
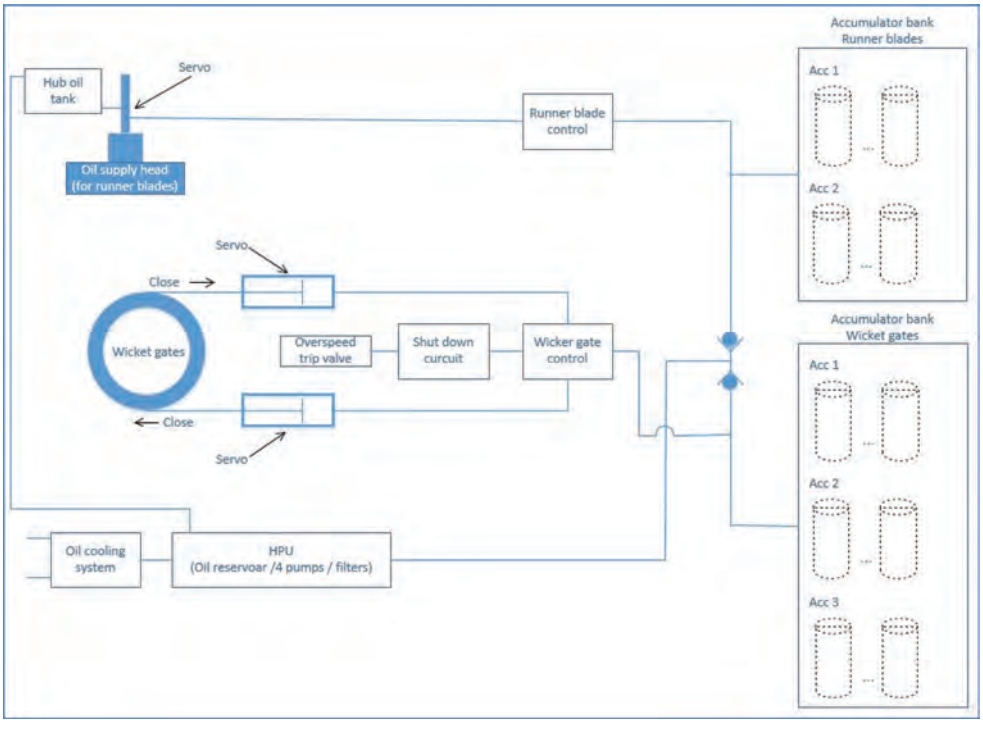

Figure 2. Simplified view of the hydraulic system.

tank and the hub oil are not a part of the high-pressure circuit, but a leakage in the runner blade servo will influence the oil level in the hub oil tank and will eventually sound an alarm or stop signal.

4 MODELS OF NORMAL BEHAVIOUR

An industrial component or system can be stressed due to normal operation, extraordinary operation and extreme environmental conditions or to a combination of all. Over time, these facts along with ageing factors can produce different ranges of typical values observed in measured variables even when the functional objectives of the component or system as expected have been reached (Sanz-Bobi, 2011). However, when a component has been stressed or overloaded over time, an increasing risk of occurrence of a failure is probable. For this reason, it is important to characterize the normal behavior expected for an industrial component or system when it is performing its function under several typical working conditions, because any deviation with respect to this behavior could alert about the presence of an incipient failure. The sooner this is detected, the sooner it is possible to mitigate the effect of a failure.

This section describes real examples of normal behavior models. These models are able to characterize the typical dynamical evolution of variables when the component is working under different operating conditions without symptoms of failure or stress.

In particular, the models developed and presented as an example in this paper, are based on information collected in real-time from a hydraulic power plant located in Norway. The models developed use neural networks based on multi-layer perceptrons (Bishop, 1995; Kruse, 2013) because this is a method able to approximate non-linear relationships among variables.

An basic model to characterize the normal behavior of the hydraulic power plant can be expressed by function *f* in Equation 1

$$P = f(GVP, WF, HW - TW) \tag{1}$$

where:

P: Power generated by the power plant in MW

GVP: Guide Vane Position in percentage

WF: Water flow through the turbine in m^3/s

HW-TW: Difference between headwater and tailwater levels in m.

Equation 1 tries to predict the power generated as function of the values of the main variables contributing to the power generation.

In order to build a normal behavior model characterizing the function *f* in Equation 1, a training set was selected covering different seasonal conditions from January 1 to August 20, 2015. The data set is based on hourly values for the variables considered. The model was developed with a multi-layer perceptron based on one hidden layer containing 20 neurons and using the Levenberg–Marquardt algorithm for learning. The model obtained is very good, as it can be observed in Figure 3, where the estimated values for the power generated and the real values observed are almost identical. The mean value of their difference (error of the trained model) is 0.0012 MW and the standard deviation is 0.067 MW. This error is distributed according to a normal distribution with narrow shape.

An interesting family of models will be presented in the following for the characterization of the normal relationships that exist between the tank oil level of the turbine regulator and variables observed in different components of the turbine regulator that uses this oil. It is important to monitor that the oil in the tank is at the expected level, because if this is not the case, a possible leakage could be present.

The first normal behavior model of the family that was tested is described in Equation 2 using the function *f*1.

$$OTL = f1(P, OTT, A1TR) \tag{2}$$

where:

OTL: Oil tank level in the HPU in percentage

P: Power generated by the power plant in MW

OTT: Oil tank temperature in ºC

A1TR: Oil level in accumulator 1 of the turbine runner.

Equation 2 tries to predict the oil tank level in the HPU of the turbine regulator knowing the working conditions of the plant, the level of one oil accumulator of the turbine runner and the temperature of the tank oil.

The model for *f*1 was obtained with a similar architecture as for *f* in Equation 1. Also, the same dates as in the previous case were used to obtain the samples of the training set. The model obtained is good, which can be observed in Figure 4 where the estimated values for the oil tank level and the real observed are very close. The oil tank level is measured in percentage (%). The mean value of their difference (error of the trained model) is 0.0007% and the standard deviation 0.0644%. This error is distributed according to a normal distribution shape.

The hydraulic power plant studied has another similar accumulator given the number 2 in the turbine runner. A normal behavior model was fitted and the results obtained were very similar to those obtained for accumulator 1 of the turbine runner.

Other important components in the turbine regulator of the hydraulic power are three oil accumulators for the guide vanes. These are very important for the correct regulation of the hydraulic turbine. Three models, one considering each of the oil accumulators, were developed such as in Equation 2. For simplicity, only one of them will be presented. Equation 3 describes it using function *f*2.

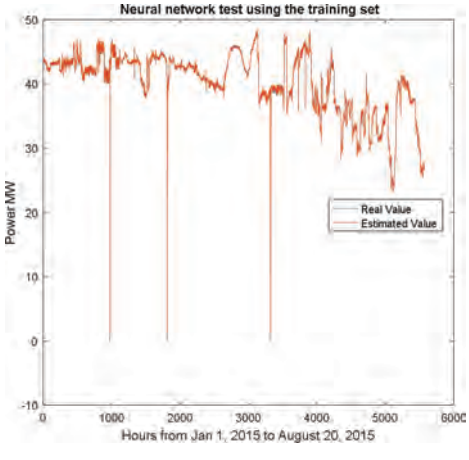

Figure 3. Estimated value for power generated predicted by the normal behavior model and the real value observed for the training set using the guide vane position, the flow through the turbine and the difference between headwater and tailwater level.

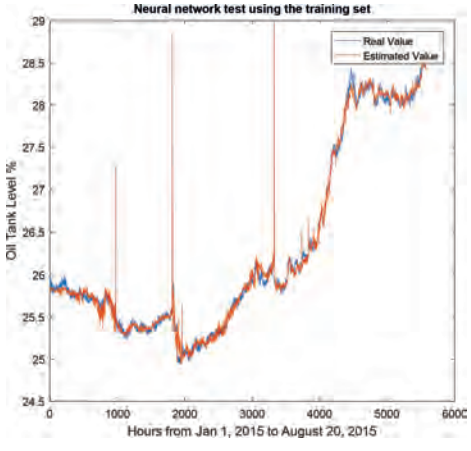

Figure 4. Estimated value for oil tank level in percentage predicted by the normal behavior model and the real value observed for the training set using as inputs the power generated, the oil tank temperature and the oil level in accumulator 1 of the turbine runner.

$$OTL = f2(P, OTT, A3GV) \quad (3)$$

where:

OTL: Oil tank level in percentage

P: Power generated by the power plant in MW

OTT: Oil tank temperature in ºC

A3GV: Oil level in the accumulator 3 for the guide vanes.

Equation 3 tries to predict the oil tank level in the turbine regulator knowing the working conditions of the plant, the level of the oil accumulator 3 for the guide vanes and the temperature of the tank oil.

The model for *f*2 was obtained following the same method as in the previous cases described. However, the main difference was that the data used in the training set covered the period from April 9, 2016 to October 13, 2016, because before that period some measurements of the oil accumulators of the guide vanes were not collected correctly. In any case, more than half of this period overlaps with the one used for obtaining *f* and *f*1. The model resulting for *f*3 obtained is good, as it can be observed in Figure 5 where the estimated values for the oil tank level (in percentage %) and the real observed values (in percentage too) are very close. The mean value of their difference (error of the trained model) is 0.0022% and the standard deviation 0.09%. This error is distributed according to a normal distribution shape.

Good results were also obtained for the two models that are similar to the one in Equation 3, where the variable oil level in accumulator 3 has been changed to the oil levels in the corresponding accumulators with numbers 1 and 2, respectively.

5 ANOMALY DETECTION BASED ON PATTERNS OF NORMAL BEHAVIOUR

Once a normal behavior model has been elaborated, it can be used in real time with real-time values from the required inputs. The output from the model can then be compared with the corresponding real measured output variable. The prediction will correspond to the expected value for normal behavior under the current working condition. Any incipient failure will produce a deviation between the expected value and the real value measured of the monitored variable. This section presents how the normal behavior models obtained in the previous section respond to new inputs of data collected after the training set dates. This will allow for the discovery of abnormal behavior different to the one expected.

Model *f* was used with data not contained in the training set, covering the period from November 25, 2015 to May 31, 2017. Figure 6 shows the results obtained by the model. The real behavior observed is very near to the predicted one and this confirms that the behavior observed in this new period of time is similar to the previous one in the training set. No abnormal behavior was detected in the power generation according to model *f*. The mean value of their difference (error) is –0.017 MW and the standard deviation is 0.7 MW. Both are higher than what was obtained for the training data set, but the prediction is still reasonable. Also, this error is distributed according to a normal distribution shape.

Furthermore, model *f*1 was used with data not contained in the training set, covering the period from November 25, 2015 to May 31, 2017. Figure 7 shows the results obtained from the model. The real behavior observed is near to the predicted

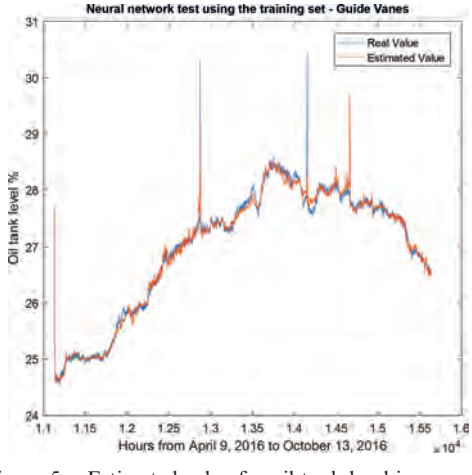

Figure 5. Estimated value for oil tank level in percentage predicted by the normal behavior model and the real value observed for the training set using the power generated, the oil tank temperature and the oil level in accumulator 3 for the guide vanes.

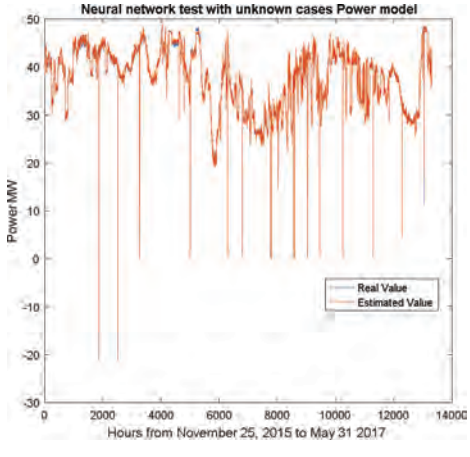

Figure 6. Estimated value for power generated predicted by the normal behavior model and the real value observed for the testing data set using the guide vane position, the flow through the turbine and the difference between the headwater and tailwater levels.

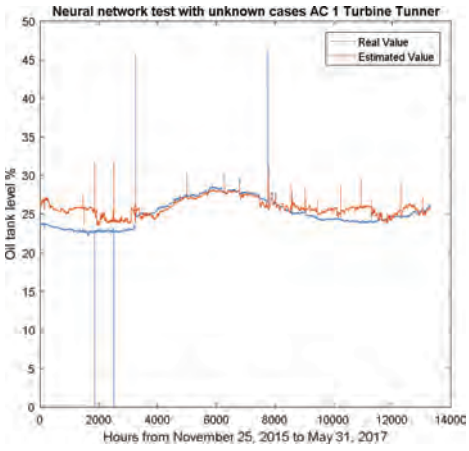

Figure 7. Estimated value for oil tank level in percentage predicted by the normal behavior model and the real value observed for the testing data set using as inputs the power generated, the oil tank temperature and the oil level in accumulator 1 of the turbine runner.

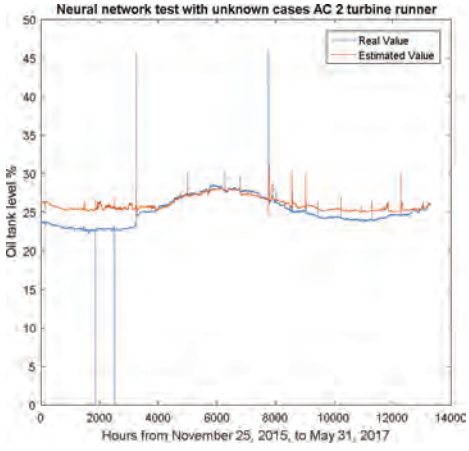

Figure 8. Estimated value for oil tank level in percentage predicted by the normal behavior model and the real value observed for the testing data set using as inputs the power generated, the oil tank temperature and the oil level in accumulator 2 of the turbine runner.

one in some cases in the central part of the figure and different in the rest of the period studied. This means that the behavior observed in the training data set is different from the one observed in the new test data set at some periods. An abnormal behavior was detected in the relationships between the output and input variables of this model for the test period. Once this was detected, it became necessary to investigate the cause.

The cause of abnormal behavior detected that is breaking the relationship modelled by *f*1 can be any of the variables used in this model. The variable power generated cannot be the cause due to the test carried out in model *f* and presented in Figure 6 which confirms that no abnormal generation of power exists. The rest of the variables could be candidates to be anomalous and they are related with the oil tank (level and temperature) and the accumulator 1 level of the turbine runner.

A model similar to the one presented in Equation 2 was developed replacing the variable A1TR (Oil level in accumulator 1 of the turbine runner) by another equivalent model, but measuring the oil level in accumulator 2 of the turbine runner. The model obtained was very good and similar to that presented in Figure 4. This model was checked with data not contained in the training set, covering the period from November 25, 2015 to May 31, 2017 as for accumulator 1 of the turbine runner.

The result is presented in Figure 8. The profile between predicted and real oil tank levels are almost the same in Figures 7 and 8. The same broken relationship is shown between the oil tank level and the oil level in accumulators 1 and 2 of the turbine runner. This induces the thought that it is not probable that the problem of the abnormal behavior observed is due to some anomaly in both turbine runner accumulators at the same time and it is therefore convenient to closely monitor the oil tank level.

In this way, model *f*2 was also tested with data covering the period from October 14, 2016 to May 31, 2017. This period includes data from sample 8000 till the end of the graphics in both Figures 7 and 8. Figure 9 presents the results of the application of model *f*2 to the data set mentioned. The discrepancy between predicted and real values for the oil tank level is clear. This is lower than expected for the working conditions of accumulator 3 of the guide vanes. In fact, it seems that the difference between the real and expected values for the oil tank level is increasing over time, except in the last part of the graphic in Figure 9 where the real and expected values are approaching.

Two similar models to *f*2 were built and tested during the same periods of time replacing the variable A3GV (Oil level in accumulator 3 for the guide vanes) by other equivalent elated respectively to accumulators 1 and 2 for the guide vanes. The results were similar.

According to the results obtained, all five models applied for anomaly detection in the oil tank level (three of them presented in Figures 7, 8 and 9) coincide in that they indicate a lower level of oil over time. This is an indicator of a possible leakage of oil in the oil tank level or surrounding locations. The accumulators are working as expected, but the total oil level in the tank of the HPU is decreasing. This was verified and a leakage was discovered from the oil side to the nitrogen side of the accumulators.

These examples demonstrate that the deviation values obtained from the comparison of the real value and predicted one by the patterns of normal

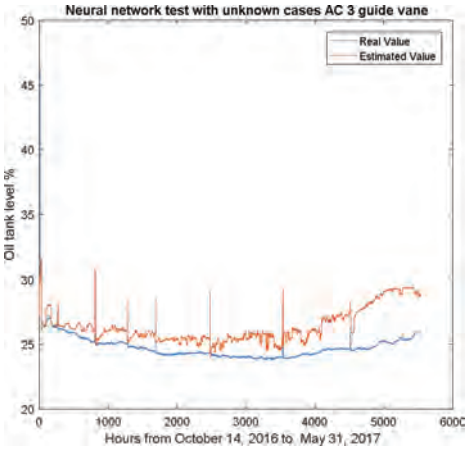

Figure 9. Estimated value for oil tank level in percentage predicted by the normal behavior model and the real value observed for the training set using the power generated, the oil tank temperature and the oil level in accumulator 3 for the guide vanes.

behavior can be good indicators for alerting when a typical relationship among variables could be broken.

In this case, the unexpected decreasing level in the oil tank must be monitored.

6 CONCLUSIONS

This paper describes a methodology for the early detection of anomalous behavior conditions of selected Kaplan turbine components. The method is based on discovering behavior patterns, also called normal behavior models, from the observation of the typical relationships existing between a set of variables used as inputs to the models and the corresponding output of a target variable whose expected value has to be predicted. The criteria to select the variables to use in the models are based on the physical working principles of the component in order to detect symptoms of abnormal behavior that can cause a possible failure mode.

The data set used for pattern discovering of normal behavior comes from the SCADA system of the plant. Abnormal behavior is any significant deviation or difference between the predicted output of the models and its corresponding real observation.

The paper presented some examples of normal behavior models for the cases of characterization of power generated by the hydropower plant and the oil tank level considered from different perspectives such as the oil level in the bank of accumulators of the turbine runner and the bank of accumulators of the guide vanes. Once the models were created, they were applied to new examples of operation. The predicted amount of generated power was always as expected, but the oil tank level was not. The analysis of deviations of normal behavior described in the paper shows that the oil levels in the accumulator banks were according to their working conditions, but the oil tank level was continuously decreasing during the time analyzed. This suggests a need for close monitoring of this level in order to search for the cause of this potential detected leakage.

In future works, an approach based on different algorithms working in parallel for anomaly discovering will be tested. This will improve even more the robustness of the anomaly detection method proposed.

ACKNOWLEDGEMENT

The research leading to these results has received funding from the MonitorX project from the Research Council of Norway (project no. 245317/E20) and the MonitorX industrial partners.

Current status of the MFM suite for diagnostic and prognostic reasoning of industrial process plants

Harald P.-J. Thunem
Institute for Energy Technology, OECD Halden Reactor Project, Norway

ABSTRACT: This paper presents the status of a software system, the Multilevel Flow Modeling (MFM) Suite, dedicated to the design and analysis of MFM models related to diagnostic and prognostic analysis of physical processes. New and updated features of the system are described, as well as some examples of its practical use. The paper also briefly describes how the system facilitates the collaboration between control room and field operators via the Android-based MFM Viewer app.

1 INTRODUCTION

Multilevel Flow Modeling (MFM) (Lind, 2011) is a methodology for graphical modeling of industrial processes by representing the goals and functions of industrial plants. The purpose is to model the combined functions of any number of physical process components, which together provide the means to achieve one or more goals. The model may then be used for diagnostic and prognostic purposes to determine the possible causes and potential consequences of unwanted process events.

Since MFM models consist of graphical, interconnected elements arranged in specific structures, there is an apparent need for dedicated software to design them. The MFM models also need to be connected to the process, the functionality of which they represent.

For several years such a dedicated software system, the *MFM Suite*, has been under development at the Institute for Energy Technology (Thunem, 2013, Thunem and Zhang, 2015). The system will allow a user to graphically design and verify the semantic correctness of MFM models, in addition to creating graphical models of the industrial process. It will provide associations between process components and MFM functions. Using a dedicated MFM reasoning engine developed at the Technical University of Denmark (DTU), the system will perform diagnostic and prognostic analyses of anomalous events on online process data.

This paper provides an update of the system's features, a brief description of results from applying it in a practical experiment, and the functionality and use of the Android-based MFM Viewer app.

2 APPLICATIONS IN THE MFM SUITE

The MFM Suite primarily consists of three applications: the *MFM Editor* for graphical creation, editing and verification of MFM and process models, the *MFM Runtime* for real-time acquisition and analysis of on-line sensor data, and the *MFM Playback* for step-wise and simulated real-time playback and analysis of sensor data. Since the applications share a lot of functionality, they are all based on the *MFMApplication* Java class.

The MFM Suite also includes a simple launcher from which to start the applications.

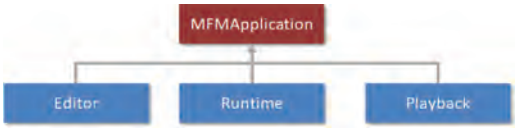

Figure 1. Inherited functionality in MFM Suite applications.

Figure 2. The launcher application.

3 THE EDITOR APPLICATION

The *MFM Editor* contains two essential graphical modelers, the MFM modeler and the process modeler. As both are based on the *ShapeShifter* framework (Thunem et al, 2011, Thunem, 2012), they share a lot of functionality.

3.1 *Meta-model display*

Most complex processes may be in more than one operating state (e.g. start-up, normal, shutdown), and the functionality of the process components and the process goals may depend on the operating state. Therefore, it may be necessary to create separate MFM models to describe the component functionalities and goals for each of the operating states.

The MFM Suite applications includes a meta-level display (Figure 3), which allows MFM models to be connected by arrows, indicating transitions from one operating state to another.

Note that only *one* MFM model may be considered *active* at any point, and any MFM reasoning analysis will be performed on the active model only. This furthermore requires that for each MFM model, the alarm limits for process sensors associated with MFM functions must be set individually, as their alarm limits may depend on the operating state.

3.2 *Click-and-drop model design*

Both the MFM and the process modelers provide graphical click-and-drop design of models in a manner similar to e.g. Powerpoint. For both modelers, a list of available components is shown to the left of the editing area (see Figure 4 and Figure 5). Clicking on one of them changes the cursor into a miniaturized version of the component. Clicking anywhere within the editing area will place the component at this point.

The MFM modeler provides another, faster method which also facilitates the creation of semantically correct models. When selecting an MFM function in the editing area, a list of allowed (according to MFM rules) connections (consisting of one MFM relation and one MFM function) will be displayed (see Figure 6). Clicking on one of them will create the connection from the selected function and place it at a suitable position. The modeler will automatically select the newly added function and update the list of available connections. In this way, complex MFM structures can be designed in relatively few steps.

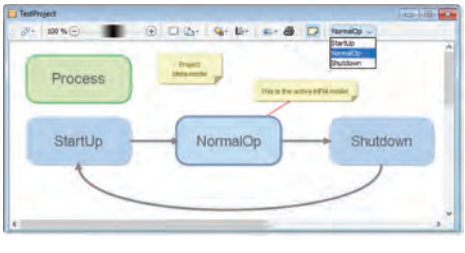

Figure 3. A project's meta-model.

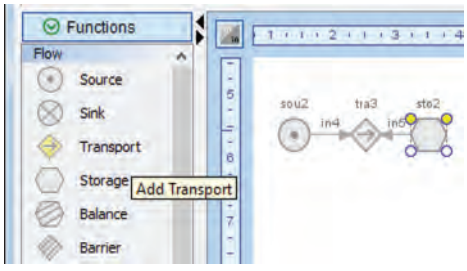

Figure 4. Designing an MFM model by click-and-drop.

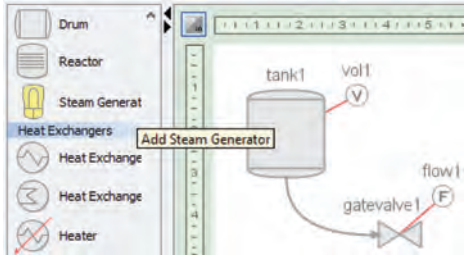

Figure 5. Designing a process model by click-and-drop.

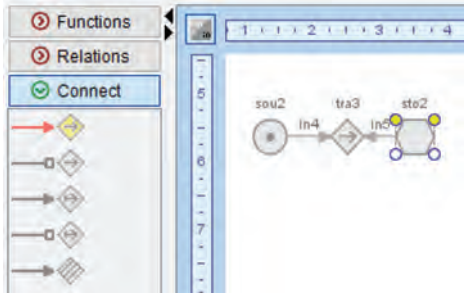

Figure 6. Assisted design of MFM structures.

4 THE RUNTIME AND PLAYBACK APPLICATIONS

The *MFM Runtime* and *MFM Playback* applications use the same *ShapeShifter*-based graphical components for displaying the MFM and process models as the MFM Editor, however in this case the editing functionality is disabled.

4.1 *Separate analysis threads*

The applications will perform diagnostic and prognostic analyses on a given MFM model using the reasoning rules that are explained in detail in (Zhang, 2015). The analysis processes will run in separate execution threads, which will set flags to avoid e.g. starting a new diagnosis before the previous has terminated (however, a diagnosis may run concurrently with a prognosis). This will prevent two problems; the analysis process will not lag the sensor sampling in cases where the sampling interval is shorter than the analysis time, and the user interface remains responsive since the main application thread is not blocked (Figure 7).

4.2 *Sensor display based on value and origin*

In addition to indicating the sensor range by changing the shape, color coding is used to indicate whether the sensor's value is obtained from the process, manually set by an operator, or inferred from an MFM model analysis.

An example is shown in Figure 8, where the shape (down-arrow) and color (red) of sensor PI444 indicates that it has a value below the low limit, and that the source is the actual process/simulator. This value, possibly along with other abnormal sensor values, has triggered an analysis in the associated MFM model.

The analysis has concluded that a *possible* cause of PI444's low value is a high value in sensor TI463, so this sensor is visualized with an up-arrow shape and a yellow color (indicating that the sensor state is inferred from an MFM analysis). Note that if the sensor is functioning correctly and shows a high value, it would be visualized using the red color. Since it is not, we can conclude that either this is not the cause of the abnormal value in PI444, or the sensor is malfunctioning.

The shape and color of sensor TI465 indicates that the sensor has a normal value/state (round shape), and that it has been set manually by an operator (green color), perhaps as a result of a visual inspection.

4.3 *Sensor trend display*

The process viewer component in the Runtime and Playback applications will display trend graphs for

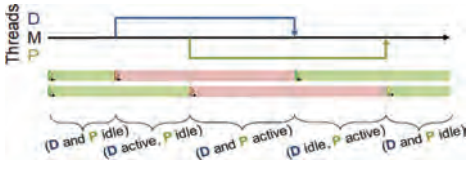

Figure 7. Concurrent main (M), diagnosis (D) and prognosis (P) threads.

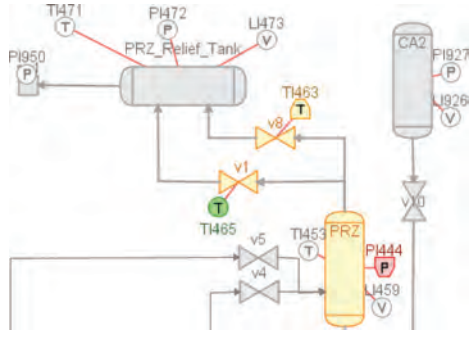

Figure 8. Sensor visualization.

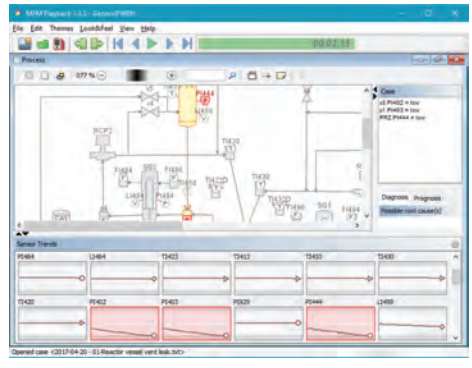

Figure 9. Process sensor trend panels.

selected process sensors (Figure 9). Through a dedicated settings menu the user may select which sensor trends to display (using a searchable selection panel), whether to show different markers depending on sensor type, and specify all colors used in the trends.

4.4 *Playback of existing data (Playback)*

The MFM Playback application will read stored sensor data from files to allow step-wise playback and analysis of previous experiments. The application also includes a slider to move back and forth freely. Furthermore, it can also replay a previous experiment in simulated real-time by activating a timer in a separate thread, and using the stored sampling intervals to update all sensors and re-run any analyses at correct times.

5 FEATURES COMMON TO ALL APPLICATIONS

5.1 *Server functionality*

The MFM Suite applications include functionality to allow external network clients to download the currently open MFM project (process and

MFM models) and to access updated MFM function states and sensor values. The MFM Suite also accepts commands from external clients for setting MFM function states and sensor value ranges (Figure 10). This allows e.g. a field operator to have a situation understanding similar to a control room operator and to prune away cause paths that have been determined irrelevant.

5.2 *Web export*

The MFM Suite applications will provide updated displays of models with dynamic data accessible through an ordinary web browser. When opening an MFM project, the applications will generate several files, depending on the number of models. An example of the files is shown in Figure 11.

Figure 10. Data server connectivity.

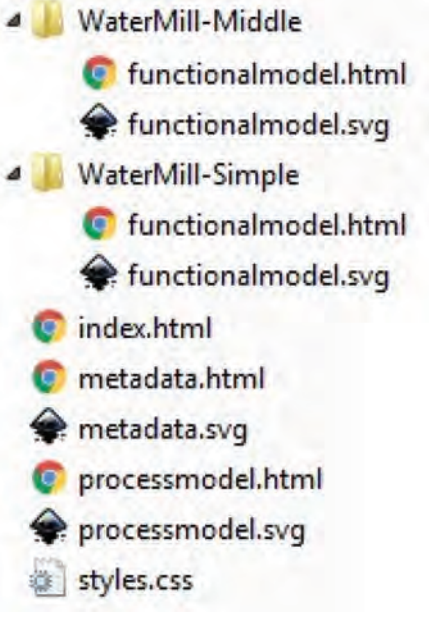

Figure 11. Web export files.

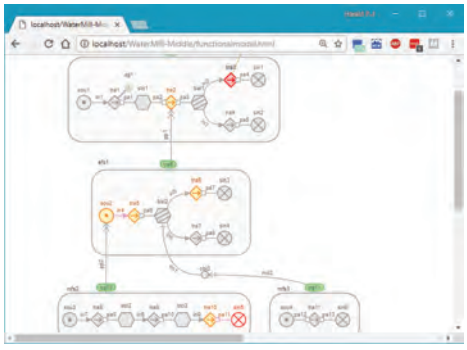

Figure 12. Web-page showing an MFM model.

The graphical models are exported as SVG (Scalable Vector Graphics) files, and since these graphics files are (as the name implies) scalable, they can be zoomed in the browser without the loss of any details (Figure 12).

Whenever the visual appearance of any element (MFM function, sensor etc.) in a model changes (e.g. due to an analysis affecting the elements), or whenever the user saves the project, the files are updated. Code is included in the HTML files to reload the pages at given frequencies (default every 5 seconds). This frequency is specified using the Settings dialog box of the applications, which also allows specifying an output folder, to which the generated files are exported. In order to make the web pages available to other devices in a network, this folder could be set to the active root folder of a web server application, such as e.g. Apache or IIS.

6 EXAMPLES OF USE

Several tests have been conducted using an MFM model of the primary side of two PWR simulators; the RIPS simulator which is based on the Ringhals power plant, and a generic PWR simulator (Zhang et al, 2014, Zhang et al, 2016, Thunem, 2017). Several scenarios were tested, including reactor trip cause by too low pressure in the steam generators, and a high pressure in the reactor coolant system.

Before running the experiment, the simulator was initialized to a normal running state. At this point, the values of all sensors were registered and used to set the individual alarm limits. The process model contained a total of 49 sensors, 21 of which were associated with MFM functions.

Before running each scenario, the simulator was reset to a normal running state. The control room operator would run the selected scenario by adjusting selected process parameters and letting the simulator run its course.

In most cases, the reasoning engine performed flawlessly. Figure 13 shows one scenario with multiple anomalous sensor readings (right side) and the successful diagnosis using MFM reasoning (left side).

It was, however, noticed that in some cases the selection of trigger function in the MFM model would cause a memory problem (stack overflow) in the reasoning engine. By manually selecting another trigger function, the problem would disappear.

The MFM reasoning engine uses the Java-based JESS inference engine (Friedmann-Hill, 2003), which employs recursion, a common cause of stack overflow problems. It is reasonable to assume that the selection of different trigger functions resulted in different recursion levels during the rule-based reasoning. One solution to this problem is to increase the Java call stack; however, the maximum size of the call stack may be platform dependent and difficult to ascertain.

Since the JESS system is no longer supported, the MFM reasoning engine has been re-implemented using the Drools inference engine, however, the experiments have not yet been re-run to verify any performance improvements.

7 MFM VIEWER

The *MFM Viewer* is a graphical model viewer designed for Android-based portable devices such as tablets and cell phones. The use of this application will facilitate a distributed team of e.g. control room and field operators to gain a common understanding of a process situation regardless of their location. For practical purposes a cell phone was used to create the images below, while in a work situation a tablet may be more suitable. The application will scale appropriately to all common display resolutions.

The main menu will allow the user to specify relevant settings, including the IP address and port number of the data server, i.e. any of the MFM Suite applications currently running. The main menu further provides a "Download project" menu item, which will instruct the MFM Suite applications to package the currently open project into a zip file and to transmit the zip file to the device. After receiving the zip file, the MFM Viewer will unzip the project files and display the project meta-model. Clicking on any of the model boxes (MFM or process) opens the model in a new window. In any of the models, the user may scroll and zoom using common finger gestures.

At the bottom of the MFM and process displays is a green button. Pressing this will cause the application to connect to the MFM Suite and retrieve and display the current MFM states and sensor values at a sampling frequency specified in the "Server Settings". The button will turn red, indicating the retrieval of data (Figure 14). Pressing the red button or returning to the meta-model will disable the connection. Note that for both models there is a search icon in the upper right corner. Clicking this will open a search field, which allows the user to find (by highlighting) any MFM function or process component whose outer label contains the given text string.

The MFM Viewer also allows the user to set the states of individual MFM functions or sensors. This is done by clicking on the desired element, which will open a dialog box, and clicking on the desired state (Figure 15). This will in turn trigger a re-analysis of the models in the MFM Suite application.

8 FURTHER WORK

The primary focus on the MFM Suite development has until recently been on including necessary functionality to graphically design MFM and process models, create links between them, and perform online analysis with simulated process sensor data. When presenting the analysis results, focus has primarily been on how the MFM functions are affected, and which MFM functions have been identified as root causes. Interpreting the results has required some familiarity with the MFM methodology, which is unreasonable to expect from e.g. a control room operator.

To make the analysis results more accessible to someone without MFM training, the focus of the analysis presentation will therefore shift towards the process display, indicating which process components are the possible root causes and which components may be affected by the identified anomalies.

The activity will further evaluate various display modes to enhance the operators' comprehension of a given process situation in light of established analysis results, and to facilitate collaboration between control room and field operators via dedicated interaction mechanisms.

Prognostic and health management design for subsea applications

Xiaojing Gao, Octavian Niculita, Don McGlinchey & Babakalli Alkali
Department of Engineering and Built Environment, Glasgow Caledonian University, Glasgow, UK

ABSTRACT: The design of a subsea production system needs to ensure high reliability and safety figures since these assets will be deployed in harsh environments for extended periods of time. Maintenance costs associated with these systems represent a significant percentage of the total operational expenditure incurred by an Oil & Gas operator. Traditional reactive maintenance approaches applied on subsea equipment are starting to drop in their efficiency as degradation occurs on such systems resulting in prolonged downtime periods. Prognostics and Health Management is a relatively new topic and other industry sectors have demonstrated that it can provide a solution for reducing maintenance costs and improving systems' overall availability. This paper presents a prognostic and health management development process suitable for subsea production systems.

1 INTRODUCTION

When oil and gas exploration is not economically viable through tradition oil platforms, subsea production systems represent an alternative for the majority of operators. A Subsea Production System (SPS) is a collection of hydrocarbon extracting equipment located on the seabed and its main components consist of a seabed wellhead, subsea x-mas tree (XT), manifold, umbilical, riser, a network of pipelines, flowline as well as subsea power and control systems. The amount of shallow water oil and gas reserves is decreasing. This has led exploration and production into deep waters where SPS are the preferred solution to make development economically viable. The subsea industry is now facing a number of challenges on how to improve reliability and safety of critical assets in an economical way. Subsea lifecycle analysis demonstrated that Capital Expenditure and Reliability Availability Maintenance Expenditure (RAMEX) are the two major costs of a subsea asset, with downtime cost making up the majority of RAMEX. Prognostic and health management (PHM) has the capability to address these financial challenges and reduce the downtime cost by assessing and predicting the Remaining Useful Life (RUL) of a component/system while supporting the system's goal and compliance with high level requirements- safety, reliability, availability, maintainability etc.

At present, the main research focus area of PHM in the context of subsea applications is only targeting the development of such capability for isolated components. This paper introduces on an integrated approach to design the PHM for a SPS at the system level. This approach is mapped on a typical engineering design and operational process of a subsea system and it involves integration and concurrent analysis of multi-disciplinary sources of knowledge and interaction between several engineering functions.

Section 2 of this paper discusses the current prognostic approaches and the level of adoption of PHM for subsea equipment. Section 3 will cover four engineering disciplines and their potential use for the development of the PHM capability. Section 4 will present a novel PHM development process capable of integrating knowledge, information and data within concurrent engineering analysis. In section 5, an instantiation of the PHM development process for a XT will be presented.

2 STATE OF THE ART OF PHM

Four different types of prognostic approaches currently exist:

- Experience-based prognostic approaches are based on historical data and knowledge accumulated during the lifecycle of systems.
- Model-based approaches involve the construction of mathematical model which integrates the underlying physics of failure of the critical components of the system, their degradation and their failure modes.
- Data-driven prognostic approaches specify the behavior of a system through gathered operational data (CM data via sensors and/or event data). The data is processed and compared with key parameters/features to predict the probability of fault occurrence.

- Hybrid prognostics are a combination of the model-based and data-driven with parameters in the model being continuously updated when data from service becomes available with the ultimate purpose of improving the accuracy of the prediction (Vachtsevanos, Lewis, Roemer, Hess, & Wu, 2006) (Medjaher & Zerhouni, 2013), (da Silva & Radespiel, 2013).

The majority of industry sectors adopted the data-driven prognostic approaches as a first attempt for the development PHM capability, particularly for complex systems (Bykovsky, 2008) as this enables the development of the understanding of degradation without the construction of mathematical model capturing the physics of failure. Currently, in the subsea arena, there are very few Condition Based Maintenance (CBM) solutions deployed in field. The major Original Equipment Manufacturers (OEM) for SPS include companies like: Technip/FMC Technologies, Cameron, GE, Aker Solutions, OneSubsea etc. Based on information available in the public domain, Cameron provides a blowout preventer condition based monitoring system and riser annulus condition system. However, FMC has delivered a first attempt of a system level Condition and Performance Monitoring (CPM) capability for a subsea asset, currently being installed at the Gjøa field (Soosaipillai, Roald, Alfstad, Aas, Smith & Bressand, 2013).

3 ENGINEERING DISCIPLINES AND THE STAKEHOLDERS INVOLVED IN THE SUBSEA PHM DESIGN

3.1 *Overview*

To develop and implement any of the prognostic approaches mentioned in the previous section, different types of data and information is required (Vachtsevanos, Lewis, Roemer, Hess, & Wu, 2006). This information and data represents the output of several engineering disciplines being owned by various functional teams. The design stage for a subsea system is usually undertaken by the OEM and suppliers under the requirements established by an operator. During the operation period, maintenance teams will be hired by the operator to Inspect/Maintain/Repair (IMR) the subsea equipment, although, the maintenance of control systems will be the responsibility of the OEM. Very often, upgrades, overhauls and de-commissioning typically are done by different parties. During the life time of a subsea production system, multiple organizations are involved and a subsea system may include components and processes originating from all over the world. Throughout the entire lifecycle of a subsea field, interactions between different engineering disciplines belonging to different companies, which are operating under multiple languages and cultures, also take place. Hence, one of the challenges is the fact that the data/information required to develop a PHM solution is not unified and/or centralized. In the context of subsea applications, these engineering functions and the data/information associated to each of them is captured in Table 1.

3.2 *Subsea system design—initiation of the PHM design*

PHM Design must be underpinned by a level of understanding of the healthy state of a system. In the case of a subsea system, this characterization is developed during various stages of the design process (conceptual design, front end engineering design (FEED) and detailed design). Engineering modelling is carried out during the FEED. Modifications to the design (to include the PHM capability as an afterthought) might be extremely costly, therefore it is recommended to design-in the PHM function as the asset design progresses through various technical and business gates. It is instrumental at this stage to derive the PHM requirements from the subsea asset requirements, if such a capability is to be developed.

3.3 *Reliability and availability analysis—foundation of the PHM design*

In the offshore industry, Failure Modes and Effects Criticality Analysis (FMECA) tends to be one of most common approaches for reliability analysis and it has been increasingly implemented in the last ten years on subsea projects (DNV, 2013). FMECA also forms the foundation for good PHM design (Vachtsevanos, Lewis, Roemer, Hess, & Wu, 2006) although, in the context of subsea

Table 1. Engineering disciplines.

Engineering disciplines	Information
System design	Engineering models Schematics, Reports, Hierarchical levels Dependencies
Reliability & Availability	Failure concepts Criticality information (Re) Certification
Control and Instrumentation Condition and Performance Monitoring (CPM)	Operational conditions Condition, Performance Indicators Control data
Inspection, Maintenance and Repair (IMR)	Past operational conditions Maintenance records Failure history

equipment, it is mainly used to support qualification of new technologies or re-qualification of legacy systems. Reliability analysis must be based on the actual design of the system therefore a concurrent engineer design and reliability analysis is recommended to ensure the both disciplines are targeting the same point of truth. Input is required from IMR to ensure the efficiency and accuracy of this analysis. A FMECA study attempts a good understanding of system behavior under faulty conditions is instrumental to be able to design the diagnostic and prognostic capability. Historical data and knowledge can also be employed to adjust or re-design components/equipment/systems to improve reliability targets. This information usually resides with the operators and OEMs, but it is very often not available for the reliability team responsible with the qualification of the subsea equipment under investigation.

3.4 *Control & instrumentation/CPM—core of the PHM design*

A large number of parameters to assess the condition of an SPS is currently captured by CPM through sensors i.e. acoustic control systems, multiphase flow meters, accelerometers, pressure and temperature sensors, sand and leak detection systems, as well as detectors for dropped objects (ISO:13828, 2010). These types of sensors found their way into the subsea design either through regulations or recommendation and there is a consensus in the industry that they are not engineered for the purposes of ensuring higher availability figures. Production efficiency performance of subsea equipment has been particularly poor in recent years, reaching a low point of 60% in 2012 and averaging at 71% in 2015 although back in 2004 the production figures were above 80%. Degradation of production equipment is one of the contributor factors to this drop. Abnormal behavior of subsea equipment can be detected by condition monitoring solutions and information sensed by instrumentation is sent to the control module and interpreted by the operational teams (Markeset, Moreno-Trejo, & Kumar, 2013) to allow informed decisions guiding the operation and maintenance.

3.5 *Maintenance—exploitation of the PHM design*

Various types of maintenance strategies exist and can be implemented for subsea equipment in service. Corrective maintenance is typically applied after the failure has occurred. A scheduled maintenance regime aims at dealing with faults before they occur, but they are based on fixed time intervals. The conditional maintenance only supports non-dynamic estimation of the degradation and the most recent approaches take advantage of the PHM capability to estimate the RUL of a critical component and to plan the maintenance job according to these calculations (based on data-driven, model-based and hybrid prognostics algorithms). The PHM capability of a system is represented by a set of techniques and methods from different disciplines that combine knowledge and data to support predictive maintenance by detecting, diagnosing, predicting, advising and analyzing (postmortem) the failure information (Guillén, Crespo, Macchi, & Gómez, 2016). The information and data related to functional failures (failure modes) and physical failures (faults) of subsea equipment is scarce, so the traditional reactive maintenance approaches (corrective and scheduled) are still the preferred choices for oil and gas operators. The predictive maintenance regimes also present their own set of challenges and these must be considered during the design stage (the inability to accurately and reliably predict the RUL of a component/system; the inability of maintenance systems to document, learn and recommend that action should be taken; the lack of tools capable of demonstrating the effectiveness of a predictive maintenance program). SPS have been typically designed to operate over five years without failure, thus the operator will plan to carry out preventive maintenance every five years (Moreno-Trejo & Markeset, 2012). However, over the last decade, reliability data shows some components had to be maintained/replaced sooner to prevent failure. Hence, traditional maintenance can incur huge expense and consequential damage for an asset and the environment—such as pollution, loss of production, etc. (Markeset, Moreno-Trejo, & Kumar, 2013; Uyiomendo & Markeset, 2015). In recent years, traditional maintenance activities in the oil and gas industry are transforming through the adoption of CBM which are ensuring efficient maintenance, reducing lifecycle costs and improving the systems' overall availability. The application of CBM and PHM (as an extension of CBM) in the oil and gas industry has started to be exploited on for example, drilling systems, control systems and pumping systems.

4 SUBSEA PHM DEVELOPMENT PROCESS

To determine the Prognostic method, these four major disciplines need to share information and data with each other. However, PHM development for an entire subsea system is still a challenge from the view of big data management and information support, thus it is hard to build those disciplines into system.

