2006 (Pitesky et al. 2014). Temperature affects most of the critical factors for livestock production, such as water availability, weight gain (feed conversion ratio), reproduction (semen quality, cow calf efficiency), and general health. A combination of increases in temperature, CO_2, and variability in precipitation influences the quantity, quality, and availability of forage and grain feed crops. Livestock diseases are affected primarily by an increase in the variation in temperature and precipitation (Thornton 2010).

Changes in land use, food production, animal production, manure, storage and transportation, and livestock all influence local and global weather patterns. Production of feed and manure releases CO_2, nitrous oxide (N_2O), and methane (CH_4), thereby influencing climate change. Therefore, livestock production systems increase emissions of CH_4. The production and transportation of animal products and improvements in land use contribute to increased CO_2 emissions. Research on the impact of climate change on livestock production is still minimal and need renewed attention (IPCC 2014).

Insects are ectotherms and are highly sensitive to their surrounding environmental conditions particularly the temperature; therefore temperature is a major factor affecting their reproduction (Kambrekar et al. 2015). This means increases in temperature for both edible and disease-causing insects could increase their reproductive cycle up to five cycles in a single year, which could affect farm food production negatively in terms of crop stress and yield loss. For beneficial insects, this increase in temperature will lead to increase in their metabolism (Kambrekar et al. 2015). Perhaps this provides an opportunity to develop new food systems based on insect production, either as feed for livestock and fish or directly for human consumption.

The possible effects of changing climate on insects could result in outbreaks, migration, change in biodiversity, species extinction, change in host shift, and emergence of new pests or biotypes. Due to the climate change, there is an increase in insect pest population, more outbreaks of insects, increased number of generations, as well as development of resistant biotypes (Moore and Allard 2008).

Fish plays an important role as a source of nutrients and micronutrients for human consumption, and fishing is a crucial food-producing sector and a source of livelihood for coastal farmers. Both fisheries and aquaculture make a significant contribution to food security and the livelihoods of millions of people as job creators, nutritious food providers, revenue generators, and economic growth through harvesting, processing, and marketing fish. Especially susceptible to climate change are small-scale fisherfolk and small-scale aquaculture. Their vulnerability is the function of both their location and their circumstances of vulnerability and disadvantage. Fishing and fishing communities are exposed to extreme climatic conditions and natural hazards, such as hurricanes, cyclones, sea level rise, ocean acidification, flooding, and coastal erosion, as they are mostly situated on the coastline. Millions of people living in the lowlands of coastal regions and the floodplains cannot escape regular flooding. Climate change affects living conditions as well as physical well-being of humans across many agro-forest ecosystems of the world (FAO 2016).

Forests are a climate-stabilizing force. They control habitats, preserve biodiversity, play an integral role in the carbon cycle, improve living conditions, and provide goods and services that can boost sustainable growth (Bonan 2008). A forest's position in climate change is that it both causes and mitigates greenhouse emissions; therefore, there are both pros and cons. Impacts of climate change on forests result from variations in atmospheric CO_2 concentration, and shifts in temperature and precipitation regimes, as well as an increase in climate variability reflected by increasing frequency and severity of extreme events. Change in climate will affect tree photosynthesis, rates of growth, leaf phenology, seed production, and cycling of nutrients (van der Meer et al. 2002). In some regions, forest form a vital resource for the community. For example, tropical forests cover about one third of the Kafa highland region of Ethiopia where a multiple tenure system exists for the utilization of the forest resources (Zewdie 2003). These include sharecropping and allocation of trees to sons when they come of age. However, the beekeeping and wood processing skills also need to pass from one generation to the next to maintain sustainable livelihoods (Zewdie 2003). Therefore, climate change effects on such forests will have a major impact on the livelihoods of the people.

The land management sector, the second largest driver of greenhouse gas emissions after the energy sector, accounts for around 25% of global emissions. Around half of these come from deforestation and habitat destruction (5–10 Gt CO_2e per year). Planting of forests and commercial plantations are among the most important strategies to address climate change effects. It is estimated that 2.6 billion tons of carbon dioxide, which is one-third of CO_2 from burning fossil fuels, is absorbed annually by forests. Projections show that there are nearly two billion square kilometers of worldwide degraded land – an area the size of South America – that can open up opportunities for restoration. Therefore, forest growth and preservation is an important solution to address the impact of climate change.

There are four major strategies available to mitigate carbon emissions through forestry activities:

- By reforestation (Bierbaum et al. 2013)
- Increasing the carbon content of natural forests on both stand and landscape scales
- Expansion of the use of forest products that replace CO_2 emissions from fossil fuels sustainably
- Reducing deforestation and degradation emissions

Climate also adversely affects the production of food crops that are highly sensitive to climate parameters. Long-term trends in average rainfall and temperature, interannual variability in climate, shocks during specific phenological stages, and extreme weather events affect food production (IPCC 2012). Some crops are more tolerant to certain stress types than others, and different stress types affect each crop species in different ways at each phenological development stage (Simpson 2017). Even though, crop yields are expected to decline under climatic conditions in the future, crop yields are already being affected as indicated by recent research (Ray et al. 2019).

As climate changes, crop production strategies must change also. There will always be some uncertainty associated with modeling the complex relationships between agricultural yields and future climate scenarios.

Climate Change Impact on Food Availability

Food availability is determined by the physical quantities of food that are produced, stored, processed, distributed, and exchanged (Al et al. 2008). Food production is affected by climate especially in regions where biochemical processes are being influenced by climate change. Some of these influences could be positive, negative, or even neutral (Allen Jr 1991). Location is a determinant of how the effect of climate change will be experienced in different regions (Leff et al. 2004). In temperate regions where elevated levels of CO_2 will increase plant growth and development, greenhouse fertilization effect is beneficial so crop yields will also increase. Such increase is observed to be as high as 0–10% increase in crops with very high photosynthetic efficiency, while those crops with lower efficiency have higher increase from between 10% and 25%. In such scenarios, the assumption is that the level of CO_2 in the atmosphere will increase to 550 parts per million (Tubiello et al. 2007; IPCC 2007). In some cases, increase in temperature between 1 °C and 3 °C is beneficial to plants in temperate regions; however, in tropical and seasonally dry regions, the impact is negative on crops especially cereals that are already growing near to their optimal temperature regime. Nevertheless, the impact is negative on all crops when the increase in mean temperature is more than 3 °C (IPCC 2007).

Such temperature increase will also impact livestock production as the growth of feed crops is also compromised and become an indirect effect on livestock production (Porter and Semenov 2005). Direct effects are related to exposure to solar radiation that then affects the exchange of heat between the animal and the environment (Rust and Rust 2013). This is critical, as many livestock breeds are not tolerant of high temperatures (Rust and Rust 2013). Forage production from rangelands in Africa is sensitive to changes in climate and will have a substantial impact on the livelihoods of more than 180 million people who raise livestock on rangelands (Boone et al. 2018). Climate effects on forage quality that depends on nutrient composition and affects digestibility, partitioning of metabolized products in the digestive tract, and intake of forage by animals will strongly affect animal performance.

Some drastic changes in the farming system sometimes have to be introduced, such as a change from sheep and cattle to goats, as they are the only domesticated animals with a versatile ability to adapt to a changing climate more readily than any other ruminants. Generally, goats are less affected by the harsh hot dry climates compared with other ruminants. Some of their ability to adapt is due to their habit of browsing together with the anatomical advantage of the upper lips. Therefore, goats can thrive well with limited feedstuffs, especially in arid and semiarid regions (Pragna et al. 2018). Another advantage is that during feed scarcity, goats can reduce their metabolic processes to conserve energy resource (Yadav et al. 2013). Therefore, they provide a continued supply of meat despite increases in temperature and frequencies of drought.

Climate Change Impact on Food Accessibility

"Climate change is becoming something we can taste" (Little 2019). According to Little (2019), this is the age of diversity and accessibility of food. Food accessibility is a function of being able to maintain and manage what one is entitled to, which is defined as the collection of assets (including legal, political, economic, and social) needed by a person to gain access to food (Sen 1989, cited in FAO 2003, Sage 2014).

Food accessibility refers to ability to own food, distribute it, and make food choices which allows people to turn their hunger effectively into demand (Sage 2014). Since food accessibility focuses on the power of households/individuals to be able to spend money, and the group dynamics of access to food, poverty, and vulnerability are key functions of it (Ziervogel and Frayne 2011).

Households have been observed not to grow their foods independently but either buy, trade, or exchange them (Du Toit and Ziervogel 2004). The ability to acquire food by households can be impacted by climate as it influences either the job opportunities or the availability of such foods may influence non-availability of some foods leading to increase in price, which could also make such foods unaffordable, thereby impacting on individual's nutrition and health. When there is an increase in price, low-income earning families are at the receiving end, so when they cannot purchase such foods, they either eat less preferred foods or reduce quantities of food eaten, making food prices very important to food security (Pretty et al. 2005).

Climate Change Impact on Food Utilization

Food utilization refers to how food is used and how individuals can obtain vital nutrients from the food they eat. This includes the nutritional benefits of the food, the nature and method of processing the food, and the way the society views each food that also determines when if and when such foods should be eaten. Also included are the knowledge of the quality and health of the food, which determine if there would be nutrient loss or the susceptibility of the food-to-food-borne diseases if below standard (FAO 2008).

When there is insecurity of food, dietary diversity is reduced, and this could lead to non-availability of nutritious food that form basis of balanced diet of the populace. This scarcity could be as a result of water scarcity, drought, or labor from climate change and variability. This impact of climate change on food utilization is indirect because its effect is ultimately felt on the effect of income and capacity to purchase a diversity of foods.

The way the food is utilized by the body affects the nutritional status of individuals and informs the susceptibility of such individuals to diseases. This is observed as changes in human health that has been affected by new disease patterns created as a result of the response of different pests and vectors to climate change. As climate change increases, there are more waterborne infections and diseases in areas that are prone to flooding. This is because there will be increase in the population of pests and vectors, and new diseases will emerge, which can affect plant's growth and ultimately the food chain. As a result of the diseases, people's physiological capacity to obtain necessary nutrients from the foods consumed will be affected. Therefore, they can become nutritional food insecure despite the supply of food being sufficient (FAO 2008).