In this paper, we propose an integrated approach to subsea PHM design process. This process is captured in Figure 1 and it highlights the data/information exchanged between the four main engineering disciplines, discussed in the previous

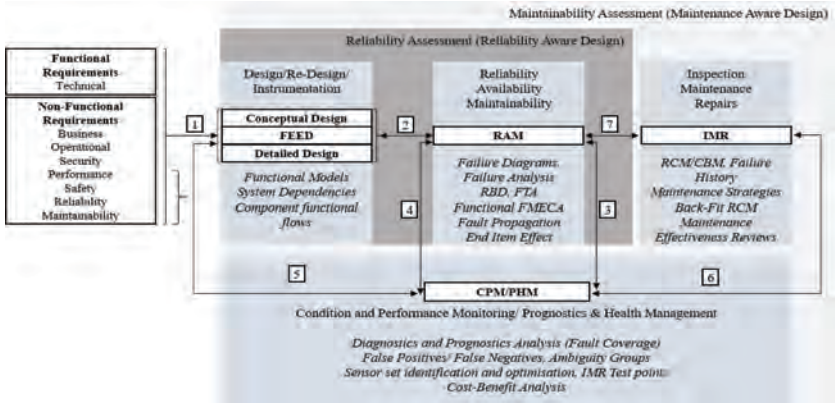

Figure 1. An integrated approach for exchanging engineering knowledge to support Subsea PHM Design.

section. The proposed subsea PHM development process includes feedback loops that are intended to enable enhanced data collection, exchange and analysis of knowledge related to the degradation of subsea components, addressed by different engineering disciplines as the subsea project moves through various technical and business reviews. Good communication during a generic design engineering process includes both historical and current information to be shared freely, problems to be reported, views to be exchanged, and positive interpersonal relationships to be retained, as the design progresses through various technical and business gates. However, the effective communication is also dependent on balancing the levels of information to the complexity of the task/topic, avoiding both over-complication and over-simplification. Hence, suitable levels of information must be delivered to the correct person at the correct time to communicate essentials without the receiver being overburdened with data (Parkes & Hodkiewicz, 2011).

Step 1 – The start of the PHM design process is represented by the requirements phase. High-Level (HL) requirements are typically divided into functional requirements (FR) and non-functional requirement (NFR) categories. Functional requirements define the technical details of a system (including the function of the system and the functions of each individual component) and non-functional requirements cover the attributes of the system (such as safety, reliability, maintainability, usability, performance, security, etc.). The Design/Re-design/ Instrumentation phase of the PHM development process coordinates various engineering analysis to ensure the final subsea design is meeting the requirements established at the start of the project. During the design phase, data associated with the environmental conditions, reservoir, well completion, process and operations, host facilities, safety and hazards should be considered when progressing through conceptual, FEED and detailed design. These engineering efforts are targeting the technical requirements (also known as functional requirements (FR)) of a subsea system since this design element is heavily regulated and supported through recommended practices (ISO 13628–1, 2010). Non-Functional Requirements are also considered by the current subsea design best practices and they cover safety, performance and security. However, there is no attempt to define and to target the reliability and maintainability requirements at the early stage of the design. This influences the PHM requirements definition as these are derived from the reliability and maintainability requirements. Only recently, the industry has generated recommended practices like the API-RP-17 N on topics related to reliability, technical risk and integrity management (API RP 17 N, 2009). However, they are not yet adopted due to the lack of tools, processes and meaningful reliability data to support their implementation. Reliability and maintainability requirements should be part of the non-functional requirement (NFR) of the system. Deriving PHM requirements should be done from system's high-level (HL) Non-Functional requirements. For example, a HL NF requirement for a XT can be affordability by reducing the down-time periods while keeping the same levels of safety. In this manner, cost and safety become main drivers for the development of a PHM solution. Derived PHM requirements can be represented: PHM Requirement 1 – the XT must have a feature that can reliably predict functional failures at least one week prior to the actual event and PHM Requirement 2: the XT must have the capability of offering mitigation/advisory generation in the context of current operational conditions. Having access to information provided by such features, the operator reasonable time to schedule a vessel, equipment, personnel to carry out an intervention on the faulty components.

Step 2 – To support the PHM within the subsea design phase, reliability analysis needs to be carried out concurrently with the subsea system design. Reliability analysis should be based on the actual design data to support the engineering analysis that can identify the means to detect and isolate the potential faults which may occur during the operation. One way to support the realization of this step is through the exploitation of functional models which can support reliability engineers to carry out analysis such as FMECA, Fault Tree analysis (FTA), and Reliability Block Diagrams (RBD) from the very early stages of the subsea design process. These methods and techniques can also underpin the Reliability Centered Maintenance (RCM) and Back-Fit RCM analysis at later stages of the lifecycle. RCM includes four elements that are critical to a maintenance program aimed at improving availability of a given asset. These elements are: preservation of the system function, identification of the failure modes that can lead to functional failures (and sequentially downtime), prioritization of failure mode candidates based on Occurrence (O), Severity (S) and Detectability (D) by highlighting the Risk Priority Number (RPN = O $\times$ S $\times$ D) of each of the candidates and finally selections of applicable and effective tasks to control the failure modes. Back-Fit RCM builds on the same RCM principles by incorporated operational reliability figures (by updating the O, S, D parameters) and evaluating the applicability and effectiveness of the control measures. We believe that the reliability, availability and maintainability analyses should be the foundation of the PHM design as it can highlight the risk associated with a brand new subsea design or a legacy system using information from service (provided to the reliability team during *Step 7* using the output of a bespoke maintenance analytics engines). Sequentially, using this information, the design will be assessed by the reliability authority during a technical review (*targeted reliability* assessment) and if the design fails to meet a specific target, the risk and the critical components must be addressed either through re-design, redundancy or addition of instrumentation. Informed trade-off studies between these three approaches must be in place to guarantee the final design meets all the requirements of the project. However, this topic is beyond the scope of this paper. Nevertheless, for far too long, reliability assessment on subsea equipment was carried out only to present a *measured reliability* figure to support re-certification of production equipment already in exploitation.

If the PHM is channeled as derived requirement from the RAM requirements, specific levels of targeted reliability can be achieved. Also, different PHM requirements and implementation strategies can be evaluated at this stage against specific sets of RAM requirements. Very often, in subsea applications, redundancy seems to be the option preferred by the system designers as this guarantees improved availability figures when the primary component/sub-system fails. The major drawback of the redundancy approach is that fact that it does not offer any indication of the RUL for the critical component, sub-system or system, therefore, our case for addition of instrumentation supporting the PHM capability. If instrumentation is required for diagnostics and prognostics purposes, this must be defined by the PHM analysts in collaboration with the subsea design and reliability teams. We believe that majority of the condition monitoring applications existent in a subsea environment were driven by vendors of sensors capable of targeting symptoms associated with specific failures. This approach captures failures in isolation and does not account for propagation of faults leading to functional failures of other components and sequentially to failure of the system. This limitation can be overcome using functional models of the system, functional relationships and failure/effects dependencies in a system for both functional and physical failures, defined using widely accepted, well defined failure taxonomies. Once the stakeholders of the asset have validated the propagation tables (component's reaction to functional failures of the system) generated against analysis capturing various end-item effects. The end-item effect is the consequence a failure mode has on the operation, functional output of the system at the highest indenture level (an item's position in the system hierarchy relative to the top-level item).

What we propose in step 2 is an implementation of the API 17 N recommended practices through a concurrent design-reliability analysis by evaluating the actual reliability of the design by highlighting the effects of failure modes leading to functional failures.

Step 3 – enables an informed dialog between RAM engineers and PHM analysts by allowing the use of system level propagation table (a collection of all the failure mode signatures—the effects (throughout the system, and not just at the point of occurrence) of a given failure mode universe. Currently, the job description of a PHM analyst falls somehow under the control team although we believe that its responsibility and involvement goes beyond the control systems. The PHM team should liaise very closely with the design team as it aims at the identification and optimization of sensor set solutions capable of detecting, isolating and making predictions of a given set of failure modes considered under the PHM analysis. The mean of realization of this dialog is represented by the reliability models populated with failure and criticality information of failure concepts. The automated PHM instrumentation analysis aims to identify and optimize, in a systematic manner, the sensor set configurations capable of supporting the detection, diagnosis, prediction functions of a subsea asset to further enable advisory

generation. It also aims to calculate, for each sensor set solution identified during this process, the fault detection and isolation characteristic representing the proportion of failure modes selected for PHM analysis that can be detected and identified by a given sensor set under consideration. The PHM instrumentation analysis must be able to allow modification of existing sensor arrangements based on user knowledge or trade-offs. Legacy sensors present on the system can be considered as part of this analysis, although qualification institutions and regulators will not easily accept interrogation of sensors used for fail-safe control purposes (functional safety sensors). During this step, criticality of failures affecting a subsea system must be considered during the PHM instrumentation analysis. For new subsea designs, no measured criticality information exists and this must be defined using input from various stake-holders (subsea designers, RAM team, Operators, IMR personnel) by taking into account qualification of new technology standards and recommended practices (DNV-RP-A203, 2011; DNV-DSS-401, 2012). For subsea legacy systems, the criticality should be considered given what failed in service and it can be characterized through occurrence, severity and detectability parameters by calculating a risk priority number for every single component of the subsea equipment. The PHM instrumentation analysis should be capable of running the identification and optimization algorithms for specific groups of components by focusing on specific targeted criticality. There is also a feedback loop between the PHM and RAM functions meant to ensure that the selected sensor set solution meets the reliability criteria of the system (as a sensor that will fail in service ahead of the component that it is monitoring for failure does not ensure higher levels of availability for the asset). This feedback loop is represented within the PHM development process by *Step* 4.

Step 5 of the PHM development process enables the dialogue between the PHM analysts and the subsea design team. Although represented as a separate link/step, this dialog should take place concurrently with the reliability analysis of the instrumented subsea system. Decisions regarding unfeasible sensor set solutions are taken, and trade-off studies related to cost, weight, coverage, location, reliability, probability of detection, probability of prediction, likelihood positives and negatives ratios, physical constraints, loads, environmental conditions should be carried out by a multi-disciplinary team led by the RAM function. During this step, the reliability and maintainability requirements are verified and validated by group of experts. As a mean of realization of this dialogue, we propose a model-based approach as this will allow rapid generation of sensor sets spanning multiple levels of hierarchy for a subsea system by considering technical and economical metrics.

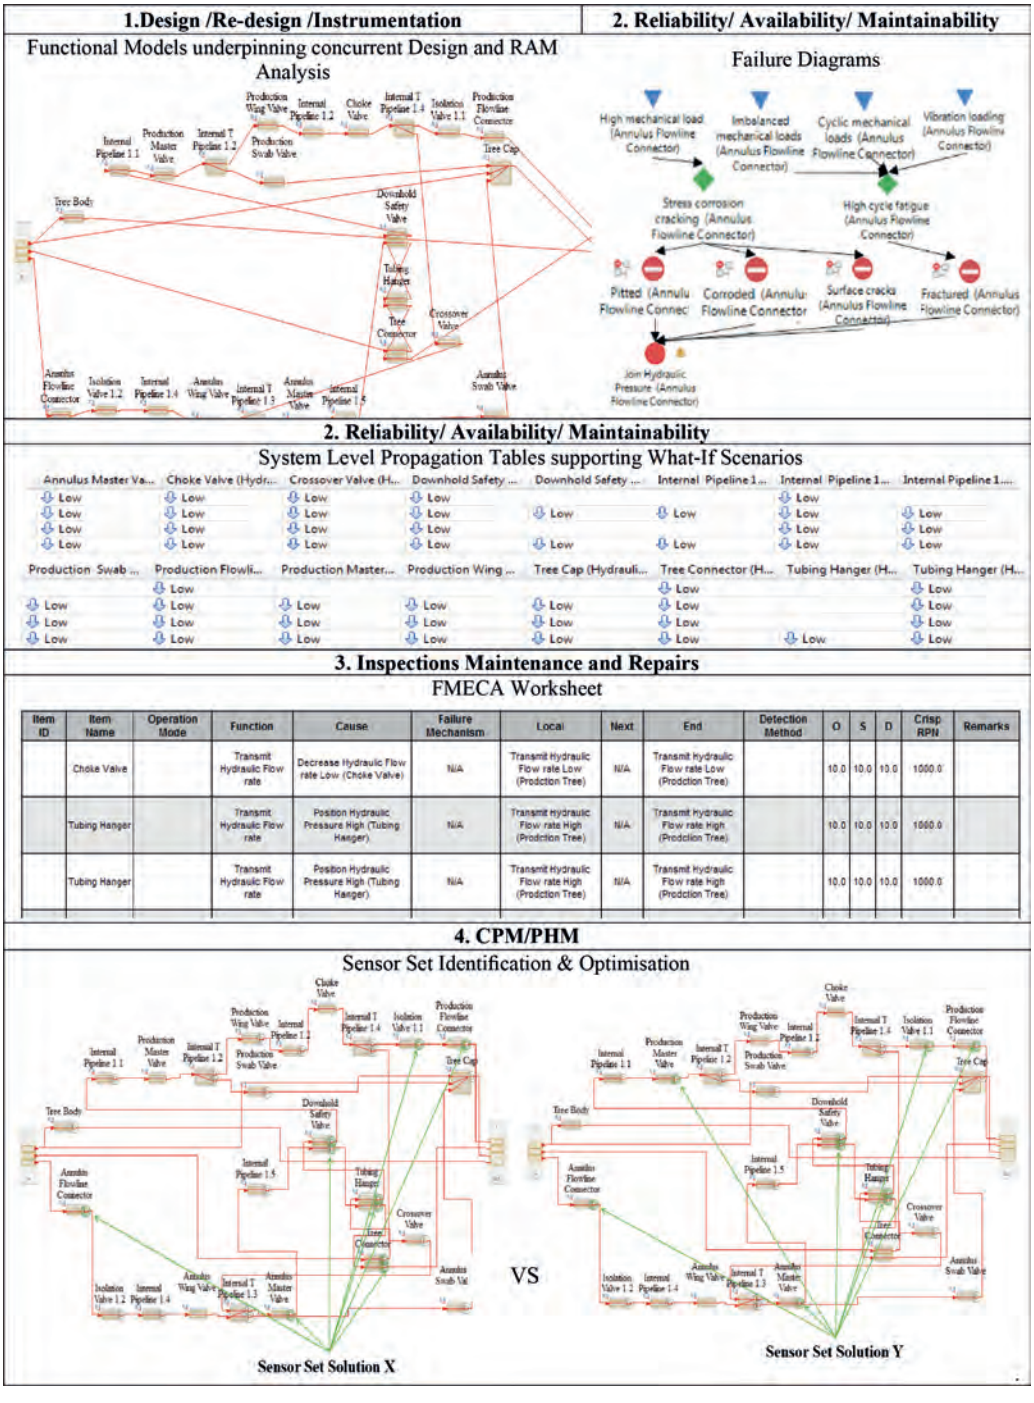
Step 6 facilitates the exploitation of the data provided by a PHM-enabled subsea system and the support offered to the IMR function. Data from sensors will be plugged to diagnostic and prognostic engines capable of supporting the IMR function on fault detection, fault isolation and ideally, prediction of the remaining useful life.

Step 7 of the PHM development process facilitates an implementation of an integrated analysis-drive sustainment activity. It provides traceability of the subsea maintenance activities when using PHM information. We recommend the use of function-based reliability models to gather, share and analyze maintenance data in order to enable automated failure and data reporting, analysis and corrective action system (FRACAS/DRACAS).

5 CASE STUDY

For the implementation of the integrated PHM development process for subsea equipment, a commercial-of-the-shelf software tool, namely Maintenance Aware Design environment (MADe™) developed by PHM Technology was employed. It was used to carry out an instantiation of the process on a XT. The selection of this software package was based on the previous success in using it in aerospace industry sector on fuel system and environmental control systems (Hess, Frith & Calvello, 2005). MADe™ is a 'model-based' engineering tool that can provide an integrated framework to manage, control and analyse the information and data throughout different disciplines including the design, safety, reliability, availability and maintainability for a high-value high-complex systems. However, a good inter-discipline communication requires expert document management and control, and in this instance this is achieved through a model gathering data and knowledge from various disciplined. The instantiation of the PHM design process was carried on a typical subsea XT. Several concurrent engineering analyses belonging to separate engineering disciplines, but derived from a single model of this XT (developed within MADe™) were carried out. The outcomes of some of these analyses are highlighted in Table 2 (a and b). These are briefly summarized further on. The functional model accommodates information describing the input and output flows of each component, the causal relationships between these flows that allow for systematic propagation of failures throughout the system and criticality data (retrieved from the 6th edition of the Offshore Reliability Data—Volume 2). Knowledge and data characterizing the failure of each of the component forming a subsea XT was added to the functional model using concepts defining the causes, mechanisms, faults, symptoms and the links to the functional failures previously

Table 2a. Outcomes of implementation of the integrated PHM development process.

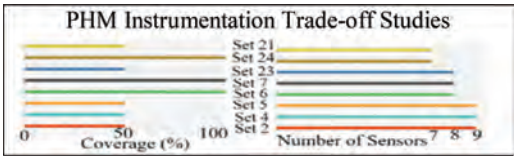


Item ID	Item Name	Operation Mode	Function	Cause	Failure Mechanism	Local	Next	End	Detection Method	O	S	D	Crisp RPN	Remarks
	Choke Valve		Transmit Hydraulic Flow rate	Decrease Hydraulic Flow rate Low (Choke Valve)	N/A	Transmit Hydraulic Flow rate Low (Prodction Tree)	N/A	Transmit Hydraulic Flow rate Low (Prodction Tree)		10.0	10.0	10.0	1000.0	
	Tubing Hanger		Transmit Hydraulic Flow rate	Position Hydraulic Pressure High (Tubing Hanger)	N/A	Transmit Hydraulic Flow rate High (Prodction Tree)	N/A	Transmit Hydraulic Flow rate High (Prodction Tree)		10.0	10.0	10.0	1000.0	
	Tubing Hanger		Transmit Hydraulic Flow rate	Position Hydraulic Pressure High (Tubing Hanger)	N/A	Transmit Hydraulic Flow rate High (Prodction Tree)	N/A	Transmit Hydraulic Flow rate High (Prodction Tree)		10.0	10.0	10.0	1000.0	

defined. Significant challenges were faced when trying to align the failure taxonomy used by the OREDA (based on the ISO: 14224 standard) and the failure taxonomy employed and defined by PHM Technology in MADe™.

A clear understanding of the causes, mechanisms, potential symptoms leading to a fault and the way this fault develops into a functional failure is instrumental in selecting the correct maintenance task or the PHM instrumentation, in an informed manner.

Table 2b. Outcomes of implementation of the integrated PHM development process.



Four components were selected during the criticality assessment as having a significant impact on the function of the XT, namely the choke valve, the down hold safety valve, the production master valve and the tubing hanger. For the scenario of these four functional failures, 100 sensor set solutions were automatically generated from the functional model, having between 7–9 sensors (measuring pressure and flow rate) offering between 50–100% fault coverage. Ambiguity groups were clearly highlighted during this process due the similarities in the fault signatures characterizing two of the faults. At this stage, the PHM development process allow investigations on the trade-off studies on the sensor set solutions very early on during the design process and various maintenance strategies can be benchmarked when using specific diagnostic and prognostic engines coupled to the instrumentation identified in the previous step.

6 CONCLUSIONS

The definition and articulation of cost-effective maintenance regimes is a challenging task for subsea assets. Very often, they are over-engineered since they are required to operate in harsh conditions for long period of times. Various stakeholders are involved with these assets throughout the entire lifecycle of these assets and knowledge related with the de gradation of this equipment is scattered throughout various organizations being owned and used by different engineering functions. In this paper, an integrated PHM development process was presented as a multi-disciplinary engineering analysis, complementing the current development of subsea equipment. The proposed development process aims to help subsea designers to integrate the development of the PHM capability of a subsea asset with the actual design of such systems. This is meant to happen at the early stages of the design process, but the process also enables the retrofit of such capabilities on legacy subsea fields to achieve higher availability and operational reliability figures. This is achieved by placing the reliability, availability and maintainability engineering analysis at the heart of the subsea asset and PHM system level design.

ABSTRACT: Rubber-metal-elements are used in a wide range of applications for vibration and sound isolation. Nowadays it is state of the art to calculate the lifetimes of these elements under mechanical stress prior to their service life. To establish more reliable and safer rubber-metal-elements, continuous monitoring by different sensors can be used. Especially prognostics enable a rise in reliability, availability and safety. To establish these advantages, estimating the remaining useful lifetime of rubber-metal-elements should be realized during its service life based on current information on its condition. Therefore a suitable measure to monitor the condition of the element is necessary. This work focuses on temperature signals. This approach allows including the ambient temperature and thereby involving changing operating conditions. For estimating the RUL of rubber-metal-elements a model-based prognostics approach based on particle filtering is proposed. Its performance is analyzed regarding relevant parameters to enable the best performance for the applied data.

1 INTRODUCTION

1.1 *State of the art and motivation*

Rubber-metal-elements are used in a wide range of applications for sound isolation and in particular for isolating critical components from strong vibrations. Typical applications are trains, trucks and wind turbines. The bearing in focus is displayed in Figure 1. It consists of an inner steel ring, a rubber part and an outer steel ring which is slotted. This main part is within the outer hollow cylinder which is used in combination with the inner bolt for generating a prestress on the rubber part. Nowadays, it is state of the art to follow a preventive maintenance strategy handling these bearings. Thereby, the lifetime of the bearing needs to be estimated prior to its service life. Therefore this lifetime is estimated conservatively by the developer based on experience, lifecycle tests and the conditions of the planned application. This calculation is often based on linear damage accumulation theory (Spitz 2012). A preventive maintenance strategy shows some drawbacks regarding optimal utilization of the resource and costs. Moreover, today's industry develops growing expectations concerning efficiency of capabilities and availability. That is why condition monitoring gains more and more importance in the field of maintenance.

Figure 1. Rubber-metal-bearing.

1.2 *Maintenance strategies*

Maintenance can be divided in different strategies according to DIN EN 13306. The oldest strategy is the reactive maintenance. Technical systems were used until failure and needed to be repaired or replaced once they reached their end of lifetime. This procedure leads to a couple of problems concerning costs and time, for example possible high consequential costs due to unplanned downtime. Therefore the preventive maintenance strategy was developed. In that case mechanically lifetimes of technical systems are calculated based on experience, lifecycle tests and fatigue life calculations. However, this maintenance strategy does not enable exploiting the whole lifetime of a single product. The calculation is a generalized one that bases on assumptions regarding the expected loads over all bearings. Furthermore, safety factors are included in the calculations that ensure with a high degree

of certainty that every product is maintained or replaced previously to its end of lifetime. However, this strategy provides no information on the current state of individual bearings which experience individual loads during their lifetime and therefore degrade individually. That is why on the one side, possible early failures could occur and on the other side, bearings are replaced although their lifetimes are not yet exhausted. These disadvantages of the previous named strategies are the reason why the condition based maintenance strategy was developed. This strategy is mainly based on the condition of the product in focus. Using different kind of sensors, information about the condition of the product is acquired and progressed by condition monitoring methods. So, maintenance can be planned optimally based on the condition of the product and, in case of prognostics, additionally on the estimated remaining useful lifetime (RUL), which improves the reliability of the product and leads to an optimized efficiency.

1.3 *Structure of the following sections*

In this work the prognostics method which is used to estimate the RUL of these rubber-metal-bearings is analyzed regarding its performance on temperature data of these bearings. The used method is a particle filter. Due to the fact that different types of particle filters exist (Arulampalam et al. 2002, Jouin et al. 2016), in chapter 2 the used method is presented regarding type correlated differences. Aiming for realizing the best RUL prediction for rubber-metal-bearings, relevant parameters of the method for a performance analysis are identified. Chapter 3 focusses on necessary lifecycle tests and generated data for developing the condition monitoring system. Chapter 4 deals with the analysis of that temperature based prognostics. Two different measured values are implemented and particle filtering performance is analyzed based on varied parameters. In chapter 5 a conclusion and a short outlook are given.

2 PROGNOSTICS METHODS

2.1 *Types of particle filter*

Particle filters are Monte Carlo methods that base on Bayesian probability theory. These filters are model-based methods for state estimation that are appropriate for estimating non-linear behavior. Currently, it is a classical method for model-based predictions of RUL (Jouin et al. 2016). Moreover, particle filters create a probabilistic output which can be used to present uncertainty involved in RUL predictions. Additionally, this method was chosen because a multi model particle filter has been successfully applied to other signals of rubber-metal-elements (Bender et al. 2017b, Bender et al. 2017a, Bender et al. 2017c).

These filters can be divided in different types. The commonly known ones are Auxiliary particle filter, Unscented particle filter, Regularized particle filter, Sequential Importance Sampling (SIS) filter and Sampling Importance Resampling (SIR) filter (Arulampalam et al. 2002). In this work a SIR particle filter is used for estimating the RUL of rubber-metal-bearings due to the named advantages and the SIR related improvement of particle degeneracy. Particle degeneracy is a weakness of the classical SIS filter. The SIR particle filter is a further development of the SIS filter and prevents that degeneracy by resampling. All these Monte Carlo based filters use random samples that are called particles to estimate the state of the monitored product in the form of a distribution. Therefore, the samples' relevance is symbolized by weights. These weights are calculated based on a defined distribution and a comparison of the predicted and the measured values. In the case of degeneracy after little iteration most of the particle weights tend towards zero while only one particle has a bigger weight. That means that only one particle builds the base for the state estimation and the consecutive estimation of the RUL. Nevertheless all particles are still part of the estimation even if their influence on the result tends towards zero. This degeneracy problem can be solved by resampling. Thereby only relevant samples survive which means samples with a higher weight. Those samples build the base for the next prognostics step while the probably irrelevant particles are no longer considered. In that case a smaller variance of samples is used, but the result is more accurate. The RUL prediction is an iterative method. As long as measured data is available the weights can be updated and resampling can be proceeded (Arulampalam et al. 2002, Jouin et al. 2016).

The general structure of a particle filter is given in Figure 2. The models are developed based on data for training that is presented in chapter 3. Due to the complex, nonlinear behavior and multiple ways of degradation, no physical model of failure for rubber-metal-elements exists. Therefore empirical parameterized models are implemented. For every dataset these parameters are estimated by using Differential Evolution, a population based optimization algorithm (Elsayed et al. 2012). So, every model is related to one bearing. These models are used within the method for state estimation based on samples. Therefore a multi model version of a SIR particle filter is implemented. The general state equation to estimate the samples is given in Equation 1 (Vachtsevanos 2006, Arulampalam et al. 2002) and the particular state equation in Equation 2.

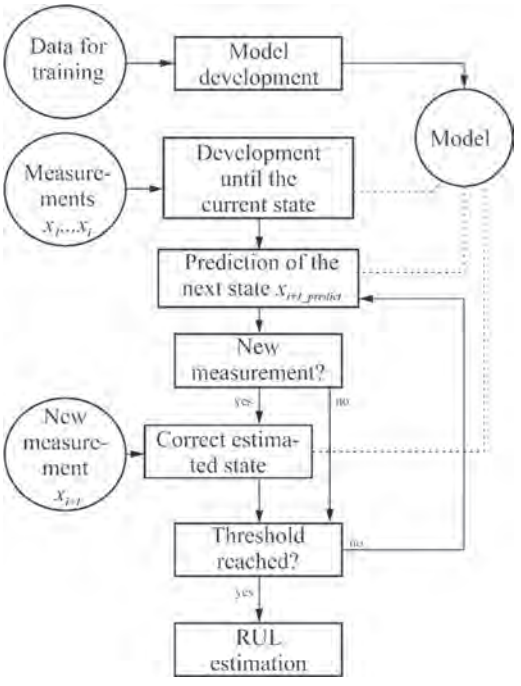

Figure 2. Structure of a particle filter.

$$x_i = f(x_{i-1}, mdl_{i-1}, v_i, t_i); \tag{1}$$

$$x_i = x_{i-1} \cdot \frac{\left[e^{p_{i-1,1} \cdot \left(\frac{t_i}{p_{i-1,2}} \right)^{p_{i-1,3}}} + e^{\frac{p_{i-1,4}}{p_{i-1,5} \cdot t_i + 1}} \right]}{2} + v_i; \tag{2}$$

where x_i is state vector at time ti, mdl_{i-1} is the model with parameters $p_{i-1,1-5}$ and vi is added noise. The model parameters are chosen based on the weights of the previous state vector. In this version the initial samples or initial states are in each case generated by one of the models and the first measurement. By an appropriate number of samples, model choice is equally distributed for the initial sample generation. Therefore different numbers of samples are evaluated in chapter 4. If new measurements are available, the estimated states can be corrected through resampling. With the aim of estimating the RUL, the prediction step is repeated until a given threshold is reached by the samples.

2.2 *Relevant parameters*

Variable parameters of a particle filter influence the accuracy of prognostics. The parameters to be analyzed are number of simulations, number of samples, the measured values and the resampling strategy.

Accuracy of particle filter strongly depends on the number of particles. That is because it is more likely that a big random sample of a defined distribution is able to show a good representation of that distribution than a smaller random sample. To show the influence of variable number of samples on predictions of RUL, three possible numbers of samples should be compared. In this context the number of simulations is analyzed as well.

The measured values in focus are temperatures acquired in or close to the bearing. It was observed that the temperature of rubber-metal-bearings changes over their lifetime, especially in the end of their lifetime. Due to the fact that bearing temperature is influenced by operating conditions, these conditions should be considered. In chapter 4 measurements based on similar conditions are implemented including similar exciter power, similar frequency and similar bearings. Nevertheless, there is one parameter that cannot be kept constant, the ambient temperature. That is why the ambient temperature is measured as well. The relative temperature ΔT involves both temperatures in the form of a subtraction, ΔT = T (bearing) – T (ambient). In the following chapter both measured values, absolute bearing temperature and relative temperature are presented.

To improve the degeneracy problem, resampling can be involved in the particle filter. Multiple resampling schemes exist (Arulampalam et al. 2002, Ignatious, Lincon 2013), in this work the SIR is implemented. One point of interested in this context is the question when to resample. Two possibilities are compared for the application of rubber-metal-bearings. The first continuous strategy enables resampling in every iteration step which is easy to implement but leads to high computational cost. The other strategy is based on a defined threshold for resampling. In this case resampling is only executed if the condition is fulfilled. The realized threshold is based on the effective sample size N_{eff} which is a measure for degeneracy. The effective sample size cannot be computed exactly, therefore an estimate $\hat{N}_{eff}$ of N_{eff} is used here, see Equation 3.

$$\hat{N}_{eff} = \frac{1}{\sum_{i=1}^{N_S} \left(\omega_k^i \right)^2} \tag{3}$$

where ω_k^i is the normalized weight (Arulampalam et al. 2002). A threshold needs to be defined which

allows resampling when $\hat{N}_{eff}$ is smaller than that threshold. This resampling strategy needs less computational time because resampling is not realized in every iteration step.

3 LIFECYCLE TESTS

3.1 *Lifecycle tests*

Testing rubber-metal-elements is a complex task. Due to their nonlinear behavior and wide distributions concerning lifetime characteristics of rubber caused by manufacturing, lifetime estimation is not trivial (Steinweger 2006, Wallmichrath et al. 2009). That is why nowadays preventive maintenance based on prior calculated lifetimes, often using linear damage accumulation, is state of the art in applying rubber-metal-elements.

Due to a lack of real data, lifecycle tests are performed to generate data for prognostics. Here accelerated lifecycle tests with an increased excitation force are realized because of the long lifetime of these bearings. In the suspension system of trains they are used for up to 8 years (Bender et al. 2017b). These lifecycle tests are performed on a vibration analysis system using a hydraulic cylinder as exciter. It enables movements of the outer ring of the bearing, whereas the inner ring is fixed. The rubber between those rings allows a small movement. Under this mechanical stress the characteristics of rubber change over time due to degradation. Finding a suitable measure to monitor a rubber-metal-bearing condition is a challenging task due to non-linear rubber characteristics and many possible impacts on the lifetime of rubber. Moreover, the structure of the elements increases the difficulty of installing a sensor for a suitable and reliable measure. In this work the focus is on temperature, a measure that is used in other applications as well, for example ball bearings (Kimotho, Sextro 2015) or subsystems of wind turbines (Crabtree 2011). The correlated concept for temperature measurements in rubber-metal-bearings is introduced in (Bender et al. 2017c). Based on that work, a prototype of a rubber-metal-bearing was developed that enables temperature measurement inside the bearing. Integrating a sensor inside the rubber presents a weakness and could lead to a shorter useful lifetime. Moreover, (Molls 2013) showed that temperature inside the rubber part of rubber-metal-bearings have deviations of maximum 3°C compared to temperature measurements at its surface. Therefore, the used thermocouples are placed inside the outer ring of the bearing close to the surface of the rubber. Little pockets are shaped in the metal, in which the thermocouples are bonded. These pockets protect the sensible thermocouples from external influences. Additionally to the absolute temperature of the bearing, the ambient temperature is measured close to the lifecycle tests.

3.2 *Measurement data*

For temperature measurements sheath thermocouples of type K are inserted in the lifecycle tests that are able to monitor the temperature of the bearing. Moreover, they are robust to weather the conditions of the tests and real applications. Data is measured over the whole lifecycle test including data of the failure state. Prior to the prediction, the measured data is preprocessed for generating empirical models. As shown before these models are based on a combination of e-functions which describes the graph of the measurements. The characteristic graphs of the absolute temperature of three bearings are shown in Figure 3.

In the beginning the absolute temperature of bearings raises strongly, before it fluctuates during the main part of the life of a bearing. Bearing 2 shows a small fall of temperature during that time whereas the temperature of bearing 3 stays almost constant. In the last part all temperature curves rise until the end of lifetime is reached. Analyzing Figure 3, it becomes obvious that in addition to their common characteristics these curves differ in aspects such as starting and ending temperature, lifetimes of bearings and the corresponding graph. This has different reasons based on characteristics of the bearing and operating conditions, especially the ambient temperature. That is why the ambient temperature is involved in the second measured value, the relative temperature. The graph of the relative temperature for bearing 3 is depicted in Figure 4. In general the curve of the relative temperature shows similar characteristics like absolute temperature of bearings during its lifetime. The significant temperature rise in the beginning and in the end is related to the absolute temperature of

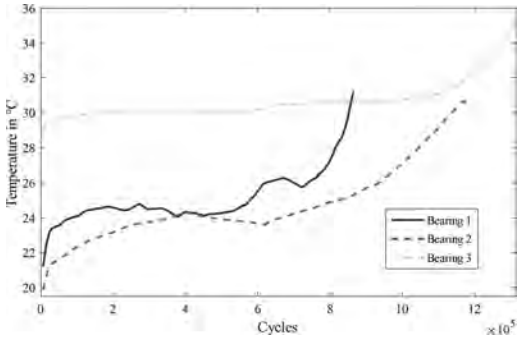

Figure 3. Absolute temperatures of bearings during lifecycle tests.

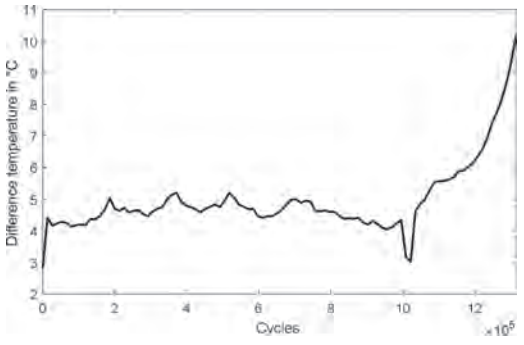

Figure 4. Relative temperature during lifetime of bearing 3.

the bearing. Due to the fact that the ambient temperature fluctuates more easily than the temperature inside the bearing, the relative temperature fluctuates during the main part of the lifecycle test. Moreover a stop of the test after about 10^6 cycles leads to a falling temperature because of a cooling. After starting the test again the temperature of the bearing raises quickly. Due to the similar graphs, all models of both measured values base on the same state equation, only the parameters differ. All in all, the relative temperatures have a more similar value range than the absolute temperatures of bearing. Therefore the models should fit better and might result in an improved prediction. Both measured values are implemented in the following analysis where the influence of the previously mentioned parameters comes under focus.

4 ANALYSIS OF PREDICTIONS

4.1 *Test structure*

In this chapter the presented measured values are used for estimating the RUL with the presented SIR particle filter. To find the best performance different parameters shall be implemented and compared. The following tests are evaluated on:

1. Measured values: absolute temperature of bearings and relative temperature
2. Number of simulations
3. Number or samples
4. Resampling strategy including different thresholds

For evaluating the performance a metric based on relative error is used. This metric is calculated analogue to Equation 4.

$$Error = \frac{RUL_{real} - RUL_{estimated}}{RUL_{real}} \cdot 100\% \qquad (4)$$

where RUL_{real} is the current RUL of the element and $RUL_{estimated}$ is the predicted RUL. In this work the RUL is estimated for different times from 15 to 95% of spent lifetime of the bearings. Thus the error is the mean error calculated as the mean of the RULs from different times. Thereby positive and negative errors compensate each other; therefore the number of negative errors is given in brackets to get an impression of the sign of single RULs. As an example Figure 5 depicts the RULs at the mentioned starting times for bearing 1. Illustrated are the real (grey circles) and the estimated RULs (black squares). The dashed lines symbolize an error band of 15%. Only one error is negative (1 N) which is good. Greater RULs present a too late prediction and thereby a possible unwanted breakdown of the system. The parameters used to generate this result are 100 particles, three simulations, resampling realized in every iteration step and the relative temperature as measured value.

4.2 *Results for bearing temperature*

In this paragraph prognostics base on absolute bearing temperature measurements and the associated models. The first parameter of interest is the number of simulations. Due to the fact that the SIR particle filter is based on probability it is necessary to reach a repeatable result within certain limits. To find a suitable number of simulations three different alternatives between three and 100 simulations are tested and the results are displayed for three test bearings in Table 1. The tests are numbered. An 'a' is added to the name as a symbol for measured value absolute temperature of bearings.

Table 1 shows that prediction of the RUL of these three test bearings do not lead to the same results regarding the best number of simulations. Each of the bearings shows the best performance for another number of simulations. However, the number of negative errors differs only slightly for

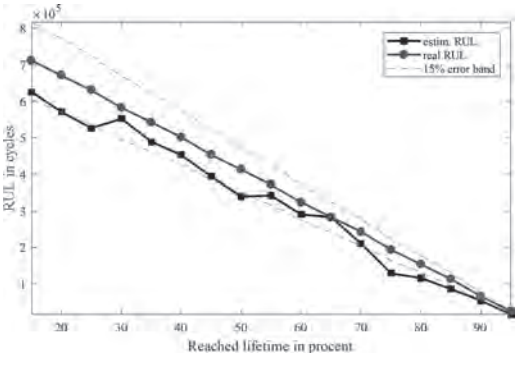

Figure 5. Estimated RUL at different times of bearing 1.

each bearing. SIR particle filter are sensitive to outliers (Arulampalam et al. 2002), that is why a high number of simulations is necessary to compensate outliers. To reach valuable results particle based methods need a suitable (minimum) number of samples or particles. Therefore in the previous simulations 100 particles were implemented.

For that reason 10 and 100 trails are analyzed again for varying number of samples from 100 to 1000 with the aim of improving the result. The performance metrics for the three test bearings are compared in Table 2. Again no consistent results over all bearings exist.

Bearing 3 performs best for 1000 samples, bearing 1 for more than 100 samples and bearing 2 for 100 samples. It indicates that especially bearing 2 leads to unexpected results. Furthermore, only 2/3 of the results exhibit a better performance for 100 simulations. This may be related to the small number of models. However, the difference between the results of variable trails decreases with a growing number of samples. To analyze the influence of the number of samples and resampling thresholds on the performance both parameters are varied in the next step for bearing 1. So far a continuous resampling was implemented; in Table 3 both resampling strategies are realized. The resampling threshold is in a first step based on the mean effective sample size measured during a continuous resampling strategy. In the following steps it is adapted to the performance metric. The chosen number of simulations is ten.

Table 3 underlines that a threshold based resampling strategy is able to improve the performance for both number of samples. While for 100 particles a threshold of around 50 leads to the best performance, for 1000 particles a threshold of 410 is the best. A threshold based resampling strategy can balance worse performance metrics based on a smaller number of simulations. As Table 3 shows, a parameter combination of 10 simulations, 1000 samples and a threshold of 410 (test 15a) leads

Table 1. Influence of number of simulations on prognostics of absolute temperature of bearings.

15a	1000	410	13.4 (0 N)
16a	1000	412	15.5 (0 N)

to a similar result like a parameter combination of 100 simulations, 1000 samples and a continuous resampling strategy (test 7a). In the context of online prognostics this could be a great advantage, since less simulations and a threshold based resampling strategy need less computational cost. However, the error is smaller for 100 samples, but more sensitive to unwanted negative prediction errors.

4.2.1 *Results for a further position of measurement*

Molls suggested that the rubber temperature inside the rubber changes quite similar to the surface temperature (Molls 2013). The measurements in this work show similar temperature behavior between the bearing temperature and the temperature measured at the bolt of a bearing. In Figure 6 these two temperatures are visualized for bearing 3.

This leads to the possibility of testing the method and the models, based on those of absolute temperature of bearings, by new bearings whose bolt temperatures are known. The used parameters are 100 particles, 10 simulations and a resampling threshold of 50 effective samples. The resulting errors are 12.6% (0 N) for bearing I and 4.0% (8 N) for bearing II. Figure 7 depicts

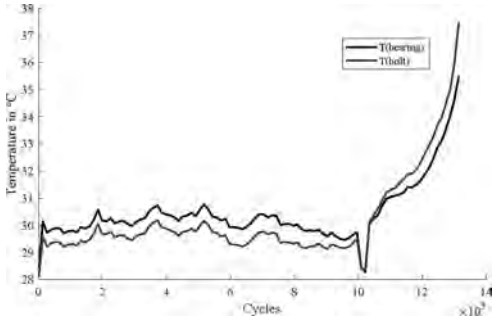

Figure 6. Absolute temperature of bearing and bolt temperature.

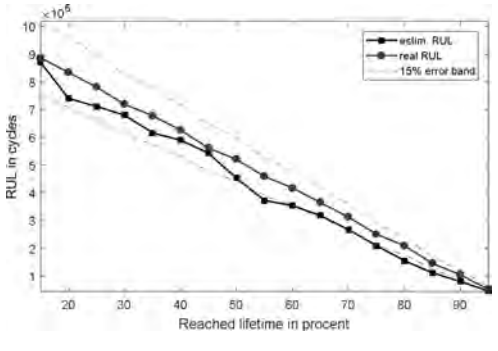

Figure 7. Estimated RULs for bolt temperature of new bearing.

the result of bearing I. The errors are within a 15% error band or just below it. The estimated RULs of bearing II fluctuate stronger as the large number of negative errors shows, while the mean error of 4.0% seems to be good.

These two tests show that temperature measurements close to the rubber-metal-element that have similar characteristics could be used for estimating RULs in the case of missing bearings' temperatures.

4.3 *Results for relative temperature*

In this paragraph predictions based on the relative temperature are evaluated. Because of the former results and the similarities between the two measured values, this evaluation is based only on bearing 1. The implemented models base on relative temperatures measurements. The structure of this analysis is similar to the one in chapter 4.2, the parameters simulations, number of samples and resampling strategy are varied and the performance metric is evaluated. In Table 4 the influence of the number of simulations on the performance of bearing 1 is shown for 100 particles. The names of the numbered tests for this measured value contain an added 'b'. The error falls with increasing number of simulations. The number of negative errors is small and nearly constant as before. The best result is based on 100 simulations that is why the predictions shown in Table 5 include 100 simulations.

Table 5 depicts an improved estimation of the RUL for an increasing number of samples. The best performance of 12.0% is predicted for 1000 particles. The former good result with less simulations and a threshold based resampling ($error_{15a}$) should be examined in the next step for the relative temperature. Table 6 shows the results for varying resampling strategies and thresholds based on

Table 4. Influence of simulations (bearing 1) for the relative temperature.

Test No.	Simulations	Error in %
1b	3	15.4 (1 N)
2b	10	12.7 (0 N)
3b	100	12.4 (0 N)

Test No.	Number of samples	Error in %
3b	100	12.4 (0 N)
4b	500	12.2 (0 N)
5b	1000	12.0 (0 N)

Table 6. Influence of resampling strategy (bearing 1) for the relative temperature.

Test No.	Number of samples	Resampling threshold	Error in %
6b	1000	–	12.5 (0 N)
7b	1000	390	12.5 (0 N)
8b	1000	395	12.0 (0 N)
9b	1000	400	11.8 (0 N)
10b	1000	405	11.9 (0 N)
11b	100	45	12.3 (0 N)

10 simulations and 100 or 1000 samples. Similar to Table 3 Table 6 presents possible performance improvements based on suitable thresholds. Due to the small differences regarding the performance metric of different number of samples, the best performance for 100 and 1000 samples were evaluated. An error of 12.3% was achieved for a threshold of 45 using 100 samples. The best threshold of 400 enables an error of 11.8% using 1000 samples. Comparing the threshold based results of 1000 particles and 10 simulations (test 9b) to the one of continuous resampling with 100 simulations (test 5b), the threshold based resampling slightly improves the former results. It can be concluded that a threshold based resampling can lead to an improvement of the performance of the SIR particle filter. At least a saving of computational time is realized.

4.4 *Comparison of the results*

In this part of chapter 4 the results of the two measured values are compared. Regarding the number of simulations, 100 simulations are less outlier prone and therefore lead usually to the best results. Comparing the errors, the measured value relative temperature enables better performance regarding the number of simulations. While the smallest error related to absolute temperature of bearing 1 is 14.0%, an error of 12.4% is related to the relative temperature of bearing 1. The errors are in most cases reduced by an increased number of samples. Once again the relative temperature performs better than the absolute temperature of bearings ($error_{5b}$ = 12.0%, $error_{4a}$ (bearing 1) = 13.3%). In the end the analysis of different resampling strategies emphasis that a threshold based resampling with a suitable threshold leads to a similar good performance with a smaller number of simulations. Moreover, in the case of the relative temperature the performance is slightly improved ($error_{5b}$ = 12.0%, $error_{9b}$ = 11.8%).

All in all estimating RUL for rubber-metal-bearings is possible based on temperature measurements and SIR particle filter for almost constant conditions. In reality applied bearings experience variable changing conditions, e.g. changing excitation. If the operation conditions are changed to a great extent, the similarity between the measurements will not be given. Therefore, implementing or adapting models for different excitation forces seems to be necessary.

5 CONCULSIONS

In this paper a temperature based estimation of the RUL of rubber-metal-bearings is introduced. To evaluate and improve the performance of the SIR particle filter number of simulations, number of samples and resampling strategy are analyzed. The predictions base on two different measured values, absolute temperature of bearings and relative temperature that includes the ambient temperature and absolute temperature of bearings. Predictions based on relative temperature show a better performance than those based on absolute temperature. The reason lies in bigger differences between temperature curves that lead to more variance in the results compared to predictions based on relative temperature. Regarding the parameter, on average 10 to 100 trials and 1000 particles are a good choice for this application. Moreover, both predictions can be improved by a threshold based resampling strategy. It can be concluded that even if rubber-metal-bearings show nonlinear behavior and slightly changing characteristics a threshold based resampling in combination with a suitable threshold enables a relative good RUL estimation based on temperature measurements.

Open questions are related to the threshold of the previous predictions. In this work the end of lifetime is defined by the last measurement. Therefore a threshold needs to be estimated that marks the end of lifetime. Moreover, finding thresholds for effective resampling can be optimized.

ABSTRACT: Different types of safety barriers are deployed in many infrastructures to reduce the occurrences of hazards, and protect people, environment and other assets in case the unexpected events have occurred and the capacity of these barriers against hazards can be weakened by degradations or the failures related to changes over time. It is natural to adapt the approaches of Prognostic and Health Management (PHM) to monitor the conditions and measurable parameters of safety barriers, and predict their future performance by assessing the extent of degradations. This study aims to identify the uniqueness and possible challenges when implementing PHM on safety barriers. Definitions and classifications of safety barriers will be discussed with considering their installation environment in infrastructures, in order to reveal what kind of characteristics of barriers can lead to higher demand on prognosis and heath monitoring. Another objective of this paper is to review the qualitative and quantitative measures for the capacity and performance of safety barriers, and to explore the possible methods and research gaps in the assessments for different PHM strategies, taking account their effects on safety barriers, and effects on the infrastructures being protected by the barriers.

1 INTRODUCTION

Maintenances can be defined as the activities to keep a system in a working order (Do et al. 2015). With the development of sensor technologies, the maintenances for many complex systems involve more and more condition-based and preventive activities to reduce maintenance costs on one hand, and improve their performance on the other hand (Sharma et al. 2017, Liu et al. 2017). Prognostics and Health Management (PHM), including fault detection, diagnostics, prognostics and health management, is a developing approach that enables real-time health assessment of a system and predicts of its future state based on up-to-date information. PHM has been conducted in many applications including manufacturing, aerospace systems, railway, energy, and military industry (Sun et al. 2012, Pecht and Rui 2010).

Safety barriers are installed in many critical systems and infrastructures to prevent hazardous events or mitigate their consequences, such as fire prevention systems and railway signaling systems. Technological safety barriers, such as shutdown valves in process, and airbags on cars, are also called as safety-critical system (Rausand 2014). But these safety barriers can also degrade and fail to accomplish their safety function under the evolving environment (Zio 2016). In case of failures of the barriers, serious accidents or disaster may occur. Many studies have been carried out on the operational and performance analysis of the safety barriers (Innal et al. 2015, Duijm and Goossens 2006, Innal et al. 2015, Rahimi et al. 2011, Cai et al. 2012), and most of them assume that the failures of components in the safety barriers follow the exponential distribution (Guo and Yang 2008, Jin and Rausand 2014, Catelani et al. 2011, Liu and Rausand 2011), meaning that their failure rate keep constant in any time.

According to IEC 61508 (2010) and IEC 61511 (2003), many technological safety barriers consist of three subsystems: sensor(s), logic solver(s) and actuating unit(s). The mechanical actuating units can degrade due to corrosion and wear-out etc, become more vulnerable along with time (Zio 2016), and so that the assumption of exponential distribution of failures is challenged. Based on this concern,

a growing attention is given to the predict degradations of safety barriers and offer suitable maintenances in advance to ensure the barrier adequacy. PHM can be a helpful approach in performance prediction and decision-making for maintenances.

The purpose of this paper is to review the techniques of PHM and designing and operational characteristics of safety barriers, so as to explore the research issues when the PHM approach is planned to be implemented for improving the integrity of safety barriers.

The remained of this paper is organized as follows: In section 2, the development and advantages of PHM are introduced; Section 3, includes the review of safety barriers in infrastructure and introduces technological barriers; Section 4 introduces several unmet problems and challenges related to using PHM on safety barriers. A conclusion is given in Section 5.

2 PROGNOSTICS AND HEALTH MANAGEMENT

2.1 *Development of PHM*

PHM is developed based on the concept of Condition-based maintenance (CBM). CBM is an approach to carry out maintenance actions based on the information collected through condition monitoring on systems in contrast to breakdown or time-based preventive maintenance. In order to make a timely decision on maintenance, prognostics is the key technology for CBM (Jardine et al. 2006, Shin and Jun 2015, Bousdekis et al. 2015). From this point, PHM is developed from the concept of CBM. A CBM program consists of three key steps (see Figure 1) (Lee 2004):

1. Data acquisition step;
2. Data processing step;
3. Maintenance decision-making step

Diagnostics and prognostics are two aspects in CBM. Diagnostics deals with fault detection, isolation and identification when it occurs (Jardine et al. 2006). Prognostics, in ISO-13381 (2015), is to estimate the time to failure and risk for one or more existing and future failure modes. The relative placement of detection, diagnostic and prognostic can be explained in Figure 2 (Gouriveau and Medjaher 2011).

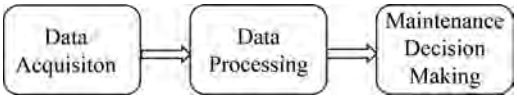

Figure 1. Three steps in CBM.

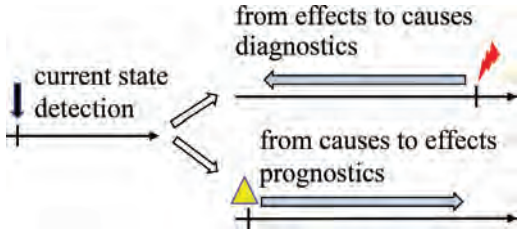

Figure 2. Complementarity of detection diagnostic and prognostic activities (Gouriveau, 2011).

In literature, prognostics is a process of health assessment and prediction, which includes incipient fault/failure detection, performance monitoring, life cracking and predicting residual useful lifetime (RUL) (Hess et al. 2005, Lee et al. 2014);

PHM is the extension of prognostics. According to CALCE (Center for Advanced Life Cycle Engineering) (2012), PHM is the means to predict and protect the integrity of equipment and complex systems, and avoid unanticipated operational problems leading to mission performance deficiencies, degradation, and adverse effects to mission safety.

Sun et al. (2010) regards PHM as a methodology to predict when and where failures will occur and to mitigate risks through evaluating the reliability of a system in its actual life cycle conditions. It is an enabling discipline of solving reliability problem in the process of design, manufacturing, operational and maintenance (Pecht and Jaai 2010). PHM is aiming to all information of an equipment in past, present and future while considering its environmental, operational and usage condition so as to detect its degradation, diagnose fault and predict and manage failures (Zio 2012).

Haddad (Haddad et al. 2012) regards PHM as a discipline that can used for: (i) evaluating the reliability of systems of their life cycle; (ii) determining the possible occurrence of failures and risk reduction; (iii) highlighting the Remanding Useful Lifetime (RUL) estimation. Actually, modern and comprehensive PHM systems take many issues into consideration, such as fault detection, fault isolation, useful life remaining, and performance degradation trending and then provides a broader set of maintenance benefits than any function by itself (Hess et al. 2005).

In this paper, we understand PHM as an approach to carry out dynamic management based on RUL which is predicted by status information collected through actual life cycle conditions, including environmental, operational and usage conditions.

2.2 *PHM architecture*

PHM means a complete process from capturing the data to decision-making (in maintenance,

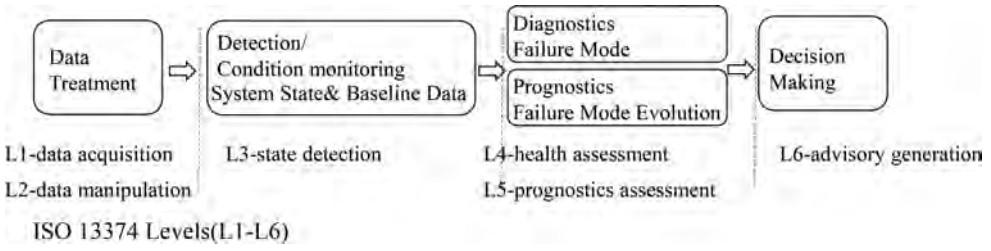

Figure 3. General process of PHM. Correlation with ISO 13374 (Guillén, 2016).

life time control, equipment design, etc.) (Guillén, Crespo, Macchi, & Gómez 2016), which is originally conceived by ISO 13374 and gradually becomes a standard in OSA-CBM (Open System Architecture for Condition Based Maintenance). As shown in Figure 3. The whole process of PHM is based on that of CBM, and can be divided into two parts. The first part (from Level 1/L1 to Level 5/L5) is related to health monitoring and prognostics, and the second part (Level 6/L6) is for health management.

In such a process, PHM attempts to answer several questions, e.g.:

- How is the status of system now? (Performance assessment).
- When will the system fail? (Remaining useful lifetime).
- What will the primary faults that cause system failure?
- Why does the incipient fault occur?

2.3 *PHM methodologies*

To answer the above questions, prognostics is currently carried out in different ways, namely with model-based, data-driven and hybrid prognostics (Brahimi et al. 2016).

The model-based approaches are based on a good knowledge of the physics of system and the available failure modes. Analysts can construct mathematical models with the above knowledge, and analyze those systems whose field operational and failure data is not enough (Lee et al. 2014, Luo et al. 2003). However, for many complex systems, one of limitations of the model-based approaches is the difficulty to create deliberate models representing the multiple physical processes (Pecht 2008). Moreover, it is very difficult to adopt the models built for some specific applications to the others, even though the systems are very similar.

The data-driven approaches are based on statistics and machine-learning techniques (Gu et al. 2007). In data-driven the remaining useful life would be predicted by fitting the monitoring data of developing fault to the degradation mechanism before it reaches the predetermined threshold level (e.g., see (Medjaher et al. 2012)). These methods are relatively simple to deploy due to the necessary of an analytical model of behavior and failure of the system.

The hybrid approaches are proposed in consideration of the pros and cons of the previous two groups (Lee 2004), in which prognostics results are claimed to be more reliable. The hybrid approaches have been used for the RUL prediction and maintenance of systems, such as (Kumar et al. 2008, García et al. 2010, Skima et al. 2015, Zhang et al. 2009).

PHM has been conducted in many areas, such as the infrastructures, aerospace industry, and in this paper we focus on the approach for safety barriers.

3 SAFETY BARRIERS

3.1 *Safety barriers and classification*

Safety barriers, or simply barriers are the equipment and features that are installed to protect people, the environment and other assets against harm should features or deviations occur in the most-designed system (Rausand 2013). Safety barriers are always related with a certain safety functions, which are defined by Sklet (2006) as the functions planned to prevent, control, or mitigate undesired events or accidents.

Figure 4 is a Bowtie diagram widely used in the field of risk analysis, where we can identify the two different roles of safety barriers. A hazardous event can occur due to some causes, so that some barriers can be located on the left side of the diagram (the causes side), to reduce the probability of the hazardous event. This kind of barriers are called as proactive barriers or prevention barriers, such as antilock braking system, electronic stability control system in automobiles. On the right side, some barriers are located on the right side (the consequences side), in case of the occurrence of a hazardous event, for reducing its effects or failure

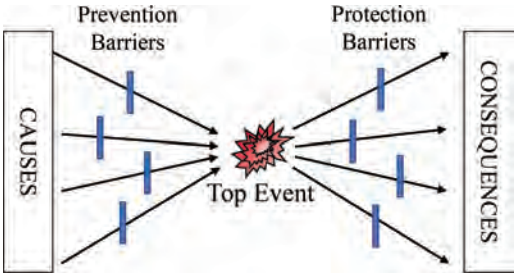

Figure 4. Bowtie diagram for a Top Event with prevention and protection barriers.

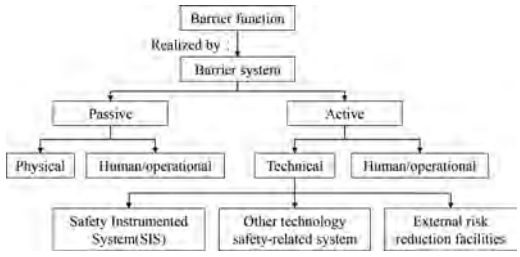

Figure 5. Classification of safety barriers (adopted from Sklet, 2006).

escalation, and they are regarded as reactive barriers, or protection barriers, e.g. seat belts, airbag systems (Hollnagel 2004, Rausand 2013, Groot 2016).

This classification is based on the objectives or functions of barriers. In addition, considering the operational modes of barriers, Rausand (2013) has distinguished safety barriers as passive and active barriers. An active barrier is dependent on some energy sources and a sequence of detection-diagnosis-action to perform its function, such as an airbag, Meanwhile, a passive system is not required to take an action and just by the presence of their elements to achieve its function (e.g. a seat belt).

Safety barriers also can be divided into on-line and off-line barriers. The on-line barriers operate continuously or so often, and on the contrary, the off-line ones are only used intermittently or infrequently. In practices, most protective barriers are off-line ones (Rausand & Arnljot 2004).

Sklet (2006), on the other hand, considers who are carrying out safety functions, and classifies barriers as the physical, technical, and human/operational barriers. Combining with the categorization based on the operational modes, we can obtain Figure 5. In the figure, technical barriers are always active. They are further divided into three groups: Safety Instrumented System (SIS), meaning that a technical barrier which involves the electric, electronic, and programmable electronic (E/E/PE) technologies, other technology safety-related systems and External risk reduction facilities. In the rest of this paper, we focus on technical barriers.

3.2 *Technological barriers*

A technological barrier, involving E/E/PE technologies and some mechanical items, generally consists of three subsystems: input element subsystem (e.g., sensors, transmitters), logic solver subsystem (e.g., programmable logic controllers [PLC]) and finial element subsystem (e.g., safety valves, circuit breakers). The main parts are illustrated in Figure 6.

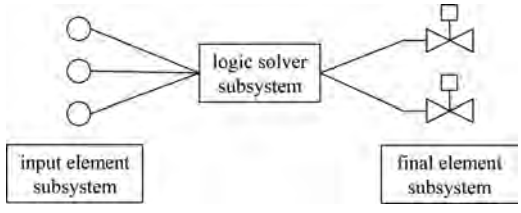

Figure 6. Main parts of a technological barrier.

The system protected by a technological barrier is called the Equipment Under Control (EUC). A safety-instrumented function (SIF) is a function that has been designed to protect the EUC against a specific demand. To enhance the reliability of a barrier, redundancy is often implemented in the system configuration.

4 DEVELOPMENT A PHM FOR SAFETY BARRIERS

We can introduce the PHM to safety barriers, with the purpose to assess the degree of deviation or degradation of barriers, and then plan maintenances in advances, so as to improve their availability and bring safety to EUC.

4.1 *Main functions of PHM on barriers*

Compared to the existing diagnostics of barriers, PHM is expected to predict failures from incipient failures or deviations in components. The main functions and potential benefits of the PHM on barriers can include:

- Advance warning of failures—Prognostics in PHM can evaluate the degradations of barriers, so as to detect incipient deviations. It is possible for maintenance staffs with prognostic results regarding the operational conditions to take actions on a barrier before a failure really occurs.

- Optimized maintenances—With prognostics, maintenance staffs also can estimate the remaining life of a component, especially a mechanical one, in a barrier, and then develop a maintenance, repair or replacement plan. Compared with scheduled maintenances, these condition-based and predictive maintenances eliminate unnecessary activities, and keep the barrier effective.
- Logistic support and cost reduction—Ideal prognostics tell the maintenance staffs when and where failures will occur, and thus they can identify and fix the failed components easily. PHM can reduce lead time and therefore increase the available time of safety barriers. Moreover, the "just-in-time" maintenances based on prognostics decrease the unnecessary costs of scheduled inspections and interruptions.

4.2 *Challenges of PHM on barriers*

Although PHM has been proved in many applications, we may meet challenges when we implement PHM on the technological safety barriers, due to the following design and operational characteristics of barriers:

4.2.1 *Operational modes of barriers*

Current PHM is always used for systems continuously running, while safety barriers have several operational modes in stead:

- Low-demand mode: where the safety function is only performed on demand, and where the frequency of demands is relatively low;
- High-demand mode: where the mechanism is same as low-demand, but the frequency of demands is relatively high;
- Continuous mode: where the safety function is a part of normal operation.

In the latest version of IEC 61508 (2010), the borderline between low-demand and high-demand is once per year in terms of demand frequency.

For those technologies barriers with demanding operational modes, they are usually in a dormant state and transit to an active state in case that demands come. The degradation mechanisms in different states are varied. Not many studies have been conducted so far on degradation prediction with state transitions. We need new approaches of parameters to predict the future performance of a barrier in response to demands during the durations of demands.

4.2.2 *Structures of barriers*

Redundancy structures are often used in barriers to improve availability and to enhance safety, e.g., two shutdown valves are installed in parallel to stop flow when the downstream pressure is too high. When one of them cannot activate, the process is still safe if the other works. Such kind of structures is called as 1-out-of-2 configuration. For a system with N channels, if at least K of the N channels need to be functional to ensure that the system is functional, the system has a K-out-of-N (Koo$N$) configuration.

Many barriers can be adaptive, meaning that they can change their configurations to perform safety functions when some expected occur. For example, a 2oo3 barrier can automatically transit to a 2oo2 configuration when one of the three channels fail. The challenge for PHM is to predict the effects of degradations in one channel on the entire barrier system with complex configuration and adaptivity, as well on the EUC.

4.2.3 *Failure modes and tests of barriers*

Failures of technological barriers can be classified as dangerous (D) failure and safe (S) failure. D failure refer to a failure that has the potential to put the barrier in a hazardous or fail-to-function state, while S failure does not leave the barrier in fail-to-function state (Rausand 2014), e.g. a valve shuts down unnecessarily.

The integrity of a technological barrier is highly related with tests, especially for those running in the low-demand mode. Regular proof tests are conducted on technological barriers (e.g. once per year), to reveal failures and then initiate maintenance activities if necessary. Many modern safety barriers have installed automatic self-testing modules, which has a diagnostic function and detects some failures. The D failures that can be found in diagnostic tests are called as dangerous detected (DD) failures, such as signal loss, signal out of range and final element in wrong position (Rausand 2014). The D failures that are not detected are called dangerous undetected (DU) failures. DU failures are only revealed in proof tests with regular intervals.

A research challenge of PHM is therefore to find suitable approaches to link the incipient failures or deviations with those D failures of interest in integrity of barriers. Most data-driven PHM approaches depend on the historical/training data to predict the trends of failure, but in those published data sources for technological barriers, such as Offshore Reliability Data (OREDA) and Process Equipment Reliability Data, we cannot find any clues. For model-based PHM approaches, no guidance is given to deal with those DU failures.

Another challenge is from the failure occurring in the redundancy structures. Common cause failures (CCFs) are the main contributor of the unavailability of redundant safety barriers (Hauge

et al. 2015). CCFs are the failures of multiple components simultaneously or with a short time interval due to a shared root cause or a common cause. It is valuable to identify those deviations that can lead to CCFs and predict their potential influences in PHM.

4.2.4 *Measures of technological barriers*

IEC 61508 (2010) suggests the average probability of failure on demand (PFD) as a measure for technological barrier of low-demand, and the probability of failure per hour (PFH) as the measure for technological barrier of high-demand. And then, for different results of PFD and PFH, safety barriers can be located at different integrity levels (SILs), from the loose SIL 1 to the strictest SIL 4. These measures are widely used, and they are calculated always on the basis of some basic assumptions (Jin and Rausand 2014, Wang and Rausand 2014, Rausand 2014), including: (1) each failure is assumed to occur at a constant rate (i.e. exponential distributed failures); and (2) the channels in a redundant structures are identical and independent.

We release these assumptions when implementing PHM, and so weaken the theoretical foundations of measure calculations, since we have realized that deteriorations in mechanical components of a technological barrier is unavoidable. However, to evaluate the effectiveness of a PHM program, we still need to utilize the widely accepted measures, and build a relationship between SILs and effects of PHM.

4.2.5 *Cost-benefit analysis of PHM*

Safety and availability are dominator in the assessment of safety barriers. But for PHM, the return-on-investment (ROI) needs to be considered (Saxena et al. 2008, Wang and Pecht 2011), especially for the fact where other test and diagnostics are also employed on safety barriers.

The main work for ROI analysis or cost-benefit analysis is to quantify the costs and benefits of PHM (Scanff et al. 2007). The costs of a PHM program can includes: the cost of acquisition and installation for data, such as sensors and microprocessors, the cost of re-design of host product, which can be a big investment (Sun et al. 2012). The benefit is more complex including the decrease of proof tests and maintenances. It is challenging on how we choose the indicators to calculate the ROI of a PHM program. Moreover, we also need to determine the best PHM program for a specific technological barrier.

5 CONCLUSIONS

In this paper, a short review of PHM is presented. PHM enables estimating the RUL of the in-service equipment which can provide timely decision for maintenance. Due to the vital role of technological barriers and the advantages of PHM, an idea for developing a PHM system for SIS is presented. Compared with mechanical systems, technological barriers have their own characteristics which propose new challenges.

Therefore, we propose several research topics to be addressed in future, specifically in a PhD project:

- New approaches for predicting degradations of a component with state transitions;
- Mechanism of incorporating redundancy structures and varied configurations in degradation modeling and analysis;
- Models to link the effectiveness of PHM with the measures for safety barriers;
- Methods to optimize PHM and other maintenance activities under the constraints of SIL requirements by safety barriers.

ABSTRACT: One of the main challenges faced by the industry in the context of failure diagnosis is the high quantity and high dimensionality of the available data. Due to the increasing capability and availability of sensing technology, nowadays it is possible to acquire a large amount of (unlabeled) data on many operational and maintenance related variables from monitored machines. The problem lies on how to extract useful information from such data. A standard approach in fault diagnosis is to first apply a dimensionality reduction method. In this paper, we propose a method for dimensionality reduction based on Variational Auto-Encoders (VAEs). VAEs have shown good results in areas such as image processing, image generation and speech processing. In particular, in this paper, the VAE based method works on spectrograms generated from vibration signals measured during system's operation. This approach is applied to the fault diagnosis of ball-bearings.

1 INTRODUCTION

The early detection of faults in machinery is nowadays one of the main challenges faced by industrial sectors. In general, faults in machinery components yield to one of two possible results. Either the component is replaced according to the manufacturer instructions, which in the majority of the cases leads to a less than optimal useful life of the element, or the sudden failures occur that causes a performance drop in the machine. Nowadays, the development of new methods that can identify faults early and that make use of the entire useful life of the component is an active topic of research (Hasani, Wang, & Grosu, 2017; Liu, Li, & Ma, 2016).

One possible approach to this problem is to assume that data measured during the operation of a machine contains useful information about its health state and that such information can be extracted if a proper technique is used. Machine Learning has been used in the past to excerpt useful information from fault data (Blum & Langley, 1997; Cireşan, Meier, & Schmidhuber, 2012).

Nevertheless, the use of Machine Learning in conjunction with operational and maintenance data brings another problem to the table: the curse of dimensionality. Usually, data obtained during the operation of a system tends to be noisy and high dimensional. The use of a dimensionality reduction techniques is a popular strategy to improve diagnosis or prognosis performance; see for example (Shuang, Automation, ICMA, & 2007, n.d.) for Support Vector Machines and (Pan, Rust, Networks, IJCNN, & 2000, n.d.) for Artificial Neural Networks (ANN).

In fact, one type of model that has been developed with the objective of performing dimensionality reduction within the Machine Learning field are Auto-Encoders (AEs) (Hinton & Salakhutdinov, 2006). AEs are unsupervised models based on the use of neural networks. They are trained passing the data through an intermediate layer that is of lower dimensionality than the input, thus generating a latent representation and performing a dimensionality reduction. Then, the rest of the neural network tries to reconstruct the input from this reduced representation, forcing this latent space to be meaningful. In the area of fault diagnosis, AEs and its variants have been used recently with great success (Liu et al., 2016; Zhou, Gao, & Wen, n.d.).

Another model that also uses the idea of reducing the dimensionality of the data feeding it through a pipeline that generates a latent representation are Variational Auto-Encoder (VAE) (Kingma & Welling, 2013). VAEs nowadays are one the most auspicious unsupervised machine learning techniques, mainly because of their success in the processing of complex data such as images (Rezende, Mohamed, & Wierstra, 2014; Salimans, Kingma, & Welling, 2015) and speech (Hsu, Zhang, & Glass, 2017). VAEs use a combination of variational inference (Blei, Kucukelbir, & McAuliffe, 2017) and neural networks to solve the difficult problem of finding a good approximation of a posterior distribution in a Bayesian model. However, not attempt has been made to develop a dimensionality reduction method using VAE as the underlying model for fault diagnosis.

Therefore, this paper presents a VAE based dimensionality reduction approach for fault diagnosis in machinery using spectrogram images extracted from vibration signals, and evaluate it by comparing the classification results between the proposed approach and the case where no reduction in dimensionality is performed.

This paper is organized as follows. Section 2 introduces the VAE model. Section 3 discusses the proposed VAE's architecture for performing fault diagnosis. Then, Section 4 presents an example of application. Finally, Section 5 draws some concluding remarks.

2 VARIATIONAL AUTO-ENCODERS

Variational Auto-Encoders (VAEs) are generative models originally proposed by (Kingma & Welling, 2013) that are built on top of the concept of variational inference (VI) (Blei et al., 2017). VI is an approach used for solving the problem of approximating difficult to compute probability distributions. In a Bayesian framework, the observations x are assumed to be produced by a set of latent or hidden variables z. In general, the objective is to compute $p(z|x)$ because of two main reasons. First, for an observation x_i, the vector of latent variables that produce such observation can be of interest in itself, for example, when the latent variables represent physical magnitudes that are not easily measurable. Second, using $p(z|x)$ and the Bayes theorem, one would be able to compute $p(x)$ which represents the model that generates the data itself. This is of special interest for generative models where the objective is to produce new data that shares characteristics with the data that is already in the dataset.

The main difference between VAEs and others variational inference based approaches is the assumptions made over the distributions that controls the model. In the VAE model, such distributions are assumed to be parametrizable by a set of parameters (e.g., Normal or Bernoulli distributions). These parameters can be found by neural networks via a proper training. The combination of the assumptions made for the distributions and the use of neural networks is what made the VAE model so efficient in searching the approximation of the true posterior $p(z|x)$. For the proposed VAE based dimensionality reduction approach, in the following sections we discuss the parametric form for the prior over the latent variables $p(z)$ the data conditioned over the latent variables $p(x|z)$ and the approximate posterior distribution $q(z|x)$ along with the form that the objective function of the VAE.

2.1 *Prior over the latent variables $p(z)$*

The definition of the latent variables of a certain model is usually a complex problem. The nature of those variables or the relationship between them are very difficult to express beforehand without deep knowledge about the situation that we want to model. VAEs takes an easy approach to this, assuming that the latent variables are distributed according the following distribution:

$$p(z) \sim N(z \mid 0, I) \tag{1}$$

From Equation 1, the prior distribution for $p(z)$ assumes no prior information about the relationship between the latent variables or the nature of them (other than they are Normally distributed). As it is mention in (Doersch, 2016), this can be done because any distribution of k dimensions can be originated by a vector of k variables Normally distributed if they are processed with a function that is complex enough. This function corresponds to the neural network of the VAE's decoder.

2.2 *The data conditioned on the latent variables $p(x|z)$*

This distribution represents the probability of x being generated by the latent variables contained in z. Note that the family of $p(x|z)$ should be defined based on the nature of the data. For example, for black and white spectrograms, or gray scale ones that are real valued but restricted to the interval (0,1), $p(x|z)$ is chosen to be a Bernoulli Distribution, in the form of:

$$p(x|z) \sim Be(x \mid f(z, \theta)) \tag{2}$$

The function $f(z|\theta)$ is a neural network that takes as inputs both the latent variables z and a

vector of parameters θ that represent the weights and biases of the NN, and then outputs a vector of Bernoulli parameters, $\vec{\rho}$, to define the distribution. Here we can see that it does not matter if z is sampled from a simple distribution such as a standard Normal, because if we let f to have an acceptable level of complexity (i.e., number of neurons and layers), then f will be able to first find the mapping between those Normally distributed samples for z to the true but unknown distribution that controls the latent variables, and then find the relationship between that distribution and the vector of Bernoulli parameters. The Bernoulli distribution is chosen to represent the output of the decoder for cases where binary data is being reconstructed by the VAE, as it is the case in this paper where we use images as inputs for the model.

The structure formed by f and $p(x|z)$ is named the decoder of the VAE, since its job is to output a reconstruction of the original input from the latent variables z.

2.3 *The approximate posterior q(z|x)*

In variational inference, the true posterior $p(z|x)$ is approximated by a distribution $q(z|x)$ that is searched in a family of parametric distributions of probabilities Q. In the VAE model, Q is assumed to be the family of multivariate isotropic Normal distribution. So, the following is true for $q(z|x)$:

$$q(z|x) \sim N(z|\vec{\mu}(x,w_1),\vec{\sigma}(x,w_2)I) \tag{3}$$

In Equation 3, the distribution $q(z|x)$ have both of its vectors of parameters, $\vec{\mu}$ and $\vec{\sigma}$ parametrized by neural networks that take as inputs the input data and vectors of weights and biases denoted as w_1 for the means vector and w_2 for the variances vector. The structure formed by the distribution $q(z|x)$ in conjunction with the neural networks for $\vec{\mu}$ and $\vec{\sigma}$ is called the encoder of the VAE since its task is to transform the input data to the latent representation z. The choice of a Normal distribution to represent the approximate posterior in the VAE model serves a double purpose. First, as we shall see in the next section, this choice allows a very quick and efficient training of the VAE. Second, without adding excessive complexity, the use of a Normal distribution adds flexibility to the model, since every latent variable will be controlled by its own mean and variance.

Since VAEs uses variational inference to find the approximate distribution $q(z|x)$, the idea is to train the neural networks that parametrize the vectors $\vec{\rho},\vec{\mu}$ and $\vec{\sigma}$ optimizing the VAE's objective function. But before, we need to be precise about the form that the VAE's objective function will take with the assumptions made for $p(z)$, $p(x|z)$ and $q(z|x)$.

2.4 *Objective function of the VAE model*

As stated before, the VAE model uses variational inference to solve the problem of finding a good approximate to the true posterior distribution $p(z|x)$. Variational inference proposes the following objective function to optimize and find $q(z|x)$, named the Evidence Lower Bound (ELBO) function:

$$ELBO(q(z|x)) = E_{q(z|x)-Q}[\log p(x|z)] - KL(q(z|x)\|p(z)) \tag{4}$$

It can be proved (Blei et al., 2017) that by maximizing Equation 4, variational inference is able to find the parameters that determines the best possible approximate distribution $q(z|x)$ within the chosen family of distributions Q.

In the ELBO function, there are two terms that need to be computed efficiently in order to find $q(z|x)$. First, as both distribution $q(z|x)$ and $p(z)$ belong to the Normal family, the Kullback-Leibler divergence that appears in Equation 4 between them will have closed form. The KL divergence between an isotropic Normal and a standardized normal, as stated in (Doersch, 2016), is shown in Equation 5:

$$KL(N(\vec{\mu},\vec{\sigma}I)\|N(0,I)) = 2(tr(\vec{\sigma}I) + \vec{\mu}^T\vec{\mu} - k - \log det(\vec{\sigma}I)) \tag{5}$$

where k is the dimensionality of the distribution, i.e., the dimensionality of the latent space of the VAE model.

The first term that appears in the ELBO function is the expectancy of the logarithm of $p(x|z)$. Computing that expectancy by sampling from z would be extremely inefficient because that would require the evaluation of f (which is a neural network that may be very complex) many times in order to obtain a good estimation of the expectancy. The neural networks within the VAE model are trained using stochastic gradient descent (SGD), so we could also use SGD in the evaluation of this expectation by sampling one time from z, compute $logp(x|z)$ from that value of z and then use that results as an estimation of the expectancy above mention. This process will be repeated until the solution converges to a good result for the posterior approximation.

2.5 *The variational auto-encoder model*

In Figure 1 a graphical representation of the VAE that comprises all the elements discussed before model is portrayed.

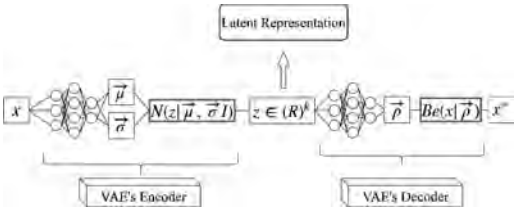

Figure 1. VAE model, with both neural networks, one for the encoder and the other for the decoder. Notice that it is the encoder that generates the latent representation z, and then the decoder, from that latent representation, reconstruct the input.

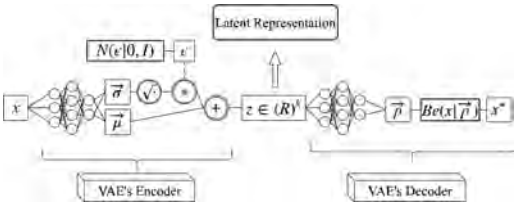

Figure 2. VAE model with the reparametrization trick applied.

Nevertheless, there is still one difficulty with the VAE model. It is known that neural networks use the back-propagation (BP) algorithm for performing a more efficient training. But BP does not work if there are stochastic units within the network, as it is the case when we sample from the encoder's distribution, since they have no gradient, therefore cannot propagate the error using the chain's rule. Kingma and Welling (Kingma & Welling, 2013) proposed a solution for this problem called "the reparametrization trick", in which all the stochasticity of the model is moved to an input, so the error can be propagated without problems. Figure 2 shows the VAE's model with the reparametrization trick applied.

3 PROPOSED VAE'S ARCHITECTURE FOR DIMENSIONALITY REDUCTION

The VAE model have as core components two neural networks, one for the encoder and other for the decoder. In what follows, the proposed architectures for such neural networks are described.

3.1 *Encoder's deep neural network architecture*

In Figure 3, a graphical representation of the encoder's neural network is portrayed.

The encoder's neural network is chosen to have three hidden layers with a number of units equal to 400, 200 and 100 for the first, second and third

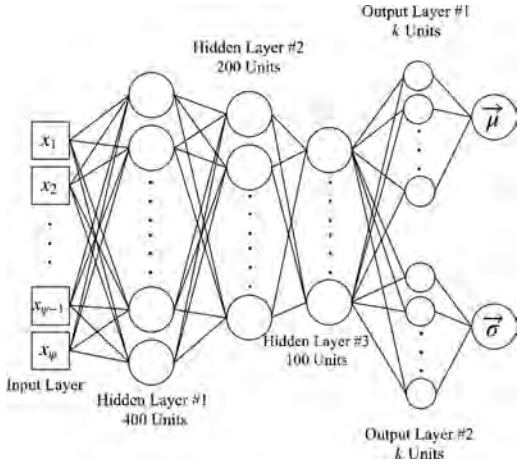

Figure 3. The encoder of the proposed VAE has three hidden layers, and two output layers, one for the means vector $\vec{\mu}$ and other for the variances vector $\vec{\sigma}$. The number of units in both output layers is k, the chosen dimension for the latent space of the VAE.

layer, respectively, and two different outputs layers, one for the vector of means, $\vec{\mu}$, and one vector of variances, $\vec{\sigma}$, to parametrize the approximate posterior distribution $q(z|x)$. In this case, both outputs layers have k units, where k corresponds to the target latent space dimension, i.e., the dimensionality of the data once the reduction is performed. This neural network uses the ReLU activation function in all the hidden layers.

3.2 *Decoder's deep neural networks architecture*

In Figure 4, the decoder of the proposed VAE model is portrayed.

As shown in Figure 4, the decoder of the proposed VAE has three hidden layers with 100, 200 and 400 units for the first, second and third hidden layers, respectively, and one output layers with ψ units, where ψ is the dimensionality of the data prior the reduction. Similarly to the encoder's case, this neural network has in all its hidden layers the ReLU activation function.

Both the VAE's encoder and decoder work together to first compress the data to its latent representation by computing the parameters that controls the distribution $q(z|x)$ to sample from it the latent variables and then decompressing the data from this latent representation to a reconstruction of its original form by first computing the vector of Bernoulli parameters $\vec{\rho}$ and then, depending on whether the data is binary or real valued restricted to the (0,1) interval, sample from the distribution or take $\vec{\rho}$ as the reconstruction itself.

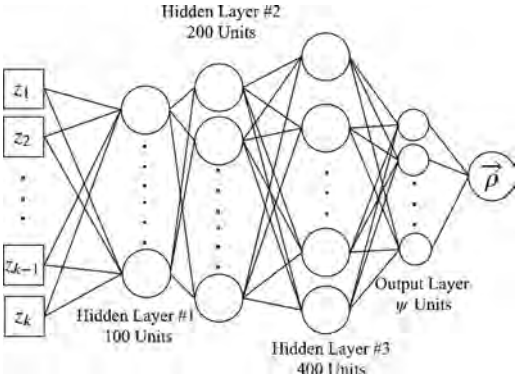

Figure 4. The decoder of the proposed VAE model has three hidden layers and one output layer to compute the vector of Bernoulli parameters $\vec{\rho}$. The number of units in the output layer is equal to ψ, the dimensionality of the input data.

Figure 5. Dimensionality reduction method based on the Encoder of a VAE that has been trained successfully.

Once the VAE is trained, the neural network of the encoder can be used as a feature map to reduce the dimensionality of the input data to the lower dimensionality space by computing the means and variance vectors. Nevertheless, it is usually the case where the dimensionality reduction is preferable to be deterministic, i.e., it does not include any sampling in its process. This can be done if we note that the probability distribution of the encoder is a Normal distribution, so we could take the vector of means from the encoder's neural network as the latent variables directly in the form of $z = \vec{\mu}$. This provides a latent representation that does not vary each time a reduction over an specific data point is performed. A graphical representation of the dimensionality reduction process using the VAE's encoder can be seen in Figure 5.

4 EXAMPLE OF APPLICATION

4.1 *Dataset*

We use vibration data from the Society for Machinery Failure Prevention Technology (MFPT) open dataset (Bechhoefer, 2016) that was obtained during the operation of a NICE ball-bearing element. The dataset contains three main classes, each corresponding to one health condition: baseline (where no failure is present), outer race fault and inner race fault. The original signals for each class were first divided into portions of length $L = 1024$ points each. Besides, we use 50% of overlap between adjacent chunks. Then, by means of the Short Time Fourier Transform (STFT), a spectrogram of each section of data was computed, and then via a bilinear interpolation (Raveendran & Thomas, 2014), it was transformed into an image of 96 by 96 pixels. We chose to use spectrograms because they can portray both time and frequency information of the signal, instead of just time information as it would have been the case if we fed the original signal directly into the VAE model. Table 1 shows the total number of images per class in the dataset.

But, in order for the VAE model to work properly, as we can recall from Figure 3, the VAE's encoder has to receive as input a vector of CH131_181-E021.eps components, not a two dimensional array as it would be if we fed the spectrogram images directly to the model. Thus, we need to first reshape the images by stacking horizontally their rows to form vectors, as it is shown in Figure 6.

4.2 *Validation experiments*

We are interested in two situations. First, we want to know if the VAE's latent representation is stable across dimensions of the latent space. This is of important because the decision of the dimensionality k is not clear beforehand, and it usually relies on the person in charge of the analysis, so models that are less sensitive to variations of this parameter present an advantage over those who needs a fine tuning to be effective. For this purpose, we perform reductions using the VAE approach to a series of different values of k and then analyze if variations in the dimension of the latent space pro-

k	ε
2, 4, 8, 16, 64, 128	1%, 100%

duce variations in the accuracy of classification. The values of k tested can be seen in Table 2.

The second situation of interest is when the amount of labeled data available is low. This is usually the case in industrial applications, because it is usually cheap to acquire data from installed sensors, but the process of labeling such data for training machine learning models requires highly qualified personnel and often further analysis on the machine's degradation process. For this, we will test two extreme situations: where the size of the training dataset training for the fault diagnosis model is either the full training dataset or only 1% of it. This is represented by the parameter ε, the percentage of the training dataset available. This emulates situations where we might have a very reduced amount of labeled data versus when the availability of labeled data is not a concerning issue and from there, evaluate if the VAE based reduction generates a representation of the data that makes the differences between the different health states more explicit, so that the NN based classifier can still learn even if less data is available. Recall that as the VAE is an unsupervised model, it does not require labels for its training, so even when working with ε = 1%, the VAE can use the whole training dataset for its unsupervised training.

For the classification tasks, we use a neural network based classifier with a single hidden layer of 100 units and ReLU activation function. The regularization is performed via dropout with probability equals to 50%. For the output layer, softmax is used as the activation function. The model is trained using the cross entropy cost function, a learning rate of 10^{-4} and a maximum of 15000 epochs. The VAE's weights and biases are initialized with the Xavier initialization (Glorot & Bengio, n.d.) and with an array of zeros, respectively. For the NN based classifier, the weights and biases were randomly initialized with a Normal distribution of zero mean and unity variance.

The results shown in the next section were obtained following the steps below:

I. Choose a value for ε and k from Table 3. Then, divide the whole dataset into a training and testing set in the proportion 3:1.
II. Train the VAE in an unsupervised way using the full training dataset. This training is performed using a maximum of 500 epochs and learning rate equal to 10^{-4}.
III. Reduce the dimensionality of the training and testing datasets with the trained VAE's encoder as discussed in Section 3.
IV. If ε = 1%, extract that proportion from the training dataset, and train the NN based classifier. If ε = 100% use the whole dataset to perform the training.
V. Use the full testing dataset to evaluate the accuracy of the classification obtained.

We also compare the results obtained with the VAE model against results obtained when the spectrograms are fed directly to the NN-based classifier. To perform this type of experiment, the same procedure as before applies except for steps II and III.

The hardware and software used in the example of application are: Nvidia GPU Titan X, an Intel Processor i7 7700k, 32Gb of RAM DDR4 and Tensorflow 1.2.0 combined with CUDNN 8.0.

4.3 *Results and discussion*

In Figure 7 and Figure 8, results regarding the accuracy obtained in the classification of health states when using the VAE approach to reduce the dataset to different values of k are compared against the case where no reduction is performed to the dataset.

Table 3 shows the best accuracy results obtained with the VAE approach and the model that does not perform a reduction in dimensionality, for either ε = 1% or ε = 100%

As we can see from Figure 7 and Figure 8, fault diagnosis accuracies obtained with the VAE model are almost always better than the ones obtained when no reduction is performed. The only excep-

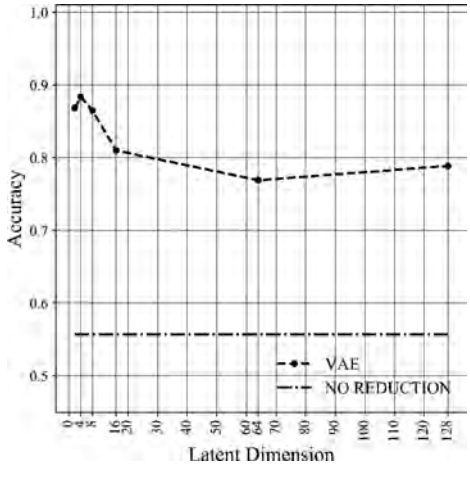

Figure 7. Accuracy versus latent space dimension for the case where only 1% of the training dataset is used to train the NN classifier.

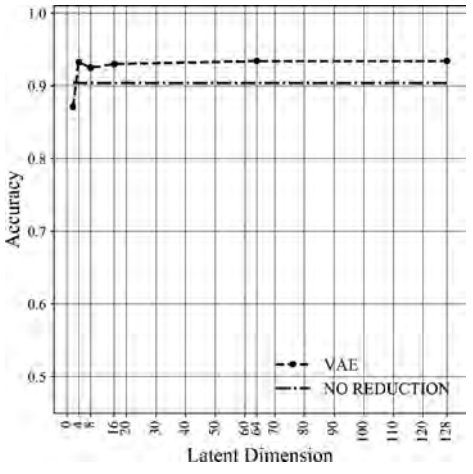

Figure 8. Accuracy versus latent space dimension for the case where the full training dataset is used to train the NN classifier.

Table 3. Best accuracy results for both models tested. The VAE model achieves its better results for values of k equal to 4 and 64 for ε = 1% or ε = 100% respectively.

VAE	No reduction
$\varepsilon = 100\%$	
93.43%	90.38%
$\varepsilon = 1\%$	
88.39%	55.76%

tion is when the full training dataset is used and the VAE model reduces the dimensionality to $k = 2$. This can be explained from the fact that the spectrogram images have an original dimensionality of $\psi = 9216$ data points (96 by 96 pixels), and to reduce from that dimension to $k = 2$ will induce some loss of information. Nevertheless, from Figure 8 and for every other choice of k (including $k = 4$) the VAE model surpasses in terms of fault diagnosis accuracy the model that do not perform reduction.

Also observe that the drop in accuracy caused by the reduction in the size of the training dataset is much less notorious for the VAE model. As we can see from Table 3, the drop in accuracy for the VAE model is approximately 5% for reducing the training dataset a 99% of its original size, but for the model that do not perform a reduction in dimensionality, the drop is about 45%. That clearly indicates the robustness of the VAE's latent space in making the different health states present in the dataset more differentiable for the NN based health state classifier.

In terms of the results obtained with the VAE by varying the latent space's dimensionality, the size of the training dataset does affect the stability of the model. For ε = 100%, except for $k = 2$, the model is very stable with differences in accuracies of maximum 2%. Instead, when ε = 1%, the model needs to be tuned prior its application in order to find the dimension that delivers the best performing latent space, since the differences in accuracies reach 12%.

5 CONCLUDING REMARKS

We have introduced a new method for performing dimensionality reduction in a dataset using deep Variational Auto-Encoders. The VAE model maps the data to a latent representation that can be chosen to have a lower dimensionality than the original data, thus producing a dimensionality reduction.

Results show that when using the STFT and spectrogram to preprocessed ball-bearings operational data provided by vibration sensors, the VAEs approach produces better accuracies in the classification tasks performed than the model that do not perform a reduction in dimensionality, especially when the available labeled data to train the fault classifier is limited.

ABSTRACT: System health management is of upmost importance with today's sensor integrated systems where a constant stream of data is available to feed information about a system's health. Traditional methods to assess this health focus on supervised learning of these fault classes. This requires labeling sometimes millions of points of data and is often laborious to complete. Additionally, once the data is labeled, handcrafted feature extraction and selection methods are used to identify which are indicators of the fault signals. This process requires expert knowledge to complete. An unsupervised generative adversarial network based methodology is proposed to address this problem. The proposed methodology comprises of a deep convolutional Generative Adversarial Network (GAN) for automatic high-level feature learning as an input to clustering algorithms to predict a system's faulty and baseline states. This methodology was applied to a public data set of rolling element vibration data from a rotary equipment test rig. Wavelet transform representations of the raw vibration signal were used as an input to the deep unsupervised generative adversarial network based methodology for fault classification. The results show that the proposed methodology is robust enough to predict the presence of faults without any prior knowledge of their signals.

1 INTRODUCTION

Much of fault diagnostics involves the use of labeled data. This is challenging for new assets outfitted with sensor suites capable of generating massive amounts of data. Without knowledge of faults or their corresponding signals, engineers may not be able to diagnose faults effectively. Traditional methods include feature extraction and selection methods which attempt to use a specific feature of the signal to diagnose the faults. This method requires knowledge of which features are relevant for the task. Moreover, if an engineer has some knowledge of the fault, that knowledge could be biased or incomplete. Unsupervised fault diagnostics attempts to fill in that knowledge.

Deep learning algorithms can perform automatic feature learning to better understand the underlying data features that are most relevant. This automatic feature learning attempts to fill in the gaps of knowledge of relevant features to the fault signals. There are challenges with this automatic feature extraction and selection.

Unsupervised learning has been attempted for fault diagnostics previously. Indeed, Langone (2017) took pre-stressed concrete bridge natural frequency data and proposed an unsupervised adaptive kernel spectral clustering for damage events. Wang (2016) proposed unsupervised feature extraction via continuous Sparse Auto-Encoders (SAE). Once the SAEs extracted the features supervised learning was used on transformer faults. Lei (2016) proposed unsupervised sparse filtering feature learning. Faults were then diagnosed with supervised softmax regression. Jiang (2016) proposed unsupervised feature learning with SAEs for chemical sensor data. These features were fed into supervised softmax regression to diagnose faults. Sun (2016) took induction motor fault data and proposed the use of SAEs for unsupervised feature extraction. These features were again followed by supervised learning for classification by neural networks (NN). Of these approaches, only Langone et al. could be considered truly unsupervised. The rest are restricted to unsupervised feature learning followed by supervised fault diagnostics. Moreover,

apart from the use of SAEs, none of these methods would be considered deep.