Climate Change Impact on Food System

Yields of crops particularly crops grown on an annual basis will fluctuate as a result of the change in rainfall and temperature patterns; these changes will affect the continuous supply of such crops (Al et al. 2008; Ali et al. 2014). Droughts and floods will become more frequent because of climate change, and this will adversely affect stability and availability of food leading to food security. Therefore, in local communities, the food system will be adversely affected by the timing and amount of rainfall in different seasons because most agricultural systems in such communities are rainfed (Al et al. 2008; Ali et al. 2014).

Grain reserves are used to mitigate for crop failures in disaster situations and to sustain food aid programs for displaced persons and refugees. For grain to be kept as reserves, they have to be properly stored or preserved correctly. When humidity and temperature increase because of climate change, some areas become unfit to store the grains, and additional funding will be required to store or preserve them. Invariably because of the higher cost, the ability of many underdeveloped countries to maintain sufficient grain reserves is limited or grain reserves can be inadequate to respond to natural or human disaster (Al et al. 2008; Edame et al. 2011).

Impact of Climate Change Adaptation on Food Security and Nutrition

A significant effect of global climate change is the altering of global rainfall patterns, with certain effects on agriculture (Ali et al. 2014). Climate change will have variable impacts on agriculture based on multiple factors including changes in temperature, precipitation, and humidity (Pitesky et al. 2014). Rainfed

Table 1 The impact of climate change on food security

Climate change	Impacts
Increase in average temperature	Reduced quantity and reliability of agricultural yield
	Increased heat stress in livestock
	Destruction of crops or lowering crop productivity
	Decline in certain fish stocks due to increased sea temperature
Change in amount of rainfall	Reduced water availability for crop and livestock
	Heavy reliance on irrigation
	Poor quality of crops due to deteriorating water quality
Increased severity of drought	Decreased crop yield
	Increased probability of fire
Increased intensity of extreme events	Soil erosion
	Increased land degradation and desertification
	Inability to cultivate land
	Damage to crops and food stores

Source: Masipa (2017)

agriculture constitutes 80% of global agriculture. Many of the 852 million poor people in the world live in parts of Asia and Africa that depend on rainfall to cultivate food crops. Climate change will modify the components of the water balance, namely, rainfall, evaporation, runoff, and soil moisture storage. This means that the full crop water requirement will not be satisfied in such a growing season. Extended drought can cause the failure of small and marginal farms with resultant economic, political, and social disruption, more than is currently observed (Table 1).

Crop Diseases and Effects on Crop Yields

Crop diseases are very important because of their economic impact (Esker et al. 2012), and how they are managed can have a large influence on agricultural productivity (Savary et al. 2012; Carroll et al. 2017). The growing population of the world and the overall reduction in global production of staples such as rice and wheat due to climate change (Ray et al. 2019) are two fundamental challenges that need to be tackled, with crop protection against diseases having an obvious role to play in bringing solutions to these challenges. Crop diseases affect the life cycles of any growing plant. They affect crop production from seedling stage through budding, flowering, and fruiting until harvesting. Crop diseases that occur during seedling and budding stages will in most cases cause the death of the plants as the growing point is damaged. These deaths lead to complete crop failure and high losses. In addition, losses at the time of harvest in most cases cause the reduction in yield in terms of size and quality and thus also a reduction in overall production (Savary et al. 2012). Therefore, loss of crops caused by pests, infections, or even weeds or animal attacks is a risk to farmers, their family or household income, and food security worldwide. Losses of crops due to yield reduction can be defined qualitatively and quantitatively (Cerda et al. 2017) in terms of the reduction in the value of the crop or the financial gain from crop sales.

In order to assess crop loss based on decrease in yield of crop, the variance between the real yield (Y) and the attainable yield that can be obtained (Ya) is taken into consideration as Ya – Y according to the definition of crop loss by Esker et al. (2012). The attainable yield can be achieved based on the different climatic and environmental conditions at specific locations without the impact of pests, pathogens, and weeds as well as other influences that may decrease yields within available production techniques. These climatic conditions among others include temperature, rainfall, solar radiation, and soil composition. The influence of pests, diseases, and other limiting factors in the actual sense and in real-life situation is reflected on the real yield (Esker et al. 2012; Savary et al. 2006).

Plant diseases are not just important because of their impact on crop yield, which is quantitative, but also their impact on the quality of the grain or product. As crops are attacked by disease pathogens, toxins are released into these crop which reduces the quality of the crop and can also cause infection in both animals and humans (Gururani et al. 2012).

Climate Change Impact on the Spread of Plant and Animal Pests and Diseases

Climate change can influence trends in seasons and the prevalence of disease-causing organisms and vectors and therefore also the use of herbicides and fungicides (Boxall et al. 2008). These reactions will vary among crops and geographical location. As a result of climate variability, the use of pesticide is expected to increase in the United States (Chen and McCarl 2001). Nevertheless, the estimated effects of climate change on pesticide use are a function of the type of crop and the geographical location. For example, from the United States, in Kansas and Colorado, the projected use of pesticides on wheat increased by 14% and decreased by 10%, respectively, while that of Illinois differed based on which crops was planted with increases on corn and decreases on soybean by 10% and 3%, respectively (Harrus and Baneth 2005). This shows that when there is an increase in temperature due to climate variability, there could be an outbreak of pests, pathogens, and/or vectors and their hosts (Lake et al. 2012). This outbreak could also lead to the use of more biocides and veterinary medicines in livestock management and eventual resurgence of antibiotic-resistant pathogens in both animal and human populations (Lake et al. 2012; Kemper 2008).

Climatic Conditions Favoring Crop Diseases: Wheat Rust Disease Example

As climate changes, the way disease pathogens adapt to the environment also changes leading to new disease occurrences (Fig. 1). For example, it was observed that warmer weather conditions favor the establishment and progress of wheat stem rust infection (Saunders et al. 2019). In certain regions of the world, during early growing season, high temperatures are experienced. This can cause the wheat plants that mature early to be at risk of the stem rust infection due to not being able to resist the buildup of the fungal inoculum (Saunders et al. 2019). This is because stem rust mainly needs warmer conditions for infection (Saunders et al. 2019). For example, in Germany in 2013, winter wheat production was hindered by a wet winter with low temperatures, and early warm summer temperatures led stem rust infection afterward. (Olivera Firpo et al. 2017).

Climatic Change Impact Postharvest

Over 80% of attainable yield of cotton and over 50% for other crops would be affected by pests and diseases with resulting effects on humankind. These effects which also include spoilage during postharvest and storage are felt more in resource-poor regions (Oerke 2006). It is estimated that an average of 13% of global harvest is lost to pests and diseases, and an average of 9% to postharvest losses especially in developing countries that lack the infrastructures to store harvested crops (Oerke 2006). In some cases, such infrastructures are destroyed due to climate change such as storms, hurricanes, and tornadoes (Agrios 2005). Also, destruction caused as a result of plant diseases can be far reaching and alter the course of society and political history (Chakraborty and Newton 2011).

Storms have led to loss of crops, livestock, and infrastructure and increase in the cost of grains as a result of increase in production cost. This increase also leads to lack of resource power of the minority poor in gaining access to food and invariably increases food insecurity.

The production and quality of essential food crops are hindered by plant diseases, which also affect food quality and safety. Besides reducing yield, they have significant effects on human and animal health. As a result of global climate change, the challenge of mycotoxins and pesticide residues are serious safety issues to be mitigated (Miraglia et al. 2009). Mycotoxins are important as they cause serious health issues because of the interactions between fungus and plant cells, which are also stimulated by conducive weather conditions and the soil type. In some areas like the United States, increases in temperature increased the production of mycotoxins such as aflatoxins, while in other regions like Australia, increase in temperature could be effective in the reduction of fungal growth and invariable mycotoxin production (Russell et al. 2010; Lake et al. 2012).

Climate change may affect the transport of pathogens and chemicals into food from flooding and wind bearing aerosols from contaminated environments and may change the composition of the transported materials (Plumlee et al. 2005; Boxall et al. 2008). This is also observed in the transportation of food crops from the farm before it is consumed where higher temperatures can favor the growth and replication of bacterial population like *Salmonella* spp. leading to food poisoning (Lake et al. 2012).

Climate Change Impact on Microbial Biodiversity

Climate change affects the diversity and types of macro- and microorganisms globally. Biodiversity can be measured at three levels, that is, genetic, species, and ecosystem level. Agriculture and the livelihood of most people globally depend on the genetic diversity of species and the types of species within the ecosystem (ten Kate and Laird 1999). Based on the adverse effect of chemicals in agriculture, and on human health and the environment, the use of chemicals is gradually being phased out to accommodate other techniques and technologies that can control plants and animal's pests and diseases and reduce adverse effects currently experienced by living things and the environment.

In order to achieve agricultural biodiversity, diseases and pests must be dealt with since they are one of the most deadly blows to food security. Seven thousand plant species and several thousand animal species have been used historically for human nutrition and health requirements (Toledo and Burlingame 2006). However, since the 1900s, only 12 crops and 14 animal species now provide most of the world's food, so there is a very real threat to global biodiversity and also food security.

Soil biological management techniques can improve crop yield and quality, especially through controlling pests and diseases and enhancing plant growth. Soil biodiversity determines the resource use efficiency, as well as the sustainability and resilience of low-input agro-ecological systems, which ensure the food security of much of the world's population, especially the poor (Paoletti et al. 2000). Part of the value placed on soil biodiversity is seen in biological control of pests and pathogens that improve plant health and thus also crop production and invariably improving local food security.

Biocontrol of Plant Diseases

Biocontrol is one of the integrated disease management practices that help to reduce yield loss of crops (Thurman et al. 2017). It is the control of plant diseases by applying living biological agents or exudates from such biological agents to the plants. The application could be via foliar application to the leaves or via the roots or seed inoculation prior to planting. Most biocontrol agents (BCA) are either from the bacterial or fungal families with a few from the viral and nematodal families (O'Brien 2017; Ajilogba and Babalola 2019). Some BCAs are either rhizospheric or endospheric microbes, as they attack the pathogens using different modes including phosphate solubilization, antagonism, and hydrogen cyanide production (Ajilogba and Babalola 2016). One important fact about biocontrol is that they are specific to pathogens and sometimes to crops making them very effective. Their effectiveness is also determined by the mode of inoculation, duration of inoculation, time of inoculation, and whether they are applied singly or in a mixture. Climate change also influences biocontrol because changes in the environment affect different dimension of agricultural production. In the context of climate change, with increasing temperature and variable rainfall patterns, changes are also observed in the cycling of nutrients and amount of soil water as a result of decreases in rainfall. The rainfall pattern also affects the patterns of incidence of plant pests, pathogens, and diseases, and invariably food production and security are ultimately affected (Lin 2011; Fuhrer 2003; Jones and Thornton 2003).