In this paper, we propose a GANs based methodology application to unsupervised fault diagnostics on scalogram image representations. To validate the proposed methodology, the public Machinery Failure Prevention Technology (MFPT) Society bearing data set (Bechhoefer 2016) is used. The remainder of this paper is structured as follows. Section 2 gives an overview of GANs and the methodology. Section 3 presents results of the GANs based methodology applied to the MFPT data set. Section 4 provides conclusions.

2 GENERATIVE ADVERSARIAL NETWORKS

Generative adversarial networks (GANs) have at their core a minimax game which seeks to pit a forger, the generator network, against a detective, the discriminator network. The generator seeks to create fake data, or scalograms in this paper, to trick the discriminator who must discriminate between the real data and the fake data as shown in Figure 1. Back propagation is performed on the weights and biases and the process is repeated. The benefit to this training is while the generator seeks to develop an underlying distribution of the real data, the discriminator is feeding information back to the generator, not on the real data, on the weights and biases of the learned features. This helps to prevent overfitting of the data.

Within this minimax game, the objective function's goal is to maximize the value, V, to the point where the discriminator and generator no longer find it necessary to make changes to their weights and biases. While this is the goal of GAN training, there is functionally no mechanism with the training to control it. Therefore, there can be issues with convergence. More formally in Eq. 1 from Goodfellow (2014):

$$\min_G \max_D V(G,D) = \mathbb{E}_{x\sim P_{data}(x)}\left[\log(D(x))\right] + \mathbb{E}_{z\sim P_{noise}(z)}\left[\log\left(1-D\left(G(z)\right)\right)\right]. \quad (1)$$

where, $P_{data(x)}$ is the data distribution, $P_{noise(x)}$ is the noise distribution, $D(x)$ is the Discriminator objective function, and $G(z)$ is the generator objective function.

The GANs based methodology used in this paper can be found in Figure 2. The methodology starts with developing a scalogram image representation of the raw data, and then proceeds to training of the deep convolutional generative adversarial network (DCGAN). Once the DCGAN training is completed and visual inspection of the generator output images is done, concatenation of the last activation layer of the discriminator is completed. Once the activations are concatenated, kmeans++ is used for clustering on the first two principal components. Visual inspection of the generator output is still needed within GANs training and is a crucial step within the training.

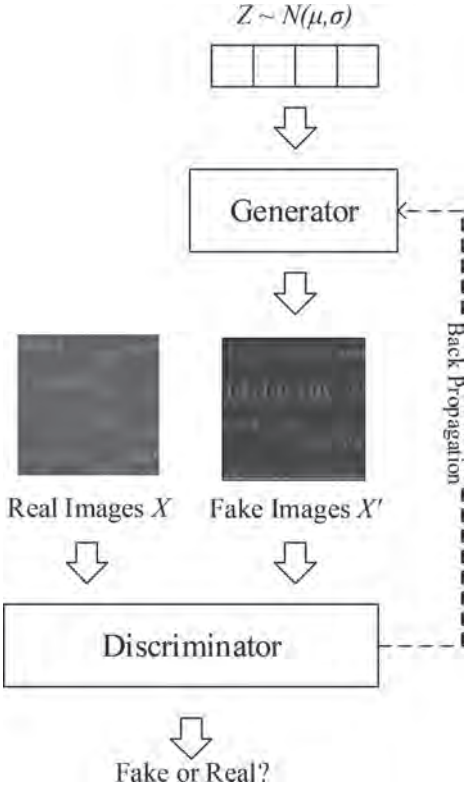

Figure 1. GAN training.

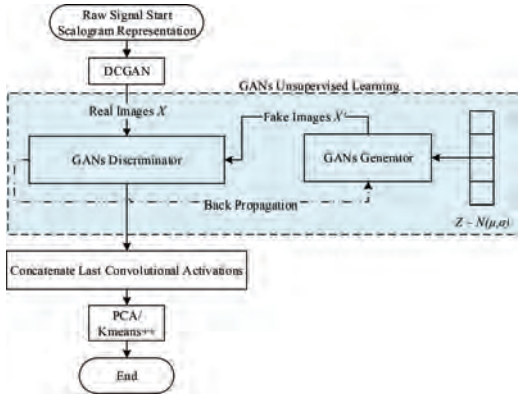

Figure 2. Proposed unsupervised GAN methodology.

There are two goals for the output of this methodology: 1) Separation of the baseline healthy data with the fault data, and 2) Separation of the individual faults. When a new sensor system comes online, the engineer needs to know when the system drifts from healthy signals to a signal with which to decide when to conduct planned maintenance. Once the engineer has familiarity with the system and signals can be identified as individual faults on the inner or outer raceway, then better predictions and a fully supervised methodology can be used (Verstraete 2017).

The GAN architecture used in this paper incorporates the guidelines proposed in Radford (2016); however, adjustments to that paper's architecture were made for handling the MFPT data set. Radford et al provides the following five GANs architecture guidelines: 1) generator and discriminator network pooling layer replacement with strided convolutions, 2) Batch normalization (BN) is required for both the discriminator and generator networks, 3) Fully connected hidden layers should be removed for deep architectures, 4) Rectified Linear Unit (ReLU) activation use in all layers of the generator except the output should use Tanh, and 5) Leaky ReLU activation use on all layers for the discriminator. DCGANs are used in this paper as a baseline to implement GANs. The combination of these five guidelines composes what is defined as deep convolutional generative adversarial networks (DCGANs).

2.1 *Strided convolutions*

The relationship between a convolutional operation's input shape, i_j, and the operation's output shape, o_j, of a convolutional layer along axis j are related to three factors: 1) kernel size (k_j), 2) stride (s_j), and 3) padding (p_j). Convolutional strides are generally set to $s_j = 1$ for most operations; however, for GANs strided convolutions of $s_j > 1$ are used in place of pooling layers. This is applied for the discriminator to learn its own downsampling, and for the generator to learn its own upsampling.

2.2 *Batch normalization*

Batch normalization (BN) is an important addition to the architecture between each convolutional layer. (Ioffe 2015) As the data moves through the convolutional layers the weight and bias values are adjusted. This has the potential to lead to the data increasing or decreasing to unrealistic values. Batch normalization prevents this from becoming an issue with the training by normalizing the data to a mean of zero and a variance of one for each data batch. Setting values of x over a mini-batch: $\beta = \{x_{1 \ldots m}\}$ to output the learned parameters γ and β, $\{y_i = \mathrm{BN}_{\gamma,\beta}(x_i)\}$. The mini-batch mean is $\mu_\beta \leftarrow \frac{1}{m}\sum_{i=1}^{m} x_i$, the mini-batch variance is $\sigma_\beta^2 \leftarrow \frac{1}{m}\sum_{i=1}^{m}\left(x_i - \mu_\beta\right)^2$, they are then normalized with $\hat{x}_i \leftarrow \frac{x_i - \mu_\beta}{\sqrt{\sigma_\beta^2 + \epsilon}}$, and scaled and shifted with, $y_i \leftarrow \gamma\hat{x}_i + \beta \equiv BN_{\gamma,\beta}(x_i)$.

2.3 *Activation layers*

The following activation functions are used throughout the architecture. For the generator, two activations functions are used: 1) Rectified Linear Unit (ReLU), $f(x) = \begin{cases} 0 \text{ for } x < 0 \\ x \text{ for } x \geq 0 \end{cases}$ and 2) Hyperbolic tangent (tanh), $\mathrm{f}(x) = \frac{2}{1+e^{-2x}} - 1$). Within the generator network ReLU is used between every layer except tanh activation is used after the last layer. For the discriminator, Leaky ReLU is used on every layer: Leaky ReLU $f(x) = \begin{cases} 0.01 \text{ for } x < 0 \\ x \text{ for } x \geq 0 \end{cases}$.

Leaky ReLU differs from ReLU in values less than 0.

2.4 *Neural network architectures*

The neural network architectures used in the proposed methodology incorporate the guidelines as proposed by Radford et al. Two networks were developed to account for the data set presented in Section 3. The generator network, as shown in Figure 3, takes the vector of noise and through deconvolution, BN, and activation functions creates an image. In this case the output of a 96×96 image of a scalogram of a signal. To do this, a 100×1 vector is projected and reshaped to deconvolve into a $6 \times 6 \times 512$ feature space. This space is then deconvolved to a $12 \times 12 \times 256$, then $24 \times 24 \times 128$, $48 \times 48 \times 64$, and finally a $96 \times 96 \times 3$ image.

The discriminator network, as shown in Figure 4, then takes that generated image and judges whether the image is real or fake. It does this by taking the real images and automatically learning the feature subspace. For the 96×96 images this results in a network of convolutional layers

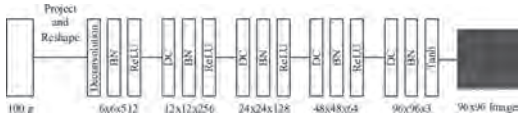

Figure 3. Generator network.

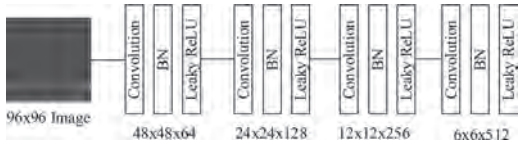

Figure 4. Discriminator network.

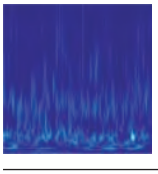
consisting of a $48 \times 48 \times 64$ layer, $24 \times 24 \times 128$, $12 \times 12 \times 256$, and $6 \times 6 \times 512$ layers. The output of this last activation holds a lot of information about the feature space and is useful for unsupervised fault diagnostics.

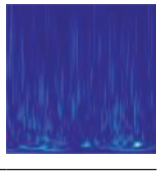
3 PROPOSED METHODOLOGY APPLICATION

The MFPT data set is a good test of any algorithm as the outer race fault and baseline conditions are difficult to separate. NICE bearings were used within an experimental test rig. Accelerometer data was gathered on three conditions. First, at a sampling rate of 97,656 Hz, a baseline condition at 270 lbs of load was captured. Second, a total of ten faults on the outer-raceway were gathered. At the same sampling rate and loading condition as the baseline, three outer race faults were tested, and the remaining seven outer race faults had the following load cases: 25, 50, 100, 150, 200, 250 and 300 lbs. These seven load cases had a sampling rate of 48,828 Hz. Third, with a sampling rate again of 48,848 Hz, seven inner race faults at a loading of 0, 50, 100, 150, 200, 250 and 300 lbs were gathered. From these raw signals, scalogram image representations were created with the following three classes as shown in Table 1: normal baseline (N), inner race fault (IR), and outer race fault (OR). In total 10,808 scalogram images were generated with 3,423 baseline, 1,981 inner race, and 5,404 outer race images. The training set used was fifty percent. Bilinear interpolation (Raveendran 2014) aided in reducing the original images to down to a trainable size for the GAN architecture.

The first step once the GANs training is completed is visual inspection of the generator image outputs. These can be seen in Figure 5. The different fault conditions can be identified within the images. This step is a key indicator for identification of mode col-lapse, vanishing gradients, non-convergence, or checkerboarding artifacts. With this completed, the last activation layer of the discriminator network is concatenated and clustering can be done.

Table 1. 96×96 pixel MFPT scalogram images.

Baseline	Inner race	Outer race
		




The first step once the GANs training is completed is visual inspection of the generator image outputs. These can be seen in Figure 5. The different fault conditions can be identified within the images. This step is a key indicator for identification of mode collapse, vanishing gradients, non-convergence, or checkerboarding artifacts. With this completed, the last activation layer of the discriminator network is concatenated and clustering can be done.

Kmeans++ is used for clustering within the paper to demonstrate how robust the GANs training can be towards a simple clustering algorithm. Figure 6 shows the resultant clustering predictions of the first two principal components of the last activation layer of the discriminator and colored by the predicted labels. There is overlap in the outer and inner race predictions, but the GANs training plus kmeans++ does an excellent job separating the baseline signals from the fault conditions.

Figure 7 shows the first two principal components of the last activation layer color coded by the real labels. It appears the GAN training with kmeans++ had the most difficulty with separating the fault conditions. A clustering algorithm more capable of handling the non-convex nature of the outer race fault could potentially increase the evaluation metrics but is beyond the scope of this paper.

Since the labels to the data are known, evaluation metrics like purity (Manning 2008), normalized mutual information (NMI) (Kuncheva 2004), and adjusted RAND index (ARI) (Hubert 1985) can be used to validate the architecture. Table 2 has the overview of these metrics for this methodology.

Overall these number could be improved; however, the first goal of this methodology is to

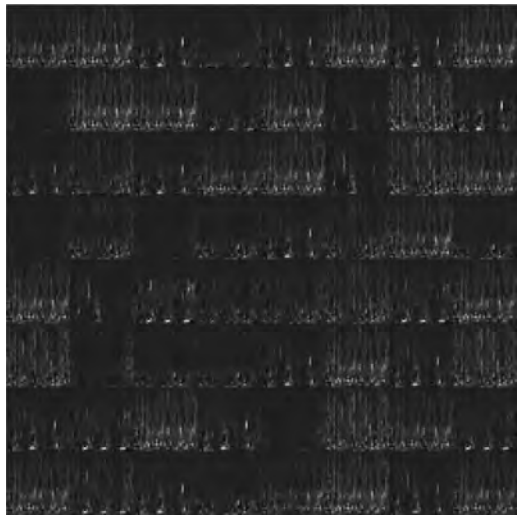


Figure 5. Output images of DCGAN generator training.

ARI	Purity	NMI
0.50	0.79	0.62

separate the baseline healthy system state with that of the faults. This methodology proves it can handle that. More work can be done to improve these numbers and provide better information to the engineer regarding which individual fault case the signal is presenting itself as.

4 CONCLUSIONS

Generative adversarial networks and deep learning as a field stand to unlock numerous potential applications within the field of engineering research. This application is the first of its kind and shows great promise.

The proposed architecture demonstrates its abilities with automatic feature learning to a level with which a simple clustering algorithm can separate the healthy baseline signals with the fault data. An engineer can easily make an engineering decision on maintenance without the need for any knowledge of the individual signals.

The practical application of this paper has far reaching possibilities into many engineering fields and is not limited to rolling element bearings. Aerospace, automotive, oil & gas, and many other industries can utilize this unsupervised methodology.

ABSTRACT: Recent advances of deep neural networks have revolutionized the techniques of machine learning for practical applications involving computer vision tasks. The flexibility of these models has allowed difficult tasks such as image segmentation to be tackled by this type of algorithms with much improved results. In this work, we propose and explore the capabilities of a novel deep residual neural networks with atrous convolutions for pixel to pixel classification tasks to achieve localization and quantification of structural damage in noisy image datasets. The proposed model is applied to a dataset of images synthesized to resemble debonding damage in honeycomb structures.

1 INTRODUCTION

Critical infrastructures such as bridges or complex systems in the mining industry might present damage that severely reduces the reliability. Inspections are important to warrant that a dangerous and costly failure does not take place. In this context, Structural Health Monitoring is critical to ensuring cost-effective and safe operational efficiency.

Inspections of structures usually includes some form of visual tasks that heavily rely on individuals with domain knowledge. In scheduling these inspections, a preventative maintenance program must balance a system's safety and the cost of an expert analyst. Moreover, there are situations where these tasks are carried out in perilous of difficult circumstances.

To tackle these limitations, automated visual inspection systems might help to reduce costs, increase accessibility, and improve safety. For instance, unmanned aerial vehicles (UAVs) can autonomously produce videos and photographs of damaged areas. This can be further improved by methods based on computer vision to identify damage in real time.

For certain structures and equipment, the identification of the type or location of damage is not enough. It is also important to quantify the size of the damage as it can be can be used for the tracking of damage growth over time and therefore assess possible effects and their severity they may have on the structure or equipment health state. However, damage quantification is not widely used by current forecast algorithms (Douka et al, 2003) (Ohno et al, 2010) because it is a complex and complicated process as well as difficult to automate.

The existing methods for damage quantification are based on processing of images (Zhou et al, 2015) that in general require different parameters for each image and manually extracted features, a procedure that is labor intensive and costly as well as usually not adequate in real time damage quantification.

Thus, we propose a deep learning based model for damage quantification based on deep residual neural networks with atrous convolution layers. Applied in the context of semantic segmentation (L.-C. Chen, et al 2016) (J. Long, et al 2015), these convolution operations use contextual information to perform pixel-by-pixel image classification by identifying which pixels correspond to damaged areas in a structure or equipment. The proposed model is applied to a dataset of images synthesized to resemble debonding damage in honeycomb structures.

The remaining of the paper is organized as follows. Section 2 introduces the building blocks of residual networks and presents the proposed

model. Section 3 discusses the example of application and results based on the proposed model and compares it to fully connected neural network and k-means for image segmentation. Section 4 presents some concluding remarks.

2 PROPOSED DEEP RESIDUAL NEURAL NETWORK MODEL WITH ATROUS CONVOLUTIONS

In this section, we discuss the proposed model based on deep residual neural network with atrous convolutions and operating on images for damage quantification. We first introduce the several building blocks of the proposed model and then the proposed architecture is presented.

2.1 *Deep learning*

Deep learning is a set of techniques based on neural networks that in recent times have shown better results than traditional techniques. The great success of this framework is due to the increase of the computational power added to the increasing availability of larger datasets, thus being able to train more complex and robust models.

These techniques are based on the hierarchy of the layers of a neural network, which can vary from a few layers to hundreds (He et al, 2016). The success of deep learning lies in how information is distributed throughout the network, extracting the most abstract characteristics of the data in the first layers and locating the most specific characteristics in the latter layers.

Deep learning has established a change in how to solve machine learning problems by generating a variety of architectures that are not limited to supervised tasks. The applications range from unsupervised models such as auto-encoders (Vincent et al., 2010) to autoregressive models as recurrent networks (Gregor et al., 2014). In the case addressed in this paper, a supervised task is analyzed that encompasses a deep neural network architecture with multiple outputs, each corresponding to a pixel.

2.2 *Segmentation*

Semantic segmentation consists in the pixel to pixel classification of an image, allowing to predict whether a pixel is considered a part of the damage. This type of algorithm takes into consideration the pixel context in the image, establishing whether it corresponds to an isolated damage without importance to the problem at hand or belonging to a damage type of interest. This type of segmentation is not limited to binary classification, as they can also be extended to establish if the damage is considered of a certain type, that is, how it was generated since different damages result from different failure modes.

By obtaining the pixel to pixel prediction of the image it is possible to obtain the size of the damage (e.g., crack), essential information to diagnose the damage and predict the Remaining Useful Life (RUL) of a structure or machine.

One of the disadvantages of this type of algorithm lies in the construction of the dataset required for its training. In fact, since the prediction of the model is pixel by pixel, the classification task for the training images must also be pixel to pixel. An example of the data that should be available is shown in Figure 1 where the left image shows the training image while the right image is the corresponding ground truth. If the training set is properly constructed, a procedure can be automated that delivers a damage prediction that is flexible for a given application, which is determined by the ground truth.

2.3 *Convolution neural networks*

Convolutional neuronal networks are a type of neural networks that take advantage of the translational invariance that images have. In summary, the parameters that these networks learn are filters W that are convolved with a subarea of the features maps. As the convolution is done in only one sector of the feature maps, the number of parameters learned is smaller, and therefore the computational cost is reduced and more relevant characteristics are learned for data that fulfill the assumption of translational invariance. Mathematically, a convolutional layer can be written as shown in equation (1).

$$x_{i,j}^{l} = \sum_{m}^{f1} \sum_{n}^{f2} \sum_{c}^{C} w_{m,n,c}^{l} s_{i+m,\, j+n,c}^{l-1} + b^{l} \tag{1}$$

in which 1 is the number of the layer. The input of each layer is x, of dimensions $H \times W \times C$. These variables are the height, width and quantity of features maps, respectively, with x^0 the training image that is input to the network. The weights of the network are w. The variable s are the feature maps after the activation function; m and n iterate over the width

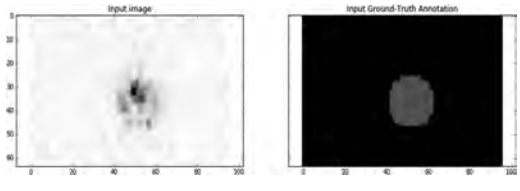

Figure 1. Left, Image of data training. Right, ground truth.

and height of the filter, f1 and f2. The variable c iterates over the number of channels C, i and j iterate over the width and height of the feature map, H y W. In addition, the convolution in equation (1) is carried out a number of times equals to the number of feature maps desired for the layer 1.

2.4 *Atrous convolutions*

In the context of semantic segmentation, it is relevant to establish the information of the context in which a pixel is found. To do this, previous algorithms based on deep networks (Krizhevsky et al, 2012) used a series of convolutions followed by pooling layers and with a subsequent layer known as deconvolution. This increases the size of the smaller feature map to establish a cost to what the pixel to pixel prediction should be. This type of model has a disadvantage: the resolution is lost with increasingly deeper network architectures, so it is not possible to use this type of transformation when the number of layers is large, as is the case of residual networks used in the proposed model. Atrous convolutions (Holschneider et al, 1989) try to solve this problem by creating filters that have zeros in between. For a traditional filter, this means increasing its size, placing zeros in between and making a standard convolution. Mathematically this shown in equation (2) for the case of one dimension (1D). If the rate r is equal to 1, we have the usual convolution; x is the input and K is the filter length w[k]. Figure 2 shows the variation of the filters used in the atrous convolution for different rates, with the green color representing 0 values in the filter. As these are parameters are not learned, performing atrous convolution does not increase the number of parameters. The blue color represents values of the filters that are learned by backpropagation.

$$y[i] = \sum_{i}^{K} x[i + r * k]\, w[k] \tag{2}$$

2.5 *Atrous pyramid pooling*

In the proposed architecture discussed in Section 2.7, the concept of pyramid pooling is used in which atrous convolution is performed in parallel using different resolutions and, therefore, capturing contextual information at different levels.

2.6 *Residual neural network*

In general, deep neural networks before 2015 did not exceed a number of layers greater than 20 as trying to increase this number resulted in performance deterioration. This is known as vanishing gradient, which consists in that the earliest layers of the neural network receive updates that are too small and, therefore, a null learning. This is due to the rule of the chain and how backpropagation is made.

Recently this difficulty was surpassed by a type of neural networks called residual networks (He et al, 2016) These networks allow the use of architectures with an even larger size reaching block numbers of up to 151, in which each block has several layers, thus overcoming the usual convolutional networks. For example, in ILSVRC & COCO 2015 Competition (ImageNet, 2015), residual networks obtained the first place in all categories (He et al, 2016). Some known residual networks are ResNet-50, ResNet-101 and ResNet-151 (He et al, 2016), where the name number represents the number of residual blocks it has.

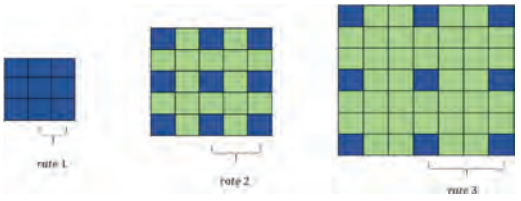

Figure 2. Atrous convolutions for different rates.

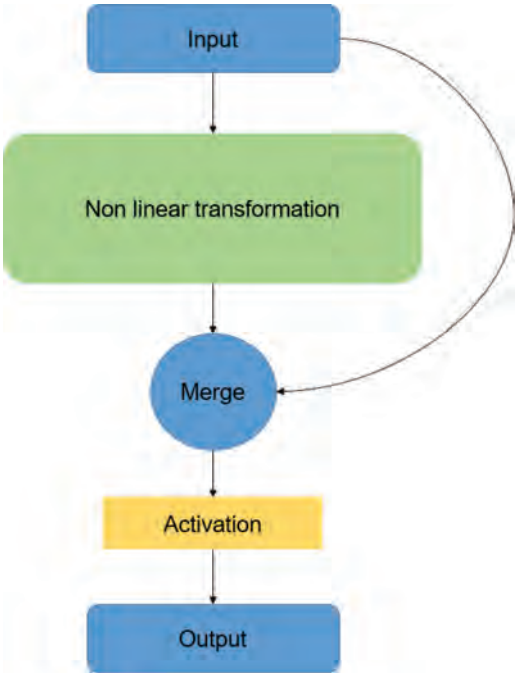

Figure 3. Residual block.

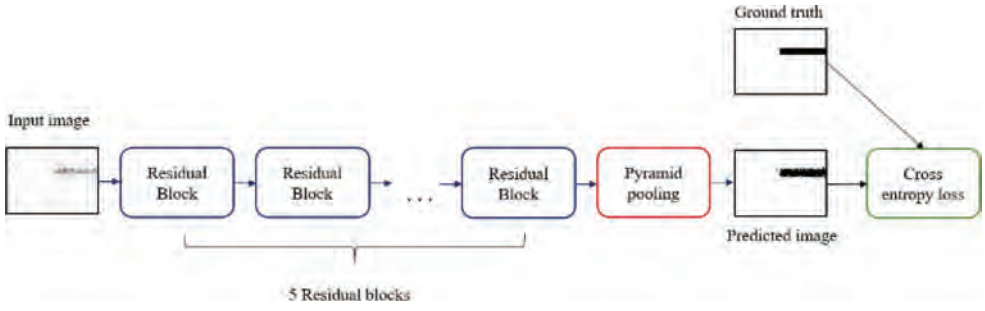

Figure 4. Proposed architecture.

The main idea underlying the residual networks is that if a network is working properly, it should not worsen its performance by increasing the number of layers. In this way, the residual networks are constructed in blocks as shown in Figure 3, where the information flows through the identity mapping if the network does not need to change the information that is reaching a certain layer. On the other hand, if it is required to make changes in the feature maps, mapping with different non-linear functions are applied.

In Figure 3, the classical components that have a residual block are shown, where the non-linear transformations correspond to the transformations that a traditional convolutional network could have. The "Merge" is the function designated to how the input of the block should be united with the output of the non-linear transformations. Following the "Merge", a non-linear activation is placed.

2.7 *Proposed architecture*

The proposed residual neural network architecture is comprised of five residual blocks followed by a pyramid pooling layer, as shown in Figure 4. Each residual block has the following structure (see Figure 5): (i) one convolution with stride of 1×1 and batch normalization; (ii) atrous convolution with filter of 3×3 and rate of 2 followed by batch normalization; (iii) another convolution with stride 1×1 and batch normalization; (iv) addition operation over all the resulting features maps and passed to a ReLU activation function. The resulting feature map is the input to the next residual block.

Note that the number of feature maps (FM) varies from block to block. For the first two blocks, the feature maps FM_1, FM_2 and FM_3 are equal to 256, 256 and 1024, respectively. For the remaining blocks, the number of feature maps FM_1, FM_2 and FM_3 are 512, 512 and 2056, respectively. After all the residual blocks, pyramid pooling is applied with 4 different rates, i.e., atrous convolutions with rates of 6, 12, 18 and 24. Moreover, the model uses cross entropy loss function and the parameters are updated via back-propagation with ADAM optimizer.

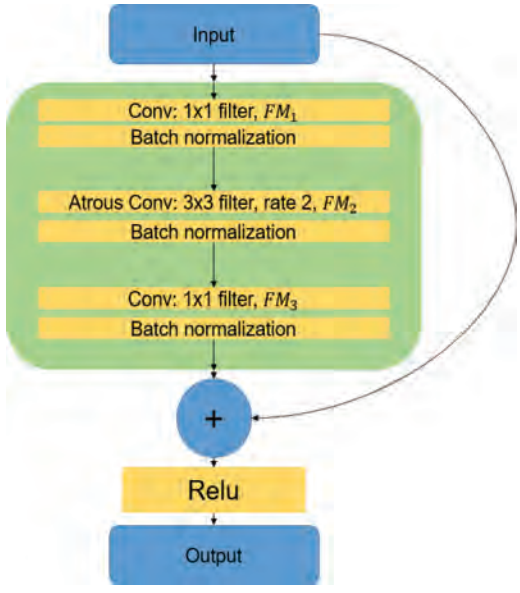

Figure 5. Residual block used.

3 EXAMPLE OF APPLICATION

3.1 *Data*

The dataset used in this example was obtained via finite element modeling of debonding damage in honeycomb structures and consists of 6000 noisy images of 98×69 pixels, of which 2000 images with circular damage, 2000 with rectangular damage and the remaining are undamaged. Note that the damage quantification is performed pixel by pixel, thus the classification task is separated into two: quantification of rectangular damage and

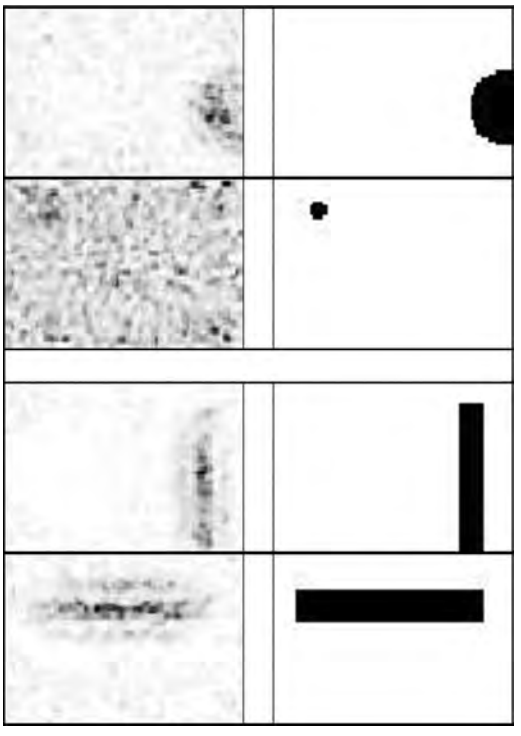

Figure 6. Examples of damage types and corresponding ground truth used for training: the two top images are for circular damage while the two bottom images are for rectangular damage.

quantification of circular damage. In both cases, the ground truth is the original image without noise. Figure 6 shows examples of rectangular and circular damage images.

The results presented in the next section were obtained by running the experiments in a computer with intel core i7 and 4.2 GHz processor capacity, 32 Gb RAM, Nvidia Titan X Pascal GPU with TensorFlow 1.3, Cuda 9 and Cudann 5.1 for compiling and neural networks optimizers.

3.2 *Metrics*

To analyze the damage quantification results, the following semantic segmentation metrics are considered: pixel accuracy (PA), mean accuracy (MA), mean intersection over union (MIoU) and frequency weighted intersection over union (FWIoU). Pixel accuracy in equation (3) corresponds to the overall accuracy. Mean accuracy, given in equation (4), is the average accuracy over all classes involved in the segmentation task. Mean intersection over union is shown in equation (5) and is the average of the correct pixel classification divided by the total number of pixels of that class, thus is an important performance metric for semantic segmentation as it encompasses true positives and false positives for the pixel by pixel classification. Frequency weighted intersection over union, as shown in equation (6), is similar to MIoU, but with the difference that FWIoU takes into account the number of data points in each class.

Therefore, MIoU and FMIoU are stricter metrics, while MIoU and MA are not sensible to unbalanced datasets, but FMIoU and PA could be inflated if that is the case.

$$\mathrm{PA} = \frac{\sum_i n_{ii}}{\sum_i t_i} \tag{3}$$

$$\mathrm{MA} = \frac{1}{n_{cl}} \sum_i \frac{n_{ii}}{t_i} \tag{4}$$

$$\mathrm{MIoU} = \frac{1}{n_{cl}} \sum_i \frac{n_{ii}}{t_i + \sum_j n_{ji} - n_{ii}} \tag{5}$$

$$\mathrm{FWIoU} = \left(\sum_k t_k \right)^{-1} \sum_i \frac{t_i n_{ii}}{t_i + \sum_j n_{ji} - n_{ii}} \tag{6}$$

n_{cl}: Number of classes included in the ground truth segmentation.

n_{ij}: Number of pixels of class i predicted to belong to class j.

t_i: Total number of pixels of class i in the ground truth segmentation.

t_k: Total number of pixels in the ground truth segmentation.

3.3 *Results and discussion*

In this section, we present the results of the damage quantification obtained from the proposed model as well as comparison to two other approaches: K-means for segmentation with feature space in a similar fashion as presented in (Dhanachandra et al, 2015) and a deep fully convolution neural network (FCN) with the same architecture shown in (Long et al, 2015).

Indeed, Table 1 shows the results for damage quantification for the test dataset containing 200 images. For circular damage, both the proposed model and the FCN deliver quite similar performance metric results and significantly superior to the unsupervised K-means. This is mainly because the deep learning based models are supervised thus taking into consideration the source of the damage images. In terms of the MIoU metric, the proposed model performs better than the FCN because atrous convolutions do not lose detail information as occurs with the standard convolutions used in the FCN architecture.

Table 1. Segmentation results for exposed metrics. R: Rectangular damage, C: Circular damage.

	Proposed model %		FCN%		K-means clustering %	
	R	C	R	C	R	C
PA	97.8	98.5	97.5	98.6	96.5	97.2
MA	89.3	90.0	83.9	85.5	86.4	85.7
MIoU	81.2	82.6	76.7	81.6	76.5	76.9
FWIoU	96.1	97.2	95.5	97.4	94.2	95.3

The performance metrics for rectangular damage quantification for all models are worse than in the previous case as segmentation for this type of damage is a more complex task than the circular one because it requires obtaining greater contextual information and, at the same time, determining greater details (e.g., corners). Moreover, the proposed model outperforms the two other algorithms. In particular, the performance deterioration of the FCN model might be attributed to the information loss due to the use of pooling layers, whereas the proposed model uses atrous convolution that permits to capture contextual information without losing information.

Figure 7 shows examples of predicted damage quantifications delivered by the proposed and the FCN models for two test images: the top images are the noisy test data, the middle ones are the ground truths and the bottom images correspond to the predicted damages. It can be observed that the rectangular damage prediction from the proposed model is able to better capture the shape of the damage, in particular the corners, whereas the FCN model struggles in that task and thus leading to deterioration in its performance when quantifying this type of damage.

Table 2 and Table 3 show the no normalized and normalized versions of the confusion matrix for the proposed model for every pixel in test data and for both rectangular and circular damages. Note that the true negatives are 99.1% and 98.9% for circular and rectangular damages, respectively. These results can be explained by the unbalanced pixel count in the ground truth between no damage and damage. It is important to note also that the proposed model has higher scores for true positives with 85.9% and 79.7% for circular and rectangular damages, respectively, arguing in favor of the proposed model's robustness for the unbalanced data in this example of application.

The promising results obtained by the proposed model come at a computational cost that might be perceived as a disadvantage. In fact, the training time for the proposed model takes forty minutes for twenty epochs. However, it is significantly faster than the K-means in predicting the damage size of an unseen image: 0.07 second against 0.6 second for the latter. These results indicate that the proposed model might be a candidate for developing

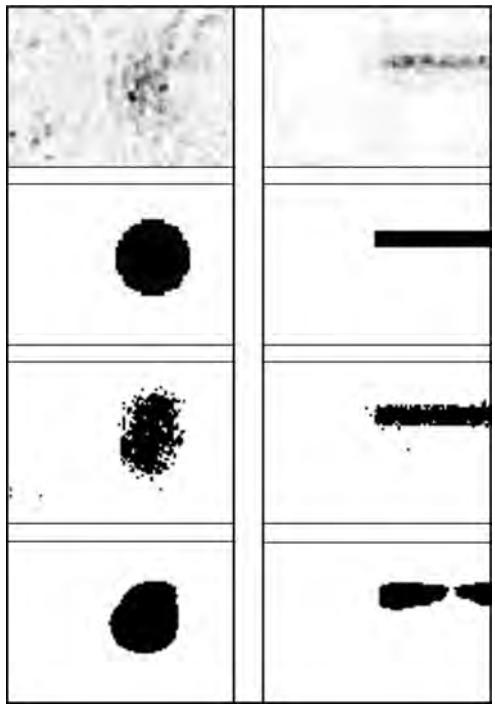

Figure 7. Top: test images; second row: ground truth; third row: damage prediction from proposed model; bottom: damage prediction from FCN.

Table 2. Confusion matrix of the proposed model. ND: No Damage, D: Damage.

	Circular damage		Rectangular damage	
	ND	D	ND	D
No Damage	1277298	11532	1262236	14340
Damage	8962	54608	15394	60403

Table 3. Normalized confusion matrix of the proposed model. ND: No Damage, D: Damage.

	Circular damage (%)		Rectangular damage (%)	
	ND	D	ND	D
No Damage	99.1	0.9	98.9	1.1
Damage	14.1	85.9	20.3	79.7

online monitoring systems where fast responses are required.

4 CONCLUDING REMARKS

This paper presented a novel residual atrous convolution neural network model for quantification of damage based on image processing. The proposed model was applied for damage quantification and segmentation of debonding damage in honeycomb structures.

The results show that the proposed model is a promising tool for damage quantification and segmentation with superior performance in noisier and more complex damage types and shapes than both deep fully convolutional networks and K-means algorithm.

Return on investment on PHM systems

A. Segal & Y. Bot
BQR Reliability Engineering Ltd., Rishon LeZion, Israel

ABSTRACT: Return On Investment was calculated regarding a PHM system for a fleet of rolling stock. We show that the financial feasibility depends strongly on expected asset life as well as on the asset reliability model. The tool that was used for the analysis can be used for choosing the optimal PHM system for various assets.

1 INTRODUCTION

The goals of PHM systems are to provide advanced warning of system failures, enable Condition Based Maintenance (CBM), increase system availability, reduce Life-Cycle Cost (LCC), and reduce No Failure Found events (Pecht 2008).

While these goals are appealing, PHM integration projects include expensive installation of sensors, communication networks, big data storage and computing hardware or services (Feldman, Sandborn, and Jazouli 2008).

Therefore, it is not surprising that many asset owners are reluctant to venture into such projects. In order to assess the pros and cons of a suggested PHM project, Return On Investment (ROI) Analysis is required. The PHM system ROI is defined as:

$$ROI = \frac{C_1 + C_2 - C_3}{C_3} \quad (1)$$

where C_1 represents the financial cost reduction due to decreased downtime, C_2 is the financial savings due to reduced maintenance costs, and C_3 is the cost of PHM system procurement, installation and services.

While the cost of investment is relatively easy to quantify, the expected gain is hard to asses. A good PHM system is expected to reduce the occurrence of some failure modes. Therefore, Failure Mode, Effects, and Criticality Analysis (FMECA) is a good basis for PHM design (Meng and Zhang 2013; Banks, Reichard, Crow and Nickell 2009) and ROI analysis.

However, additional considerations are required. Maintenance policies such as inspections and scheduled maintenance affect the number of expected corrective and preventive maintenance events during the lifetime. Logistics policies affect the transportation and spare waiting times. These parameters heavily influence the asset/fleet maintenance cost as well as downtime penalties. Therefore, expected financial gain depends also on the facility/fleet operation profile, maintenance and logistics policies, and related LCC (Kacprzynski, M. J. Roemer and A.J. Hess 2002).

The general tradeoff of initial investment and maintenance cost for LCC optimization was discussed by W. Taylor (Taylor 1981). The question of PHM system ROI is a classic case for such tradeoff analysis.

Several PHM ROI evaluations were reported in the literature (see references in Feldman, Sandborn, and Jazouli 2008), mostly related to the defense industry. In recent years PHM and the Industrial Internet of Things (IIoT) penetrated other industries with focus on critical expensive equipment such as turbines in the Oil & Gas, wind farms, and aviation industries. These cases relate to new equipment with built in sensors.

In this paper we present an example regarding the ROI on a PHM system for an existing rolling stock asset. The LCC of several scenarios is considered and it is shown under which conditions PHM installation is financially advantageous.

2 CASE DESCRIPTION

A fleet of 17 trains located in two sites (10 trains in site A and 7 trains in site B) is considered. The trains operate 18 hours each day, and have 6 hours for scheduled maintenance and inspections during the night. A central stock services both sites.

The suggested PHM system will monitor the state of the rolling stock motors and pantographs. Adding the PHM system is expected to increase visibility and control of the rolling stock fleet, and to reduce failure events and downtime.

Following is a financial analysis of the ROI on the suggested rolling stock PHM system.

2.1 *Investment*

Adding the PHM system is expected to cost $20,000 per train for motor and pantograph sensors, and $160,000 for the central servers and operation center dashboard displays. An additional cost of $4,000 per month is paid for support and maintenance of the PHM system by the PHM provider.

This amounts to an investment of $1.22M for a 15 years period, or $1.94M for a 30 years period.

2.2 *Calculating expected gain*

In order to calculate the mean expected gain, the fleet behavior over the life period has to be predicted.

Most commercial system simulation software are based on the Monte-Carlo method. Indeed, Monte-Carlo simulations are flexible and easy to create. However, in order to achieve highly accurate results, many simulations have to be carried out. This is especially important in systems where rare events can have significant effect on the LCC.

We used the apmOptimizer software that includes a combination of analytic methods (Birolini 1999) for calculating the fleet Life-Cycle Cost (LCC), and identifying cost and failure drivers. The advantages of analytic calculations are speed and accuracy.

Calculations were carried out for various scenarios with and without the PHM system.

A detailed model of the existing fleet was constructed, accounting for:

Reliability Data

- Component failure distribution
- Component failure modes
- Rolling Stock redundancies
- Operation profile

Maintenance Data

- Component repair / discard policy
- Repair time
- Corrective maintenance
- Preventive maintenance
- Inspections

Logistic Data

- Spare parts
- Transportation times
- Procurement time

Financial Data

- Cost of spare parts
- Penalties due to service agreement
- Corrective maintenance
- Preventive maintenance
- Inspections

Using the input data, the apmOptimizer calculates the expected rolling stock availability, failures, maintenance, inspections, and LCC.

Figure 1 presents the breakdown tree of rolling stock in site A. The "Reliability Model" column in Fig. 1 describes the relevant model for each subsystem. The "Distribution Type" column in Fig. 1 presents the failure distribution type for each component. Electronic components were assigned an Exponential failure distribution whereas the mechanical components were given a Normal distribution that describes their ageing behavior.

The initial model described the fleet behavior without a PHM system. In order to calculate the behavior of the fleet with PHM, the original model was copied, and the following changes were implemented:

- Motor and several pantograph components have sensors; therefore, there is no need for scheduled maintenance, only Condition Based Maintenance (CBM).
- When CBM is conducted instead of scheduled maintenance, only the problematic components are treated. Therefore, each CBM event is cheaper than the corresponding scheduled maintenance event.

Four scenarios were considered:

- No PHM system, life-cycle of 15 years
- No PHM system, life-cycle of 30 years
- Added PHM system, life-cycle of 15 years
- Added PHM system, life-cycle of 30 years

Head	1	Leaf	-	Normal

Figure 1. Breakdown tree of rolling stock in site A.

For each scenario the optimal maintenance and logistics policies were found using apmOptimizer's enhanced dynamic programming algorithms. The optimization process was very fast due to the use of analytic calculations (as opposed to Monte Carlo). The optimizations goal is to minimize the LCC. LCC includes downtime penalty, therefore the optimization also ensures low downtime (high fleet availability). Furthermore, LCC includes the cost of spare parts, corrective and preventive maintenance and inspections.

The net gain of a PHM is equal to the calculated LCC of the fleet without PHM minus the LCC of the fleet with PHM, minus the PHM investment (this is $C_1 + C_2 - C_3$ from Eq. 1).

3 RESULTS

LCC was calculated for each optimized scenario. Table 1 presents a summary of the calculated results.

From Table 1 it is clear that a PHM system is not expected to yield financial savings when a lifecycle of 15 years is considered (ROI < 0). On the other hand, some savings are expected when a lifecycle of 30 years is considered (ROI = 0.278).

The analytic tool that was used produced additional useful information: it was found that the main contributor of rolling stock downtime is bearing failure. The suggested PHM program did not include bearing monitoring.

Table 1. Expected LCC for various scenarios.

Model	PHM investment	LCC	Total
Lifecycle 15 years			
No PHM	$0	$43.52M	$43.52M
With PHM	$1.22M	$42.35M	$43.57M
Lifecycle 30 years			
No PHM	$0	$100.9M	$100.9M
With PHM	$1.94M	$98.42M	$100.4M

Table 2. Expected LCC for various scenarios with enhanced PHM.

Model	PHM investment	LCC	Total
Lifecycle 15 years			
No PHM	$0	$43.52M	$43.52M
With PHM	$2.44M	$14.3M	$16.74M
Lifecycle 30 years			
No PHM	$0	$100.9M	$100.9M
With PHM	$3.88M	$29.38M	$33.26M

Next we consider the case where bearing sensors were also added. The bearing sensors, data analysis, storage and maintenance are expected to double the PHM cost. Table 2 presents a summary of expected LCC for the enhanced PHM system.

Data in Table 2 clearly demonstrates the financial advantage of PHM systems which are applied to the asset/fleet critical failure driver. The reduced LCC results from reduced maintenance costs as well as greatly reduced service penalties. ROI for 15 years is 10.97 while for 30 years the ROI is 17.43. These values are very high. One possible reason for the high ROI is the assumption that bearing failures are 100% prevented by the PHM system. The apmOptimizer can also account for non-ideal PHM systems.

4 CONCLUSIONS

A general conclusion is that PHM systems are most suited for asset intensive systems with long expected life-cycles (aircrafts, rolling stock, utilities, mining and O&G). The reason is as follows: While PHM reduces downtime penalties and maintenance cost, a high installation cost is incurred. For long life-cycles the accumulated savings overcome the initial PHM installation cost.

Another conclusion is that the right PHM system has to be selected in order to address the asset/fleet main drivers of failure and downtime. This requires preliminary field data collection and sensitivity analysis using modeling software such as the apmOptimizer.

ABSTRACT: The development process of complex technical products of the last years shows an increasing amount of sensors, electronic control units, data logging and monitoring systems within consumer goods (e.g. automobiles, washing machines) and industrial goods (e.g. machine tools, manufacturing systems). In many cases, the main goal of data logging is monitoring, controlling and optimisation of the product functionalities within the usage phase. A further aim is the fulfilment of the process capability of manufacturing processes. Therefore, the layout of the concept of operating data logging and monitoring systems—especially operating data (mainly type, volume, and format) as well as hardware (like sensors and storage)- is designed by the development engineer within the product concept development phase. This paper discusses challenges, requirements and approaches for future conceptual design of operating data logging concepts of technical products related to reliability engineering. Base of operations is the state of art. Based on that, the concept for operating data logging within a monitoring system is shown. The concept draft is subdivided in three parts which are divided as follows: part one deals with data analytics, part two contains data requirements, and part three focuses on hardware requirements. The presented research study was worked out on the international research platform "Computational Reliability Engineering in Product Development and Manufacturing (CRE) – 2017" and contains contributions of universities, institutes and original equipment manufacturers of industrial nations: Germany, United Kingdom, Japan, Turkey and France.

1 INTRODUCTION

The development process of complex technical products of the last years shows an increasing amount of sensors, electronic control units, data logging and monitoring systems within consumer goods (e.g. automobiles, washing machines) and industrial goods (e.g. machine tools, manufacturing systems). In many cases, the main goal of data logging is monitoring, controlling and optimisation of the product functionalities within the usage phase. A further aim is the fulfilment of the process capability of manufacturing processes.