Ocean Acidification

This is more of a recent phenomenon with climate change. It is one of the potentially most harmful and deleterious effects of climate change. Over 30% of carbon dioxide produced in the atmosphere is absorbed by sea and oceans leading to the production of acids when carbon dioxide mixes with water. Most marine creatures cannot survive at low pH. Fish production is at a risk both directly and indirectly. The basic producers in the food chain such as planktons are also at risk, and this creates a reduction in food available to the large fish that consume then directly such as tuna, making them at risk of starving. Increasing acidity could harm shellfish by weakening their shells, which are created by removing calcium from seawater (Doney et al. 2014). Acidification also threatens the structures of sensitive ecosystems upon which some fish and shellfish rely (Hatfield et al. 2014; Ziska et al. 2016). Fish is not only a source of proteins and healthy fats but also a unique source of essential nutrients, including long-chain omega-3 fatty acids, iodine, vitamin D, and calcium. Therefore, the effects on climate change on the acidity of the oceans will cause a decrease in annual fish caught and processed at a good source of protein for humankind. Particularly in the Asian-Pacific region, fish protein forms a vital component of the diet (Needham and Funge-Smith 2014). It is not only true for small island states, with their strong dependence upon fisheries; it was also found in continental Asian countries even far inland due to large rivers, waterways, and many rice paddies. Therefore, the importance of fish in the diet should not be overlooked in discussions on nutrition and food security and expected changes under the climate change conditions.

Conclusions

Climate change is a reality, both at global and the regional scales. The magnitude of change is still uncertain and highly variable, as is the timing of the change. However, the severe nature of the impacts which climate change could have on all sectors of Africa's economy is becoming clear. The ability of individuals and communities to adapt to climate change depends on their vulnerability, exposure, and adaptive capacity. In turn, this is related to their financial and social capital, such as social networks and community cohesion.

Recommendations

Adaptation is a key factor that will shape the future severity of climate change impacts on food production; therefore, consideration of additional food such as underutilized crops and/or neglected foods can play a role in increasing food and nutrition supply.

There is, therefore, a need for an integrated policy approach to protect the arable land.

Further assistance needs to be given to small-scale farmers in rural areas in order to strengthen their crop production.

The restoration of forestation should be encouraged in order to make adequate use of forests to address climate change.

Globally and whenever necessary, nations should specifically relate their mitigation and adaptation initiatives to their policy decisions on environmental sustainability in agriculture industry. These policies should both be holistic and anti-poor in order to bridge the gap on the unequal effect that climate change may have on the different agricultural industries.

Consideration should be given to the economic, institutional, and social impacts of climate change by making policies that will target the global poor and vulnerable especially gender based in order to help them create communities that are resilient and robust.

Disasters caused by climate change in agriculture communities demand immediate emergency relief response and comprehensive facilities such as shelters especially in the animal farming communities. Such developments frequently involve initiatives that will provide opportunities for people to develop societies and cooperatives that are stronger and more productive and thereby becoming more self-reliant.

Adaptation and mitigation measures and strategies for climate change need to be designed and implemented through widely understood processes. Affected agricultural communities, organizations, the poor, and other vulnerable groups must be allowed to participate as stakeholders.

Global and national relevant indicators to ensure the participation of the poor and vulnerable should be developed; this could be done by keeping gender-stratified data to predict and determine the impacts of climate change on them and also their geographic locations.

Other recommendations include availability of suitable technology and decision support tools, removal of institutional barriers, and need for basic research to increase knowledge and information.

Conflict of Interest

Authors have no conflicts of interest to report.

Abstract

Brachiaria grass is a "climate smart" forage that produces high amount of palatable and nutritious biomass for livestock and performs well in infertile soils, sequesters carbon in soil, and provides several environmental benefits. The objective of the study was to validate the productivity of *Brachiaria* grass and upscale the suitable cultivars for improved livestock feed resources in Kenya. We assume integrating *Brachiaria* grass into mixed crop-livestock system will enhance feed availability and livestock productivity, leading to increased food and nutrition security. Farmer participatory approach was adopted to evaluate and promote four *Brachiaria* grass (*Brachiaria decumbens* cv. Basilisk, *B. brizantha* cvs. Xaraes, Piata, and MG-4) in the Central Highland and Eastern Midland of Kenya. The extension/advisory approaches used to promote *Brachiaria* grass cultivars included field days, village knowledge centres, agricultural shows, posters, and linkages with other institutions through multi-actor platform established under the InnovAfrica project. Generally, *Brachiaria* grass cultivars were more productive than the control (Rhodes grass) in most harvests reaching peak of 5.1–7.7 t/ha in the fifth harvest. For Rhodes grass, DM was less than 4 t/ha in all harvest and died by sixth harvest. Similarly, based on farmers' evaluation using phenotypic traits, the *Brachiaria* grass cultivars had higher score than Rhodes grass except cv. Piata. The mean score ranged from 2.75 to 3.19 for *Brachiaria* cultivars, while for Rhodes the mean score was 2.63. Within 2 years of intervention, over 4000 farmers in the 2 project sites and additional 1500 farmers from other parts of the country have planted the *Brachiaria* grass. The demand for *Brachiaria* grass seeds is increasing due to benefits gained, e.g., increased milk production from dairy cattle fed on the grass. Our study will quantify the associated benefits from cultivation of *Brachiaria* grass with respect to a set of ecological, food and nutrition security, and social-economic indicators.

Introduction

There is wide empirical evidence that livestock plays an important economic role in Kenya. The livestock subsector contributes about 12% to the national Gross Domestic Product in the country (RoK 2019). Livestock serves multiple purposes that include food and nutritional security. Livestock is sold to generate income; provide manure and draft power for crop production, skins, and transport; and serve in social-cultural function and source of prestige within the pastoral society. The effects of climate change have challenged the sustainability of livestock sector. The changing pattern and frequency of extreme climatic conditions such as droughts and floods have great impacts on livestock and the associated livelihoods (Freier et al. 2012; Schilling et al. 2012). Extreme climatic events such as droughts and heavy rains are expected to become more frequent in the Horn of Africa and part of East Africa (Christensen et al. 2007; World Bank 2013). Climate change leads to reductions in livestock productivity by indirectly compromising the availability of forages (Martin et al. 2016). The impacts on forage availability and quality may include changes in herbage growth, changes in composition of vegetation, and overall changes in herbage quality (Thornton et al. 2009).

In the mixed crop-livestock production systems where dairy farming is practiced, several forage innovations have been in use to alleviate livestock feed shortage. Napier grass is the most widely cultivated forage in the humid and subhumid regions of Kenya, and over 90% of dairy farmers depend on it, but it is threatened by smut and stunting diseases. These diseases have been reported to cause damage ranging from 5% to 90% (Lusweti et al. 2004). There is need to introduce climate smart technologies to improve resilience and sustainable livestock systems to climate change. One option is the *Brachiaria* grass which is a "climate smart" and increases livestock productivity (Muinga et al. 2016; Ngila et al. 2016).

Brachiaria is one of the important tropical forage grasses of African origin. It is widely cultivated in South America, Australia, and East Asia and has demonstrated success in transformation of beef and dairy industries (Ghimire et al. 2015). The perennial *Brachiaria* grass species produce high tonnage of foliage biomass, possess large root systems, sequester carbon into soils, is adapted to drought and low fertility soils, and provide several environmental benefits and ecosystem services (Djikeng et al. 2014; Njarui et al. 2016).

Although native to Eastern and Central Africa, its use as livestock feed has been extremely limited in the region including Kenya. Improved *Brachiaria* grass cultivars identified in evaluations conducted in Eastern Midlands (EM) region of Kenya can bridge the gap on livestock feed scarcity. However, there is limited information available on the productivity of different *Brachiaria* cultivars in different agroecological zones (AEZ) of Kenya. For instance, only a limited number of farmers are aware on benefits of *Brachiaria* grass to livestock productivity. The dry matter (DM) yield of *Brachiaria* grass varies in different AEZ and is influenced by a range of factors including cultivars, moisture, soil fertility, pest and disease, and management options. To achieve a sustainable impact of *Brachiaria* grass in Kenyan livestock sector, a wide-scale adoption of this grass is necessary. This requires selection of right cultivars for a given production environment prior to integration in the farming system, and engaging farmers in the cultivar selection would be crucial for adoption and scaling of the technology. The objective of the study was to validate the productivity of *Brachiaria* grass and upscale the suitable cultivars for improved livestock feed resources in Kenya.

Methodology

Description of the Study Area

The study was carried out in Kirinyaga County in Central Highlands (CH) and Kangundo subcounty in EM (Fig. 1). These sites differ in agroecological characteristics and diversity in farming system. *Brachiaria* grass had been tested and found to be suitable in the EM and hence was upscaled among the smallholder crop-livestock farmers who keep dairy cattle for commercial production. We adopted farmer participatory approach to evaluate and promote *Brachiaria* technologies in the CH and EM of Kenya using a novel extension approach – i.e., the Village Knowledge Centre (VKC) supported by innovative institutional approach – multi-actor platforms (MAP) that was established and being operational under the InnovAfrica project (www.innovafrica.eu). On the other hand, *Brachiaria* grasses were evaluated in the CH since no research had been conducted on this grass in the region. The biophysical, farming system and other features of study sites are described below.