Therefore, the layout of the concept of operating data logging and monitoring systems—especially operating data type, volume, format and storage—is up to this point of time in most cases designed by the development engineer within the product concept development phase. However, the design engineer is also responsible for the product functionality. Hence, the logged data is very often directly related to a technical discipline (e.g. automotive engineering: the rotation angle and cycle sensor is related to the antilock braking system which belongs to the division of chassis engineering). But this data can also serve as a foundation for the reliability analysis (e.g. automotive engineering: amount of steering turns, or frequency gathered from rotation angle sensor are live span variables, which can be used for statistical reliability models). Consequently, a comprehensive operating data logging (software) and monitoring system (hardware) for future technical complex product generations is needed with complementary functionality: Controlling product functionality and ensure product reliability of the actual and subsequently following generation.

2 GOAL OF RESEARCH ACTIVITIES

This paper discusses challenges, requirements and approaches for future conceptual design of operating data logging systems of technical products related to reliability engineering. In detail: (1) Requirements regarding operating data structure: e.g. data type, data volume, data format; (2) Requirements regarding data recording structure and hardware aspects: e.g. frequency, sensors and storage; (3) Aspects of data analytics based on gained operating data in the usage phase.

3 FUNDAMENTALS

3.1 *Design of the monitoring system within the product life cycle*

The product life cycle of technical products can be described in four main and eight subordinate phases, cf. (Bracke 2016):

1. Concept phase
   1a. Definition of the product characteristics
   1b. Development of the product concept
2. Development phase
   2a. Construction stages (different prototype levels and finalising the design)
   2b. Preparation of manufacturing
3. Production phase
   3a. Start of production (SOP)
   3b. Production
4. Sale/Usage phase
   4a. Sale of products to the markets
   4b. Usage phase and product observation

The concept of operating data logging and monitoring systems—especially operating data type, volume, format and storage – has to be designed by the reliability engineer of the Original Equipment Manufacturer (OEM) or Supplier within the product concept development phase (Phase 1b, cf. section 3.1).

3.2 *Design of operating data type*

In general, the operating data types can be subdivided in following different categories:

a. Secretly compiled data (OEM / Supplier):
   – Definition logging logic OEM,
   – Data encryption through OEM,
   – Storage strategy: “fleeting”, “semi-permanent”, “permanent”
b. Officially compiled data:
   Example automobile: eCall emergency system (since 31-03-2018), which gives an emergency call after an accident (“sleeping system”) and transfers basic automobile operating data.
c. Voluntarily compiled data:
   Example: Vehicle insurance, Policy with scoring option, logging function is always on.

The reliability engineer has to define the essential life span variables and operating data types in the concept development phase (cf. section 3.1). To ensure a long-term availability of the operating data regarding reliability analysis within the entire product life cycle, the storage strategy “permanent” (cf. numeration (a) above) is to be pursued. The strategy “fleeting” is only interesting for direct operating decisions, the strategy “semi-permanent” does not allow the data analysis after the end of product life. Officially compiled data is also interesting, if the storage strategy is “permanent”. Voluntarily compiled data is not in focus of this study.

4 OPERATING DATA AND MONITORING SYSTEM: DATA ANALYTICS, DATA AND HARDWARE REQUIREMENTS

Within this section, the data and hardware requirements, based on data analysis strategies, for an

operating data and monitoring system are shown. The concept draft is subdivided in three following parts: Part one deals with data analytics e.g. uncertainty, second life and lessons learned aspects (cf. section 4.1). Based on the goal of data analysis, part two and three contains data requirements (cf. section 4.2; e.g. structure and format) and hardware requirements (cf. section 4.3, e.g. sensors and storage availability within monitoring systems in products and facilities).

4.1 *Data analytics*

4.1.1 *Aspects of data uncertainty regarding a reliability model*

Operating data logging and monitoring systems are largely used to improve the knowledge of a specific system or component. However, data are always associated with some noise or measurement error, e.g. due to different environmental conditions. In turn, the model used to, e.g. predict the useful reaming life of a component, or schedule maintenance is also affected by uncertainty. If such uncertainties are neglected, some wrong and costly decision can be made (for instance, recall a product). Such uncertainty can also nullify the benefits of using machine learning frameworks for analysing the continuously increasing available data.

One of the current challenges in the capability is to discriminate when such machines and tools are providing reliable estimate or their prediction has been fooled by noise. One possible solution is to use past experience and predictions to determine precise levels of confidence for the new predictions (Shafer and Voyk 2008). Another popular approach is based on the Bayesian paradigm for inference. In such framework, Bayes' rule is used to update our believe on validity of the model prediction with information from empirical observations (data) taking into account the associate uncertainty in such observations. The reader is referred to (Aki Vehtari and Janne Ojanen 2012) for detailed description of Bayesian methods.

4.1.2 *Aspects of the use of product operating data for a second life cycle*

In order to avoid environmental issues, it is necessary to minimize the material and energy consumption during the whole product lifecycle (Yamada 2012). One of the potentials for material circulation environmentally and economically is to reuse the End-of-Life (EOL) assembly products by remanufacturing in the second life cycle. Remanufacturing is the process of bringing an assembly to like-new condition through replacing and rebuilding its components at least to current specification (Ilgin and Gupta, 2012). There are two essential processes in the remanufacturing: disassembly and re-assembly of the EOL products (Lambert and Gupta 2005).

To conduct the data analytics for the disassembling process in an environmental friendly and economical way, a parts selection method (Igarashi, et al., 2016; Kinoshita et al., 2016) including reuse (Hasegawa et al., 2017a, 2017b) shows which parts should be reused, recycled and disposed in terms of environmental impacts and costs. The operating data of a part in the usage stage of the first life cycle helps on the parts selection that can be disassembled. Here, one of the challenges is that the data affects the decision of the part selection itself by the recovery costs with different sales revenues for the parts.

4.1.3 *Transforming operating data in Lessons-Learned-Data-Structure for subsequently following product generations*

Application of data analytics to improve manufacturing operations and transferring critical information to following product generations are an integral part of data-driven decision making. When processes are better defined and more standardized, lessons can be combined into standards and guidelines. It is rather hard to share lessons in areas of complex or context-specific need, for topics that are rapidly changing, and where new problems are frequently being identified. Therefore, lessons should be written down and stored in a database in such a way that other related people can find and access the required knowledge. It is important to sort the individual lessons and store them under themes or topics in the lessons learned database. By this means, data can be filtered and previous actions of any problem can be considered during product's engineering design process. Updating the database (i.e., guidance documents, best practices and standards for the process) is also a crucial issue to sustain the garbage in, garbage out philosophy. The quality of lessons knowledge may change from extremely useful to completely unhelpful. Therefore, the ease and accuracy of transforming data for product generations depend on how data is collected, stored, and updated.

Commonly used data mining applications in manufacturing include failure evaluation, quality control, safety analysis, and capacity planning. Statistical Process Control (SPC) is one of the techniques suggested for real-time monitoring of operational performance of manufacturing systems. There is an ongoing research on better ways of collecting data and developing big data infrastructure technologies. Besides sensor technologies, Enterprise Resource Planning (ERP) and Manufacturing Execution Systems (MES) are also used for data collection technology the development of cloud service platforms.

4.1.4 *Aspects of reliability analytics: Probabilistic uncertainty based on input data/operating data*

The quality of the data can have a significant influence on the analysis results and their interpretation

which could cause a wrong conclusion of the product reliability. In fact, the amount, quality, format and processing of the data are only few of many other factors which have to be considered during the statistical analysis of operating data. It is still uncertain, whereupon and in which order it is necessary to pay attention by the examination of particular properties during the statistical analysis. A comprehensive list of factors which can influence the data analysis, or much more the results, is shown in (Hinz 2015). The proposed factors are divided into four groups:

- Data quality – demonstrates the requirements with respect to the compound of diverse inputs and properties of a data set (e.g. diverse load profiles or the unit on life span variables)
- Empiricism – knowledge based on experience regarding the application of the product fleet as well as market specific boundary conditions (e.g. product derivatives or user profiles)
- Aim of analysis – various purposes of the statistical analysis will result in the application of different methods which may cause further uncertainties (e.g. the kind of a damage case)
- Mathematical models – this group describes statistical models, equations and algorithms which can be used with regard to the reliability analysis (e.g. various methods for the estimation of the distribution parameters).

In plenty of cases, even the application of methods that can be expected to provide always reliable results may lead to high uncertainties. For example, the estimation of the shape parameters of Weibull distribution based on different estimators (here: Maximum Likelihood, Gumbel, Least Squares, Method of Moments, Nelson, and DIN 55303) and various sample sizes (varying between 10 and 1000) shall be considered. The results are shown in Figure 1. The mentioned methods are compared to the maximum likelihood (MLE) and the relative error is plotted as a function of the sample size.

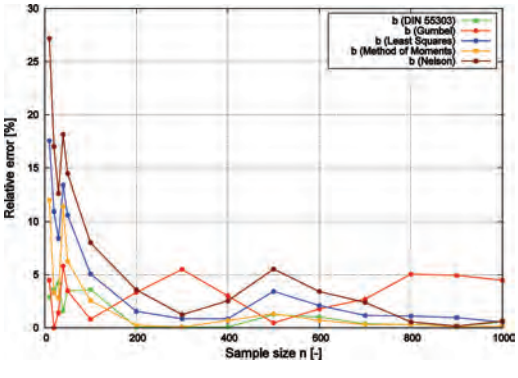

Figure 1. Relative error of the estimated shape parameters of Weibull distribution using various estimation models.

It can be easily observed, that especially for the small sample sizes, the application of different parameter estimators can cause big differences in the gathered results. For a sample consisting of 10 entries, the difference between MLE and Nelson equals to 28%.

In many cases combinations of multiple factors play a major role during the data analysis. This can cause a high uncertainty of the results which can differ exponentially from the reality.

4.2 *Data requirements: Operating data structure: e.g. data type, data volume, data format*

To some extent, the requirements for data are relatively flexible as long as that data supports the data-scheme for monitoring systems. The requirements therefore focus on data scheme and depend less on the actual data itself. The objective is to enable communication between the data-sender and the data-receiver. The data sender, say a logging system, has a data scheme to store relevant information in its own local database (which may be small if there are detectors only). The data may be system state messages, error messages or alarms that may contain a timestamp, serial numbers, identification codes, numeric values and meta-data. The date receiver, say a Matlab application for reliability engineering, has its own data scheme. Only part of the data from the data logger is useful for the Matlab application; some kind of data transformation is required. Such transformations can be made in many different ways; the key, however, is that the meta-data about the data-scheme is correct, informative and up-to-date. In many industries data standards have been developed to harmonize efforts of different industry partners; this tends to be efficient for many industries. For instance, the Oil and Gas industry uses ISO 15926 as an International Standard for the representation of process plant life-cycle information. This standard specifies a generic, conceptual data model that is suitable as the basis for implementation in a shared database or data warehouse. Many industries have developed similar standards; aligning with them in own field is well-worth the effort; IT solutions that do not follow the standards may not be accepted in the industry. Summarizing, data requirements focus on correct data scheme descriptions. For engineers, such descriptions are captured in technical reports. For the computer it is captured in the format of database.

4.3 *Hardware requirements*

4.3.1 *Aspects/requirements of hardware (sensor and storage technologies) within certain products*

The hardware components of data recording and monitoring systems typically represent a measurement chain that consists of four blocks for sensing, signal conditioning, signal processing, as well as data presentation and storage (Bentley 2005). Depending on the field of application, each hardware component has to fulfil certain requirements that are typically provided by established standards. An example of a general high-level standard is the RTCA-DO-160 standard for the environmental testing of hardware in an aerospace context (RTCA-DO160). The related tests are, for example, of a mechanical, chemical, or electromagnetic nature and, as a whole, rather involved and time-consuming. Depending on the field of application of a data recording and monitoring system, it might be neither feasible nor economical to perform the whole variety of desirable tests for each component. This leads to the challenge of determining, on a component level, meaningful hardware requirements that avoid excessive testing while keeping necessary standards. There is no general solution to this problem, which highly depends on the actual case. Existing standards, however, can provide valuable guidelines.

Moving from component to system level, the proper integration of a data recording and monitoring system into a complex technical product is required. Due to the general increase of complexity and electromagnetic sensitivity within technical systems, this task becomes increasingly challenging as well. The traditional approach for a proper integration involves the analytical and numerical modelling of possible unwanted electromagnetic couplings between different components (Tesche 1997). This is caused by the signal propagation between sensor and data unit along the aforementioned four blocks which is mainly of an electromagnetic nature. However, it has recently become apparent that increasing complexity requires, besides deterministic methods, also statistical methods that are adapted from reliability engineering to electrical engineering (Mao 2016). As a result and new development, both hardware requirements and aspects of uncertainty have to be considered as a whole during the system integration.

4.3.2 *Hardware requirements: Aspects of monitoring systems in complex technical facilities*

In an industrial environment a monitoring system will be developed, installed and operated only if a commercial benefit, either direct or on multi-level basis, can be expected.

The basic kind of monitoring is meant to prevent from system damage under use, offering upfront indications (e.g. life span variables like temperature, vibrations, etc.) for imperative service, usually combined with routine maintenance. It is applied for cheap and simple mass products. Second order monitoring is used to acquire data about the product quality during production (etc. weight, shape, homogeneity); it is recommended for mass products of some value and complexity. Ideally, this information is used to control the production process inline.

On the next level, sensor data combined with the operating parameter log can be used to continuously diagnose the present system status and so the product quality. It is combined with preferably non-destructive sample inspection of the product to verify the process' stability. Such kind of monitoring may also allow to adapt the maintenance frequency to the actual strain of the system. It is used for complex processes where reliability is the most important aspect (low-volume, costly or safety-related products).

Finally, these vast amount of information and data has to be merged with a system behaviour model to approve, recommend or tune warily operation modes and to venture a prediction for remaining lifetime, while the maintenance schedule is aligned with production requirements. On this level, the product is not necessarily a touchable item but could also mean energy (battery), information (data storage), or movement (aircraft engine).

Some of the economic effects of such monitoring efforts are obvious: increased lifetime, less downtime, higher throughput, less spares on stock and sufficient time to plan inevitable replacements. But there are also savings due to less failure in general, and less risk caused by unknown defective parts distributed into the market (product liability: documented monitoring is mandatory to defend claims). Wherever potential savings outbalance the costs an appropriate level of monitoring will be established.

4.3.3 *Conceptional aspects of standardisation of operating data recording within technical products*

The purposes of the operation data logging system regarding reliability engineering are detection of the cause of a failure or observation as well as prediction of failure and providence of maintenance action to user or producer. To formulate failure and its cause, monitoring system, and necessary and sufficient kind and number of sensors need to be allocated to product system. Hence, failure mode needs to be deployed into basic events by using FTA: Fault Tree Analysis (Lee et al.

1985) where designer selects appropriate sensor by reference to these events. On the other hand, many existing products such as automobiles and machine tools are already equipped with a monitoring system for attainment of its functionality. This monitoring system consists of sensors, ECU: Electronic Control Unit, and actuators and these components are modularized from the perspective of functionality usually by using DSM: Design Structure Matrix (Eppinger et al. 1994). Therefore, in the case of developing reliability monitoring system additionally, this system is desired not to change the structure of the existing functionality-it has monitoring structure which includes existing system modules. In addition, the occurrence of product failure depends on various elements such as the usage time, client usage, and other external factors. The sensors which are components of functionality-based system might not detect external factors such as temperature, humidity, and electromagnetic wave. Hence, for attainment of building failure-based monitoring system, designer needs to integrate undermentioned three steps: (1) deploying target failure mode to basic event by using FTA, (2) identifying necessary functionality-based monitoring systems and additional sensors for detecting external factors, and (3) modularizing these functionality-based sub-systems, additional sensors, and administration unit for transmitted signals. Figure 2 illustrates the concept structure of the failure-based monitoring system.

This failure-based monitoring system does not affect the structure of the existing functionality-based monitoring system. Therefore, this system has possibility to be optionally added to operating product system by upgrading without major design or structure changes.

4.3.4 *Hardware in use: Impacts on reliability of data recording safety within the product use phase*

The first impact of data recording systems within the product usage phase is related to scenarios in which the measurements are performed:

1. Field test: the goal is to measure the transient and steady state inputs of a vehicle as it operates over the real environment, in order to anticipate market region of use
2. Proving ground measurement: the goal is to replicate the most significant drive profiles from the field test, but in a more controlled environment (e.g. test track or climatic wind tunnel).

Field test are designed to capture all the environmental loadings that might affect the reliability of the vehicle or single components during its in-use phase. This type of measurements takes usually days or weeks. Data are recorded by the mean of a mobile data logger, which allows the simultaneous recording of a wide variety of sensor measurements. This type of device can be small and with integrated sensors, making them ideal for final customers' survey (Figure 3 left).

Proving ground measurements are based on the results from field test and focused on precise driving events during the development phase of a new vehicle. They are performed by an acquisition system, which guarantees more refined measurements, but it is less robust towards environmental stresses, and need to be interfaced to a laptop for data saving and storage.

Be either a road field test or a wind tunnel test, vehicle measurements are expensive. To perform such tests, one must first built a prototype (for Original Equipment Manufacturer - OEM) respectively buy or rent the selected car (for component suppliers). The required sensors need to be mounted, connected, and cabled. There must be enough room for all sensors, the cables, and a comfortable environment for both the driver and the acquisition system. Additional care must be taken when measuring the response of a component, which needs to be equipped with sensors (e.g. strain gages and thermocouples) by a reliable supplier, and then assembled in the vehicle.

Because of so many time and money consuming aspect, the key role of the test engineer is to make sure that measurement sessions are not jeopardize because of 1) improper sensor mounting 2) inadequate data acquisition/storage.

Once the suitable acquisition system has been considered for the measurements, the key aspect of a successful measurement lies on the type of sensors.

Sensors need to be tailored to the physical value of interest. It is therefore fundamental a prior

Figure 2. Structure of failure-based monitoring system.

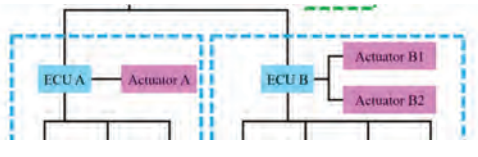

Figure 3. Small data logger with integrated sensors (left). PC interfaced Data acquisition system (right) (cf. (MSRDatenlogger)).

knowledge of the value range (maximum and minimum value, the frequency etc.).

Sensors must also be accurate, enough sensitive to properly measured small variations, but robust toward the inevitable environmental stress resulting from driving ground: shock, heat, humidity, and contamination associated to the potential adverse conditions of the road profile (dust, mud, water etc). In general, sensors must be operative under all ambient temperature conditions.

Similarly, the acquisition system must be tailored to the measurement type. There must be a trade-off between system performance and robustness and in some case its dimensions. As a typical example, integrated circuit piezoelectric (ICP) accelerometers are less intrusive (smaller and lighter) and more accurate than capacitive ones, but less resistant to high temperature and shock. ICP sensors would perfectly fit for vibration measurements on the chassis or cabin component, but be unreliable for engine vibrations, due to the high temperature reached during combustion.

High care should be taken when mounting the sensors: external factors that might interfere with the measurements are electrical leakage and shorts. Moreover, the electromagnetic compatibility of the acquisition systems and logger should be verified to avoid the presence of electromagnetic parasitic noise.

Some additional consideration and precaution should be used when planning long field measurements.

The settings of the data logger (usually mounted inside the cabin) require a trade-off between frequency of acquisition and storage memory. Particular care must be taken for acceleration measurements, since their high frequency and long acquisition time might be computationally demanding during data post-processing.

Solid State Drive (SSD) memory devices are preferred to Hard Disk Drives (HDD) because they are less affected by dust contamination and vibration loading. Moreover, SDDs do not require rotating component such as the platter or the fan system.

Planning of field measurements also need to consider the available memory and how it works, to avoid data loss. The most commonly used memory storage methods are i) erasable data storage systems (once the memory is full, after a certain time the system is erased) and ii) circular or buffer memory (oldest data gets overwritten when the memory is full).

During field or proving ground measurements, both data loggers and acquisition systems can be used to record data coming from the on Board Diagnostics (ODB) or the control area network (CAN) bus. It is obvious that when recording both data from sensor and form the vehicle on-board computer, the measurements needs to be synchronized.

A check-list to avoid potential problems encountered during field measurements could include the following topics:

– Sensors: must be robust, accurate and properly calibrated.
– Acquisition system: suitable to the type of measurements (portable PC interfaced vs. data logger).
– Memory storage: chosen with respect to the amount of expected data, limitation of the memory capability and post-processing computational effort.
– Post processing: properly labelling of measurements channels; data saved in an exploitable format.
– Privacy issue: field tests on final customers (e.g. users' fleet) must be compliant to privacy policy, which varies from one country to another.

5 SUMMARY

The development process of complex technical products of the last years shows an increasing amount of sensors, electronic control units, data logging and monitoring systems within consumer goods (e.g. automobiles, washing machines) and industrial goods (e.g. machine tools, manufacturing systems). This operating data can be a foundation for statistical analysis regarding the reliability of the product. The goals of data analytics (focus: data uncertainty, reliability analytics, second-life-cycle aspects, Lessons-Learned issues) are the base of operations for the data and hardware requirements.

Main requirements regarding the monitored data are as follows:

- Clear data Scheme regarding the local data storage system,
- Data content (storage): Messages, error, alarms, timestamp, serial number, identification codes, numeric values, meta data,
- Data receiver: Possibility of data transformation
- Consideration of industrial data standards, depending on product category,
- Possibility of technical report,

Main requirements regarding the monitoring system hardware are as follows:

- Considering standards for sensing, signal conditioning, signal processing, data presentation and storage,
- Considering possible electromagnetic sensitivity regarding signal propagation between sensor and data unit,
- Modularisation of monitoring system components,

- Considering upgrade possibility during product life cycle,
- Considering load profile regarding expected product life cycle within monitoring prototype testing (field test versus proving ground measurement).

The shown requirements can be used as a guideline for the reliability engineer for the design of operating data logging and monitoring systems within the product concept development phase of a new product generation.

Enhanced hybrid prognostic approach applied to aircraft on-board electromechanical actuators affected by progressive faults

P.C. Berri, M.D.L. Dalla Vedova & P. Maggiore
Department of Mechanical and Aerospace Engineering (DIMEAS), Politecnico di Torino, Torino, Italy

ABSTRACT: In the last generation aircraft, the architecture of the powered flight control system adopted Electromechanical Actuators (EMAs). Being some on-board actuator safety critical, the practice of monitoring their behavior to determine their health condition is a task of growing importance. The choice of the best prognostic algorithm is driven primarily by their effectiveness in correctly identifying the health conditions of the system since each technique might be more or less useful in a given situation. In this contest, the authors propose a new GA-based fault detection tool, relying on a model-based approach, comparing the system output to that of a Monitor Model (MM), which is able to reproduce accurately the dynamic response of the actual EMA in terms of position, speed and equivalent current, even under the effects of different failure modes while keeping a reasonably low computational cost; this Fault Detection and Identification (FDI) algorithm have been extended to seven progressive failures. A numerical simulation test environment has been developed to simulate progressive faults and to evaluate the accuracy of this prognostic method. Results showed an adequate robustness and a suitable ability to early identify malfunctions with low risk of false alarms or missed failures. Moreover, the effect of a failures different from those considered was studied, to avoid safety concerns related to the missed identification of an incipient failure, hidden by another unknown failure mode.

1 INTRODUCTON

Electromechanical Actuators, or EMAs, are gradually replacing hydraulic systems in aeronautical applications, starting from the less safety critical uses (such as the actuation of trim tabs, cargo bay doors, or weapon and sensor systems of military aircraft) up to the most important ones, like primary and secondary flight controls. EMAs are composed of an electric motor driving the user through a mechanical transmission; then, the main advantages over a traditional electrohydraulic system are the absence of a centralized hydraulic power generation and distribution system, leading to an overall weight reduction, and the total absence of the hydraulic fluid itself, which is usually pollutant or flammable.

Given that the EMA technology is quite new and the reliability of these systems is not yet adequately known, risk reduction methods based on redundancy and scheduled maintenance and inspections shall be heavily employed, which somehow limits the diffusion of this new technology due the unavoidable cost increase. Moreover, those risk reduction methods can do nothing against failures caused by unexpected and extreme scenarios such as the exceeding of the flight envelope.

A new approach to the risk reduction, called Prognostics and Health Management (PHM), relies on the monitoring of functional parameters of the system to detect and identify the precursors of failures at an early stage (Vachtsevanos et al. 2006), in order to estimate the Remaining Useful Life (RUL) of the components. The monitored parameters shall be usually converted into electric signals, so a PHM approach is particularly convenient when applied to an electromechanical system, where most parameters are already in form of electric signals without the need for dedicated sensors and transducers, which would increase the overall costs and worsen the system basic reliability. In literature, many different Fault Detection and Identification (FDI) methods have been investigated: model-based techniques based on the direct comparison between the output of real and monitoring system (Raie & Rashtchi 2002, Byington el al. 2004, Alamyal et al. 2013), on the spectral analysis of well-defined system behaviors performed by Fast Fourier Transform (Mamis et al. 2013, Dalla Vedova et al. 2014), on combinations of these methods (Borello et al. 2009a, Dalla Vedova et al. 2015a,b) or on Artificial Neural Networks (Su & Chong 2007, Hamdani et al. 2011, Refaat et al. 2013, Dalla Vedova et al. 2016a).

This paper proposes an FDI algorithm relying on a model based approach and, in particular, on parametric estimation, for the prognostic analysis of a typical EMA according to the More Electric Aircraft and All Electric Aircraft paradigms (Quigley 1993, Howse 2003); the robustness of this algorithm is tested under different operating conditions and the effects of its use integrated with the traditional RAMS approach is investigated.

2 REFERENCE AND MONITOR MODELS

Two numerical models of the actuator were developed for this study. A very detailed reference model is used as a virtual test rig for the FDI algorithm, simulating the behavior of the faulty physical system. The computing time required by this model, however, is not compatible with the use in the FDI algorithm itself, which involves an iterative evaluation of the fitness function in Genetic Algoritm (GA). For this reason, a simplified monitor model was built to achieve a light computing cost and, at the same time, a high accuracy in reproducing the early effects of different incipient fault modes.

The Reference Model (RM), widely described by Dalla Vedova et al. (2016b), contains a detailed simulation of the physical phenomena acting in the EMA, in particular regarding the electromagnetic stator-rotor coupling (Haskew et al. 1999, Lee & Ehsani 2003, Halvaei et al. 2009, Çunkas & Aydoğdu 2010), end-of-travels, compliance and backlashes acting on the mechanical transmission (Borello et al. 2009b, Borello & Dalla Vedova 2014), dry friction acting on bearings, gears, hinges and screw actuators (Borello & Dalla Vedova 2012) and a precise model of the behavior of the power electronics, including the solid-state inverter and the PWM control of the three electrical phases.

The Monitor Model (MM) is a simplified representation of the system using, for example, an equivalent single-phase DC motor with a single feedback loop instead of the complex electromagnetic model of the BLDC. This requires the introduction of a shape function based model for the simulation of the electrical fault, which is not strictly related to the physics of the system, but allows to reproduce the effects of faults with goof accuracy, as shown by Berri, Dalla Vedova & Maggiore (2016).

3 FAULT MODES

Five different fault modes were considered for the study. Those were chosen among the most common for EMAs, as highlighted by (Kenjo & Nagamori 2003, Chesley 2011, Weiss, 2014); moreover, they are usually characterized by a progressive evolution, making possible an effective prognostic detection.

The considered faults are briefly listed below:

- Dry friction due to the wearing of mechanical components;
- Backlash of the reducer gearbox and/or rotary-to-linear conversion device;
- Partial short circuit of the BLDC stator coils;
- Rotor eccentricity due to the degradation of its support bearings;
- Control electronics fault resulting in the drift of the PID controller Proportional gain.

The implementation of the first four faults in both the RM and MM is described by Berri, Dalla Vedova & Maggiore (2017); the last one is modelled by varying the Proportional gain parameter in the Controller subsystem of both models. Despite the relatively straightforward implementation of this fault, non negligible difficulties were found due to the position of the affected subsystem in the feedback loop, in particular considering the interactions with other fault modes: in fact, its effects are hardly distinguishable from those of partial short circuit.

4 FITNESS FUNCTIONS

The objective function to be optimized by a GA is known as the fitness function. In the proposed FDI technique, it is the cumulative error in terms of equivalent single-phase current between the MM and RM. This results in a 8-variables function to be optimized: in fact, two of the considered fault modes have multiple degrees of freedom. The rotor eccentricity is characterized by a its magnitude ζ and its phase ϕ (i.e. the angular position of the minimum air gap measured from the reference rotor angular position); similarly, the partial short circuit can affect each of the three stator phases, which have to be treated separately in order to isolate this fault mode from the others.

The fault parameters are normalized as follows:

- $k(1)$ is the normalized friction: $k(1) = 0$ means nominal conditions, while $k(1) = 1$ means 300% of nominal condition;
- $k(2)$ is the normalized backlash: $k(2) = 0$ means nominal condition, $k(2) = 1$ means 100 times the nominal condition; although at a first glance this range may seem exaggerated, 100 times the nominal condition means about half a radian of mechanical play on the fast shaft, reduced by the gear ratio to $5.7 \cdot 10^{-2}$ degrees on the slow shaft or 20% of the already small chirp command amplitude.

– *k(3)*, *k(4)* and *k(5)* are respectively the normalized short circuit of phases A, B and C; for example, $k(3) = 0$ means a fully functional phase A, while $k(3) = 1$ means a complete short circuit for the same phase.
– *k(6)* is the rotor static eccentricity amplitude: $k(6) = 0$ means no rotor eccentricity, while $k(6) = 1$ means $\zeta = 1$; in fact, *k(6)* is equal to the eccentricity parameter ζ (Belmonte et al. 2015)
– *k(7)* is the phase of rotor eccentricity ϕ, i.e. the direction corresponding to the minimum air gap; $k(7) = 0$ means $\phi = -180°$, $k(7) = 1$ means $\phi = 180°$.
– *k(8)* is the normalized variation of the proportional gain: $k(8) = 0$ is a 50% reduction of the proportional gain, while $k(8) = 1$ means a 50% increase.

The fitness function is then computed with a modified total least squares method, which is tolerant to small phase lags cumulated between the two EMA models, even in presence of steep gradients and abrupt changes in the equivalent current (Markovsky & Van Huffel 2007, and Berri, Dalla Vedova & Maggiore 2016). The resultant error is therefore:

$$err = \int_0^{t_{sim}} \frac{\left(I_r - I_m\right)^2}{\frac{\left(dI_r / dt\right)^2}{k} + 1} dt \quad (1)$$

where I_r and I_m are the reference and monitor single phase currents, t_{sim} is the duration of the simulation and k is a constant used normalize the derivative of the reference current. Alternatively, computing the integral with a numerical scheme, considering the discrete nature of the simulations:

$$err = dt \cdot \sum_i \frac{\left(I_{r(i)} - I_{m(i)}\right)^2}{\frac{\left(dI_{r(i)} / dt\right)^2}{k} + 1} \quad (2)$$

It has to be noticed that in this formulation dt assumes the meaning of the finite time step of the numerical integration.

5 GA SETTINGS

The genetic algorithm used for this study is based on the *ga* function available in the MATLAB *Optimization Toolbox*. Employing an eight-variables fitness function requires a little calibration of the GA to achieve a good convergence. However, various parameters are left to their default value, so a further optimization of the algorithm settings is likely to allow a performance improvement, increasing the convergence speed. In particular, the *function tolerance* in the *stopping criteria* is tightened from the default $1 \cdot 10^{-6}$ to a value of $1 \cdot 10^{-9}$, to prevent the method to stop in a local minimum; moreover, the maximum iterations parameter is changed from 100 to 200, in order to avoid stopping the algorithm too early, before convergence is reached. Moreover, the *hybrid function* option is set to start a deterministic optimization with the *fmincon Interior Point* solver at the end of the genetic algorithm to refine results. The gradient based algorithm starts from the final point of the GA, offering a faster way to converge on the optimum solution, while the genetic algorithm provides a suitable start point to prevent convergence on local minima, ensuring robustness of the method.

6 RESULTS

In order to measure the accuracy of the fault identification in all the eight variables, a total error was defined as the quadratic mean of the errors on single variables:

$$e_{tot} = \sqrt{\frac{1}{8}\left(e_1^2 + e_2^2 + e_3^2 + e_4^2 + e_5^2 + e_6^2 + k_6^2 e_7^2 + e_8^2\right)} \quad (3)$$

The FDI algorithm was executed several times, with the fault parameters set to different values, in order to test the effectiveness and accuracy of the proposed method. For each combination of faults, the GA was executed ten times, because the method is inherently non-deterministic, involving the iterative random choice of points for evaluating the fitness function. This way it was possible to assess the repeatability of results, which were not strongly influenced by the aforementioned random choice.

Then, to assess the robustness of the algorithm, the variance σ^2 of results and total error is used:

$$\sigma^2 = \sum_{i=1}^{N} \left(k(j)_i - \overline{k(j)}\right)^2 \quad (4)$$

where N is the number of optimizations, $k(j)_i$ is the value of the j-th fault parameter resulting from the i-th optimization and $\overline{k(j)}$ is the average value of the j-th parameter over N optimizations.

The following table reports, as an example, the results obtained with three of the optimizations for the medium damage level combination of faults.

Tables 2 to 5 summarize the results of 40 optimizations, performed with multiple faults and different damage levels. For each damage level, the GA was executed ten times, and the arithmetic mean

Table 1. Optimizations for medium multiple damage.

Total Error e_{tot}		1.97%	8.469E-05

The high level damage, with its error rising up to over 7%, starts to show the divergence between MM and RM; however, this case is considered only to assess the range of applicability of the model, but is not of practical interest. Eventually, the introduction of a white noise disturbance superimposed to the controller output signal in the RM seems not to affect the method accuracy nor its robustness (as shown in Table 5).

Figure 1 shows the probability distribution of the total error, with data gathered in all the performed optimizations. It can be noticed that, for most optimizations, the total error has a very low value, in the order of 1%. The smaller peak of the probability distribution, settled around 7%, is indeed caused by the simulations executed with a high damage level, which causes the behavior of the two models to diverge slightly. However, this case is not of practical interest for prognostic applications (in fact, such a high damage results in a jammed actuator response and therefore lies in the field of diagnostics), but rather is considered to assess the limits and the applicability of the MM damage implementation.

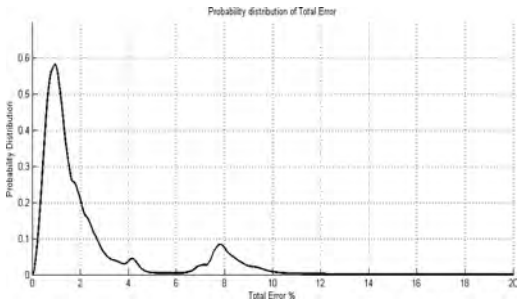

Figure 1. Probability distribution of the total error e_{tot}.

Table 6. Effect of unknown failure mode.

Initial conditions	Fitness function final value
k_f = 0.02 Nm/rad	0.0618
k_f = 0.05 Nm/rad	0.3609
k_f = 0.1 Nm/rad	1.8743
Baseline (low to medium damage, known faults only)	3.049E-04

In addition, in order to partially rule out the possibility of an unknown failure mode (i.e. one different from those considered in the models) not being detected by the GA, a fictitious failure consisting in the introduction of an elastic external force, with elastic constant k_f varying between 0.02 and 0.1 Nm/rad on the motor shaft, has been added to the RM only, to evaluate its effect on the FDI algorithm. The system health status in this case is partially misinterpreted, since the total error shows an increase in its value. However, the presence of an unknown failure is detected by the fitness function failing to converge to a near zero value.

Table 6 shows the optimized value of the fitness function for different entities of the added fictitious failure, compared to the mean baseline value referred to low to medium damage status with only known fault modes.

It can be seen that the introduction of an although small unknown failure results in an increase of the fitness function value after the optimization of 2 to 4 orders of magnitude. This increase can be easily related to the presence of a condition not identifiable by the algorithm, as an unknown failure mode or a too high damage level.

Each failure mode affecting the waveform of the monitored variables in a recognizable pattern, it appears unlikely that two failures can cancel each other resulting in a missed identification; however, this aspect shall be further investigated in future works.

7 RELATION BETWEEN RAMS AND PHM APPROACHES

Although the RAMS and PHM disciplines are seldom considered together in practical applications, they are closely related and their integration in a unified approach to the system life cycle management can lead to significant benefits in terms of safety and cost effectiveness (Dersin et al. 2017).

7.1 *Effect of PHM approach on RAMS*

The use of a prognostic tool to detect the early effects of incipient faults can be an effective and powerful method to improve the characteristics of Reliability, Availability, Maintainability and Safety of a system. A reliable PHM strategy can in fact enable the cost effective implementation of Predictive Maintenance and Condition Based Maintenance practices: with this approach, maintainability is affected by the improvement of the self-diagnostic capability of the system, which reduces the time to detect the fault to be fixed. In fact, with a PHM approach for the management of the system life cycle, most maintenance interventions are actually preventive scheduled maintenance. The corrective maintenance is then reduced to the replacing of those components that underwent failure modes impossible to detect in advance.

The overall Maintenance Man Hours/Flight Hour of a given aircraft system are then decreased, as well as the maintenance related operating costs.

The above mentioned effect on maintenance greatly improves the availability of the system. Being the corrective maintenance reduced, most of the necessary interventions can be scheduled in advance to be performed in the already slated ground time.

This allows a more cost effective management of the fleet, and in some cases also the reduction of the number of aircrafts necessary in the fleet for a given commercial airline or military service.

On the other hand, a prognostic fault detection and useful life estimation would virtually eliminate the risk of having faulty components flying on an aircraft in service. Then, the effective failure rate of the considered components is reduced, since worn components are replaced before their damage level starts affecting the performance of the system. Therefore, both the reliability and safety are improved, since they are both related to the failure rates of the system (the difference between them is only the potential effect of the considered failures).

7.2 *Use of RAMS tools for PHM purposes*

Various analytic tools commonly used in the RAMS disciplines can be employed to perform an

effective PHM activity, leading to safety improvement and cost reduction. Through the Failure Modes Effect & Criticality Analysis (FMECA) it is possible to identify the most significant failure modes of the system in terms of their impact on service reliability and on safety, based both on their effects at subsystem and aircraft levels and on their failure rate, estimated through statistical analysis of field data and return on experience. Therefore, focusing the PHM activity on the prediction of the occurrence of those failure modes can lead to a significant benefit in terms of improvement of safety and service reliability.

On the other hand, the Life-Cycle cost analysis is intended to identify the most cost affecting and availability affecting maintenance actions. Then, prognostic tools can be proficiently employed to reduce the number of required cost affecting maintenance actions and to plan the availability affecting ones into the already slated ground time windows, thus improving the availability of the aircraft and reducing its operating costs.

8 CONCLUSIONS

A satisfyingly effective FDI tool intended to be applied to an electromechanical actuator for flight control system has been implemented by the authors and tested in a simulated test bench in presence of different working conditions in terms of fault modes combinations of the monitored system.

The algorithm has shown an adequate robustness also in presence of a noisy input signal or the effects of failure modes not considered in the monitor model. In particular, the presence of an unknown failure mode leads to a partial misinterpretation of the system health status, but this condition is correctly recognized and reported coherently. On the other hand, the possibility of an unknown failure mode and a considered one cancelling each other effects, thus producing a missed fault identification, despite appearing as extremely unlikely, shall be further investigated. The future work on this FDI algorithm will include the extension of the models, taking into account a greater number of fault modes, and their validation on a physical test bench, also to ensure the required accuracy and resolution of the measured signals is matched by the currently available sensors. The implementation on a flying aircraft of an FDI algorithm similar to the one proposed (adapted to match the parameters of the particular actuator installed on-board), coupled with a statistical RUL prediction, could then reduce the maintenance related operating costs, reduce the downtime and increase both safety and availability of the system, integrating the traditional RAMS disciplines with the emerging PHM approach.

A method for wind speed generation

J. Ma, M. Fouladirad & A. Grall
Institut Charles Delaunay, LM2S, Université de Technologie de Troyes, CNRS, Troyes, France

ABSTRACT: This paper proposes a flexible continuous wind speed model based on first order Markov chain and Stochastic Differential Equations (SDE). This model permits to generate wind speed sequence with high frequency with statistical properties similar to an observed wind speed in a given geographical site. This model can be merged with the deterioration health indicators of wind turbine to make prognosis and plan maintenance actions.

1 INTRODUCTION

Since the Paris Agreement has been signed among the 195 members of the United Nations Framework Convention on Climate Change (UNFCCC), more and more countries have announced their plans to reduce the emission of CO_2 and to develop alternative clean energies like wind energy, solar energy, tidal energy, energy of natural gas, etc. Consequently, in the past decade, the world widely exploitation and technical development of wind energy have increased. In Europe, the capacity installed in 2016 reached 13489.9 MW and the estimated electricity production from wind power in the European Union (EU) in 2016 is 302.7 TWh (windeurope 2017a). By 2030, wind energy could cover 29.6% of EU's electricity demand (windeurope 2017b). However, because of the inbred randomness of wind speed, the wind power industry faces enormous challenges in practice and the development of wind power industry is very laborious.

To obtain a good prognostic of the wind turbine lifetime as well as to carry out efficient maintenance policies, it is necessary to study the impact of the wind speed on the wind turbine deterioration. It is important to rely on an appropriate wind speed model which permits to simulate the wind sequence related to a required geographical region with the same features as the real wind sequence and put in our disposable high frequency data of wind speed sequence.

The literatures on wind speed can be classified into three groups.

- Wind characteristics study on a specific site
- Wind speed generation
- Wind speed prognosis

The wind characteristics study is more quantitative and focuses on statistics properties of the wind speed, such as its average, maximum, minimum, standard deviation and its statistical distribution (usually consider the Weibull distribution function) ((Shu et al. 2016, Barthelmie et al. 2005, Celik 2004)). The daily patterns in wind energy production has been investigated (Scholz et al. (2014),Lennard (2014)), and studies the modelling for extreme events, refer to Baseer et al. (2017). Wind speed generation and wind speed prognosis are two different subjects. However, they have similarities regarding the modelling aspect. A great effort is deployed for wind speed modelling. To achieve the accuracy, models using environmental parameters such as temperature, pressure and humidity are proposed. Generally, these models require the computation of fluid dynamics in order to simulate the environmental conditions on different grids (Sezer-Uzol and Long 2006, Landberg et al. 2003). Since these latter are computationally burdensome they are not capable of generating a large data set and therefore not very suitable for applications requiring a good knowledge of the wind sequence in a short time.

Using probability distributions such as Weibull distribution to generate wind speed data which permits to reproduce wind speed data with the same statistical features as the wind data in our disposal. Regrettably, wind speed samples are measured at hourly time scale and data generation based on this type of data can only reproduce the macroscopic features of the wind behaviour.

Discrete models with memory applied in time series analysis such as Autoregressive Moving Average (ARMA) models (Poggi et al. 2003), Autoregressive Integrated Moving Average (ARIMA) models (Kavasseri and Seetharaman 2009) and Generalized autoregressive Conditional Heteroskedasticity (GARCH) models (Liu et al. 2011) are commonly used to reproduce wind speed data for a particular location depending on available

historical measured data. Although these models have efficient computational capacity for generating wind speed data, their linearity discard the possibility of nonlinearity in time series (Wanga et al. 2018). Since a simple model ignores the complexity of the wind behaviour and an elaborate model is not easy to deal with, some numerical methods based on computer capacity have been proposed to make predictions in wind behaviour only according to historical data.

Recently, wind speed prognosis based on machine learning and artificial neural networks (ANNs) has become very popular, see (Bilgili et al. 2007, Ji et al. 2007). Generally, the method is to generate wind speed by training the historical information about wind speed data. Easily trapped in local optimisation is a key problem related to ANNs. Moreover, without a model it is difficult to make instantaneous predictions and to control the behaviour of the engineering systems impacted by wind speed evolution.

Lately, in order to reduce the computational complexity and still propose a model for the wind evolution memoryless or short-memory stochastic models are getting more attention. In this framework, Markov processes, lévy processes or diffusion processes are proposed. For instance, based on Brownian motion and Langevin equations, the wind evolution is described by Wilson and Sawford (1996). More accessible, Markov chains have the capability to model wind speed data. Despite the simplicity of first-order Markov chain, it can generate wind speed time series with very similar statistical characters as the observed data (Nfaoui et al. (2004), Ettoumi et al. (2003), Yang et al. (2011)). However, Markov chains are not able to capture wind speed characteristics at high frequency. Research done by Brokish and Kirtley (2009) shows the limits of Markov chains for simulation data with time step smaller than fifteen minutes. To generalise, second or third order Markov chains and semi-Markov chains are used for wind speed modelling in order to improve the accuracy (D'Amico et al. 2013). Diffusion processes or stochastic differential equations are very flexible with short memory and as mentioned in (Zárate-Miñano et al. 2013), they seem to be suitable candidate wind speed modelling. Since SDE models are continuous, technically, they can be used to simulate wind speed at any time scales. Considering the diurnal and seasonal influences, the wind speed generation length of SDE models is limited to a few hours. SDE models are especially suitable for modeling wind speed turbulences.

An epitome could be summarized from the literatures is that the existent wind speed models focus on either short term modeling or long term modeling with large time scale. Hence, if these models are required for the analysis of wind turbine performances and operation related to wind speed their utility is limited. Short term models limit the analysis to a current short period; long term models can't provide sufficient and qualitatively useful data for analysis.

This problem is especially prominent in reliability analysis and failure prognosis and output power estimation of wind turbine. It has been highlighted that wind speed has a significant impact on degradation of wind turbine components. Particularly, the blade-pitch system has high failure rate among the components. Moreover, as it is indicated in Barthelmie et al. (2005), the wind turbulence intensity (variance divided by mean wind speed) has key influence on wind turbine lifetime. For instance, the fast variation of wind speed leads to frequent and sudden actions of the blade-pitch system. It has been demonstrated that turbulence intensity affects turbines power production ((Elliott and Cadogan 1990, Frandsen et al. 2000, Kaiser et al. 2007, Gottschall et al. 2006, Gottschall and Peinke 2007, Lubitz 2014)). Furthermore, from the point of view of prognosis and remaining useful lifetime (RUL) estimation, hourly average wind speed data is not satisfiable because it reflects the trend of wind speed by losing details, namely, the turbulence of wind speed. In addition, degradation occurring to wind turbine components is a long term process, and the RUL of wind turbine components are dynamically changing according to the working conditions of wind turbine.

Presently, wind speed at different time scales are applied to different problems, such as long term wind speed data are used to estimate wind energy for a future wind farm; diverse wind speed sequences are used to test a new control strategy; annual wind sequences with detailed information are indispensable to reliability research about the wind turbine, for example, the degradation of blade/yaw pitch system.

A method taking into account a continuous wind speed generation during a long period can fill the existing gap in the literature. This fact encourages us to propose a wind speed model that satisfies the following requirements.