Kirinyaga County: Kirinyaga is one of the counties in the CH of Kenya. It is located between latitudes 0° 1′ and 0° 40′ South and longitudes 37° and 38° East and

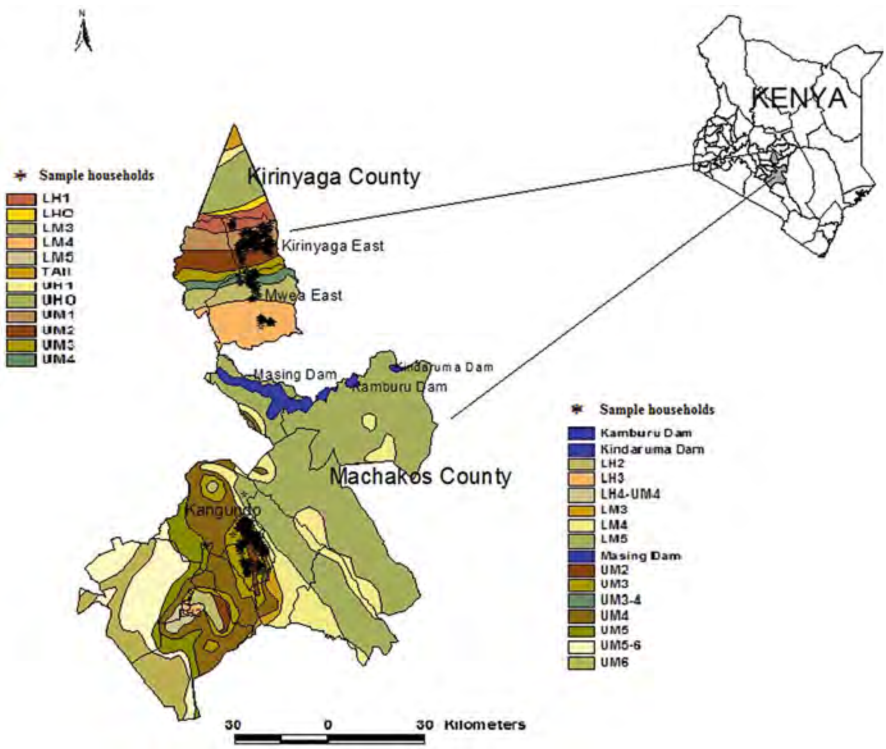

Fig. 1 Map showing project study sites

covers an area of 1478 km^2. The altitude ranges from 1200 to 1700 m above sea level (asl), but in the northern side, it rises to 5200 m at the top of Mt. Kenya. The major soil is Humic Nitosols (Jaetzold et al. 2006). According to 2009 census, the population stood at 528,054 persons comprising 154,220 households (KNBS 2010).

Rainfall is bimodal, the long rains occurring from March and May and the short rains from October to December with average annual rainfall from 1200 to 1500 mm, which is well distributed and reliable for forage production. Temperature ranges from 12 °C to 27 °C (Jaetzold et al. 2006). Farming is predominantly mixed crop-livestock system. The main cash crop are rice, tea, and coffee, while maize, beans, bananas, and sweet potatoes are the main food crops but are often sold to generate income. Major livestock are cattle, goats, sheep, and poultry. Dairy farming is an important enterprise and is based on exotic cattle and their crosses, mainly under stall feeding system. Napier grass is the main feed resource, while banana stems, sweet potatoes, and crop residues are fed during the dry season.

The *Brachiaria* grass validation trial was conducted at Kamweti Agricultural Training Centre (ATC) in Kirinyaga Country. Kamweti ATC lies on the southern slopes of Mt. Kenya at an altitude of 1755 m asl. The soil characteristics from samples taken (0–30 cm depth) indicated that the texture of the soil was sandy clay, with average pH of 4.87, total nitrogen content (0.23%) and organic carbon about 2.5%.

Kangundo subcounty: Kangundo, a subcounties of Machakos County, lies between latitudes 0° 45′ and 1° 31′ South and longitudes 36° 45′ and 37° 45′ East With altitude range of 800–1600 m asl. This subcounty has an area of 177 km^2 with population of about 94,367 (KNBS 2010). The predominant soils are Luvisols, Acrisols, and Ferralsols derived from the Precambrian “basement-complex” rocks (Simpson et al. 1996). They are often shallow, contain low organic matter and high sand content (Kusewa and Guiragossion 1989), but are well drained.

Rainfall pattern is similar to Kirinyaga County but is lower and ranges from 800 to 1050 mm annually. Inter-seasonal rainfall variation is large with coefficient of variation of between 45% and 58% (Keating et al. 1992). Temperatures vary from 14 °C to 29 °C with February and September being the hottest months and July and August the coolest months.

Maize is the most important cereal and is commonly intercropped with beans, cowpea, and pigeon pea. Coffee is an important cash crop in the Upper Midlands AEZ. The dairy cattle are mainly kept under stall feeding where feed is delivered. Improved forages such as Napier and Rhodes grass are planted but occupy only in a small proportion on the farm. Seasonal shortfall of feed resources is common due to prolonged drought and erratic rainfall and poor management of pastures.

Brachiaria Grass Validation Trial

The *Brachiaria* grass cultivars tested in this study were identified from an evaluation conducted on several accessions and cultivars in Kenya (Njarui et al. 2016). They were found to be productive and had positive responses to livestock productivity. The objective of the validation trial was to evaluate the growth and productivity of best bet *Brachiaria* grass cultivars. The validation trials were managed by researchers and were conducted at Kamweti ATC involving farmers.

Treatments, Field Design, and Management

Four best bet *Brachiaria* grass cultivars, namely, *Brachiaria decumbens* cv. Basilisk, *B. brizantha* cvs. MG-4, Piata, and Xaraes, were compared with Rhodes grass – a commonly cultivated grass in the region. The treatments were arranged in a randomized block design with three replications in plot sizes of 4 m × 5 m with 1 m alley between plots. Ten rows were planted in each plot at interrows spacing of 50 cm. The land was ploughed and harrowed to a fine tilth before planting the seeds. The seeds were drilled by hand along shallow furrows of about 0.5–1 cm deep at a rate of 5 kg/ha for all the grasses and covered lightly with soil. Triple Super Phosphate fertilizer (TSP 46% P_2O_5) was applied in the planting furrows prior to sowing the seeds at a rate of 40 kg/ha P.

The trial was established in March 2018, during the long rains (LR) season (March–May). A standardization cut was made after the end of first wet season in June 2018 in all plots to stimulate uniform plant growth. Calcium ammonium nitrate (CAN, 26% N) was applied at a rate of 50 kg N/ha/season and commenced after the standardization cut. The fertilizer was broadcasted in the plots and covered slightly using hand hoes, approximately 1 week after onset of rainy season. The plots were kept weed-free by weeding using handheld hoes until the grass were fully established.

Data Collection and Statistical Analysis

Weather and Agronomy Data

Rainfall data was recorded from the weather station near the experimental plots. The first wet seasons (LR 2018) was regarded as the establishment phase and subsequent seasons as production phase. During the production phase, the data collected included plant numbers, tiller numbers, plant height, pests and diseases damage, and dry matter (DM) yield at 8 weeks interval. Numbers of plants were determined by counting plants within a 1 m^2 frame, randomly placed over two central rows. Tiller numbers and plant height were recorded for four plants in the same quadrat. Plant height was measured for from ground to the tip of plant. Pests and diseases damage were rated on a 1–5 scale; where 0 = no damage and 5 = highest damage. For dry matter (DM) yield determination, an area of 2 m × 2 m fixed quadrat was sampled by cutting the plants to around 5 cm stubble height using handheld sickles. The fresh materials were weighed, a subsample taken where necessary, and dried at 105 °C for 48 h. The rainfall at Kamweti ATC from January 2018 to December 2019 is given in Fig. 2. The total monthly rainfall in March and April 2018 was greater than 2019 rainfall recorded during the same months, whereas October and December rainfall was higher in 2019 than in 2018.

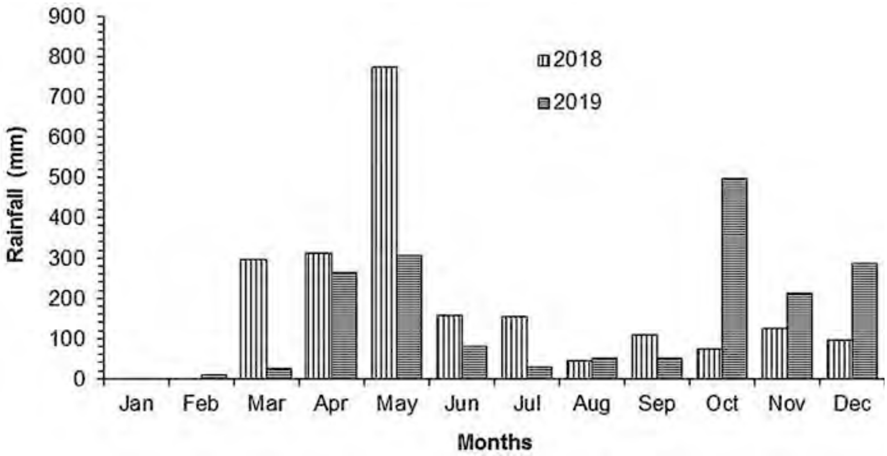

Fig. 2 Monthly rainfall during the experimental period, March 2018–December 2019 at Kamweti ATC, Kenya

Forage Quality Analysis

The herbage was analyzed for phosphorus, calcium, crude protein (CP), fibers, lignin, and ash for samples harvested in July 2019. The samples were dried at 65 °C in an oven to a constant weight and then ground with a hammer mill fitted with a 1 mm sieve, and about 200 g was preserved for analysis. Ash was determined by heating the samples at 550 °C for 8 h in a muffle furnace. Crude protein was determined using Micro-Kjeldahl according to the method of Association of Official Analytical Chemists (AOAC) (1990). The neutral detergent fiber (NDF), acid detergent fiber (ADF), and acid detergent lignin (ADL) were determined using the Ankom method of Van Soest et al. (1991).

Soil Mineral Analysis

The soil samples were taken from a depth of 0 to 30 cm in each grass plot and air-dried. Analysis was carried out for organic carbon (OC), total N, K available P, and pH. Soil pH was measured in water (soil/water ratio of 1:2.5).The N was determined following the Micro-Kjeldahl method after Bremner and Keeney (1965), while P was measured by ascorbic acid method (Watanabe and Olsen 1965). The total OC and K were measured according to methods described by Okalebo et al. (2002).

Participatory Evaluation of *Brachiaria* Grass Cultivars

The criterion for evaluation of the *Brachiaria* grasses was developed through a focus group discussion of 26 farmers randomly selected from the region. Scientists and extension officers guided the farmers. A pairwise ranking matrix was used to rank the listed plant attributes in their order of importance which were then applied in the *Brachiaria* evaluation process. At the end of wet season, 72 farmers (26 females, 46 males) participated in the evaluation of the *Brachiaria* grass cultivars and Rhodes grass in the validation trial established at Kamweti ATC. The field assessment was based on grass phenotypic traits (visual herbage production, tillering capacity, height, hairiness, and easy to cut). For each trait, farmers recorded their individual scores for each individual grass cultivars in an evaluation form using a Likert scale of 1–4, where, 1 = poor, 2 = average, 3 = good and 4 = very good.

On-Farm Evaluation of *Brachiaria* Grass Cultivars

Farmers who had previously participated in the project household baseline survey in Kangundo subcounty and Kirinyaga County were selected for *Brachiaria* grass on-farm trials. The criteria for selection of farmers were based on ownership of dairy cattle, willingness to participate in data collection, and ability of farmers to establish at least 0.1 ha of *Brachiaria* grass. The farmers were trained on establishment, management, and harvesting of the grasses. Individual farmers were provided with seeds of two cultivars (either Piata, Xaraes, or Basilisk). A total of 84 and 74 farmers received *Brachiaria* seeds in Kangundo subcounty and Kirinyaga County, respectively. Only 16 farmers were monitored in each site, and a farmer was considered as a replication. The land was prepared using local practices and sown in March and April 2018. Close supervision and monitoring was undertaken through joint action with farmers, extension, and researchers. A range of data was collected for assessment of ecological, food and nutrition security, and social-economic impact. For the ecological impact, the data collected includes *Brachiaria* biomass yield, soil organic carbon, effect of *Brachiaria* on milk production, and acreage under *Brachiaria*, while for the food and nutrition security impact, the data include availability of milk, level of consumption of milk, and dietary diversity. For the social-economic impact, the data collected include people aware of the technology, people growing *Brachiaria*, income from *Brachiaria*, and milk sales.

Strategies Used to Upscale *Brachiaria* Grass Cultivars

Different extension and advisory services (EAS) have been used to upscale the suitable *Brachiaria* grass cultivars in Kangundo and Kirinyaga counties and other areas in Kenya. Some of the EASs include VKC, field days, agricultural shows, posters, and linkages with other institutions with support of multi-actor platform. VKC is a digital-based system linking farming communities with shared interests through smart phones and social media platforms such as WhatsApp. The VKC has been adopted to disseminate technology. The process involved sensitizing farmers on benefits of the grass, providing information on planting, management, and harvesting followed by seed distribution. Each farmer was provided with seeds of two *Brachiaria* cultivars (40 g of each cultivar) enough to cover an area of 160 m^2.

Statistical Data Analysis

From the validation trial only data on plant tillers, height and dry matter yield were analyzed at each harvest. Likewise the values for forage quality were also statistically evaluated. The participatory evaluation scores from each farmer were entered in Microsoft Excel spreadsheet and a mean score for each criterion calculated for each grass cultivar by gender. The data were subjected to Analysis of Variance (ANOVA) using the statistical software GenStat 15 for windows (VSN International Ltd 2013). And where significant differences occurred, the means were separated using the Fisher's protected least significant difference (LSD) test at $p < 0.05$.

Results and Discussion

Brachiaria Grass Validation Trial

(i) *Plant Height*

Table 1 shows the mean plant height of four *Brachiaria* grass cultivars and Rhodes grass. Plant height at each harvest period varied among the grass cultivars and showed significant differences ($p < 0.05$). Rhodes grass was taller than all the *Brachiaria* cultivars in the first three harvests and in the

Table 1 Mean plant height (cm) of four *Brachiaria* grass cultivars and Rhodes grass (at 8 weeks cutting interval) at Kamweti ATC, Kenya

	2018		2019			
	Harvest 1	Harvest 2	Harvest 3	Harvest 4	Harvest 5	Harvest 6
Grass cultivars	29 Sept	20 Nov	15 Jan	12 Mar	4 July	22 Aug
Brachiaria decumbens cv. Basilisk	21.8^{B}	31.5^{B}	18.4^{B}	5.7^{A}	63.9^{B}	9.2^{A}
Brachiaria brizantha cv. MG-4	18.5^{B}	37.3^{B}	18.5^{B}	7.2^{A}	75.4^{B}	$8.9^{A,B}$
Brachiaria brizantha cv. Piata	13.5^{B}	43.0^{B}	11.0^{B}	7.0^{A}	27.9^{C}	6.4^{C}

[b]*N.S.* not significant

fifth harvest, but in the fourth harvest, there was no significant difference among grass cultivars tested (Table 1). Lack of significance difference among the grasses in the fourth harvest was mainly due to poor rainfall experienced during the growing period, which reduced the growth of all grasses. Similarly, the low plant height in sixth harvest was attributed to low rainfall and low temperatures in 2019 (see Fig. 2)

(ii) *Tiller Numbers*

All the *Brachiaria* cultivars had higher tiller numbers than Rhodes grass at all harvests (Table 2). Xaraes recorded the highest number of tillers in most of the harvests. Tiller numbers increased from less than 100 tillers/plant at first harvest to greater than 120 tillers/plant in the fourth harvest for all the *Brachiaria* cultivars and Rhodes and declined in subsequent harvest except for Basilisk which increased slightly in fifth harvest. *Brachiaria* forms a massive root development, and hence nutrient uptake is likely to be high allowing the plant to continue increase in tillers. Reduce tillers number in fifth and sixth harvest were attributed to low rainfall and temperatures (see Fig. 2). The higher tillering ability of *Brachiaria* grass than Rhodes grass is due to difference in growth habit where *Brachiaria* forms rhizomes, while Rhodes grass spreads by stolon. Moreover, number of tillers is an indicator of resource use efficiency and increases the chances of survival and influences herbage yield (Laidlaw 2005) if water and nutrients are not limiting.

(iii) *Dry Matter Yield*

Six harvests for the DM yield were conducted during the production phase (Fig. 3a–f). There were no significant differences ($p > 0.05$) on DM yield among the *Brachiaria* cultivars and Rhodes grass in the first three harvests and

Table 2 Mean number of tillers/plant of four *Brachiaria* grass cultivars and Rhodes grass (at 8 weeks cutting interval) at Kamweti ATC, Kenya

	2018		2019			
	Harvest 1	Harvest 2	Harvest 3	Harvest 4	Harvest 5	Harvest 6

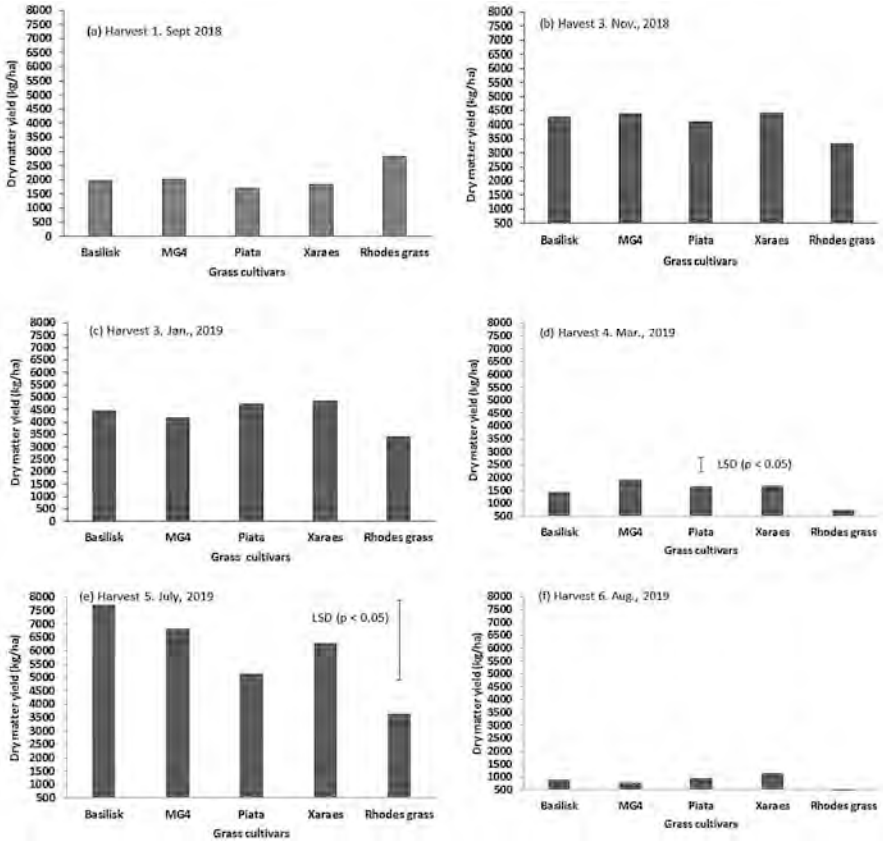

Fig. 3 Dry matter yield of four *Brachiaria* grass cultivars and Rhodes grass harvested every 8 weeks at Kamweti ATC, Kenya

sixth harvest. Significant ($p < 0.05$) difference in yield was recorded in the fourth (Fig. 3d) and fifth harvests (Fig. 3e). In the fourth harvest, all *Brachiaria* cultivars outyielded Rhodes grass, but yields were not significant different among themselves (Fig. 3). Similar studies by Nyambati et al. (2016) in an area that has unimodal rainfall pattern showed no significance difference among the same *Brachiaria* cultivars, but their yields were higher than those of Rhodes grass. However, in the fifth harvest, only Basilisk had higher ($P < 0.05$) DM yield (7.7 t/ha) than Rhodes grass (3.6 t/ha) but did not differ significantly with the other *Brachiaria* grass cultivars. Generally, *Brachiaria* yields were relatively higher in the second (4.1–4.4 t/ha), third (4.1–4.8 t/ha), and reached peak in the fifth (5.1–7.7 t/ha) harvests, and this was attributed to moisture availability. The first harvest (Fig. 3a) was conducted during the long dry season, while the fourth (Fig. 3d) was carried out toward the end of the short dry season. The second and third harvest was conducted during the wet season. The DM yields were appreciably higher than yield recorded by Njarui et al. (2016) in EM.