- It can reflect the trend of wind in a long term period.
- It can contain turbulence information at small time scale.
- It can be accord with real wind speed data's probability distribution
- It can be generated quickly

In other words, this paper aims to propose a mathematical model which is able to generate satisfiable wind speed series for wind turbine components RUL study and accurate output power estimation.

The main contributions of this paper could be summarized as follows.

- Proposition of a new wind speed model considering Markov chains embedded with SED model;
- Consideration of different SDE models to be able to generate different wind profiles.

The remainder of this paper is organized as follows. After the model description a brief introduction on Markov chains and SDE models is given in section 2. In the same section, model parameters estimation methods are mentioned. An illustrative example is given in section 3. Conclusions in section 4.

2 MODEL DESCRIPTION

In wind industry, the Reynolds decomposition need to be considered for analyzing turbulence effects. Hence, the wind speed time series $U(t)$ is decomposed into its mean value $\bar{U}(t)$ and the fluctuation $u(t)$..

$$U(t) = \bar{U}(t) + u(t) \tag{1}$$

This gives us an idea to model mean wind speed and wind speed fluctuation separately. Refer to Calif (2012), $\bar{U}(t)$ can be considered as a low-pass filter corresponding to the hourly, daily, monthly, seasonal or annual effects; turbulence $u(t)$, which has a zero mean value and can be seen as a high-pass filter corresponding to turbulent effects.

Depending on research emphasis, wind speed can be modeled in different ways at different time scales. In wind energy industry, choosing continuously wind speed is more appropriate when we study the operation of wind turbine, as studies show that wind turbulence intensity has enormous effect on energy production and detected failures about wind turbine; hourly average wind speed is a good choice when we want to estimate the wind resource of a site; 10 minutes's average wind speed is noted down by SCADA system.

In this paper, we propose a Markov chain model embedded with SDE. Due to its properties, this model is very flexible. Markov chains is used to model macroscopical wind speed trend. It represents hourly average wind speed or different wind speed classes relating to wind turbulence intensity. The embedded SDEs are mainly used to model a continuous wind speed depending on the environmental states which are set by Markov chain. Different setting parameters and different applications of SDE give different continuous wind speed models. Other SDE models also can be considered for simulating different conditions such as gust or extreme weather. Hence this model is easily adapted according to the location of interest.

Here we would like to give two illustrative examples.

- One day's (24 hours) wind speed generation
  Each state in Markov chain represents hourly average wind speed and drives the choice of related SDE. In this case, 24 states are randomly generated to represent the average wind speed time series. In each state, continuous wind sequences are generated from specific SDE at small time scale like secondly data.
- Different wind condition generation
  Refer to IEC standards Commission et al. (2005), wind conditions contains normal, extreme and gust which could be generated by Markov chain. Inside Markov chain, SDEs are used to simulate wind speed associated with the certain wind condition.

2.1 *Markov chain*

A Markov chain process is uniquely defined by its state space, transition matrix and initial distribution. Markov chains wind speed modelling consists of two main steps: state classification and transition matrix estimation. The state classification is arbitrary depending on the purpose. In this paper, the range of wind speed $[U_{min}, U_{max}]$ is divided into serval intervals, each interval's index is identified by its central point, changing the event "the wind speed value is in the range [a, b]" to the event "the wind speed is $\frac{1}{2}(b + a)$". We introduce the notation for the wind speed states as $S = \{s_1, s_2, \cdots, s_N\}$; and make $\{X_t\}_{t\in\mathbb{N}}$ represent the wind speed time series. Hence, the event "$X_0 = s_5$" means at time t = 0, the wind speed belongs to state s_5. Table 1 shows an example for state assignment.

The initial distribution is estimated by dividing the dataset into bins according to the states, then normalising the vector of the occurrences in each bins. For example, to calculate $p_1^0 = \mathbb{P}\{X_0 = s_1\}$, which is the probability that the first element of the wind time series is in state s_1, we need to count the number of times that a value enters in state s_1 in the entire recorded time series and divide it by the total number of recorded values.

The empirical frequencies are the estimation of the transition probabilities

$$\begin{aligned}\mathbb{P}(X_{n+1} = s_j \mid X_n = s_i, X_{n-1} = s_{i_{n-1}}, \cdots, X_0 = s_{i_0}) \\ = \mathbb{P}(X_{n+1} = s_j \mid X_n = s_i) = p_{ij}\end{aligned} \tag{2}$$

where s_i, $s_j \in S$. The transition probability p_{ij} can be estimated by counting how many times a value from s_i goes to state s_j in the wind time series, normalised over the total number of occurrences of

Table 1. Example for Markov chain's state space.

State	S_1	S_2	S_3	S_4	S_5	S_6	S_7	S_8
Interval	[4, 8]	(8, 9.4]	(9.4, 10.2]	(10.2, 10.7]	(10.7, 11.2]	(11.2, 12]	(12, 12.8]	(12.8, 25)

values in state s_i. The transition matrix denoted π is filled with transition probabilities p_{ij}, $1 \le i, j \le n$.

2.2 *SDE*

After studying 1 million of wind speed fluctuation distributions, Calif (2012) concludes that it is more common to have three classes of wind speed fluctuation distribution. The distribution classes are as follows. The 90% wind speed turbulence follows a kind of symmetrical mono-modal PDF which is well fitted to a Gaussian PDF (class 1 shown in Figure 1). The 9% wind speed turbulence follows a kind of dissymmetrical mono-modal PDF which can be described by Gram-Charler series (class 2 shown in Figure 1) and the rest 1% follows a kind of bimodal PDF which is fitted by mixture of Gaussian PDF (class 3 shown in Figure 1). Figure 1 illustrates the mean PDF of wind speed turbulence for each class. In this paper, we consider more about the wind with speed fluctuation of class 1 and class 2.

2.2.1 *SDE model selection*

In order to randomly switch between the two classes, one considers an inner Markov chain inside each inner state s_i. To avoid confusions between the wind speed Markov chain and this SDE switching Markov chain, the latter one is designate as a SDE-Selection model (SSM) in this paper. A transition probability matrix of SSM is directly assigned as follow.

class	$Class_1$	$Class_2$
$Class_1$	0.9	0.1
$Class_2$	0.9	0.1

Since the majority of turbulence seems to follow a gaussian distribution and some can be fitted to mono-modal distributions, it seems natural to propose a stochastic process where increments are gaussian or functional of a gaussian distribution. Potential candidates are diffusion processes which are derived from stochastic differential equations. The general form of one-dimensional SDE equation is as follows:

$$dx(t) = a(x(t),t)dt + b(x(t),t)dW(t), t \in [0,T] \quad (3)$$

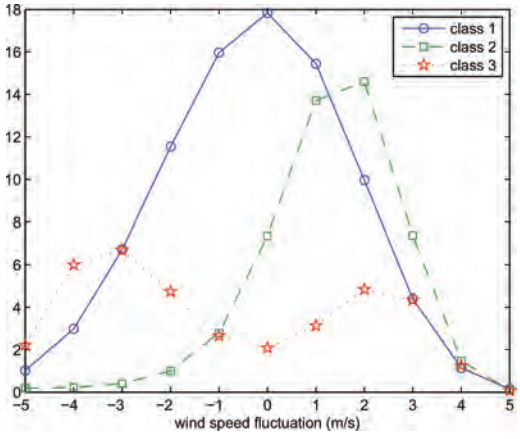

Figure 1. Wind speed fluctuation (Source: (Calif, R.2012)).

where $a(x(t), t)$ and $b(x(t), t)$ are the drift term and diffusion term, respectively. $W(t)$ is a standard Wiener process described as follows:

- $W(0) = 0$, with probability 1.
- For $0 \le t_i < t_{i+1} \le T$, the increments $\Delta W_i = W(t_{i+1}) - W(t_i)$ is a Gaussian distribution with zero mean and $\sigma = t_{i+1} - t_i$, namely, $\Delta W_i \sim \mathcal{N}(0, t_{i+1} - t_i)$
- for $0 \le t_i < t_{i+1} < t_{i+2} \le T$, the non-overlapping increments $\Delta W_i = W(t_{i+1}) - W(t_i)$ and $\Delta W_{i+1} = W(t_{i+2}) - W(t_{i+1})$ are independent.

Hence, a standard Wiener process describes a continuous Gaussian process whose increments are of unbounded variation. Since there is a large variety of functions $a(x(t), t)$ and $b(x(t), t)$, the diffusion process can model a large range of phenomenon. In this paper, we focus on a special case of SDE initially proposed by Vasicek (1977).

2.2.2 *Ornstein-Uhlenbeck process*

Figure 2 lists 3 histograms of wind speed turbulence. This group wind data is downloaded from the site *www.winddata.com*, recorded the wind speed during one hour at the site San Gorgonio, USA. It can be observed that the wind speed turbulence follow a kind of symmetrical mono-modal PDF and the mean value is almost around zero.

Combining with the research results of Calif (2012) (shown in Figure 1), Ornstein-Uhlenbeck

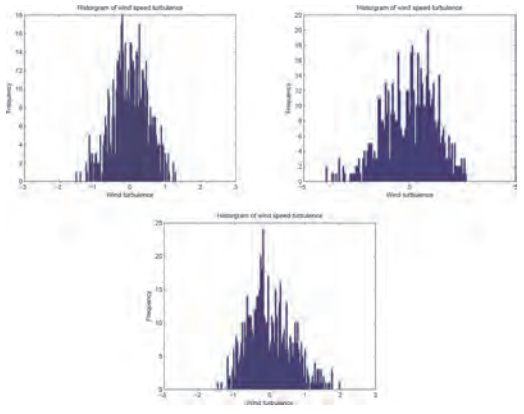

Figure 2. Histogram of wind speed turbulence (data downloaded from *www.winddata.com*).

processes appear to be suitable candidates for wind speed fluctuations modelling. In other words, the aim of SDE application here is to model a continuous wind speed during a short period, such as several seconds, 10 minutes or 1 hour.

Form A

Langevin's equation is considered to describe the first process that is chosen to depcit the increments of wind speed, namely,

$$\begin{aligned} dx(t) &= ax(t)dt + bdW(t), t \in [0,T] \\ x(0) &= x_0 \end{aligned} \tag{4}$$

where, $x(t)$ is the wind speed turbulence at time t, $W(t)$ is a standard Brownian motion, a and b are constants. $x(t)$ is a stationary autocorrelated Gaussian diffusion process.

Fouque et al. (2000) provides a maximum likelihood estimation method. The logarithm likelihood function is defined as

$$\begin{aligned} L_{a,b}(x_1,\ldots,x_n) &= -\frac{n}{2}\left(\ln(b^2) + \ln(v(a))\right) \\ &+ \frac{1}{2b^2 v(a)}\sum_{i=0}^{n-1}\left(x_{t_i+1} - \exp(a\Delta)x_{t_i}\right)^2 \end{aligned} \tag{5}$$

with $v(a) = \dfrac{\exp(2a\Delta - 1)}{2a}$. Therefore, we can get the estimated parameters.

$$\hat{a} = \frac{1}{\Delta}\log\left(\frac{\sum_{i=1}^{n} x - t_{i-1}x_{t_i}}{\sum_{i=1}^{n} a_{t_i-1}^2}\right) \tag{6}$$

$$\hat{b}^2 = \frac{1}{nv(\hat{a})}\sum_{i=1}^{n}(x_{t_i} - \exp(\hat{a}\Delta)x_{t_i-1})^2 \tag{7}$$

Form B

A classical mean-reverting Ornstein-Uhlenbeck process is chosen as the second one for wind speed simulation. It has the following form:

$$\begin{aligned} dx(t) &= -\left(x(t) - \mu\right)dt + \sigma dW(t) \\ x(0) &= x_0 \end{aligned} \tag{8}$$

where $x(t)$ is wind speed at time t, μ, σ are parameters and W_t is the standard Brownian motion. Make $\Delta t = t_i - t_{i-1}$, according to Deng et al. (2016) the transition density function is

$$\begin{aligned} \mathbb{P}(x_{t_i}, t_i \mid x_{t_{i-1},t_{i-1}}; \mu, \sigma) &= \frac{e^{\Delta t}}{\sqrt{\pi \cdot \sigma^2\left(e^{2\Delta t} - 1\right)}} \\ &\times \exp\left(-\frac{\left(x_{t_i} \cdot e^{\Delta t} + \mu\left(1 - e^{\Delta t}\right) - x_{t_{i-1}}\right)^2}{\sigma^2\left(e^{2\Delta t} - 1\right)}\right) \end{aligned} \tag{9}$$

Hence, the log-likelihood function is as follows:

$$\log L(\mu,\sigma) = \prod_{i=1}^{N}\mathbb{P}(x_{t_i}, t_i \mid x_{t_{i-1},t_{i-1}}; \mu, \sigma) \tag{10}$$

The parameters μ and σ are estimated by maximizing (10).

3 APPLICATION

3.1 *Experimental dataset*

Long term (as long as one year) hourly average wind speed data can be easily accessed at *www.ncdc.noaa.gov/cdo-web*, and *www.winddata.com* provides free time series of wind characteristics measured under different conditions during 10 minutes or 1 hour. The real data used in this paper is downloaded from the two websites.

3.2 *Wind speed generation*

It exists two difficulties when we use real wind speed data to estimate the transition probability matrix of Markov chain model:

- A Markov chain with a great deal of states could be constructed resulting in a huge transition matrix that might cause additional difficulties in estimation.
- The number of elements in certain states could be much smaller than others, resulting in a lot of small probabilities near 0 in the transition probability matrix.

In order to avoid the former phenomena, the number of states should be determined relatively smaller. The number of states could be determined

by the user or some criterions. Tang et al. (2015) recommend to determine the interval with the empirical quantiles. Suppose that the wind speed time series is stationary and ergodic. Hence, the empirical cumulative distribution function is a consistent estimator of the cumulative distribution of the invariant measure of this time series. The boundaries are taken to be $\hat{F}_N^{-1}(j/k)$, $j = 1, 2, \ldots, k$, where k is the number of state and $\hat{F}_N$ is the empirical cumulative distribution function.

The principal steps for wind speed data generation (shown in Figure 3) are as follows,

Step 1 Chose appropriate wind speed data for Markov chain and diffusion process model estimation separately

Step 2
- Determine the states of Markov chain
- Estimate transition probability matrix of Markov chain by using real wind speed data
- Estimate parameters of SDE with real wind speed data

Step 3 Generate hourly average wind speed

Step 4 Select SDE model and generate detail wind speed data inside each state

3.2.1 *Generation of wind speed in macroscopic scale using Markov chain model*

A sequence of hourly average wind speed during one year is used to estimate the transition probability matrix of the Markov chain model. Due to data acquisition issues, the available number of the data is 6180 instead of 8760 (24 hours/day × 365 days). The number of state is determined as 8, recall the states shown in Table 1, we can obtain the transition probability matrix of the Markov chain.

3.2.2 *Generation of wind speed at secondly time scale using SDE*

As Markov chain's states represent the hourly average wind speed, the aim of using SDE is to generate secondly wind speed data during a short period. Taking account the common data collection frequency of SCADA—10 minutes, a state contains 6 groups SDE models which represent the wind speed at secondly scale during 10 minutes, depending on the hourly average wind speed set by Markov chain. We class the real wind speed sequences according to their average values associated with the states determined in section 2.1.

An example of wind speed generation by SDE

To illustrate the performance of SDE wind speed model, the parameters with respect to the state s_3 are chosen to build the two Ornstein-Uhlenbeck process, with form A expressed by equation (11) and form B expressed by equation (12). For $x(0) = 0$

$$dx(t) = -0.0314x(t)dt + 0.2517dW(t), \quad (11)$$

$$dx(t) = -\left(x(t) - 10.0245\right)dt + 0.6459dW(t), \quad (12)$$

In Figure 4, the red line shows the probability density of a real wind speed sequence, the blue lines show the probability density of 500 samples simulated data generated by Equation (12).

SDE model has the ability to generate continuous wind speed.

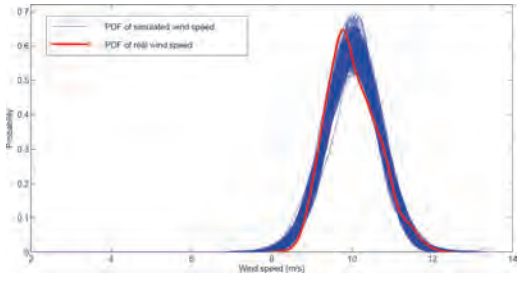

Figure 4. Probability density of real data and simulated data.

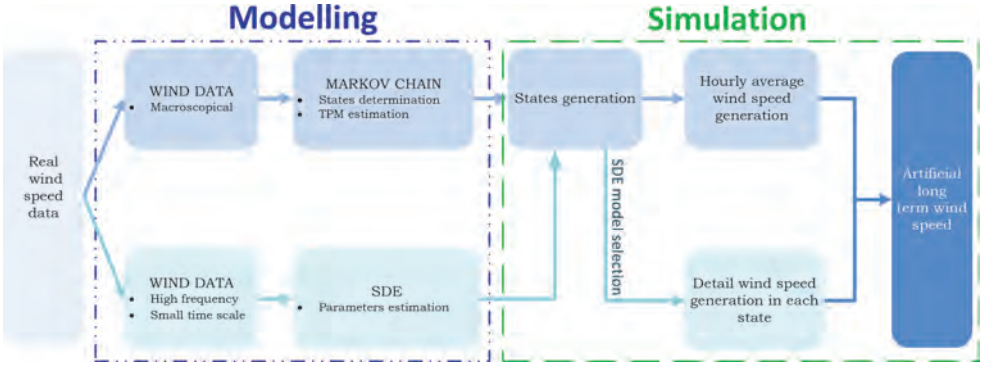

Figure 3. Steps for wind speed generation.

4 CONCLUSION

In this paper, a continuous wind speed generation model based on Markov chain and stochastic differential equation is proposed. This model is flexible enough to generate wind speed at different time scale without time length limitation. Having low computational requirement is another advantage of the model. Two forms of SDE are studied in this paper, other forms of SDE could be applied to this model according to the user's requirement. Particularly, this developed model is suitable to be merged with the deterioration model of wind turbine's key component, like blade-pitch system. Also, this model could be used in the analysis of wind turbine's power system such as dynamic behaviour of generator.

The class of life time distributions with a mean residual life linear in time: Application to prognostics and health management

P. Dersin
RAM (Reliability-Availability-Maintainability) and PHM (Prognostics & Health Management), Alstom Digital Mobility, St-Ouen, France

ABSTRACT: Prognostics and Health Management (PHM) elicits increasing interest in view of its potential economic impact both through service-affecting failure avoidance and maintenance cost reduction. One of the key challenges in the PHM discipline is the estimation of Remaining Useful Life (RUL), i.e. the time remaining until failure in the absence of maintenance. The expectation of RUL, Mean Residual Life (MRL), has long been studied by reliability engineers, dating back to the nineteen sixties. There is a one-to-one relationship between MRL, reliability function and failure rate (also called hazard rate): each one of three functions uniquely determines the other two. Usually, MRL varies with time. We study here a special class of life-time distributions characterized by the fact that their MRL is a linear, non-increasing function of time, and highlight the central role of the time derivative of the MRL, called ageing rate, for PHM; and then generalize to piecewise-linear MRL.

1 INTRODUCTION

Since the pioneering work of (Barlow & Proschan 1965), the notion of MRL is well known, as well as its relation to reliability function and failure rate.

However, we have not seen in the literature any study of the class of life-time distributions which have a MRL that varies linearly with time, even though the literature on RUL is quite extensive; see e.g. (Si et al. 2011).

This class of distributions is important for two reasons:

- because a linear relationship is always a good approximation locally; more-general functions can be approximated by piecewise-linear ones.
- because this class contains important, well-known special cases: the exponential distribution, the uniform distribution, and the deterministic ('Dirac') distribution.

Explicit expressions for reliability function, MRL and failure rate are given here for this class. Cases of special interest are presented and the meaning of some relationships is discussed. A simple relation is derived between the coefficient of variation of the time to failure and the derivative of MRL with respect to time (which we call the rate of ageing). A confidence interval for the RUL is derived, in terms of this rate of ageing; the width of the confidence interval decreases as the rate of ageing grows from 0 (corresponding to the exponential distribution failure) to 1 (corresponding to the 'Dirac' deterministic case). Potential use of those results for PHM, and their generalization to piece-wise linear MRL, are discussed. In Section 2, a reminder of the key relationships between MRL, reliability function and failure rate is provided. In Section 3, expressions for those quantities are derived for the family of lifetime distribution with MRL linear with time, and special cases are identified. In Section 4, a confidence interval for the RUL is provided, in that family. In Section 5 an explicit relation is given between the rate of ageing and the coefficient of variation of the time to failure. Potential use in PHM and generalizations to the family of lifetime distributions with piecewise-linear MRL are discussed in Section 6. Finally, Section 7 presents the conclusions, followed by bibliographical references in Section 8.

2 REMINDER OF KEY RELATIONSHIPS

2.1 *Mean residual life, reliability function and failure rate*

If T denotes the time to failure of an item not subject to maintenance, the reliability function is defined by:

$$\begin{aligned} &R(t) = P[T > t], t > 0 \\ &R(0) = 1, \ \lim_{t \to \infty} R(t) = 0 \end{aligned} \tag{1}$$

Then the Mean Residual Life (MRL) at time t is the expectation of the remaining time to failure from time t under the condition that no failure has taken place until time t. The following relation

results directly from the definition. In what follows, the notation V(t) will be used for MRL(t).

$$V(t) = \frac{1}{R(t)} \int_t^\infty R(s)ds \tag{2}$$

From Equation 2 it is seen that, for t = 0, MRL(0) = MTTF. i.e., the a priori value for the mean residual life is the mean time to failure. The failure rate λ(t) (sometimes called hazard rate, especially in safety contexts), on the other hand, is given by:

$$\lambda(\mathrm{t}) = -\frac{R'(t)}{R(t)} \tag{3}$$

so that R(t) can be derived from it by integration (see e.g. Birolini 2017). Finally, under simple regularity conditions it can be shown (Swartz 1973) that the reliability function R(t) can be derived directly from the MRL function:

$$R(\mathrm{t}) = \frac{\mathrm{V}(0)}{V(t)} e^{-\int_0^t \frac{dx}{V(x)}} \tag{4}$$

Therefore, any one of those three functions determines the other two.

2.2 *Differential equation formulation*

There is also a simple relationship between the MRL and the failure rate which takes the form of a differential equation:

$$\frac{dV(t)}{dt} = \lambda V - 1 \tag{5}$$

Equation 5 can be derived immediately from Equation 2 and Equation 3 (Watson & Wells 1961). When Equation 5 is written in differential form:

$$dV(t) = -dt + \lambda V dt \tag{6}$$

its interpretation provides an interesting insight: usually

$$\frac{dV(t)}{dt} \le 0 \tag{7}$$

as the mean residual life does not increase with time.

Equivalently,

$$\lambda V \le 1 \tag{8}$$

In a time interval of length dt, the loss in mean residual life during the time span dt is given by :

$$dV(t) = -(1 - \lambda V)dt \tag{9}$$

Therefore it is usually less than the elapsed time dt.

The limiting case when: $\lambda V = 1$, corresponding to a distribution for which V(t) = MTTF is constant with time, which is the exponential distribution, also characterized by the property that its failure rate λ is constant in time.

Moreover, Equation 5 then yields:

$$\lambda(t) = \frac{1}{MRL(0)} = \frac{1}{MTTF} \tag{10}$$

a relation valid only in the exponential distribution case.

This property is the 'no aging' property of the exponential distribution in the reliability context.

More generally, in the next section, will be studied the class of time-to-failure distributions for which the MRL is a linear function of time, i.e.

$$\frac{dV(t)}{dt} = -k \tag{11}$$

where the constant k will be called the ageing rate. It is assumed that $0 \le k \le 1$ so as to ensure, according to Equation 11, that

$$-1 \le \frac{dV(t)}{dt} \le 0 \tag{12}$$

i.e. the mean residual life either is constant or decreases with time but no faster than time (in a time interval ΔT, the item does not lose more than an amount ΔT of its remaining life). Note that k is dimensionless.

The case k = 0 corresponds to the limiting case of the exponential distribution.

3 THE FAMILY OF LIFE DISTRIBUTIONS WITH MRL LINEAR IN TIME

3.1 *General case*

We study the family of time-to-failure distributions characterized by the property that their mean residual life MRL(t) is a linear non-increasing function of time or, equivalently, it satisfies Equation 11.

For convenience, from now on, the MTTF will be denoted by the symbol μ. Thus:

$$V(0) = MTTF = \mu \tag{13}$$

From Equation 11 and Equation 13, we obtain

$$V(t) = \mu - kt \tag{14}$$

The range of the time variable t is the interval $[0, \frac{\mu}{k}]$, so that

$$0 \le V(t) \le \mu \tag{15}$$

(In the limiting case of the exponential distribution, k is allowed to vanish asymptotically, and the range of the time variable becomes the nonnegative real half line).

From Equation 5 and Equation 14, there follows that the failure rate of such a distribution is given by:

$$\lambda(k,t) = \frac{1-k}{\mu - kt},\ for\ 0 \le t < \frac{\mu}{k} \tag{16}$$

From Equation 3 the reliability function, denoted from now on D(k,t), can be derived as

$$D(k,t) = e^{-\int_0^t \frac{1-k}{\mu - ks} ds} \tag{17}$$

which yields:

$$D(k,t) = \left(\frac{\mu}{\mu - kt}\right)^{1-\frac{1}{k}},\ for\ 0 \le t < \frac{\mu}{k} \tag{18}$$

And D(k,t) = 0 for $t > \mu/k$.

Thus Equations 14, 16, 18 characterize the one-parameter family of probability distributions, with parameter k ranging over the interval [0,1].

3.2 *Special cases*

3.2.1 *Exponential distribution*

If the parameter k is allowed to go to 0, the range of the variable t becomes (0, ∞).

The following limit is obtained from Equation 16:

$$\lim_{k \to 0} \lambda(k,t) = \frac{1}{\mu} \tag{19}$$

It can also be verified from Equation 18 that:

$$\lim_{k \to 0} D(k,t) = e^{-\frac{t}{\mu}} \tag{20}$$

Those properties characterize the exponential distribution.

As seen previously and confirmed from Equation 14, the mean residual life is then constant in time: $V(t) = \mu = MTTF$.

3.2.2 *Dirac distribution*

At the other extreme, if k = 1, the evolution of the mean residual life over time is characterized by:

$$V(t) = \mu - t,\ for\quad 0 \le t \le \mu \tag{21}$$

which means that, over any time interval Δt, the loss of mean residual life is precisely equal to Δt.

Equation 16 shows that the failure rate remains equal to zero as long as t<μ and jumps to infinity as t approaches the life limit μ. This is best seen by first taking k = 1–ε with ε close to 0 and letting t go to μ/k.

Likewise the reliability function has a discontinuity at t = μ, where it jumps from 1 to 0, which corresponds to a deterministic lifetime equal to μ. It can also be verified that the right-hand side of Equation 6 is always equal to –1, meaning that, over any time interval Δt, the loss of mean residual life is precisely equal to Δt.

3.2.3 *Uniform distribution*

The intermediate case $k = \frac{1}{2}$ defines the uniform distribution, over the range (0, 2μ).

Indeed, from Equation 18, the corresponding reliability function is given by:

$$D\left(\frac{1}{2}, t\right) = 1 - \frac{t}{2\mu},\quad 0 \le t \le 2\mu \tag{22}$$

The mean residual life (Eq. 14) is given by

$$V(t) = \mu - \frac{t}{2},\quad 0 \le t \le 2\mu \tag{23}$$

which states that, over a time interval Δt, the loss of mean residual life is equal to $\frac{\Delta t}{2}$.

The failure rate is given, as a function of time, by:

$$\lambda\left(\frac{1}{2}, t\right) = \frac{1}{2\mu - t} \tag{24}$$

Table 1. Family of life distributions with MRL linear in time.

Value of k	Range of t	D(k;t)	V(t)	λ(t)
$0 < k \le 1$	$\left[0, \frac{\mu}{k}\right]$	$\left(\frac{\mu}{\mu - kt}\right)^{1-\frac{1}{k}}$	$\mu - kt$	$\frac{1-k}{\mu - kt}$
0 (exp.)	[0, ∞]	$e^{-\frac{t}{\mu}}$	μ	$\frac{1}{\mu}$
$\frac{1}{2}$ (uniform)	[0, 2μ]	$1 - \frac{t}{2\mu}$	$\mu - \frac{t}{2}$	$\frac{1}{2\mu - t}$
1 (Dirac)	[0, μ]	1 for t < μ	μ–t	0 for t < μ

3.2.4 *Synopsis*

The results just derived are summarized in the table below.

4 CONFIDENCE INTERVAL FOR RUL

It is now possible to obtain the residual life-time distribution, i.e. the probability distribution of the Remaining Useful Life (RUL), or time to the next failure, under the condition that no failure has taken place up to time t, for the class of lifetime distributions under study. Note that the concept of 'failure' is understood in a broad sense and can also apply to pseudo-failures, such as the crossing of a threshold by a health indicator.

First let us rewrite Equation 18 slightly differently:

$$D(k,t)=\left(1-\frac{kt}{\mu}\right)^{\frac{1}{k}-1} \tag{25}$$

The probability distribution of the remaining useful life (RUL) at time t can be characterized by the conditional survival function. Let us denote by $D_t(s)$ the probability that the item survives at least for a duration s given that it has lived (without failure) up to time t. Then:

$$D_t(s)=\frac{D(k;t+s)}{D(k;t)} \tag{26}$$

Or, according to Equation 25),

$$D_t(s)=\left(\frac{1-\frac{k(t+s)}{\mu}}{1-\frac{kt}{\mu}}\right)^{\frac{1}{k}-1} \tag{27}$$

Or

$$D_t(s)=\left(1-\frac{ks}{\mu-kt}\right)^{\frac{1}{k}-1} \tag{28}$$

for $0<k\le 1$; $0\le t<\frac{\mu}{k}$

Let us now determine the confidence interval of the RUL at time t, with confidence level 1-α.

To that end, define s^+ and s^- by:

$$D_t(s^+)=\frac{\alpha}{2} \tag{29}$$

$$D_t(s^-)=1-\frac{\alpha}{2} \tag{30}$$

Then, if T denotes the random variable "survival time to failure after time t", the conditional probability of survival for a time between s^- and s^+ is:

$$P(t+s^-<T<t+s^+/T>t)=1-\alpha \tag{31}$$

i.e., the interval $(t+s^-,t+s^+)$ is the confidence interval with confidence level 1–α.

In other words, $t+s^-<\mathrm{RUL}<t+s^+$ with probability 1–α. Equations 28–30 determine the confidence bounds. Consequently, from Equation 28–29 one obtains:

$$s^+=\left(\frac{\mu}{k}-t\right)\left(1-\left(\frac{\alpha}{2}\right)^{\frac{k}{1-k}}\right) \tag{32}$$

Similarly, from (28) and (30), one obtains:

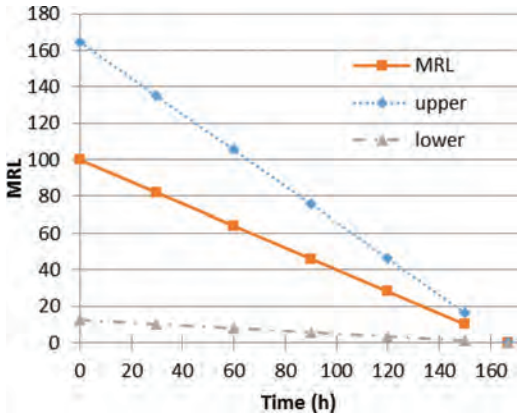

Figure 1a. Confidence interval for RUL for k = 0.6 (MTTF = 100 h).

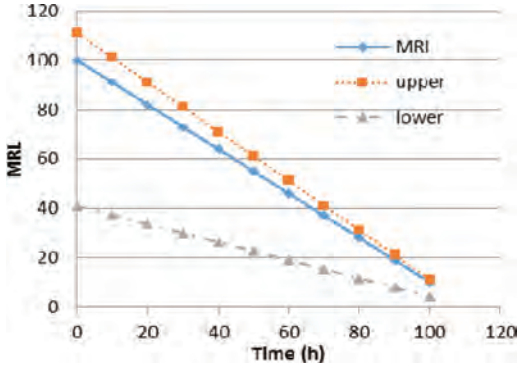

Figure 1b. Confidence interval for RUL for k = 0.9 (MTTF = 100 h).

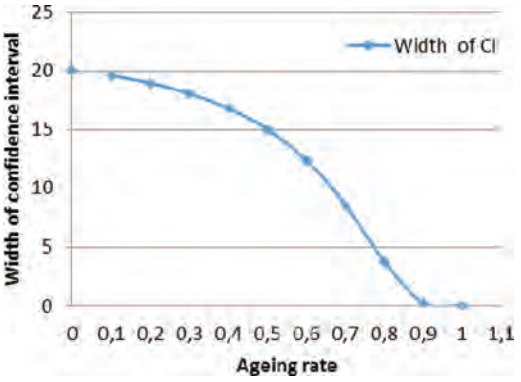

Figure 2. Width of confidence interval versus ageing rate k. (CI calculated at t = 50 h, for MTTF = 100 h).

$$s^- = \left(\frac{\mu}{k} - t\right)\left(1 - \left(1 - \frac{\alpha}{2}\right)^{\frac{k}{1-k}}\right) \tag{33}$$

Confidence intervals are illustrated in Figure 1: on (Fig. 1a) for k = 0.6 and on (Fig. 1b), for k = 0.9, where the confidence interval is narrower at any time.

For k = 1 (deterministic case), it is verified that the confidence interval reduces to a point (no uncertainty) and, for k = 0, the known result for the exponential distribution is found:

$$s^+ = -\ln\left(\frac{\alpha}{2}\right) \tag{34}$$

$$s^- = -\ln\left(1 - \frac{\alpha}{2}\right) \tag{35}$$

Indeed the width ($s^+ - s^-$) of the confidence interval decreases as k grows from 0 to 1, as illustrated in (Fig. 2).

Thus, the faster the asset ages, the narrower the confidence interval for the RUL is. This property is intuitive. For instance, in the limit of deterministic ageing (k = 1), the RUL is known with certainty and the failure rate jumps from 0 to infinity at t = RUL. In the other extreme (k = 0, exponential distribution), there is no ageing and the confidence interval is the widest and stays constant with time (Eq. 34–35).

5 RELATION BETWEEN AGING RATE K AND COEFFICIENT OF VARIATION OF TIME TO FAILURE

The probability density function f(k;t) for the time to failure is obtained from Equation 16 and Equation 18:

$$f(k;t) = \lambda(k;t).D(k;t) \tag{36}$$

$$f(k;t) = \frac{1-k}{\mu - kt}.\left(\frac{\mu}{\mu - kt}\right)^{1-\frac{1}{k}} \tag{37}$$

Or equivalently,

$$f(k;t) = \frac{(1-k).\mu^{1-\frac{1}{k}}}{(\mu - kt)^{2-1/k}} \tag{38}$$

It follows that the variance of the time to failure is given by:

$$\sigma^2 = \int_0^{\mu/k} \frac{(1-k).\mu^{1-\frac{1}{k}}}{(\mu - kt)^{2-1/k}}(t-\mu)^2\,dt \tag{39}$$

This integral can be calculated in closed form, which results in:

$$\left(\frac{\sigma}{\mu}\right)^2 = \frac{1-k}{1+k} \tag{40}$$

an expression for the coefficient of variation σ/μ as a function of the ageing rate k. Equivalently:

$$k = \frac{1 - \left(\frac{\sigma}{\mu}\right)^2}{1 + \left(\frac{\sigma}{\mu}\right)^2} \tag{41}$$

Equations 40 and 41 show that the coefficient of variation of the time to failure decrease from 1 (exponential distribution) to 0 (deterministic case) as the ageing rate increases from 0 to 1.

For instance, the uniform distribution (k = 1/2) corresponds to $\sigma/\mu = \sqrt{1/3}$, as is well known.

6 POTENTIAL USE FOR PHM AND GENERALIZATION

6.1 *Use for RUL estimation*

In PHM applications, one of the key concerns is to estimate the RUL of a monitored asset on the basis of past observations. If, for some reason, based for instance on physics, it is believed that MRL decreases linearly with time, then Equations 32–33 can be used to determine a confidence interval for the RUL at any time t. To that end, it is necessary to estimate the ageing rate k. If field data or simulation data are available that represent failure times or pseudo-failure times (a pseudo-failure may defined as the crossing of a threshold by a health

indicator, for instance), then those data can be used in order to obtain a MLE (Maximum Likelihood Estimator) of k, or a Bayesian estimator, on the basis of Equation 38. If on the other hand an estimate of the coefficient of variation of time-to-failure (or time-to-pseudo-failure) can be obtained from field data or simulations, then Equation 41 can be used in order to estimate k.

However, in general, the assumption of linear evolution of MRL with time may be unrealistic.

Below it is now shown that the results demonstrated so far can be generalized to the case of a MRL which is a piecewise linear function of time.

Therefore the generality of the method is considerably extended, as any continuous function can be approximated by a piecewise-linear function.

6.2 *Generalization*

Let us consider the case of a MRL consisting of two linear segments, as in Figure 3; it is then possible to generalize to any number of segments.

In that example, the MRL has a change of slope at $T_1 = 40$ h. It is defined as follows:

$$\text{For } 0 < t < T_1,\ V(t) = \mu - k_1 t \tag{42}$$

$$\text{For T1} < t < T_2, V(t) = \mu - k_1 T_1 - k_2 (t - T_1) \tag{43}$$

where $V(T_2) = 0$

Therefore the parameters are linked by the relation $\mu - k_1 . T_1 - k_2 (T_2 - T_1) = 0$.

In the example of Figure 3, ageing accelerates after $T_1 = 40$ h. The slopes are $k_1 = 0.5$ before T_1 and $k_2 = 0.9$ after T_1, and $T_2 = 133.33$ h

From Equation 42, the reliability function is obtained, using Equation 4.

In this example,

$$\text{For } 0 < t < T_1, D(k_1;t) = (1 - \frac{k_1 t}{\mu})^{\frac{1}{k_1}-1} \tag{44}$$

And, for $T_1 < t < T_2$,

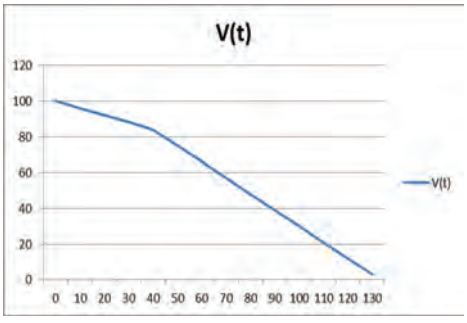

Figure 3. Piecewise linear MRL (2 segments).

$$D(k_1;t) = \left(1 - \frac{k_1 t}{\mu}\right)^{\frac{1}{k_1}-1} \left(\frac{\mu - (k_1 - k_2)T_1 - k_2 t}{\mu - k_1 T_1}\right)^{\left(\frac{1}{k_2}-1\right)} \tag{45}$$

From those expressions, it is possible to derive a confidence interval for the RUL in the same manner as was done in Section 4 for the linear case, i.e. from the conditional survival function.

Similarly, the probability density can be derived from Equation 44 and Equation 45 and therefore the MLE of parameters k_1 and k_2 can be obtained..

Increases in the ageing parameter k should alert the maintainer as they are reasonably correlated with reduction in the RUL.

Generalization to a piecewise linear function with any number of segments (instead of two) is relatively straightforward.

7 CONCLUSIONS AND SUGGESTIONS FOR FUTURE RESEARCH

Prognostics methods usual fall into the following categories: physics-of-failures analysis, data-driven methods, and fusion methods which combine both.

Unlike traditional reliability engineering, PHM focuses on individual assets rather than on a population of assets. However, the author contends that some methods of reliability engineering can be of use to PHM and can complement the other approaches, in particular for the elaboration of maintenance policies at fleet level. The recent work by (Huynh et al. 2017) points in that direction.

In this paper, a class of time-to-failure distributions characterized by a mean residual life evolving linearly in time has been studied, to derive confidence intervals for the RUL of assets whose time-to-failure follows such distributions.

Despite the fact that that class contains very important representatives such as the exponential distribution, the uniform distribution and the Dirac distribution, we have not found such a study in the literature.

The relationship between the ageing rate and the coefficient of variation of the time to failure is interesting to the extent that it exhibits an intimate link between the variability (measured by the coefficient of variation) and the rate of ageing: the higher the former, the lower the latter. It also allows to estimate one from the other.

The results have also been generalized to distributions with piecewise linear MRL, which can approach any distribution if enough segments are considered. The challenge then will consist of identifying the 'knees', i.e. the points of change of slope in the MRL. Methods such as trend filtering

(Tibshirani 2014), for instance, could be used for that purpose. It would be of interest to investigate how coefficient of variation of time to failure and ageing rate are linked in that general case; and to study in that respect the coefficient of variation of the RUL rather than that of the time to failure.

Recent contributions (Atamuradov et al. 2017) have highlighted the importance of changes in coefficient of variation of extracted features in detecting faults and in segmenting time series for health assessment and prognostics.

Since useful health indicators normally vary monotonically with RUL, changes in their coefficient of variation could be used as proxies for changes in that of the RUL.

In conclusion, the author believes that PHM stands to gain from cross-fertilization with traditional reliability engineering.

Join optimization of detectors' fleet settings to maximize global detection power

P. Beauseroy & E. Grall-Maës
Institut Charles Delaunay/ROSAS Departement/ Systems Modelling and Dependability Team, CNRS, ICD/ROSAS/M2S, Université de Technologie de Troyes, Troyes, France

ABSTRACT: In many applications, detection methods are implemented to monitor systems. Detector may be built upon analytical model of the system behaviors, or based on recorded data. Lately lots of efforts have been put in developing methods that enable to transfer a detector from an assessed system to a new one when the 2 systems are similar. These so-called transfer learning approaches have shown efficiency when dealing with a fleet of systems composed of different similar systems. For the detector of each model of system a tradeoff between false alarm and non-detection must be chosen. One question that has not retained much attention up to now is the tuning of these detection systems. The common practice is to tune the detection system associated with each model individually. In this communication we tackle the problem of the global efficiency of this practice. How can we tune all those detection systems together so that the group of detectors satisfies some performance constraint? The formalization of the problem is introduced, discussed and commented based on detector ROC curves. Three toy examples are used to show the gain one could expect from join optimization of detectors and to illustrate optimization issues. Example results show that non detection probability can easily be reduced by up to 50%. In conclusion several extensions of this work are discussed.

1 INTRODUCTION

1.1 *Context*

In many applications, detection methods are implemented to monitor systems. The aim of these detectors is basically to setup an alarm when the monitored system behavior changes from its regular behavior. Detector may be built upon analytical model of the system behaviors (Tartakovsky et al. 2015), or based on recorded data (Pimentel et al. 2014). Lately lots of efforts have been put in developing methods that enable to transfer a detector from an assessed system to a new one when the 2 systems are similar (He et al. 2014), (West et al. 2007), (Evgeniou et al. 2005)]. These so-called transfer learning approaches have shown efficiency when dealing with a fleet of systems composed of different similar systems. The transfer learning idea is to adapt a decision system trained on a source system to a new target system using a limited amount of data coming from the target system. The adaptation process enables to keep most of the information coming from the source system, so to have good performances with few data. An informal way to put it would be to consider transfer learning as a calibration operation of a trained detector on a target system. To give an example of such a fleet, we can consider car engines in the case of K car models sharing the same engine. Since the models differ, the monitoring system may slightly differ from one model to another. It leads to define one detector D_i ($i = 1$ to K) with its specific tuning parameters for each car model.

For each detector, so for each model, a tradeoff between false alarm and non-detection must be chosen. One question that has not retained much attention up to now is the tuning of these detection systems D_i. A quite common practice is to tune the detection system associated with each model individually, so that each individual detector satisfies the global targetted performance constraint.

1.2 *Considered problem*

In this communication we tackle the problem of the global efficiency of this practice. Can we tune all the detection systems together so that the group of detectors satisfies some performance constraint? Does it make sense to tune all the detectors together? Is it feasible? And finally can we expect gain from such an approach?

2 FORMULATION OF THE PROBLEM

Consider K systems and the corresponding K detectors. Each detector makes decisions according

to measurements x between two hypotheses: H_0 the system is working fine and H_1 the system experiments a problem. Measurements x are considered as realization of a random variable X. Without loss of generality, we can assume that each detector D_i takes decisions depending on a function of the measurements $d_i(x)$. Each detector compares the output value of the function $d_i(x)$ with a tuned threshold t_i which is equivalent to decide according to:

$$D_i(x) = sign\left(d_i(x) - t_i\right). \tag{1}$$

H_1 is chosen and an alarm is set when $D_i(x) = 1$.

In this context the thresholds t_i must be tuned according to some criteria. Criteria are usually related to performance constraints. A very well-known performance constraint setting is the Neyman Pearson framework which is adopted here (DeGroot and Schervish 2002), (Neyman and Pearson 1933). So detectors are tuned according to a false alarm rate.

We assume that the owner of these systems considers that a global acceptable false alarm rate is α_G, so systems must be tuned according to this objective.

A usual mean to respect this objective is to tune each model so that its false alarm rate is α_G:

$$P_{fa_i} = P(D_i(X) = 1 \mid H_0) \tag{2}$$

$$= \int_{\{x \mid d_i(x) - t_i \rangle 0\}} f_i(x)\,dx \tag{3}$$

where $f_i(x)$ is the probability density fonction of X for system i.

A basic solution consists to choose $t_i^{(0)}$ so that $P_{fa_i} = \alpha_G$ for all systems i.

By doing so we ensure that the global performance, considering all models, named P_{fa_G} is α_G:

$$P_{fa_G} = \sum_{k=1}^{K} P_k P_{fa_k}. \tag{4}$$

where P_k is the a priori probability of using system k.

This solution is valid. But in such a case a very specific setting has been chosen among many possible ones. One could allow a larger false alarm rate on some models and a smaller one on others and still respects the constraint. As in Neyman Pearson problem, we consider that the best solution is the one that respects the constraint and that maximizes the detection power of the global system P_d:

$$P_d = P(D(X) = 1 \mid H_1) \tag{5}$$

$$= \sum_{k=1}^{K} P_k P(D_k(X) = 1 \mid H_1) \tag{6}$$

So the aim is to find $(t_1, t_2, \ldots, t_K)^*$ that maximize P_d under the constraint $P_{fa_G} \le \alpha_G$.

3 OPTIMIZATION

The optimization problem we want to solve is the following:

$$\begin{cases} \min\limits_{(t_1, t_2, \ldots, t_K)} P_d \\ \text{with} P_{fa_G} = \alpha_G \end{cases} \tag{7}$$

This problem could be optimized based on lagrangian formulation as in (Grall-Maes and Beauseroy 2009). But this would lead to a quite complex optimization problem for at leazt two reasons. The change of a threshold t_l has an indirect effect on both $P(D_l(X) = 1 \mid H_1, t_l)$ and $P(D_l(X) = 1 \mid H_0, t_l)$. To express the dual Lagrangian problem one would need to express the partial derivatives of these probabilities according to t_l for all l. Such expression cannot be computed in the case of trained detector, and in case of toy problem, as in this paper, this formulation would be rather complex even for simple laws on X. The second reason is that the function P_d may be non-convex leading to local minima.