(iv) *Forage Quality Composition*
The result of forage quality analysis is presented in Table 3. The calcium, phosphorus, and CP content were not significantly different among the tested grasses. Significant differences were recorded in ADF, NDF, ADL, and ash content. Rhodes grass had higher ADF and NDF than *Brachiaria* grass cultivars, while the ADL content did not differ from that of MG-4. Xaraes had the highest ash content (11%), and the Rhodes grass had the lowest. However, all *Brachiaria* cultivars contained more CP than those reported from the Eastern Midland (7–10%) by Njarui et al. (2016) but were lower than that reported from a similar region – CH (12–15%) by Nyambati et al. (2016). The lower CP content from this study was attributed to difference in the sampling time as the grasses were harvested during the dry season and growth was poor. Nevertheless, CP $\geq$ 11% during the dry season is an indication that *Brachiaria* can provide good quality feed in CH. All the *Brachiaria* met the minimum level of CP required for ruminant maintenance (7%) and milk production (11%). Moreover, the NDF was below 72%, above which generally decreases DM intake. All the *Brachiaria* cultivars had lower ash content (12–15%) than those reported by Njarui et al. (2016).

(v) *Soil Nutrients*
There was no statistical significance difference ($p > 0.05$) on soil properties (pH, N, org C, P, and K) among the tested *Brachiaria* grass cultivars and the Rhodes grass (Table 4). However, the total N (0.20–0.21%) and organic carbon contents (2.2–2.3%) in all *Brachiaria* cultivars were higher than the Rhodes

Table 4 Effects of *Brachiaria* grass cultivars and Rhodes grass on soil pH, organic carbon, and nutrients (nitrogen, phosphorus, and potassium), 18 months after planting

Grass cultivars	Soil pH (1:2.5 soil:H_20)	Nitrogen (%)	Org. carbon (%)	Phosphorus (ppm)	Potassium (me %)
Brachiaria decumbens cv. Basilisk	4.84	0.21	2.28	20.0	0.09
Brachiaria brizantha cv. MG-4	4.89	0.21	2.34	18.3	0.11
Brachiaria brizantha cv. Piata	4.74	0.20	2.29	15.0	0.09
Brachiaria brizantha cv. Xaraes	5.01	0.21	2.33	21.7	0.09
Rhodes grass cv. KAT R3 (control)	4.91	0.16	1.74	20.0	0.11
LSD ($P < 0.05$)	N.S.[a]	N.S.	N.S.	N.S.	N.S.
CV (%)	3.6	13.9	15.4	22.3	15.9

[a]*N.S.* not significant

grass. The org C contents in the *Brachiaria* fields will improve the organic matter content of the soils, which in turn will enhance soil fertility and increase productivity. This makes *Brachiaria* grass suitable for adaptation and mitigation measures to climate change effects in Kenya and possibly in other sub-Saharan African countries. However, the effect of *Brachiaria* on soil pH would require relatively a longer period.

Brachiaria Grass On-Farm Trials

The mean DM yield of *Brachiaria* grass cultivar in Kirinyaga and Kangundo is given in Table 5. There were no statistical significant differences ($p > 0.05$) on DM yield among the *Brachiaria* cultivars grass within and between sites. Of the 16 farms monitored in each site, there were large variations in yield for each *Brachiaria* cultivars tested.

The large difference in yield between farms for a given cultivar was attributed to farmers' failure to follow recommended agronomic practices such as proper plant spacing, lack of weeding at establishment, limited use of fertilizer, etc. Generally, where the yields were poor the grasses were established in eroded and less fertile part of farm and no fertilizer application. In contrast in farms where the yields were high, the land was well terraced, and farmer had adopted proper soil conservation practices. Additionally, farmers had applied either cattle manure or inorganic fertilizer or both. The higher yield achieved in Kirinyaga was attributed to more rainfall experienced from June to October unlike in Kangundo where there was no rains resulting in the cessation of plant growth.

Table 5 Mean DM yield among the *Brachiaria* grass cultivars in Kirinyaga and Kangundo study sites

Brachiaria grass cultivars	Kirinyaga	Kangundo	LSD ($p < 0.05$)
	DM yield (kg/ha)

Box 1

***Effects of* Brachiaria *forage on social-economic conditions:* By August 2019 approximately 1320 smallholder farmers (18.2% females) mainly involved in dairy cattle farming had been provided with *Brachiaria* grass seeds in Kirinyaga County. In Kangundo, 720 smallholder farmers (23% were females) received the seeds. Report from field indicates that each farmer has given out splits to at least two other farmers. Conservative estimate put the numbers of farmers to over 4000 farmers implying a high rate of uptake of the technology in the project areas. Seeds were also distributed to 1200 farmers in Nyeri County and over 300 farmers in other parts of Kenya. So far, the project has not found any farmer who has abandoned growing *Brachiaria*. Farmers are enthusiastic about the grass, and a good number have expanded the acreage under *Brachiaria* grass. Farmers have also reported increase in milk production from dairy cattle fed *Brachiaria* grasses. However, there were variation in terms increase, but the values were within the range of 15–40% recorded by Muinga et al. (2016). This implies *Brachiaria* has contributed to increased milk availability for consumption at household level and for sale to generate income. However, there are plan to carry out on-farm feeding trial jointly with farmers to ascertain the actual benefits of *Brachiaria* in term of milk production. In Kirinyaga, youths have formed groups with aim of baling *Brachiaria* hay for sale to generate income. (Source: Field Survey)**

Participatory Selection of *Brachiaria* Grass Cultivars

During the FGD, farmers identified 16 plant attributes that are important when selecting grasses (Table 6). Grasses that give high milk yield when fed to livestock were ranked first followed by highly nutritious grasses while color was the least important criteria. These findings were consistent with earlier work carried

Table 6 Pairwise ranking matrix of farmers' criteria in selecting grasses for livestock production in Kirinyaga, Kenya

elsewhere in Kangundo by Gatheru et al. (2016). They reported that forages that gave high milk yield when fed to cattle and nutritionally balanced were priority traits in selecting feed for livestock. There were significant differences ($p < 0.05$) in farmers' scores for herbage, tillers, and tallness between the cultivars (Table 7). Overall, Basilisk had the highest mean score for the five attributes followed by MG-4, while Piata had the lowest. There were no significant differences on farmers' scores for hairiness and ease of cutting between the cultivars. The ranking order for the cultivars was not different between females and male farmers (Fig. 4).

Table 7 Farmers' mean scores for selected criteria from evaluation of *Brachiaria* cultivars

Upscaling *Brachiaria* Grasses Cultivars

Multi-actor Platform: The multi-actor platform (MAP) members are composed from institution in private sectors, policy makers, dairy cooperative societies, extension services, farmers, and researchers. The MAP members were involved at InnovAfrica project inception phase during planning, site selection, and development of implementation framework. The MAPs have contributed in *Brachiaria* grass validation trial particularly in selection of farmers and development of selection criteria. They participate in field project evaluation and monitoring every 6 months and provide useful feedback to correct any divergence from the planned activities. They are also involved in upscaling of *Brachiaria* grass technologies through field days and distribution of seeds. For example, one MAP member who is committee of Mukurwe-ini Wakulima Dairy Cooperative Society has distributed seeds to over 1200 farmers who are members of the society in Nyeri County.

Village knowledge Centre: One VKC was established in Kangundo village of Kangundo subcounty in May 2018. From May 2018 to December 2019, a total of 530 people (comprising of farmers, extension agents the public sector, and non-governmental organization) and other stakeholders visited the VKC (Fig. 5) primarily to get information on *Brachiaria* grasses and on other issues (e.g., horticulture, poultry, bee, rabbits, microfinance). Most of the visitors to the VKC were over 50 years old. The VKC has connected over 300 farmers on social media (two WhatsApp Group). These have provided a platform where information on cultivation of *Brachiaria* grass including management, conservation, and feeding is shared. However, social networking is an important mean for promoting technology adoption (Brhane et al. 2019).

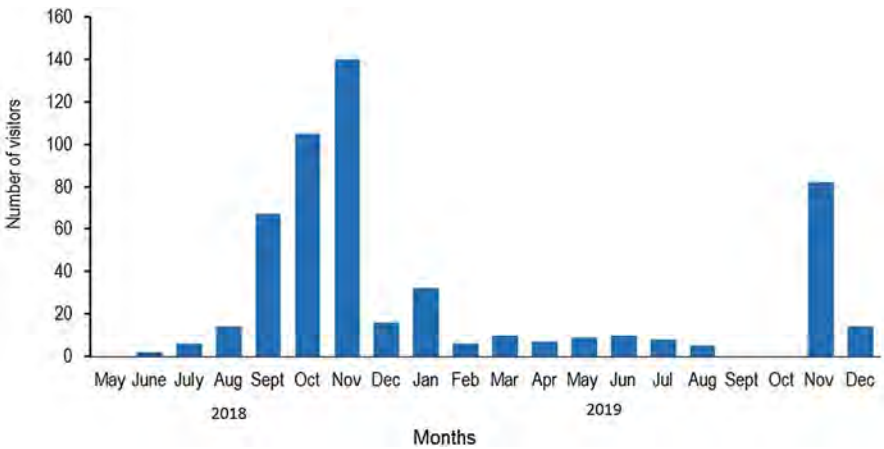

Fig. 5 Number of visitors to the Village Knowledge Centre from May 2018 to December 2019 in Kangundo, Kenya

Box 2 Other *Brachiaria* Upscaling Strategies Adopted

Field days: In May 2018, a farmer field day was held in Kangundo village to provide first-hand information to farmers and relevant stakeholders on *Brachiaria*-livestock value chain and related technologies and its impact on the feed security and livestock productivity. A total of 93 people representing smallholder dairy farmers, members of a small-scale dairy processing group, County extension agents, local leaders, and InnovAfrica partners attended.

Agricultural show and exhibition: InnovAfrica project participated in Agricultural Show of Kenya (ASK), Machakos Branch, in June 2018 and 2019 to create awareness on the *Brachiaria* technologies. The grasses were planted in small plots within the ASK ground for exhibition to farmers. Posters with details on the establishment, management, and nutritive quality of the grasses were also displayed. In 2018 an estimated 770 show attendants (farmers, scholars, and students) visited the *Brachiaria* grass plots, and the number increased to 1050 in 2019.

Posters: The project has also adopted posters to create farmer awareness on the availability of *Brachiaria* grass seeds for planting. Over 550 and 770 posters written in vernacular were distributed in Kirinyaga County and Kangundo subcounty, respectively. The posters were displayed at strategic locations where they were easily visible. This included trees along rural roads, in market centers, petrol stations, churches, dairy cooperatives, premises, and other public buildings where the local people visit frequently.

Agricultural Training Centre: The project has partnered with Kamweti ATC and Wambugu ATC in Kirinyaga and Nyeri Counties, respectively, to accelerate the upscaling of *Brachiaria* grass technology. These Centers normally organize field days, trains farmers, and conduct demonstrations on proven technologies on crops, forages, and livestock. The role of the ATCs is to bulk the *Brachiaria* grass and distribute splits to farmers.

Conclusions and Way Forward

This study is a farmer led experimentation to test *Brachiaria* grass for livestock production in Kirinyaga County and upscaling it in Kangundo subcounty. The validation trial showed that all the *Brachiaria* grass cultivars were more productive than the control (Rhodes grass) in most of the harvests. Similarly, based on phenotypic traits used by farmers to evaluate the grass, all the *Brachiaria* grass cultivars had higher mean score than Rhodes grass. Thus, *Brachiaria* has a potential to improve the feed availability in the region tested and other areas of Kenya and enhance food and nutrition security. The org C contents in the *Brachiaria* fields will improve the organic matter content of the soils which in turn will enhance soil fertility and increase productivity. This makes *Brachiaria* grass suitable for use in adaptation and mitigation measures to climate change effects in Kenya and possibly in other SSA countries. Over 4000 farmers are now engaged in cultivation *Brachiaria* grass in the study sites and additional 1500 farmers in other parts of Kenya, because of increased awareness by the InnovAfrica project using innovative EASs including VKC, ASK, posters, social media, and MAPs engagement. The demand for *Brachiaria* seeds is increasing due to benefits gained in terms of increased milk from livestock fed on the grass. Nevertheless, there is need to continue to upscale *Brachiaria* grass using already existing avenues and/or establish new ones.

W. Leal Filho et al. (eds.), *African Handbook of Climate Change Adaptation*,
https://doi.org/10.1007/978-3-030-45106-6_148

role to play in climate change adaptation and is central towards achieving Africa Water Vision 2025, and the targets set for the 2030 Agenda for Sustainable Development as well as the Kenya Vision 2030. There are fundamental challenges that need to be addressed in order to achieve sustainable water resources management, mainly, the inherent uncertainty associated with the changing climate, the inflexibility in infrastructure and institutions that manage water, and the poor integration of all stakeholders and sectors in water resources management. This study investigates the challenges and opportunities in implementing integrated water resources management and its critical role towards climate change adaptation. A preliminary assessment of sustainable management of water resources and its role in effective climate change adaptation and resilience building in Kenya is carried out through questionnaire survey and stakeholder interactions. Climate change-induced uncertainty, diminishing water sources aggravated by growing water demand, weak institutional and financial governance, and lack of transparency and stakeholder inclusiveness are identified as the main challenging factors that need to be addressed to build a climate resilient society. The study furthermore emphasizes the critical role of water management in achieving Agenda 2030, the Paris Agreement on Climate Change, and the Sendai Framework for Disaster Risk Reduction.

Keywords

Climate change · Water resources management · Climate change adaptation · Climate resilience · Sustainable development · Agenda 2030

Introduction

Our climate is changing and is affecting societies and their livelihoods (IPCC 2018). Climate change translates to water crisis in our everyday lives through the increasing uncertainty in water availability, decreasing water quality, and increasing competition over diminishing water resources (UN-Water 2019). According to the World Economic Forum's 2015 assessment of global risks, water crisis was ranked number one with the potential to severely affect poor and vulnerable population across countries and sectors (WEF 2015). As climate change impacts intensify and the populations and their water demands grow, water stress is likely to increase.

The International Food Policy Research Institute has warned the global community that if business-as-usual continues, by 2050, about 4.8 billion people and approximately half of the global grain production will be at risk because of water stress (Water Resources Group 2016). According to FAO (2013), the rate of increase in water use is more than twice the rate of increase in population during the last century. This increase in water use combined with climate change-induced uncertainty in water availability will aggravate the situation of regions that are already under water stress.

This decade marked a surge in global floods and extreme rainfall events by more than 50% with an occurrence rate that is four times higher than in 1980 (EASAC 2018). According to the Organization for Economic Cooperation and Development (OECD) Environmental Outlook (OECD 2012), the number of people at risk from floods by 2050 is estimated to be about 1.6 billion, and the associated economic risk is expected to be around US$ 45 trillion.

The UN World Water Development Report (WWAP 2019) findings show that the number of people affected and the number of people killed by water-related emergencies such as inadequate water and sanitation, droughts, and flooding are much higher than that due to earthquakes and epidemics and conflicts globally. According to EM-DAT (2019), during the past two decades, floods and droughts have caused more than 166,000 deaths leading to a total economic damage of about US$700 billion.

In Africa, the increase in floods, droughts, and storms has severely affected the livelihoods of population through lack of safe and clean drinking water, crop failures, food shortages, lack of clean energy, etc. According to the World Bank report (2019), Africa has experienced increasing climate and water risks with more than 2,000 natural disasters since 1970, of which about 1,000 happened in the last decade. According to OECD (2012), between 75 and 250 million people in Africa are projected to be under increased water stress, and agricultural production can reduce by up to 50% in some regions by 2020. The rainfall projections in Africa indicated that Southern Africa will become drier and Eastern and Western Africa will become wetter with increased risk of floods (UNDP 2018). The recent water crisis in South Africa, the food crisis in Sahel, and disastrous cyclones in Mozambique are reminders of society's vulnerability and unpreparedness in the wake of climate change reality, which in most of the cases are aggravated by incompetent institutional and financial capacities.

According to the UN Environment Adaptation Gap Finance Report (UNEP 2018), the global estimates of the costs of climate change adaptation in developing countries are between US$140 billion and US$300 billion by 2030 (which is two to three times higher than the earlier estimates cited in the Intergovernmental Panel on Climate Change [IPCC] report). By 2050, the estimates can plausibly be four to five times higher – US$280 billion to US$500 billion. For Africa, this would mean that the resources that would have otherwise directed for economic growth, to overcome poverty and to achieve the United Nations Sustainable Development Goals [SDGs] are now to be diverted toward climate change adaptation and resilience building initiatives.

East African Community and Climate Change Impacts

Climate model projections for East Africa indicate that rainfall and temperature will become extreme and intense in the future affecting both the quantity and quality of surface and groundwater in the region. This will severely affect the accessibility to safe and clean drinking water, health, food security, and energy resources (EAC and USAID 2018; Luwesi and Di Luyundi 2019). Adapting to these changes will require not only accurate knowledge of the frequency and severity of the extreme events but also planning and implementation of critical interventions to curb disasters across the East African Community (EAC). Moreover, this is highly important for the smooth implementation of the water targets of the African Union Agenda 2063, the Africa Water Vision 2025, and the 2030 Agenda for Sustainable Development, including the Kenya Vision 2030. The EAC has thus a long way to go for eliminating poverty, hunger, and food insecurity to give its citizens the right to healthy and productive lives.

Kenya: Country Climate and Water Profile, Climate Change Impacts

The National Water Policy of Kenya was developed in 1999 and based on that Water Act was established in 2002 (National Water Master Plan 2030 2013). The constitutional reforms of 2010 in Kenya introduced decentralization policy which came into effect in 2013 (Alexis and Lumbasi 2016). Since then the country has undergone significant transition through devolving governance to the 47 newly established counties. Moreover, the country's 2016 Climate Change Act formulated a comprehensive law and policy to guide national and subnational responses to climate change. The Water Resources Management Authority (WRMA) was reformed to Water Resources Authority (WRA) with a mandate that includes regulation, protection, and dissemination of information on water resources. Furthermore, WRA undertakes climate actions in terms of mitigation and adaptation to minimize the effects of global warming and climate change.

With the projected increase in temperature of about 2.5 °C between 2000 and 2050, and with rainfall becoming more intense and less predictable, Kenya is considered as very vulnerable to the impacts of climate change. The arid and semiarid lands (ASALs) in the north and the east of the country are particularly at risk because of the increased occurrence of drought and the associated food and water security challenges. The increased frequency of droughts, floods, and landslides in the Rift Valley Province and the increased floods and saltwater intrusion in the coastal areas are also posing challenges that demands efficient actions at national level to improve the adaptive capacity and resilience of the population (Government of the Netherlands 2019).

About 80% of the country's geographical area is arid or semiarid, and the main source of sustenance is pastoral and subsistence agriculture. The livelihoods of the poor are severely affected by the climate crisis and are having a severe impact on country's socioeconomic development (Mwendwa and Giliba 2012). A questionnaire survey conducted by Mwendwa and Giliba (2012) found recurrent droughts and changes in rainfall patterns to be the most important indicators of the effects of climate change and food shortage, hunger, famine, water scarcity, low yields, and high poverty levels as the most important impacts of climate change in Kenya.

According to Ng'ang'a (2006), the 2004/2005 drought resulted in a prolonged famine in the less rainfall areas in the country. Decreasing lake surface area, for example, in the case of Lake Naivasha, has affected water quality, quantity, and navigability and has affected its biodiversity (Mironga 2005).

In urban areas, the impacts of climate change are visible mainly in informal settlements, where the risks arising from droughts and floods are severe. The risks in rural areas arise because of the dependence of rural population on the increasingly diminishing and degraded water sources. The major challenges faced by the peri-urban and rural population are the limited management capacity and low operating revenues. According to Mureithi et al. (2018), the lack of access to finance is also a major constraint as funding tends to be generally allocated to develop new water systems in very low-income areas with poor access rather than on restoring an already existing but poorly performing water supply scheme.

Wise Water Management Toward Climate Change Adaptation

It is crucial to acknowledge that water is not just a sector that has been impacted by climate change. The central role of water in adapting to the climate change-driven variations has been increasingly recognized over the past decade. However, water's ability to address climate change adaptation still faces many challenges. The inherent uncertainty associated with the changing climate, the inflexibility in infrastructure, and institutions that interact with water, in addition to the lack of an integrated approach in water resources management, are the fundamental challenges that need to be addressed at global, regional, and local scale (UN-Water 2019).