3.1 *Proposed approach*

To tackle this optimization problem we propose a rather simple strategy that consists to first find a possible solution, next select 2 detectors l and m and change their settings so that their join probability of false alarm $P_{fa_{l,m}}$ does not change:

$$P_l P_{fa_l} + P_m P_{fa_m} = P_{fa_{l,m}} \tag{8}$$

and so that $P_{d_{l,m}}$ is maximized

$$P_{d_{l,m}} = P_l P_{d_l} + P_m P_{d_m} \tag{9}$$

This treatment is repeated with a new couple of detectors until the detection probability cannot be improved.

3.2 *Tuning two detectors*

To implement the proposed approach, for a given couple of detector (l, m) one need to change simultaneously their thresholds t_l and t_m so that equation 8 is satisfied.

So if t_l is changed to t'_l then P_{fa_l} is changed to P'_{fa_l} and thus the threshold t'_m that satisfies the relation:

$$P'_{fa_m} = \frac{P_{fa_{l,m}} - P_l P'_{fa_l}}{P_m}, \tag{10}$$

has to be found.

The impact of these changes can be obtained directly using the ROC curves of the two detectors since each ROC curve establishes a relation:

$$P_{d_k} = g_k\left(P_{fa_k}\right) \tag{11}$$

The ROC function $g_k()$ is a non decreasing function.

To maximize the detection probability for this couple, we search for a point that maximizes:

$$P_{d_{l,m}} = P_l g_l\left(P_{fa_l}\right) + P_m g_m\left(P_{fa_m}\right) \tag{12}$$

Combining with equation 10, we obtain

$$P_{d_{l,m}} = P_l g_l\left(P_{fa_l}\right) + P_m g_m\left(\frac{P_{fa_{l,m}} - P_l P_{fa_l}}{P_m}\right) \tag{13}$$

And deriving according to P_{fa_l} we obtain:

$$\begin{aligned}\frac{dP_{d_{l,m}}}{dP_{fa_l}}\left(P_{fa_l}\right) &= P_l \frac{dg_l}{dP_{fa_l}}\left(P_{fa_l}\right) + \\ &P_m\left(\frac{-P_l}{P_m}\right)\frac{dg_m}{dP_{fa_m}}\left(\frac{P_{fa_{l,m}} - P_l P_{fa_l}}{P_m}\right)\end{aligned} \tag{14}$$

which simplifies to:

$$\begin{aligned}\frac{dP_{d_{l,m}}}{dP_{fa_l}}\left(P_{fa_l}\right) = &\; P_l \frac{dg_l}{dP_{fa_l}}\left(P_{fa_l}\right) \\ &- P_l \frac{dg_m}{dP_{fa_m}}\left(\frac{P_{fa_{l,m}} - P_l P_{fa_l}}{P_m}\right)\end{aligned} \tag{15}$$

This formulation gives a mean to implement a gradient algorithm, increasing P_{fa_l} if the gradient is positive and decreasing it otherwise. P_{fa_m} is then set according to equation (10). The optimum point corresponds to an extreme point or to a point that cancels the derivative (equation 15). This formulation enables to optimize the local detection probability given by (9) under the constraint (8) according to the detectors false alarme rate instead of the thresholds (the threshold may be deduced afterward).

3.3 *Comments*

In order to speed up the convergence the idea is to choose the couple (l, m) so that the absolute value of the gradient is as large as possible at each iteration, meaning that the optimization focuses on the couple that locally brings the largest improvement.

It must be mentioned that the proposed alternate gradient approach can lead to a global optimum only if the starting point is located in a convex neighborhood of the optimal solution. Otherwise the algorithm converges to a local optimum.

To reach global optimum we propose to initiate the optimization process with different initial solutions when the number of detectors is large. When it is not too large a random optimization method can be applied without big computing time loss.

The experimental study that follows illustrates the optimization process for two detectors. The impact of prior on the solution are discussed. More complex cases are tested with four detectors, and the non convex case is illustrated with 2 examples.

4 EXPERIMENTAL RESULTS

We design the experiments to show the key issues related to the problem. The experimental study first illustrates the optimization process for two detectors. The impact of priors on the solution is discussed. More complex cases are tested next with four detectors, and the non convex case is illustrated with 2 examples.

4.1 *Two systems case*

Our first experiment corresponds to the simplest setting with 2 models. The ROC curves of the two detectors are shown on Figure 1. In that scenario

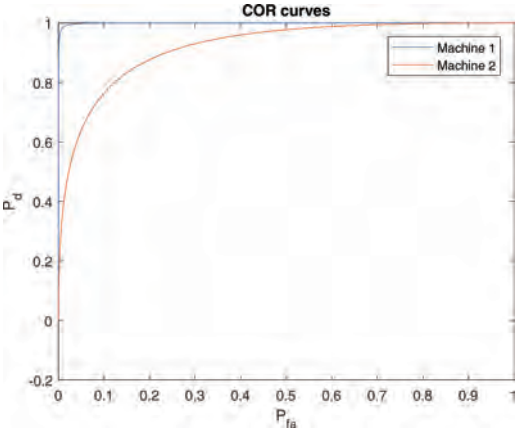

Figure 1. ROC curves of machine 1 and 2 detectors.

one detector is good while the second one is significantly less accurate.

The targeted global false alarme rate α_G is set to 0.1 and the systems are assumed equiprobable.

By tuning each detector to reach a false alarm rate of 0.1, the power of the global system is about 0.88 (Figure 2). By using the proposed optimization approach we improve the power of the global system to 0.925. To obtain this result the worst detector (system 2) is tuned to a higher false alarm rate (0.185) while the best one is reduced to less than 0.02 as shown by Figure 3.

It means that to optimize the global system we must be more demanding with the best detector: the one which detection rate decreases slowly when false alarm rate is reduced. On the contrary, the worst detector's false alarm rate is relaxed to gain a significant detection improvement. Logically, combining these two actions enables to respect the false alarm constraint and consequently improves the overall detection rate.

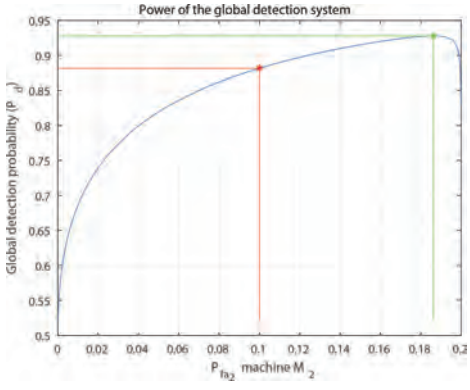

Figure 2. ROC curves of the complete system depending on systems 2 detector's false alarm with usual tuning (red) and proposed solution (green).

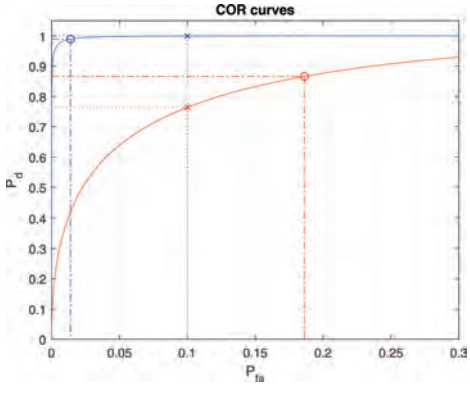

Figure 3. Tuning of each detector reported on its ROC curve—standard tuning (dotted lines) and proposed tuning (dash lines).

4.2 *Impact of models prior*

With a two system case the point which cancels the derivative (15) depends on the prior probabilities due to the argument $\frac{P_{faI,m} - P_I P_{faI}}{P_m}$ of its second term: $\frac{dg_m}{dP_{fa_m}}$. To study the impact of the prior probability the example of previous section is used again changing the prior P_1 from 0 to 1 and decreasing P_2 accordingly. The gain related to the global optimization is reported in Figure 4. It goes from 0 up to 0.047 which represents approximately a 30% reduction of the non detection rate (one minus the detection probability is plotted in Figure 5) which can be considered as significant.

The optimal false alarm tuning of machine 1 and 2 as a function of prior probability is illustrated by Figure 6. The false alarm rate of the best detector

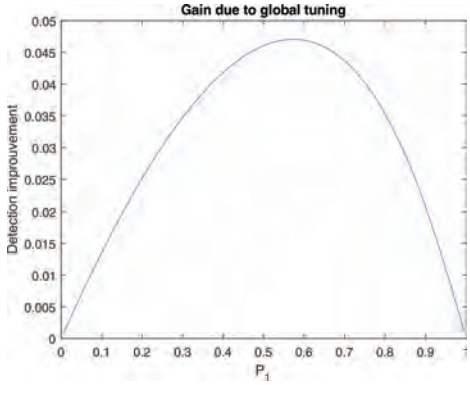

Figure 4. Performance gain as a function of the probability to use machine 1.

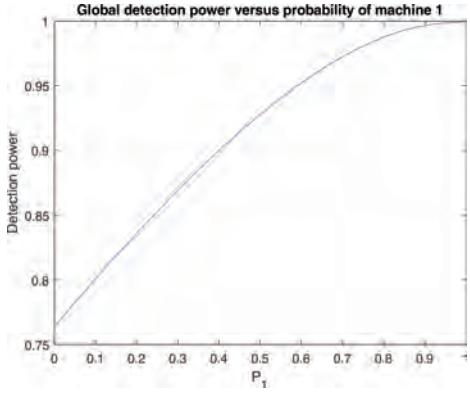

Figure 5. Power of the global system as a function of the probability to use machine 1.

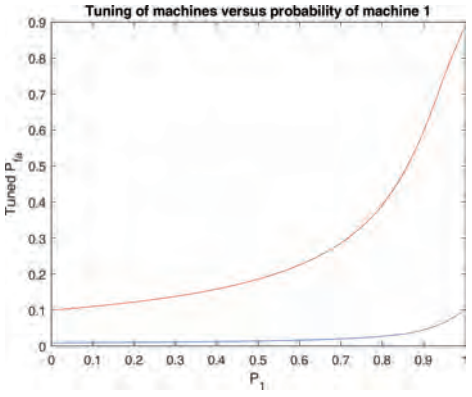

Figure 6. Tuned optimal false alarm probability for the detectors as a function of the probability to use machine 1 - machine 1 in blue, machine 2 in red.

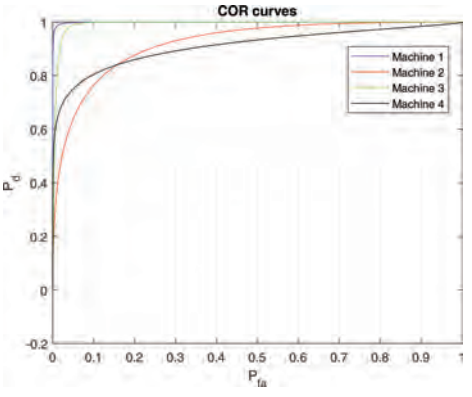

Figure 7. ROC curves of a 4 detector case.

(blue line) is always smaller that the targeted value $\alpha_G = 0.1$ but logically tends to α_G when P_1 tends to 1, while the false alarm rate of the worst detector (red line) is always larger than α_G.

4.3 *Simple four systems case*

To illustrate the proposed optimization process we designed a $K = 4$ systems case. The detector ROC curves corresponding to these systems are given by Figure 7. All priors are set to $\frac{1}{K}$ and $\alpha_G = 0.25$.

The optimal tuning is illustrated by Figure 8. The non detection rate corresponding to the reference setting $(\alpha_i = \alpha_G \ \forall i = 1..K)$ is 0.054 and decreases to 0.028 once optimized.

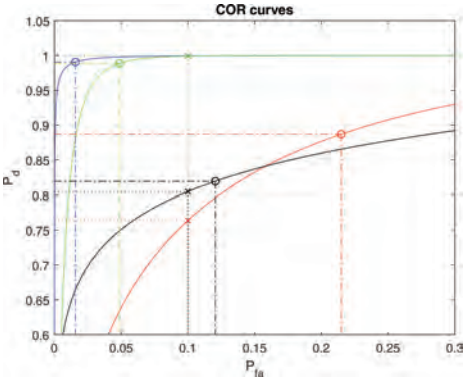

Figure 8. Tuning of each detector reported on its ROC curve—standard tuning (dotted lines) and proposed tuning (dash lines).

4.4 *Optimization limits*

To illustrate the limits of the proposed optimization process when the power function is not convex, a 3 system case has been designed and compared to a convex case.

Figure 9 shows the 3 detectors ROC curves for the convex case. The corresponding power function is displayed by Figure 10.

Figure 11 shows the 3 other detectors ROC curves. The corresponding power function is displayed by Figure 12.

In the second case the power function is not convex while the ROC curves are not so complex. It means that non convex case may not be an exception. In fact such case will appear each time the second derivative of a ROC curve becomes positive which is not so rare. It implies that the proposed optimization process may lead to a local optimum. So we have to find an optimization procedure that can cope with such non convex case.

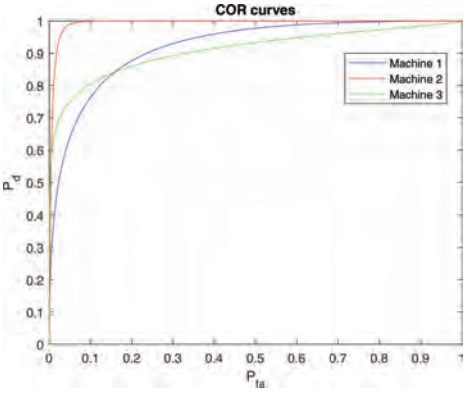

Figure 9. ROC curves of a simple 3 detector case.

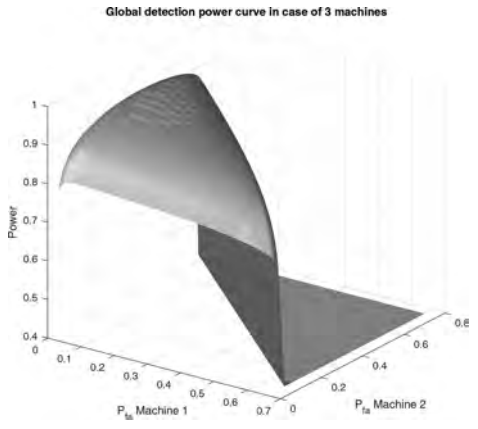

Figure 10. ROC surface of the global system as a function of detectors 1 and 2 tuning.

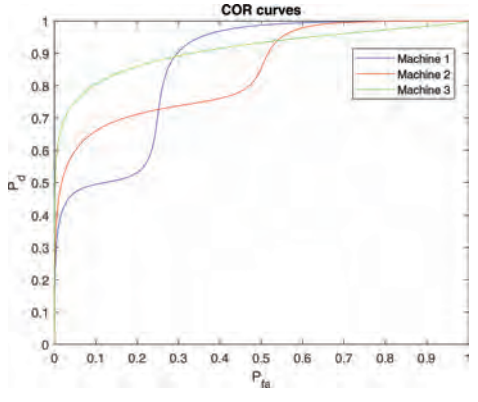

Figure 11. ROC curves of a more complex 3 detector case.

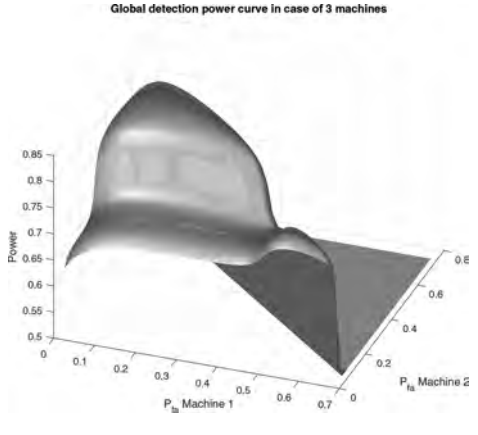

Figure 12. ROC surface of the global system as a function of detectors 1 and 2 tuning.

4.5 *Improved optimization process*

To improve the proposed optimization process, the idea is to initiate the optimization process from many different points. So we generate those initial solutions randomly. In our simulation we randomly chose initial false alarm rate for each machine and normalize those initial guess so that the global false alarm rate satisfies the constraint. Next, for each initial solution we apply the previous optimization procedure.

We apply this improved process on a 4 system example whose detector ROC curves are shown in Figure 13.

Figures 14 and 15 depict the results found with the initial optimization process and the results based on the improved one respectively.

Table 1 summarizes the tuning of each system and the overall performance in each case. The non detection rate decreases from more than 17% in that case to 10.3% in the case of a simple optimiza-

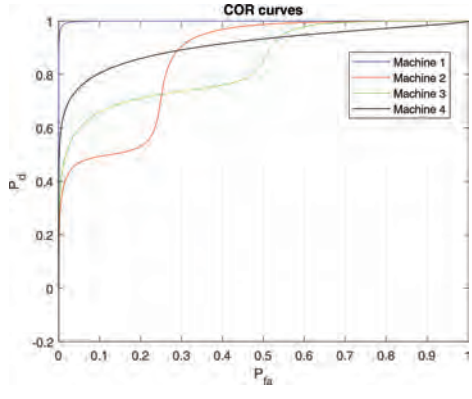

Figure 13. ROC curves of a complex 4 detector case.

Imp. opt.	0.014	0.328	0.557	0.101	0.922

tion and is reduced to 7.8% based on the improved optimization proposed in this last section. These results illustrate the influence of detectors tuning on the overall performances and show that very significant gain can be achieved.

5 CONCLUSION

This communication proposes to tackle the problem of global detection optimization of a detector fleet. This can be encountered in distributed detection systems or in detection systems applied to a fleet of similar systems. In a distributed system the question that arises is to find an optimal fusion of the local detections that all relate to the same object (Blum and Kassam 1997). In the latter case the main concern is about the global performance of the system over decisions on different populations, typically a fleet of similar systems, with a specific detector for each kind of systems.

We propose a model for this problem that fits in the Neyman-Pearson's framework. We develop the analytical formulation and discuss the optimization issue of the global detection system in terms of detector ROC curves. An approach to optimize the global system is proposed and some simulations are designed to illustrate the main issues related to the problem and to the optimization process.

It is shown that the optimization can significantly improve the global performances compared to a reference naive approach. It tends to prove the utility of the proposed approach.

The next steps are the extension of this first study to real cases. This extension seems to be quite straightforward since the approach is based on ROC curves. The fact that the ROC curves correspond to maximum likelihood ratio tests as in the proposed examples or the fact that they are build upon trained detectors makes no real difference.

A more challenging extension is to develop the same approach in the case of production lines taking into account some real time issues. Typically, in recent production systems, the production of a line may evolve due to diverse causes such as production planning, availability of the line inputs, maintenance issues…The related questions are connected to our capacity to adapt, in real time, such detection or quality control systems to these changes and what gain can we expect from such a dynamic tuning system.

Other extensions can be studied such as the impact of the number of detectors. Can we use the same optimization approach or should we adopt more efficient ones? The case of detection with a rejection option should also be considered. The optimal criteria in the latter case must be redefined and the tuning strategy must be also reconsidered.

Assessment method of the deterioration degree of asphalt concrete airport pavements

M. Zieja, P. Barszc, K. Blacha & M. Wesołowski
Air Force Institute of Technology, Warsaw, Poland

ABSTRACT: An important factor, which affects the safety of carried out flight operations, constitutes proper management of airports on the basis of information on the pavement condition of their functional elements, obtained in a systemic manner. One of the elements of the technical condition estimation of airport pavements is the assessment of their deterioration degree on the basis of identified damage and carried out repairs. Such an approach allows to forecast essential resources necessary to carry out repairs and rationally plan overhauls. The multicriteria analysis presented in this article is a method of the weighted assessment supporting the deterioration degree estimation of airport pavements. While calculating the criteria, it is important to focus on parameters characterising the deterioration degree of airport pavements, both of civil and military facilities. Therefore, it is important to diagnose the functional elements' pavements of these airports within the framework of current five-year inspections, and to carry out inspections including the inventory of damage and made repairs within the annual intervals.

1 INTRODUCTION

In the literature and operational practice, many terms related to the life phases of airport facilities, such as, e.g. durability, service life, labour resource, technical service life resource, service life resources between repairs, are used (Shahin 2007, Zieja et al. 2016, Zieja 2015, Werbińska-Wojciechowska & Zając 2015, Barszcz & Blacha 2015 & 2016). The airport facilities' life phases are characterised by their operation strategies. Figure 1 graphically shows operation strategies of the airport functional elements' pavements, which currently function within the framework of operation of airport pavements.

In case of the functional elements' pavements of airports operated by air forces, mixed strategies of their operation are used; however, a series of works aimed at proceeding to the operation according to the technical condition is taken. The operation in accordance with the technical condition requires to obtain information, which would make it possible to monitor the technical condition of airport pavements. One of the parameters characterising the pavement's technical condition includes its deterioration degree. The deterioration degree is estimated on the basis of data obtained during the inventory. The inventory includes activities aimed at drawing up a detailed physical inventory listing of components, which specify the assessed feature for a given day. The inventory of damage and repairs to the functional elements' pavements of airports is carried out in accordance with the adopted assumptions with the use of the previously prepared bases. It involves the inspection of a basic element, which includes a slab (sample). The damage and performed repairs identified during the inspection are marked on the previously prepared bases with the use of adopted symbols with appropriate colours. Within the framework of the carried out inventories, it was assumed that the identified damage is marked with red, and repaired damage with black colour. The quantities which characterise a given type of damage and repairs are marked on the previously prepared bases (Żurek et al. 2014, Barszcz & Wesołowski 2015, Zio 2009). In accordance with the adopted nomenclature, the parameters characterising the deterioration degree of the airport pavement are marked, inter alia, as follows (Figure 2):

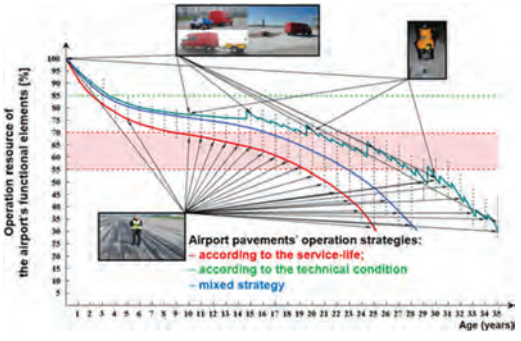

Figure 1. Operation strategies of the airport functional elements' pavements.

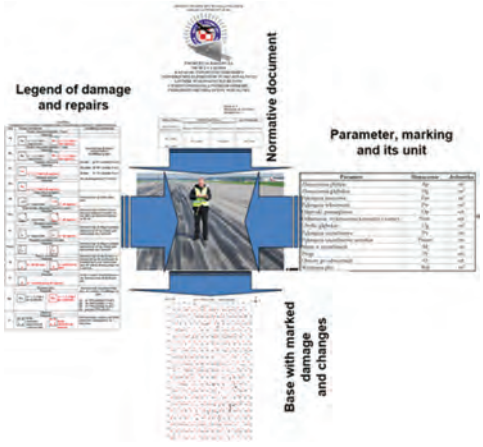

Figure 2. Inventory of damage and repairs performed by a prepared expert with the use of a visual method.

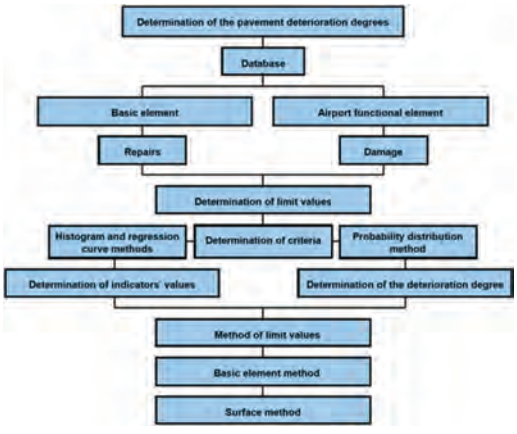

Figure 3. Algorithm of assessing the deterioration degree of airport pavements.

– alkali-silica reaction, alligator cracking;
– surface losses;
– blisters;
– chipping and loosening;
– cavity and wide cavity cracks;
– heaves or fractures;
– deep losses;
– ruts;
– boreholes.

One of the most important functional elements includes runways, and therefore, they are given a higher standard of maintenance than taxiways or airport aprons. Loose parts of the pavement can cause damage to the aircraft engines and propellers. The aircraft operational safety forces a way of conducting the runway inventory, where the slab is considered a primary element to be inspected. In case of the airports' functional elements, such as airport aprons or taxiways, the pavement tests can be carried out by analysing the number of selected samples on the tested section; however, at the same time, it is important to pay attention whether operated aircraft taxi with the use of their own drives or they are towed along the analysed test section (Smirnov & Mickiewicz 2002).

2 ALGORITHM OF ESTIMATING THE DETERIORATION DEGRE OF AIRPORT PAVEMENTS

The algorithm, presented in Figure 3, shows the way of assessment of the deterioration degree of the airport's functional element pavement.

In order to assess the pavement deterioration degree, a finite sequence of defined activities is performed, and it includes:

– determination of the parameter limit values of relative functional elements of airports on the basis of the analysis of:
  • histogram and regression curve;
  • probability distribution;
– determination of the parameter limit values characterising deterioration of a single slab on the basis of the analysis of:
  • histogram and regression curve;
  • probability distribution;
– determination of assessment criteria related to the deterioration degree of airport pavements;
– determination of the indicators' values characterising the pavement deterioration;
– determination of the pavement deterioration degree.

3 METHOD OF ESTIMATING THE DETERIORATION DEGRE OF AIRPORT PAVEMENTS

Deterioration is a slow and spread over time process. It mainly involves the reduction of construction properties by the impact of external factors, which as a result, generates changes in its structure. The deterioration degree of the airport pavement's functional element is affected by damage and performed repairs. This quantity is determined on the basis of 11 defined types of damage and repairs. In order to optimally select an indicator characterising the actual deterioration degree of the pavement surfaces, two variants of calculation are considered, where it is assumed that the performance of repairs affects the pavement deterioration in 20% or 50%. While analysing the indicators characterising the pavement deterioration, the impact of the types of damage and repairs on the aircraft operation safety

is taken into account by the introduction of properly selected weights. The indicator for assessing the pavement deterioration degree of the airports' functional elements counted with the use of a method of occupied surface including the impact of a specific parameter on the aircraft operation safety is calculated on the basis of data obtained during the inventory in accordance with the following formula:

$$\overline{D^{MF}_{BA\ w}} = w^{U}_{BA} \cdot W^{UF}_{BA} + w^{N}_{BA} \cdot W^{NF}_{BA}, \quad (1)$$

$$W^{wUF}_{BA} = \frac{\sum_{i=1}^{13} \frac{\left(w^{U}_{Ob}\right)_i \times \left(Ob^{U}_{BA}\right)_i \times \left(p^{U}_{BA}\right)_i}{F}}{\sum_{i=1}^{13} \left(w^{U}_{Ob}\right)_i} \times 100, \quad (2)$$

$$W^{wNF}_{BA} = \frac{\sum_{i=1}^{13} \frac{\left(w^{N}_{Ob}\right)_i \times \left(Ob^{N}_{BA}\right)_i \times \left(p^{N}_{BA}\right)_i}{F}}{\sum_{i=1}^{13} \left(w^{N}_{Ob}\right)_i} \times 100, \quad (3)$$

where D^{MF}_{BA} = pavement deterioration of the airport's functional element made of asphalt concrete; p_i = conversion rate of the parameter characterising damage and repairs on the surface including damaged and repaired areas; w^{i}_{BA} = statistical weight of the importance of damage and repairs in the assessment of deterioration of the airport's functional element pavement; w^{i}_{Obi} = statistical weight of the validity of specific damage and repairs in the assessment of deterioration of the airport's functional element pavement; Ob_i = measurement of damage and repairs of the airport's functional element pavement; F = total area of the tested pavement of the airport's functional element; U = damage to the airport's functional element pavement; and N – repairs of the airport's functional element pavement.

The indicator for assessing the pavement deterioration degree of the airports' functional elements calculated with the use of a method of limit values including the impact of a specific parameter on the aircraft operation safety is calculated on the basis of data obtained during the inventory in accordance with the following formula:

$$\overline{D^{MG}_{BA\ w}} = w^{U}_{BA} \cdot W^{UG}_{BA} + w^{N}_{BA} \cdot W^{NG}_{BA}, \quad (4)$$

$$W^{wUG}_{BA} = \frac{\sum_{i=1}^{13} \frac{\left(w^{U}_{Ob}\right)_i \times \left(Ob^{U}_{BA}\right)_i \times \left(p^{U}_{BA}\right)_i}{F \times \left(WG^{U}_{BA}\right)_i}}{\sum_{i=1}^{13} \left(w^{U}_{Ob}\right)_i} \times 100, \quad (5)$$

$$W^{wNG}_{BA} = \frac{\sum_{i=1}^{13} \frac{\left(w^{N}_{Ob}\right)_i \times \left(Ob^{N}_{BA}\right) \times \left(p^{N}_{BA}\right)}{F \times \left(WG^{U}_{BA}\right)_i}}{\sum_{i=1}^{13} \left(w^{N}_{Ob}\right)_i} \times 100, \quad (6)$$

where D^{MG}_{BA} = pavement deterioration of the airport's functional element made of asphalt concrete; and WG_i – limit value for specific types of damage and repairs.

The unloaded indicator for assessing the pavement deterioration degree of the airports' functional elements with the use of a method of occupied surface is calculated on the basis of data obtained during the inventory in accordance with the following formula:

$$\overline{D^{MF}_{BA}} = w^{U}_{BA} \cdot W^{UF}_{BA} + w^{N}_{BA} \cdot W^{NF}_{BA}, \quad (7)$$

$$W^{UF}_{BA} = \sum_{i=1}^{13} \frac{\left(Ob^{U}_{BA}\right)_i \times \left(p^{U}_{BA}\right)_i}{F} \times 100, \quad (8)$$

$$W^{NF}_{BA} = \sum_{i=1}^{13} \frac{\left(Ob^{N}_{BA}\right)_i \times \left(p^{N}_{BA}\right)_i}{F} \times 100. \quad (9)$$

The unloaded indicator for assessing the pavement deterioration degree of the airports' functional elements with the use of a method of limit values is calculated on the basis of data obtained during the inventory in accordance with the following formula:

$$\overline{D^{MG}_{BA\ w}} = w^{U}_{BA} \cdot W^{UG}_{BA} + w^{N}_{BA} \cdot W^{NG}_{BA}, \quad (10)$$

$$W^{UG}_{BA} = \sum_{i=1}^{13} \frac{\left(Ob^{U}_{BA}\right)_i}{F \times \left(WG^{U}_{BA}\right)_i} \times 100, \quad (11)$$

$$W^{NG}_{BA} = \sum_{i=1}^{13} \frac{\left(Ob^{N}_{BA}\right)_i}{F \times \left(WG^{N}_{BA}\right)_i} \times 100. \quad (12)$$

The indicator for assessing the pavement deterioration degree of the airports' functional elements is calculated in accordance with the following formula:

$$D = w^{U}_{BA} \cdot W^{U}_{BA} + w^{N}_{BA} \cdot W^{N}_{BA}, \quad (13)$$

$$W^{U}_{BA} = w^{wUG}_{BA} \cdot W^{wUG}_{BA} + w^{wUF}_{BA} \cdot W^{wUF}_{BA} + w^{UG}_{BA} \cdot W^{UG}_{BA} + w^{UF}_{BA} \cdot W^{UF}_{BA} \quad (14)$$

$$W^{U}_{BA} = w^{wUG}_{BA} \cdot W^{wUG}_{BA} + w^{wUF}_{BA} \cdot W^{wUF}_{BA} + w^{UG}_{BA} \cdot W^{UG}_{BA} + w^{UF}_{BA} \cdot W^{UF}_{BA} \quad (15)$$

4 ASSESSMENT OF THE DETERIORATION DEGREE OF OPERATED AIRPORT PAVEMENTS

While estimating the pavement deterioration degree, the test results, obtained during the inspections with a visual method of surfaces of the airport facilities' pavements, were taken into account. The analysed spectrum of tested facilities was divided into 7 groups, and the limits of ranges

characterising the assessment criteria of the pavement deterioration were determined. The indicators, on the basis of which the values of assessment criteria of the pavement deterioration were estimated, includes D^{UN} unloaded indicator and $D^{w(UN)}$ weighted index of deterioration of the airports' functional elements, which are defined on the basis of the indicator characterising W^U damage and W^N repairs of the airport's functional element. The values, which were achieved by indicators characterising the deterioration of airport pavements while taking into account appropriately selected weights, are shown in Figures 4 and 5. However, it should be noted that for a complete view of the pavement deterioration state, it is important to analyse indicators characterising damage and repairs, which was presented in Figures 6 and 7.

The Histogram, which has a bar graph form, was used in order to graphically display the variability of

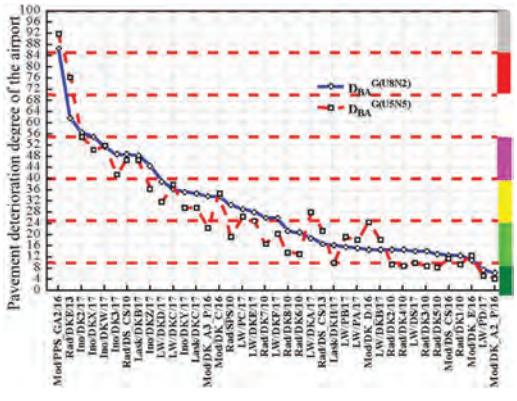

Figure 4. D^{G}_{BA} deterioration degree of the airport's functional element pavement.

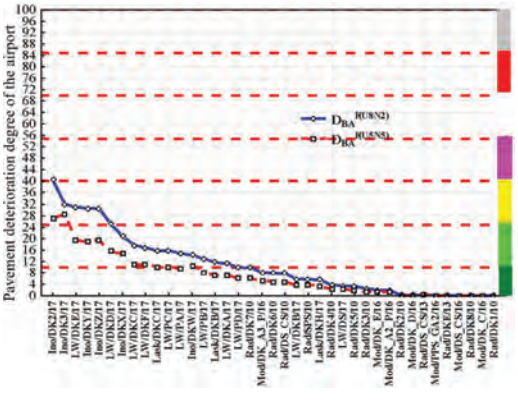

Figure 5. D^{F}_{BA} deterioration degree of the airport's functional element pavement.

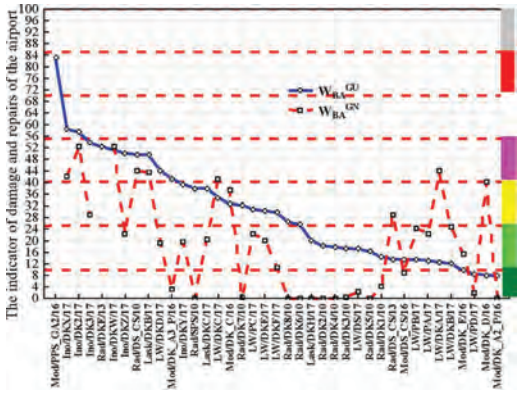

Figure 6. Indicator of the assessment of damage and repairs of the airport's functional element pavement.

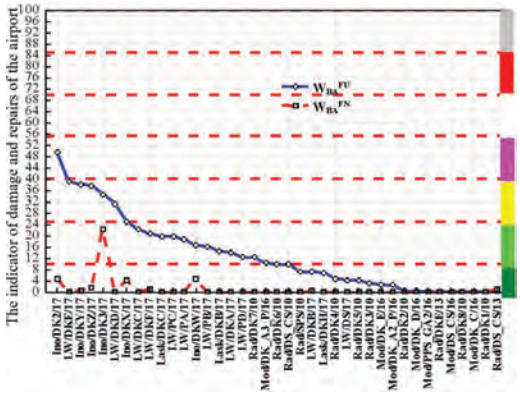

Figure 7. Indicator of the assessment damage and repairs of the airport's functional element pavement.

a particular set of data characterising the pavement deterioration. The organisation of a set of raw data is based on the division into ranges, the so-called classes. It allows to present the empirical distribution of characteristics for quantitative variables, and it determines the values at which the majority of results is located. Based on the probability distribution analysis, the corresponding distributions relevant to the nature of the probability density function were selected. The probability refers to the possibility of the occurrence of an event or several events. With data of the index development characterising the pavement deterioration degree, the probability of the occurrence of a specific event, which adopts a value in the range from 0 to 1, was determined. The probability scope of the occurrence of an event was divided into seven ranges and the possibility of the occurrence of a specific event with the specified probability was calculated.

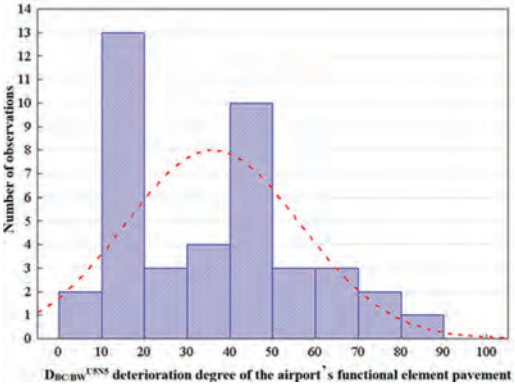

Figure 8. Standard distribution of the variability assessment indicator of the deterioration degree of the airport's functional element pavement.

The indicator offered by Air Force Institute of Technology, which characterises the pavement deterioration degree of the airport's functional elements, is within the range from 0 that means the perfect condition pavement to 100 that means the pavement unfit for further use. The calculation of D indicator is based on visual inspection results, during which different types of damage and repairs as well as their measurement are determined. The impact of a type of damage and repairs on the aircraft operation safety is included in the calculation by adopting weights estimated on the basis of the experts' method. The standard assessment scale of the pavement deterioration degree includes 7 levels, however, it is also possible to apply a simplified scale, where there are three decision-making levels of a description of the deterioration degree of the airport's functional element pavement. For each level, classes determining the pavement condition were assigned. The first one is a desired level, which includes new, renovated and operated pavements, with the assumption that these pavements will not require planned renovation works over the next five years. The indirect warning level identifies the pavement condition as the one in which it is reasonable to perform detailed tests in terms of conducting treatments in order to improve the pavement condition. The last one is a critical level, which determines the prompt performance of technical and operational research, in order to define activities aimed at the introduction of procedures to improve the pavement condition or taking the facility out of service. Figure 9 shows the relationship between decision-making levels and classes of the deterioration state of the airport's functional element pavement.

Interpretation of the pavement classes are shown in Table 1.

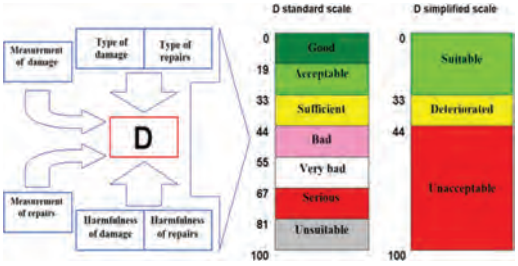

Figure 9. Assessment criteria of the deterioration degree of the airport's functional element pavement offered by Air Force Institute of Technology.

Unsuitable	55–100	86–100	70–100	86–100	86–100

5 CONCLUSIONS

On the basis of verified parameters characterising the deterioration degree of airport pavements, it is possible to predict and estimate the period of safe operation of a particular functional element of the airport, which as a result, provides the proceeding to operation of pavements of the airport's functional element in accordance with the technical condition. The deterioration degree of airport pavements is estimated on the basis of accepted indicators with the use of selected weights verified according to the experts' method. In order to reliably predict the condition of airport pavements, it is necessary to use an objective, repetitive assessment system. Designing of the IT support system for managing pavements of the airport's functional element should be preceded by the analysis of processes, which operate within the organisational unit. Currently, while estimating the assessment criteria of the technical condition, a verified database, which was obtained within the framework of works carried out on the functional elements' pavements of tested civil airports, is used. While calculating the criteria, it is important to focus on parameters characterising the deterioration degree of airport pavements, both of civil and military facilities; therefore, it is important to diagnose these airport pavements within the framework of current five-year inspections, and to carry out inspections in order to inventory damage and repairs within the annual intervals.

Applying Mahalanobis-Taguchi method to detect faults in rotating machinery

G.F.M. Souza, I.S. Melo & M.A.C. Michalski
Departamento de Engenharia Mecatrônica e Sistemas Mecânicos, Escola Politécnica da Universidade de São Paulo, São Paulo, Brazil

ABSTRACT: Monitoring systems for rotating machines has been largely used in industry even with the high reliability achieved in turbines and compressors. These systems can reduce the number of non-scheduled shutdowns and time for the scheduled ones. In this way, it remains a challenge for researchers and industry to develop better monitoring, diagnosis and prognostic techniques. These systems generally use multiple sensors to analyze the machine behavior, so the Mahalanobis-Taguchi strategy (MTS), which is recognized for its suitability for multivariate data analysis, was applied in order to integrate these sensors. Also, in order to compare and validate MTS results, a more classic approach, based in vibration analysis is also considered. Therefore, the objective of this paper is to present some initial results in the unbalance estimation in rotating machines using this method. A centrifugal compressor used in an off-shore unit is selected for application. Actual data and computational simulations were used to validate the method and to provide the unbalance estimation of the selected machine.

1 INTRODUCTION

Monitoring systems for rotating machines has been largely used in industry even with the high reliability achieved in turbines and compressors. This technology aims to reduce the non-scheduled shutdowns and the time for the scheduled ones minimizing the costs with downtime.

These problems are more severe in the off-shore facilities, because the logistics issues and weather condition play a role in reestablishing the production. In this way, it remains a challenge for researchers and industry to develop better monitoring, diagnosis and prognostic techniques.

Other peculiarity of these monitoring systems is that they have multiple sensors installed around the machine and integrate them in a troubleshooting analysis is not a simple task. So, the Mahalanobis-Taguchi strategy (MTS), which is recognized for its suitability for multivariate data analysis, was applied to improve this analysis (Cudney, 2015).

In order to verify the MTS' applicability to rotating machinery, the unbalance malfunction was chosen because, as described by Bently & Hatch (2002), this is the most common malfunction presented in this type of machines.

As it is not possible to insert an unbalance error in a real machine to validate the method, computational simulations were used to produce this data.

Also, in order to compare and validate MTS results, a more classic approach, based in vibration analysis is also considered.

Therefore, the objective of this paper is to present some initial results in the unbalance estimation in rotating machines using MTS. A centrifugal compressor used in an off-shore unit is selected for application.

2 MAHALANOBIS-TAGUCHI SYSTEM

As described by Cudney (2015), Soylemezoglu et al. (2011), Xin & Chow (2013) and John (2014), the Mahalanobis-Taguchi system (MTS) is a method that has been used in multivariable diagnostic applications. It creates two types of groups, the "normal" and "abnormal", using the Mahalanobis Distance (MD), and then optimize the number of variables used in the diagnostic by applying the Orthogonal Arrays (OA) and Signal-to-Noise ratios (SN). Finally, a prognostic can be done in order to avoid the application´s fault. The MTS can be generally summarized in four stages, as follows:

2.1 *Stage 1: Mahalanobis space construction*

The normal group is created in this step to be used as reference. The variables are selected and "healthy" samples of each one collected.

At first, calculate the mean of each variable in the "normal" condition per Equation 1:

$$\bar{x}_i = \frac{\sum_{j=1}^{n} X_{ij}}{n} \quad (1)$$

where n = number of samples of *i*th variable.

Then, calculate the standard deviation for each variable per Equation 2:

$$s_i = \sqrt{\frac{\sum_{j=1}^{n} (X_{ij} - \bar{x}_i)^2}{n-1}} \quad (2)$$

Normalize each variable per Equation 3:

$$Z_{ij} = \frac{(X_{ij} - \bar{x}_i)}{s_i} \quad (3)$$

Then, calculate the transpose of Z_{ij}, Z^T_{ij}.

Calculate the correlation matrix per Equation 4:

$$C_{ij} = \frac{\sum_{m=1}^{n} (Z_{im} Z_{jm})}{n-1} \quad (4)$$

Calculate the inverse of correlation matrix, C^{-1}_{ij}.

Calculate the MD per Equation 5:

$$MD_j = \frac{1}{k} Z^T_{ij} C^{-1} Z_{ij} \quad (5)$$

where k = number of variables.

2.2 *Stage 2: Validation of measurement scale*

In this stage is necessary to identify abnormal samples of each variable in order to calculate the abnormal Mahalanobis Distance (MD_A). The samples of abnormal variables are normalized using the mean and standard deviation of the respective normal variable. The normal correlation matrix is also used. Then, the MD_A is calculated. If the values of MD_A are greater than MD, it´s an indication that values used in the construction of MD should be right.

2.3 *Stage 3: Optimization*

To optimize the number of useful variables is necessary to construct a two-level OA. The variables will be placed in a row and will have two levels in each column. Level-1 indicates that the variable should be used in construction of Mahalanobis space and Level-2 means that it should not be used. Then, the MD_A will be recalculated following the OA.

The signal-to-noise ratio (η) is calculated per Equation 6.

$$\eta = -10 \log \left[\frac{1}{t} \sum_{j=1}^{t} \frac{1}{MD_j} \right] \quad (6)$$

where t = number of abnormal conditions; MD_j = the MD of the *i*th abnormal condition.

The gain in signal-to-noise ratio is calculated per Equation 7. If the value is positive, the variable is stored. If not, it is removed from the analysis.

$$Gain = \overline{S/Nratio}_{level-1} - \overline{S/Nratio}_{level-2} \quad (7)$$

2.4 *Stage 4: Diagnose*

As the optimization is done on stage 3, the Mahalanobis space will be reconstructed and the diagnosis process will be performed.

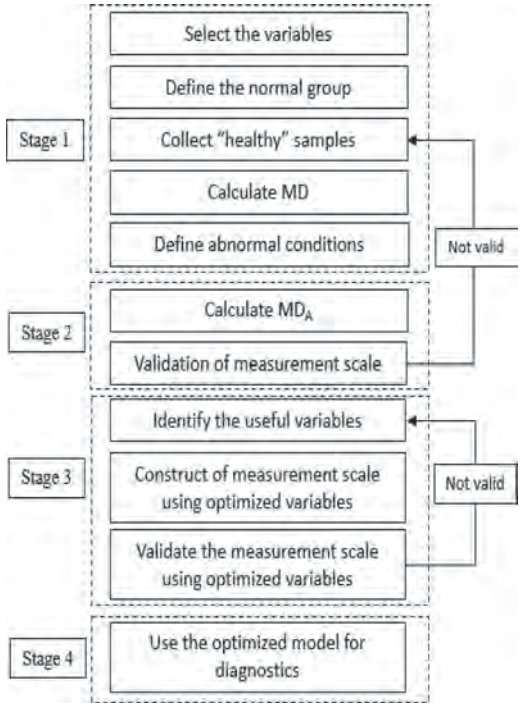

Figure 1. MTS process.

The Figure 1 summarize the four presented stages.

3 UNBALANCE

Unbalance is a centrifugal force produced by a difference between the mass center and geometrical center position of moving parts. This difference is related to manufacturing process that cannot produce a rotor with same geometrical and mass center. When the rotor is in operation, it tries to rotate around its geometrical center, but the presence of this not centered mass produces a centrifugal force resulting in unbalance vibration (Sun et al. 2017).