Water is inextricably linked with food and energy. Addressing climate change adaptation through effective water management is an opportunity by which the governance, infrastructure, and financing mechanisms can be transformed, leading to a holistic development of the community. It is highly important that the national policies should reflect on climate change adaptation strategies that are being followed in similar hydroclimatic parts of the world and at the same time incorporate the locally developed adaptation techniques to improve its climate resilience. Increased water stress coupled with increasing future water demands will require tough decisions on how to allocate water resources between competing water uses, including for climate change mitigation and adaptation.

Wise water management can be achieved through effective, efficient, and participatory management of water resources. Scarcity of water leading to drought can be addressed through increased rain water harvesting and water storage to capture the minimal available water at the source. These water harvesting structures will also aid in enhancing groundwater recharge, thereby improving the resilience of the society to future low surface water availability. In order to address the problems of excess water because of floods, the Water Resources Authority is in the process of developing plans to prepare the society towards flood disasters.

Application of innovative climate technology on the ground through sensor data, models, and weather forecasting improved water distribution systems, avoiding leakages and thereby decreasing loss through nonrevenue water are delivering positive outcomes. According to a recent report (Global Center on Adaptation 2019), researchers at Jomo Kenyatta University of Agriculture and Technology in Kenya in collaboration with Wageningen University and Research in the Netherlands is planning to launch the Climate Atlas, a localized weather monitoring system, with the aim of providing local rainfall and temperature projections across the 47 counties in Kenya for the period 2050–2100. The overall aim of this project is to protect Kenya's food supply for the future years. Another report by UNFCCC (2019) discussed a readiness proposal by Ghana on "Integrated Climate Monitoring and Early Warning System" aimed at strengthening the country's capacity to build an early warning system for droughts. In cities, nature-based solutions through restoration of degraded ecosystems in the buildup areas can improve the adaptive capacity. The city area can be envisaged as a catchment unit, and the effective capturing and managing of stormwater can make the city more resilient.

Climate Resilience Through Water Management

Adapting to climate change after the occurrence of a disaster is a reactive approach. Building resilience on the other hand is the ability to adapt to and transform and recover from that hazard in a timely, efficient, and sustainable manner. The first step towards achieving resilience is to have access to the relevant information, for example, through public campaign or by collaborating with established networks. Participatory vulnerability assessments at grassroots level are critical. Furthermore, resources should be available to make assessment and to ensure and facilitate processes leading to resilience. For instance, one need to prioritize the most critical climate change impact in a region based on the exposure, sensitivity, and adaptive capacity of the population to that impact. Based on that, a monitoring and evaluation system has to be designed and organizational capacity need to be build. Ensuring political commitment as well as facilitating implementation of public private partnerships can aid in short-term development of resilience. The final step is to develop necessary institutional arrangements that support long-term adaptation measures.

In Kenya, the relevant policy and legislative framework has been put in place to guide the country's response to the challenges of climate change. Climate change adaptation and resilience has been set in the National Adaptation Program (NAP) and is operationalized through the National Climate Change Action Plan (NCCAP). This is done by mainstreaming adaptation across all sectors in the national planning, budgeting and implementation processes, and taking cognizant of the fact that climate change is a cross-cutting sustainable development issue with economic, social, and environmental impacts (GoK 2016). The other policy documents include the National Drought Management Authority Act 2016, National Policy for Disaster Risk Management 2013, the National Climate Change Response Strategy (NCCRS) 2010, and the Climate Change Act 2016.

Climate resilience through effective water management can be achieved through sustainable implementation of integrated water resources management. Functional water governance mechanisms can reduce disasters and build capacity for adaptation and thereby improve resilience. Locally designed and implemented water storage and flood control structures and nature-based solutions, for instance, lakes as natural water storage structures and floodplains as natural excess runoff absorbers, are some examples on climate resilience through wise water management. Healthy ecosystem services are dependent on well-functioning river basins, which in turn can support agriculture and fisheries, wastewater treatment, drinking water provision, groundwater recharge, and coastal protection among others. In Zambia, the natural underground water reservoirs were protected through proper waste disposal, hence improving aquifer health and usage, thereby benefiting the local population in Lusaka (IWA 2019).

Building resilience through empowerment of the climate change-affected community has been reported in many parts of the world. One such example is the Osukuru United Women's Network in Uganda (Global Resilience Partnership 2019). The major climate change impact faced by this community was flooding and the associated displacements and health issues. This women's network initiated campaigns and improved the resilience of the community by building trenches around the houses to prevent floodwater from entering their homes. With more and more people joining this network, the success rate is high. However, there are challenges in the sustainable functioning of the network, for instance, financial viability, capacity building, training, mobility, etc. Enhanced climate resilience thus includes strong economic growth, resilient ecosystems, and sustainable livelihoods. It is noted that through climate financing (Odhengo et al. 2019) and public-private partnerships, there will be opportunities for progress in Kenya

The core approach in building resilience includes creating awareness, building social capital, improving technical capacities, and thereby empowering the community. Community-based vulnerability assessment and development of resilience action plan and promoting joint action through multi-stakeholder groups aid in faster adaptation. Furthermore, by making the livelihood-dependent economies diverse and flexible can also improve the community's resilience to climate change. Knowledge, learning, innovation, and clean technology are key towards achieving climate resilience. Smart agricultural technology such as integrated weather and market advisories inform farmers on what and when to grow and harvest, where to sell their produce, etc.

Questionnaire survey and stakeholder discussions including governmental, non-governmental, and other organizations in Kenya are ongoing. According to the survey results, climate change impacts that are being experienced in the region are manifold – floods, droughts, storms, and its associated impacts on the society and the ecosystem. One major impact is on agriculture and food production, especially on the subsistence farming. Decline in agricultural produce has reduced the marginal GDP in the agriculture sector. This along with the fluctuations in world market prices and changes in geographical distribution of trade regimes has caused an increased number of people at risk of hunger and food security. Extreme weather conditions have affected water supply and water quality, thereby affecting human health. The increased demand coupled with the decreasing supply of source water resources has led to conflicts over water sharing. The timely dissemination of relevant climate information to the most vulnerable sections of the society is yet another major challenge that needs to be addressed.

The sustainable management of water resources faces major challenges because of climate change-induced uncertainty, diminishing water resources, increased water scarcity, and lack of protection of water sources through regulation. Community engagement and stakeholder participation especially from the vulnerable communities are crucial, and ownership and control of water resources are found to have resulted in more active participation of stakeholders. Incorporation and mainstreaming of innovation and technology are increasingly applied but have more scope for improvement. Climate change adaptation through rainwater harvesting, water storage development, and climate smart agriculture is followed by communities with support from government. The major constraint in the wise management of water resources is the long-term sustainable finance and funding mechanisms.

Kenya has identified climate change and disaster risk management as two of the three thematic areas in their National Plan. The nationally determined contributions (NDC) identify mainstreaming of climate change adaptation in the water sector as one of the priority adaptation strategies (Ministry of the Environment of the Republic of Kenya 2013). Adaptation strategies include development of water resources monitoring and early warning assessments.

Water: A Cross-Cutting Factor in Agenda 2030 SDGs

The achievement of Agenda 2030 Sustainable Development Goals are dependent on improved and sustainable water management (UNESCO and UN-Water 2020). There are multiple interlinkages of SDG 6 on water to the other 16 SDGs and also intralinkages within the SDG 6 connecting water and sanitation, water quantity and quality, IWRM, and community engagement in IWRM. The institutional and financial investment in achieving SDG 6 through resilient water management will inherently advance the progress of other SDGs through: overall poverty reduction (SDG 1); water security supporting the food and agriculture sector and thereby eradicating hunger (SDG2); quality water toward good health (SDG3); safe, segregated toilets and menstrual hygiene improves girls' access to education (SDG 4); gender equality in public and working life (SDG 5); access to energy and hydropower as one solution for sustainable energy (SDG 7); inclusive and productive economic growth and employment through water (SDG 8); resilient and sustainable water infrastructure (SDG 9); reduced inequalities through accelerated and inclusive action on water supply and sanitation (SDG10); sustainable and equitable urban development (SDG 11); equitable use and efficient water resources management (SDG 12); combating climate change impacts through climate-resilient water resources management (SDG 13); water quality and water resources management upstream on the land and along the rivers impacts coastal and marine ecosystem (SDG 14); increasing sustainable management of soil (SDG 15); promoting peaceful societies and accountable and inclusive institutions through effective water governance (SDG 16); and building commitments and accountability in the water sector, institutional coordination of water programs, mobilizing funding, and improved technology through strengthened means of implementation (SDG 17). Acknowledging the significance of water in these interlinkages and increasing efforts in addressing the challenges to achieve SDG 6 will automatically advance progress in climate change adaptation through wise water resources management and will help build resilient communities.

Although water is not explicitly mentioned in the Paris Agreement or in the Sendai Framework, it is important to acknowledge its relevance in achieving most of the mitigation and adaptation strategies and targets. The United Nations Framework Convention on Climate Change (UNFCCC) assessed the link between climate change and integrated water resources management such as watershed protection, waste- and stormwater management, water conservation, recycling, and desalination (UNFCCC 2019), where water governance is emerging as a leading domain for resilience to climate change.

Conclusion

Climate change primarily impacts society through several disasters, such as floods, droughts, storms, etc. which then severely affects human security and socioeconomic development of the region. Building and enhancing resilience to these disasters through effective water management are crucial, and water can play a major role in achieving effective climate change adaptation. Furthermore, disasters are recognized as opportunities to revitalize livelihoods, environment, and economies that can then lead to communities that are more resilient.

Innovative technologies in water supply and management and active participation of civil society, government, and private sectors can improve urban resilience. An integrated water resources management is imperative for attaining both rural and urban resilience as it safeguards their livelihoods and food security. It is also essential to ensure inclusiveness and meaningful participation of all stakeholders and include indigenous adaptation practices and traditional knowledge.

National and regional climate policy and planning should follow an integrated approach to climate change and water management. It is extremely important that the national adaptation strategies assist the vulnerable sections of the society and improve their resilience to the climate change impacts. Furthermore, increased investment is needed in institutions, capacity development, better data collection, assessment, and sharing.