A strong radial vibration at the fundamental frequency is unbalance characteristic diagnostic symptom. As the response amplitude is related to the square of the rotational speed, unbalance is a dangerous condition in machinery that runs at high rotational speeds. At variable speed machines, the effects of unbalance will vary with the shaft rotational speed. At low speed machines, however, the high spot (location of maximum displacement of the shaft) will be at the same location as the unbalance. At increased speeds, the high spot will lag behind the unbalance location.

To analyze the vibration signals, and also the unbalance, a useful tool is the Fast Fourier Transform (FFT). The FFT is a mathematical algorithm that converts a periodic signal from the time domain to the frequency domain. So, when analyzing the spectrum, every periodic revolution will be presented by a peak and a respective frequency in the frequency domain (Al-Badour et al. 2011).

Every rotating machine has an unbalance degree, but when it is outside of limit, it becomes a problem (Walker et al. 2013). Unbalance is generally identified by a high synchronous vibration in frequency (1X) or time domain that, in excessive cases, may cause fatigue, internal rubs and damage bearings and seals (Bently & Hatch 2002).

Also, there are other malfunctions that produces a high synchronous vibration (for more details verify Bently & Hatch 2002), but when analyzing unbalance, it is important to remove the runout of the signal, because it can influence the 1X sensors readings and disturb the diagnosis (Bently & Hatch 2002).

Runout is a false vibration measurement which occurs when the rotor rotates its geometric center with no displacement of its center line. The runout can have two different sources, mechanical (defects on the shaft surfaces in the vibration probes area) and electrical (variance on electrical conductivity and permeability in the vibration probes area) (Bently & Hatch 2002).

Normally, there are four radial vibration probes that two are located on the drive (Fig. 3) and two on non-drive (Fig. 4) machine shaft ends mounted with 90° between each other. The recorded vibration data consists in the shaft radial displacement and phase angle measured by each probe. Also, a rotor orbit with 1X filtered signal is presented in Figure 5, the major axis is obtained by combination of the two probes displacement and phase angle.

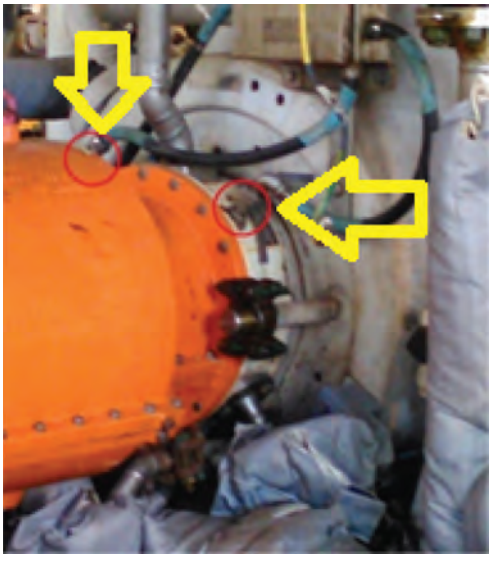

Figure 3. Drive end radial vibration probes.

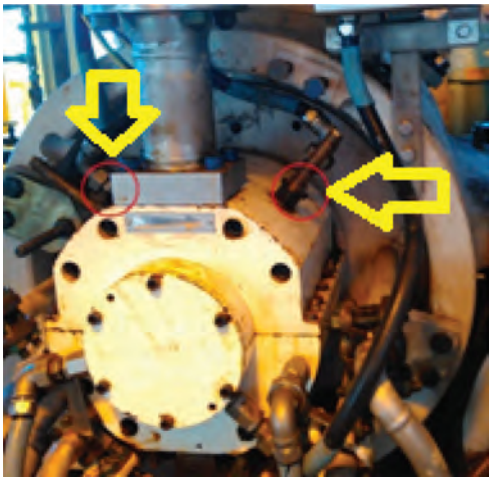

Figure 4. Non-drive end radial vibration probes.

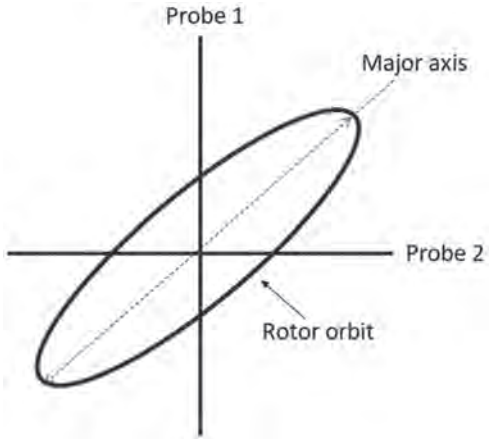

Figure 5. Rotor orbit – 1X filtered signal.

4 ROTORDYNAMICS MODELING

As described by Vance et al. (2010), rotodynamics modeling using beam elements models are generally adequate for modelling rotors. The main objective is to calculate the beam deflection to verify the internal clearances between the rotor and static parts and the rotor stability.

To construct this model, beam elements are defined with geometrical and material characteristics. Then, applying the theory of finite elements formulations, the stiffness, damping and inertia matrices are calculated.

Also, the machine´s vibrational performance is produced by the relationship between the bearings and rotor system dynamic properties. The modeling program used in this paper simulates the bearing stiffness and damping properties variation with the increase or decrease of rotor speed solving the Reynold´s equations. For more details, refer to He et al. (2005).

As described above, rotodynamic modeling is big deal, so the program called RotorLab developed by the Rotating Machine and Controls Laboratory (ROMAC) was chosen to simulate the rotor unbalance response. ROMAC is an industrial consortium at the University of Virginia with over 40 years of experience (Weaver et al. 2017).

Finally, the model was validated by the authors reproducing the API lateral analysis developed by the machine manufacturer.

5 UNBALANCE IDENTIFICATION USING VIBRATION ANALYSIS

As mentioned before, in order to compare and validate MTS results, a more classic approach, based in vibration analysis is considered. As widely reported in the literature, unbalance is strongly associated with 1X synchronous vibrations. Thus, considering the major axis displacement signal filtered at 1X the rotational speed in both bearings can give a clue about unbalance magnitude. Generally, it is expected that the greater the unbalance, the greater the vibration measured in 1x.

However, depending on the position and magnitude of the considered unbalance, the system modal response can assume different configurations and, therefore, the displacement amplitude in the bearings may not follow the logic described above.

In this case, an approach considering the virtual work (Lalanne & Ferraris 1998) of the forces acting on the shaft is applied. The bearings stiffness and damping terms are considered known and the shaft bending influence is neglect.

In fact, the bearings are considered symmetrical —since the unbalance response in both directions are almost identical—and without cross-coupled forces—since the machines has tilting pad bearings (He et al. 2005).

Considering just the forces acting on the shaft due the bearings stiffness, the virtual work can be presented per Equation 8.

$$\partial W_K = -k_b u \delta u - k_b w \delta w \tag{8}$$

where k_b is the bearing's stiffness and u and w are, respectively, the displacements in both directions.

From Equation 8 can be easily concluded that the maximum potential energy related to the shaft displacement, considering just the 1X component, occurs in the major axis direction.

The idea is to associate the energy level, considering the scalar value obtained for both bearings, with the rotor level of unbalance: the greater the unbalance, the greater the potential energy.

As the bearings' stiffness is a constant under the same speed conditions, the evaluated potential energy depends only on the major axis displacement ($d_{\max}$), as presented by Equation (9).

$$\frac{U_k}{k_b} = \frac{\left(d_{\max}\right)^2}{2} \tag{9}$$

6 CURRENT METHOD OVERVIEW

As described in Figure 6, a real tested machine will be considered as reference to construct the Mahalanobis space. Then, this machine will be modeled using the RotorLab software with two cases which produces the same vibration level as noticed in the tested machine (550 g.mm at the midspan and 275 g.mm in two points of the rotor and out of phase). This simulation will be done in order to

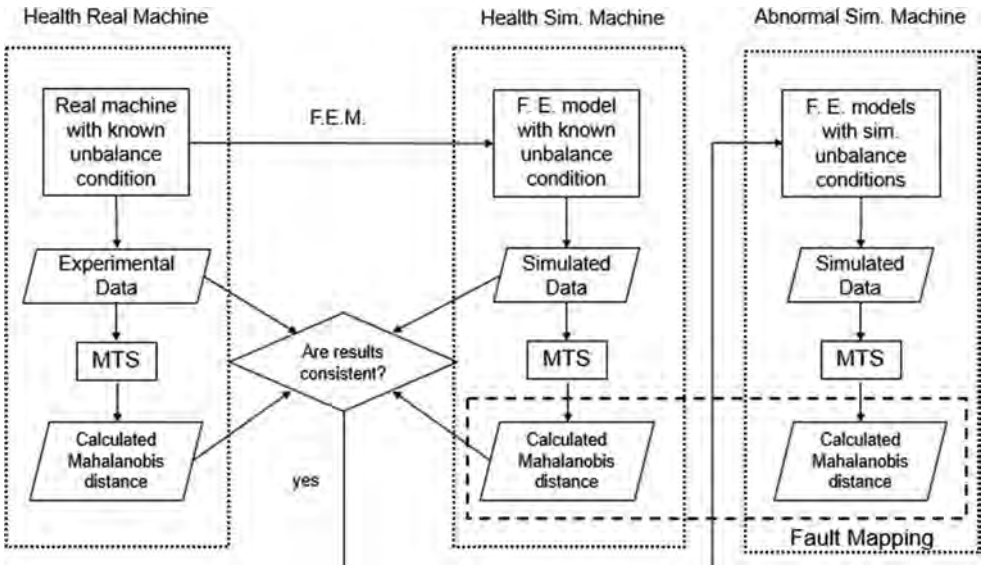

Figure 6. Method overview.

verify the similarity between the real machine and simulated data. Finally, more four unbalance cases will be simulated to calculate the abnormal Mahalanobis distance.

7 APLLYING MTS

As described on item 2, the MTS will be applied as follows.

7.1 *Stage 1: Mahalanobis space construction*

The first step is the Mahalanobis space construction which requires a "health" machine as standard. The activities developed in this step can be summarized as follows and will be detailed in the sequence.

- Collect the "health" vibration data with runout compensation of the four vibration probes during the mechanical running test (MRT);
- Filter the 1X signal (synchronous vibration) of each probe;
- Use the major axis displacement of drive and non-drive to construct the Mahalanobis space (there will be two variables to construct the Mahalanobis space);

The considered "health" machine was one that was tested and approved by API 617 7th edition MRT.

This test is conducted in a test bench with low pressure and consists in accelerating the compressor from zero to maximum continuous speed (MCOS) in increments of 10% of MCOS and run at MCOS until bearing temperatures and shaft vibrations have stabilized. Then, the speed is increased to the trip speed and kept at this level by fifteen minutes. Finally, the machine is decelerated to the MCOS and run in this condition during four hours, a schematic can be seen in Figure 7 (API 617 7th edition).

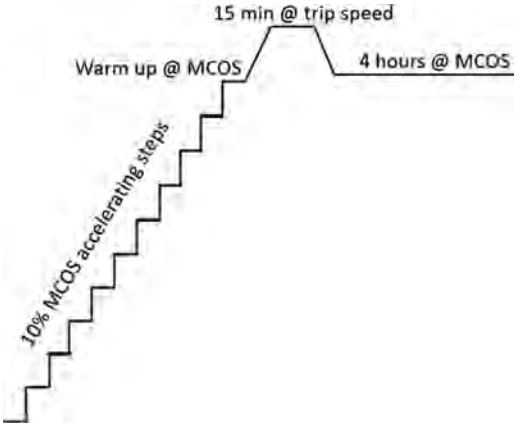

Figure 7. Mechanical running test schematic.

To construct the Mahalanobis space, vibration data were collected during the four hours operating at the maximum continuous speed with runout compensation (Fig. 8). Then, only the synchronous vibration signal (1X) of each probe was kept because unbalance is identified by high synchronous vibration.

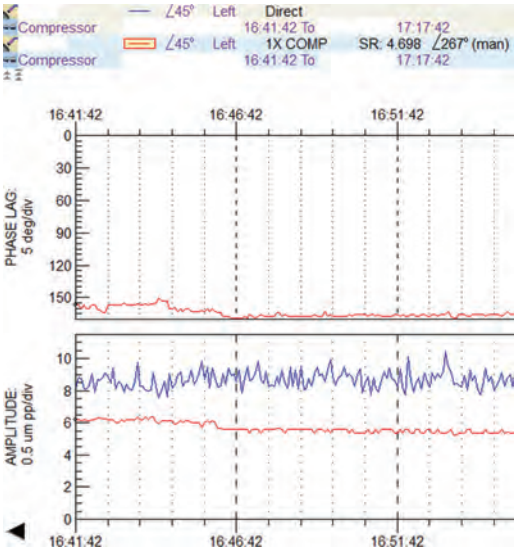

Figure 8. Trend of a radial vibration probe during the MCOS.

Table 1. Calculated Mahalanobis distance.

Minor value	−6,3
Major value	10,5
Standard deviation	0,7

Finally, the Mahalanobis space was constructed using the major axis displacement with the 1X filtered signal of drive and non-drive end, this choice eliminates the influence of phase angle.

Applying the Equations 1 to 5, the calculated MD is presented on Table 1.

7.2 *Stage 2: Validation of measurement scale*

At this point is necessary to identify abnormal behaviors to validate the measurement scale. The activities developed in this step can be summarized as follows and will be detailed in the sequence.

- Simulate four rotor unbalance cases;
- Verify the simulated vibration displacement and phase angle at the vibration probes;
- Analyze the distribution and variance of the major axis vibration data obtained during the MRT;
- Use the simulated unbalance rotor major axis displacement as the mean and same variance obtained in the previous step to create an abnormal vibration sample.

The six unbalance responses were simulated using the program RotorLab developed by ROMAC, two points following the API 617 7th edition paragraph 2.6.4 (550 g.mm at midspan to excite the first bending mode and two 275 g.mm 180° out of phase placed on the shaft maximum displacement to excite the second bending mode), one as per paragraph 2.6.4 (1100 g.mm at the coupling) and one with the same unbalance magnitude (1100 g.mm), but at the thrust disk. The other two are 1500 g.mm at the coupling and thrust disk.

At MCOS, the two first points presented the same vibration level as the "health" machine at the vibration probes. It shows that depending where the unbalance is placed and the vibration probes are located, this malfunction will not be identified. A similar case was identified in the company where one of the authors works, a centrifugal compressor was operating with a broken impeller without alarming the radial vibration probes, but presented a degraded performance and this root cause was identified during the overhaul.

The third point presented a major axis vibration of 26,1 microns pk-pk at drive end and 3,5 microns pk-pk at non-drive end. The fourth point presented a major axis vibration of 3,1 microns pk-pk at drive end and 25 microns pk-pk at non-drive end. The fifth point presented a major axis vibration of 31,4 microns pk-pk at drive end and 3,5 microns pk-pk at non-drive end. The sixth point presented a major axis vibration of 4,3 microns pk-pk at drive end and 34,3 microns pk-pk at non-drive end. A resume can be seen on Table 2.

Although the unbalance simulation produces a discrete result, the MD_A needs a sample of vibration measurements. So, it was decided to verify the major axis vibration statistic distribution on drive and no drive-end collected during the four hours mechanical running test. The drive end followed a Weibull distribution and the non-drive a mixed Weibull distribution as presented on Table 3 and Table 4, respectively.

Table 2. Unbalance response at MCOS.

	Unbalance	Position	Vibration
1	550 g.mm	Midspan	2,4 µm at drive end 2,3 µm at non-drive end
2	2 × 275 g.mm	180° out of phase	1,9 µm at drive end 8,4 µm at non-drive end
3	1100 g.mm	Coupling	26,1 µm at drive end 3,5 µm at non-drive end
4	1100 g.mm	Thrust disk	3,1 µm at drive end 25 µm at non-drive end
5	1500 g.mm	Coupling	31,4 µm at drive end 3,5 µm at non-drive end
6	1500 g.mm	Thrust disk	4,3 µm at drive end 34,3µm at non-drive end

Table 3. Weibull distribution on drive end.

F(x)	R^2
$1-\exp[-(x/11{,}3)^{25{,}7}]$	0,864

Table 4. Weibull distribution on non-drive end.

F(x)	R^2
$0{,}459\{1-\exp[-(x/5{,}15)^{1395{,}8}]\}$	0,798
$+0{,}355\{1-\exp[-(x/5{,}41)^{72{,}9}]\}$	0,765
$+0{,}186\{1-\exp[-(x/5{,}97)^{23{,}57}]\}$	0,848

As described by Lewis (1994), the Equations 10, 11 and 12 represent the Weibull distribution equations. According to Kececioglu & Wang (1998), the mixed Weibull distribution is described in Equation 13 and 14.

$$F(x)=1-\exp[-(x/\theta)^m] \tag{10}$$

where $F(x)$ = cumulative distribution function; θ = scale; and m = shape parameter.

$$\mu=\theta^*\Gamma(1+1/m) \tag{11}$$

where μ = mean.

$$\sigma^2=\theta^2[\Gamma(1+2/m)-\Gamma(1+1/m)^2] \tag{12}$$

where σ = variance.

$$f(x)=p^*f_1(x)+q^*f_2(x) \tag{13}$$

where $f(x)$ = probability density function; $f_1(x)$ and $f_2(x)$ = probability density function of two different subpopulation.

$$p+q=1 \tag{14}$$

where p and q = correspondent mixing weight of each subpopulation $f_1(x)$ and $f_2(x)$.

Then, per Equations 11 and 12, new parameters m and θ were calculated using the same variance (σ) of the measured sample with the mean (μ) as the simulated major axis vibration.

To create the new sample (the term x in Equation 10), aleatory numbers between 0 and 1 were generated for the term $F(x)$.

Finally, the MD_A is presented in Tables 5 and 7 for coupling unbalance and in Tables 6 and 8 for thrust disk unbalance. Both show higher values than the MD validating the measurement scale.

Table 5. Calculated MD_A for 1100 g.mm coupling unbalance.

Minor value	631,3
Major value	1.106,2
Standard deviation	60,8

Table 6. Calculated MD_A for 1100 g.mm thrust disk unbalance.

Minor value	4.254,8
Major value	4.841,9
Standard deviation	73,4

Table 7. Calculated MD_A for 1500 g.mm coupling unbalance.

Minor value	1.667,3
Major value	2.224,1
Standard deviation	77,9

Table 8. Calculated MD_A for 1500 g.mm thrust disk unbalance.

Minor value	10.886,1
Major value	12.175,0
Standard deviation	205,9

Table 9. MS – 550 g.mm at midspan.

Minor value	–16,4
Major value	22,5
Standard deviation	0,7

Table 10. MS – 2 × 275 g.mm 180° out of phase.

Minor value	–11,1
Major value	15,2
Standard deviation	0,7

As described previously, the cases 1 and 2 described in Table 2 presented a low vibration level. So, two health vibration samples were generated following the presented Weibull distribution and two new Mahalanobis spaces were calculated in order to compare the simulated data with the tested one. Comparing Table 1 with Tables 9 and 10, it can be seen that the simulated and tested date have similar results.

7.3 *Stage 3: Optimization*

As mentioned in item 2.3, the optimization aims to reduce the number of monitored variables. The Gain was calculated per Equation 7 per each variable (drive and non-drive end major axis vibration). The results of optimization considering the 1100 g. mm coupling unbalance and 1100 g.mm thrust disk unbalance are presented in Tables 11 and 12, respectively.

Following the optimization results in Table 11, only the drive end vibration shall be maintained, this result is consistent because when the unbalance is placed at the coupling for this machine, the high vibration signal is noticed only in the drive end probes. The same interpretation is noticed in the Table 12, at this point, only the non-drive end vibration shall be maintained, because an unbalance placed in the thrust disk, creates a high vibration signal only in the non-drive end probes.

So, in order to use the same Mahalanobis space, the optimization stage was removed from the analysis.

Table 11. Variables gain for coupling unbalance.

Vibration major axis	Gain	Result
Drive end	12,8	Keep variable
Non-drive end	–0,2	Not keep variable

Table 12. Variables gain for thrust disk unbalance.

Vibration major axis	Gain	Result
Drive end	–0,3	Not keep variable
Non-drive end	12,3	Keep variable

Table 13. MTS diagnoses.

	MD	Malfunction
1	–6,3 to 10,5	Normal operation
2	631,3 to 1.106,2	1100 g.mm Coupling unbal.
3	4.254,8 to 4.841,9	1100 g.mm Thrust disk unbal.
4	1.667,3 to 2.224,1	1500 g.mm Coupling unbal.
5	10.886,1 to 12.175,0	1500 g.mm Thrust disk unbal.

Table 14. Energy approach diagnoses.

	U_k/k_b	Malfunction
1	76,13	Normal operation
2	347,49	1100 g.mm Coupling unbal.
3	317,56	1100 g.mm Thrust disk unbal.
4	504,89	1500 g.mm Coupling unbal.
5	597,05	1500 g.mm Thrust disk unbal.

7.4 *Stage 4: Diagnose*

The diagnose is summarized in Table 13. There, it can be seen that the malfunctions have different MD from the normal operation showing the method´s effectiveness.

Considering the proposed method presented in section 5, in which the potential energy associated with the major axis displacement at 1X is related to the unbalance amount, the effectiveness of the MTS method can be confirmed. In Table 14 are presented the results considering the energy approach.

It can be seen, as in MTS method, that the malfunctions are also clearly associated with different energy levels.

8 CONCLUSION

Mahalanobis Taguchi strategy showed to be a useful tool when analyzing multivariate. This characteristic is a differential to produce a good malfunction diagnosis related to complex turbomachinery, which have many installed sensors.

In fact, considering MTS and the energy approach results, in both cases the malfunctions are clearly detected. Nevertheless, because the energy method is based on the vibration amplitude in the bearings, the results found for the analyzed cases demonstrate a much greater sensitivity to the unbalance value than to the unbalance position. In another hand, the MTS method presents different results for all cases, being sensitive to both the unbalance position and magnitude in the analyzed cases.

Considering these results, it can be said that MTS has the potential for a more complete analysis than methods based on more traditional approaches, such as vibration amplitude analysis, especially in cases with many monitored points.

However, some care shall be taken during the optimization step, because as seen in item 7.3, if the optimization were done, the different diagnosis would not be possible using the same Mahalanobis space.

Also, the first variables selection to construct the Mahalanobis space is not an easy task, some previous troubleshooting knowledge is necessary to do it, or the validation of measurement scale iterative procedure may take a long time.

This method has great potential to be applied in standard machines, because as they have similar behavior, more abnormal conditions may be identified for the same Mahalanobis space.

As well, the runout compensation is an important procedure to be done, mainly when construction the Mahalabonis space, because the “healthy”

machine presents vibration signals levels that runout can disturb them.

Finally, independently of the monitoring system, all malfunctions won´t be suitable to be identified, as described in item 7.2, two types of unbalance presented the same vibration level as the "healthy" machine on drive and non-drive end radial vibration probes.

ACKNOWLEDGEMENTS

The authors thank Petrobras for using the RotorLab software for academic purpose and CNPq for the financial support.

ABSTRACT: Periodic testing is a method to ascertain the availability of Safety Instrumented Systems (SIS). These systems are generally passive and are activated only on demand. Testing is then required to diagnose their current state and to take the corresponding maintenance action. However, the testing procedure can provoke damage on some units of the SIS (especially the mechanical parts) and the system as a whole becomes more prone to failures. This situation is currently not well covered by standards under the so-called umbrella of imperfect testing. The decision maker must in practice come across to an optimization problem where the objective is to determine the optimal compromise between an accurate diagnostic of the current system state (high tests frequency) and the possible failures or degradation provoked by the testing procedure itself. The commonly used criteria to assess the performance of SIS are all related to the mean downtime of the SIS between two tests. The IEC 61508 provides subsequent analysis for multi-unit SIS when all the units are supposed to follow exponential lifetime distributions. It cannot be applied in this case as some parts of the system have a time varying failure rate which can increase after every test. We propose the use a of Markov process to model the degradation of the mechanical parts upon test and possible preventive maintenance after testing. Since the degradation due to tests is experienced at deterministic dates, we use the modelling framework of multiphase Markov processes to calculate the mean downtime. The paper is focused on explaining the optimization problem between the frequency of testing versus PFD_{avg} and find out the optimum frequency through simulations

1 INTRODUCTION

A Safety Instrumented System (SIS) is often used to detect hazardous events and to mitigate their consequences at facilities and plants that produce or handle hazardous substances, like e.g. hydrocarbon fluids and gases. Due to their criticality, they must obey to regulatory requirements and international standards on safety. IEC 61508 (1998) and related standards (such as IEC 61511 (2002) for the process industry sector) are key in framing the design and operation of SIS. One important requirement mandated by these standards is the need to verify, by quantitative analysis, that the safety performance is adequate in light of risk acceptance criteria. Most safety functions implemented by a SIS, the so-called Safety Instrumented Functions (SIFs), are seldom demanded as the normal operation is managed by a dedicated control system. According to the mentioned IEC standards, the SIFs are classified as operating in the low demand mode.

This means that the SIFs are passive most of the time and are supposed to act only when needed ("on demand"). The reliability of low demand SIFs is measured by the average probability of failure on demand (PFD_{avg}). PFD_{avg} is calculated over a time interval between two proof tests and corresponds to the mean downtime per unit of time between proof tests. The same measure is also used to express the reliability requirement for the each SIF„ but then the associated required value is derived on the basis of a risk analysis (Jin et al. 2012). IEC 61508 suggests four levels of safety integrity levels (SIL), each giving a specified range of PFDavg. For example, a SIF with a SIL 2 requirement must demonstrate that the PFD_{avg} is within $10^{-3}$and 10^{-2}.

The PFD_{avg} can be quantified using different reliability models. These models are based on assumptions and simplifications and in some situations they can lead to different results, depending on the dominating contributing factors. Lowdemand

SIS are periodically tested (proof tests) in order to confirm that they are able to act on demand. Length of intervals between such tests is an important contributor to PFD_{avg}. Normally, it is assumed that the proof tests are perfect, and that the equipment is restored to an to as-good-as-new condition (Shao-Ming et al. 1994). These assumptions imply that the proof tests are carried out in a manner and under conditions which are similar to a real demand, so that all dangerous failure modes,- i.e. failure modes that result in a failure to carry out the SIF, are revealed.The assumptions also imply that no degradation is experienced by the SIS due to the test itself (a non-destructive test). However, in reality, proof tests may not beperfect, and the equipment may degrade from exposures that are applied during the tests. The latter example is also identified by Brissaud et al. (2010). Rausand (2014a) gives one practical example on how the proof test can degrade a Downhole Safety Valve (DHSV) installed in to protect against releases from oil and gas wells. The DHSV is exposed to harsh conditions when operated (due to high pressures drop and in some cases high temperature). A perfect proof test, would imply that the DHSV is closed with full flow from the well (which would be the real demand situation). However, this type of exposure is known to degrade the performance of the DHSV, and the proof test is therefore carried out under non-perfect/imperfect test condtions by closing DHSV with downstream valves already closed. Still, it is interesting to understand better the impact of perfect versus non-perfect/imperfect test conditions. One approach has been suggested by Oliveira et al. (2016), where an additive test-step varying (ATSV) model was elaborated to reflect the increment of the failure rate after each proof test in a blowout preventer (BOP) system. Yet, it is still not clear how to implement the full effect of degradation for the quantification of PFD_{avg}. A review of the modelling framework was performed by Rouvroye & Brombacher (1999) and Bukowski (2005) and both promoted the use of Markov processes when other states than functioning and failed are to be included.

The objective of this paper is to demonstrate the implementation of the Markov process to model the combined effects of degradation due to equipment wear out (aging) and the exposure from the proof test. A simple homogeneous Markov process cannot be used,since the transition rates will change after each proof test. Instead, a multiphase Markov approach is suggested. This method was applied in Strand and Lundteigen (2015) to assess the BOP reliability and also in Innal et al. (2016) to establish new generalized formulas with repair time. Compared to simple Markov processes, multiphase Markov processes allows one to take into account changes of the transition rates at deterministic time points (Wu et al. 2018). The paper is organized as follows: Section 2 provides the problem statement and assumptions. The model is discussed in section 3, within a multiphase Markov framework. Section 4 describes the model implementation in terms of discrete event simulation and Monte Carlo simulations. The last section is devoted to numerical results and the consequent optimization problem.

2 MODELLING FRAMEWORK AND MODEL ASSUMPTIONS

PFD_{avg} is defined as Rausand (2014b):

"..If a demand of safety function of the item occur at a random time in future, the PFD_{avg} is the average probability that the item is not able to react and perform its safety function in response to demand.."

Theoretically, PFD_{avg} value stems from the risk analysis. For practical purposes, it is estimated on the basis of the reliability model of the SIF. In general, an estimator for PFD_{avg} ($\widehat{PFD_{avg}}$) can be interpreted as long run average value of unavailability, it can be defined as:

$$\widehat{PFD_{avg}} = \frac{1}{n}\sum_{k=1}^{n}\int_{(k-1)\tau}^{k\tau}\frac{U(t)}{\tau}dt$$

where:

- PFD_{avg} Probability of failure on demand on average
- n = Total number of inspection performed
- τ= Duration between two consecutive inspection
- $U(t)$ = Unavailability of the system at t

Inspection is an integral part of the proof test which reveals about the state of the system at the time of proof test. For all calculations, frequency of inspection is equal to frequency of proof test performed. In this situation $\widehat{PFD_{avg}}$ is proportion of time on average that the multiphase Markov process spends in the failed state. It is the dangerous failure rate that is considered in the calculation of $\widehat{PFD_{avg}}$, i.e. the failures that can prevent the SIF from functioning on demand.

The modelling framework to model this problem is described hereafter.

2.1 *Modelling framework*

There are basically two different mindsets for modelling degradation due to equipment wear out (aging) and degradation due to proof test. One mindset is more inherited from Reliability theory: the main idea is to model the degraded unit by a binary random variable moving from working

state to failed state and to consider that the transition rate between these two states will increase with time or with the number of tests experienced by the unit. In other words, the unit has a lifetime law with an increasing failure rate which is a function of the number of tests. Another mindset is more applied for people working in the framework of maintenance optimization. The unit is modelled by a random variable with more than two states. The state space can be a discrete finite space, an infinite discrete one or a continuous one. The main idea is that there exists intermediate states between the new one and the failed one. All the intermediate states can be considered as working states but with possibly degraded performances and they are taken as a health indicator of the system. They often correspond to degradation phenomena or symptoms that can be monitored, diagnosed and used as a decision indicator to trigger preventive maintenance actions. The advantage of such models is that

- We can make correspondence between degradation phenomena and the performance of the system (here 1-PFD).
- We can use the intermediate states to optimize and define preventive condition-based maintenance

However, if expert judgments can be relevant enough to define the number and the nature of intermediate states, the law of the sojourn time in every single state may be difficult to estimate. A model relying only on lifetime law and a binary random variable may be then more reasonable.

Most of the existing models that are described in the introduction are inherited from Reliability theory. The calculation of the PFD for SIS is mainly based on binary random variables. In this paper, we want to explore the use of intermediate states in a specific context when the tests have a negative impact on the system condition. We want to investigate such a framework because

- The literature, guidelines and practices related to negative impact of testing should be linked at some point to the identification of some degradation mechanism.
- This seems to be a good way to go ahead and prepare the future for condition-based maintenance and optimal use of condition monitoring.

As a preliminary study, we propose a model with two intermediate states. This number is arbitrarily chosen and we do not investigate any preventive maintenance. We only aim at showing that there is a trade off between the negative effect of tests (pushingthe system randomly into more degraded states) and the added value performing more tests to detect failures earlier.

Equipment wear out is modelled by a finite number of intermediate degraded states between the new state and the failed one. Degradation due to proof test is modelled by an increase of the transition rates between two states at inspection time. In addition, direct transitions are possible from any functioning state to the failed one: they model sudden failures that are not due to wear. Since the unit is passive, all the failures are undetectable without testing, whatever the failure mode is. At last, in order to develop further analytical formulations, we chose a Markovian framework. Because the transition rates are changing at inspection times, we refer it as a Multiphase Markov process. The current paper is only devoted to Monte Carlo simulations in order to demonstrate the relevance of the problem statement and the possible trade off that arises due to the negative effect of testings. Analytical formulations seems to be tractable but are left for further work.

2.2 *Assumptions*

Modelling degradation using Multiphase Markov process, we have used following assumptions:

- In general, we can consider that a SIF equipment is exposed to two types of failures:
  - Dangerous detected (DD) failures, i.e. the dangerous failures revealed by online diagnostics.
  - Dangerous undetected (DU) failures, i.e. the dangerous failures that are not DD and which are to be revealed by regular proof tests.
- For the sake of simplicity to begin with the modelling, we only consider the effect of DU failures in our analysis, since the equipment focused in our study (valves) have no or very limited facilities for diagnostics. However, effect of DD failures,for modeling purposes beyond equipment type in our study, will be considered in the future paper. From now, when we use the term “detected” or “detectable” , it is used to denote DU failures that are revealed by the proof test, in light of the real (non-perfect/imperfect) test conditions.
- DU—failures are of two types: they can be sudden or they can be due to a progressive degradation process named hereafter aging. Sudden failures are modelled by a failure rate λ_u, and aging is modelled by several intermediate states (degradation levels) between new state and failed one, with associated transition rates. Whatever the failure mode is, the system will stay in failed state until the next inspection, and then the system is repaired as per the chosen maintenance policy.

- There are 4 degradation levels: A, B, C, D. These are the states of a Markov process. (A: System working with no degradation, B: System working with degradation of system of level 1, C: System working with degradation of level 2, D: Failed)
- In our model the following instantaneous transitions are possible:
  - System can always jump to next higher state of degradation due to effect of aging.
  - System can always jump to failed state due to sudden DU failures.
  - System can not go to lower degraded state until the maintenance is performed.
- Instantaneous transitions rate for the multiphase Markov process are represented in the Figure 1.
- In the Figures above represents the effect of aging on the system, which changes every time when a proof test is performed on the system. We consider that the proof test has a negative effect on the system condition (shock leading to extra stress) and this negative effect increases the aging transition rates. The modelling of impact of negative effect of testing is done through the following model.

$$\lambda_a(t_0^+) = \begin{cases} 1.01 * \lambda_a(t_0^-) & \text{Current State A} \\ 1.03 * \lambda_a(t_0^-) & \text{Current State B} \\ 1.05 * \lambda_a(t_0^-) & \text{Current State C} \end{cases} \quad (1)$$

We assume here that a proof test is performed at $t = t_0$ and the current state is the state of the system at $t = t_0$.

  - The underlying idea behind this modelling is to show that the negative impact of the proof test increases with the degradation of the system

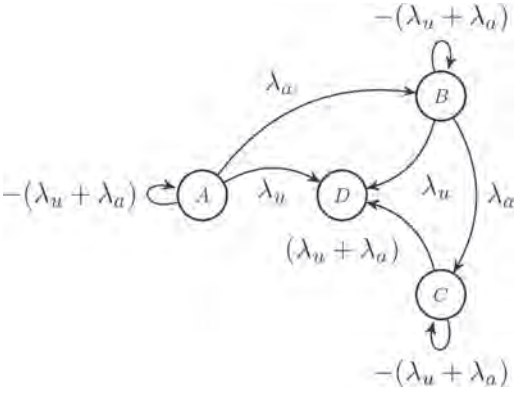

Figure 1. Instantaneous transition rates for the multiphase Markov process.

- Between two consecutive proof tests λ_a and λ_u remains constant.
- When a failure is detected after the proof test, we assume that the mean time to repair the system is negligible.

3 METHODOLOGY

The multiphase Markov process was analyzed using discrete event simulation and exponential distribution for the time spent in each state. System starts in state, degradation time (T_d) and failure time (T_f) are sampled from the exponential distribution of the respective parameters $\lambda_a(t)$ and $\lambda_u(t)$. Then based on the minimum of (T_d, T_f, τ) the next state of the process was chosen. Some specific decisions were made for the modeling:

- If system goes to a failed state (state *D*), the unavailability is calculated by measuring the time spent in the state *D* by the system. On inspection the maintenance action is taken and process is re-initiated.
- If the minimum is τ, then the system stays in the same state for the duration between two consecutive proof tests. Then the inspection is performed and we repeat the process with the increased $\lambda_a(t)$.
- If system goes to more degraded state, then the T_d',T_f', are again sampled from the corresponding exponential distributions. Now, the minimum is compared between (T_d',T_f', $\tau - T_d$). And the process repeats itself until system goes to failed state. Once the system fails, the unavailability is calculated,the maintenance action is taken and process is re-initiated.

The following maintenance policies were proposed when the system was found to be in the failed state on inspection:

- As-good-as-new (AGAN): System is reset to new state (*A*) and the failure rate of the system is reset to $\lambda_a[i + 1] = \lambda_a[1]$, ie we consider that system is as-good-as-new when we take away the effect of aging after maintenance of the system
- As-bad-as-old (ABAO): On maintenance, the new state of the system is set to *C* and the failure rate of the system is reset to $\lambda_a[i + 1] = \lambda_a[i]$

4 RESULTS AND DISCUSSION

Recall that the PFD_{avg} is the performance measure. Simulations were performed to estimate PFD_{avg} by calculating the average unavailability of the system. The proof test interval (τ) is varied from 3 days to 1 year, where represents the time

between two consecutive inspections/proof tests. We considered following values τ of for simulations: τ = (3 days, 6 days, 15 days, 21 days, 1 month, 2 month, 3 month, 4 month, 5 month, 6 month, 7 month, 8 month, 9 month, 10 month, 11 month, 12 month).

Values of parameters like λ_a, λ_u, and mission time are chosen based on industry guidelines on the performance measure. The mission time of the system for the purpose of simulation is chosen to be 5 years. Based on industrial guideline, the impact factor of the proof test is considered as per equation 1. For each value of τ, 500 random realizations were simulated to obtain average unavailability of the system.

Figure 2, shows the estimated value of PFDavg of the system for different values of τ. The borderlines of SIL 1 and SIL 2, showing that the .01 < PFD_{avg} < 0.1 for being within the range of SIL 1 and PFD_{avg} < 0.01 for being in the range of SIL 2. Left side plot in Figure 2 shows that when both λ_a and λ_u are of the order of 10^{-6} per hour, the PFD_{avg} remains within SIL 2 for both AGAN and ABAO maintenance policies for 15 days $\leq \tau \leq$ 1 year. Right side plot in Figure 2 shows that when λ_a and λ_u are increased to the order of 10^{-5} per hour, the PFD_{avg} increases for both maintenance policies. For AGAN maintenance policy, PFD_{avg} leaves the range of SIL 2 and enters SIL 1 at τ = 15 days and leaves the range of SIL 1 at τ = 6 months. For ABAO maintenance policy the PFD_{avg} leaves range of SIL 1 for $\tau \geq$ 4 months and $\tau \leq$ 15 days and stays within the range of SIL 1 for an optimal proof test interval (15 days < $\tau \leq$ 3 months).

In Figure 2, when the plots pertaining to AGAN maintenance policy are observed, it is found that the information gain through inspection is more significant over the negative effect of testing. This is because with AGAN maintenance policythe system did not carry the history of past tests experienced by the system.

The important conclusion that can be derived from Figure 2 is that when the maintenance policy ABAO is chosen, PFD_{avg} of the system shows a trade off between the negative effect of performing a proof test versus the gain of information by performing the proof test on the system. In other words, when the system undergoes through high frequency of proof tests, the unavailability represented by the PFD_{avg} increases instead of decreasing as it did for AGAN policy. At the same time, when the frequency of proof tests is reduced, the user does not get enough information about the state of the system. Therefore, there exists an optimum frequency of testing which minimizes the value of PFD_{avg} in the Figure 2.

Figure 3 shows the effect, of changing the values of λ_a while keeping the value of λ_u as constant 5×10^{-6} per hour, on the PFD_{avg}. Note that the tradeoff between multiplicative negative effect of testing by high frequency of testing versus loss of information by low frequency of testing, is an attribute of ABAO maintenance policy only. Hence, the maintenance policy considered in Figure 3 is ABAO. It is observed from the Figure 3 that the PFD_{avg} remains within the range SIL 2 when the value of $\lambda_a \leq 5 \times 10^{-6}$ per hour for $\tau \in$ [15 days, 5 months]. Plots show that for each value of λ_a, there exists an optimum value of τ for which PFD_{avg} attains a minimum value. It is also observed that the value of PFD_{avg} increases with increasing values of λ_a.

Figure 4 shows the effect, of changing the values of the failure rate λ_u, while keeping the value of λ_a constant 5×10^{-6} per hour, on the PFD_{avg}. ABAO maintenance policy is considered for obtaining these plots, using the same arguments as for plots in Figure 3. It is observed from the left side plot in Figure 4 that when λ_u is increased from 10^{-7} per

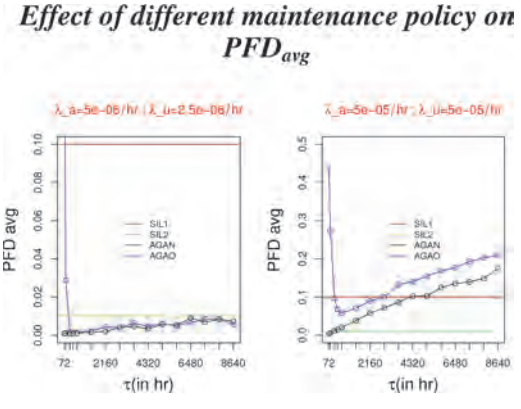

Figure 2. Effect of different maintenance policy on PFD_{avg}.

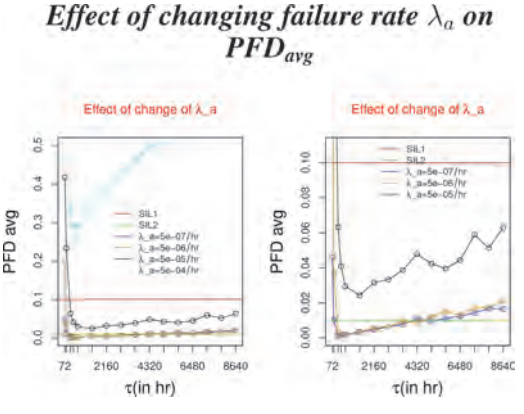

Figure 3. Effect of changing failure rate on PFD_{avg}.

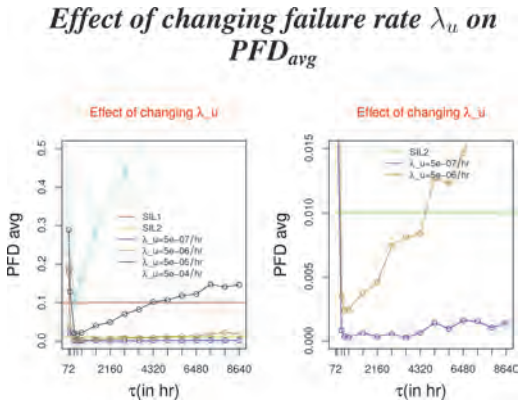

Figure 4. Effect of changing failure rate λ_u on PFD_{avg}.

hour to 10^{-4} per hour the shape of plot of PFD_{avg} changes from a flat convex to a steep convex indicating that PFD_{avg} increases with increase in λ_u.

The optimum time-interval (for performing proof test) which minimizes PFD_{avg} is significantly visible in Figure 4 for higher values of λ_u whereas for lower values of λ_u the curve needs to be zoomed up to observe the optimum time-interval (for performing proof test) as shown in the right side plot of Figure 4.

5 CONCLUSIONS AND IDEAS FOR FUTURE WORK

In AGAN maintenance policy, the technical state of the system is maintained to "as-good-as-new" after regular proof test meaning the system will not aggregate the negative effect of the regular proof test after maintenance. Hence, with AGAN we canmake PFD_{avg} as small as required by increasing the frequency of performing the proof test on the system. But using AGAN maintenance policy may not be economical in most of the practical situations, hence we focus on ABAO maintenance policy in this section.

5.1 *Conclusions*

Our case study showed that in case of ABAO maintenance policy, there are two competitive forces that can increase the PFD_{avg}. The first is the multiplicative negative effect of frequent proof tests, despite the maintenance that is carried out as part of the tests. This force becomes more dominant when the frequency of performing proof test is high. The second is the information obtained about the status of the system by carrying out the proof test. While the second force would like to increase the frequency of performing the proof test to lower PFD_{avg}. The first force would like to decrease the frequency of performing the proof test to obtain the same effect on the PFD_{avg}.

An optimum can be obtained for a regular proof test interval that can be verified against the constraints of the SIL requirement. It is therefore suggested that there exists an optimum frequency for performing the proof test that minimizes the PFD_{avg} of system whenever the following is true:

- The regular proof tests, that involves the inspection of technical state of the system, have some negative effect on the performance of the system due to test conditions and exposures.
- Some dangerous failure modes of the system can only be revealed by the regular proof tests, and not by other means (like e.g. diagnostic testing).
- System is maintained with the ABAO maintenance policy, meaning that the technical state is not "as-good-as-new" after a regular proof test. The ABAO maintenance policy will aggregate the negative effects of regular proof test.

5.2 *Ideas for future work*

The above studies were performed assuming no DD failures and mean time to repair as negligible. It would be an interesting proposition to see the effect of adding DD failures and mean time to repair to the above study. Analytical solutions need to be developed to find out the exact solution of the stochastic differential equation involved in the above situation. Two degraded states were chosen randomly in the above study, the connection between the physical phenomena of the degradation and quantification the degraded states needs to explored. Effect of the predictive maintenance and redundancies on the PFD_{avg} in this situation needs to be studied.

ACKNOWLEDGEMENTS

This paper has been written under the Norwegian Centre for Research based Innovation on Subsea Pro-duction and Processing (SUBPRO). The authors would like to thank the Research Council of Norway, as well to the industrial partners involved in this project.

Statistical comparison of three different measurement technologies

M. Hinz, A. Luecker & B. Bracke
Chair of Reliability and Risk Analytics, University of Wuppertal, Wuppertal, Germany

C. Klostermann
Klostermann Ingenieurbüro und Vertriebsgesellschaft mbH, Remscheid, Germany

ABSTRACT: Typical measurement technologies are coordinate measuring technology, structured-light 3D scanner and Computed Tomography (CT) scans. In this paper, an innovative measurement and analysis strategy for the statistical comparison of the mentioned technologies is developed. Furthermore, the measurement result can be proved with regard to the plausibility and sensitivity. This strategy can be used not only for the intern company purposes but also for the adjustment and harmonization of product and production improvement activities and corrective actions between original equipment manufacturers (OEMs) and suppliers. Plausibility checks of the gathered measurement results can be facilitated also in case of different applied technologies.

1 INTRODUCTION

To measure, to map and to analyse different parts or objects is interesting in many scopes of production respectively product development process. Especially in automotive, requirements on specification and product complexity is steadily increasing which requires high performance on measurement methods. Depending on product geometry, complexity and its critical specification, a proper measurement method has to be chosen.

Every measurement technology is basically suitable for the measurement of the product geometry but has also various advantages and disadvantages. Structured-light 3D scanner is well qualified for quick measurement of entire geometry but is sensitive for the creation of shades as well as product undercuts. An advantage of coordinate measuring technology is the high measuring accuracy of touched measure points which can be used for calculation and reconstruction of the actual product shape. In contrast, the measuring effort of explicit free-form surfaces is very high, which is a grate disadvantage of this method. Product cavities are measurable only after saw opening of a product in case of both, structured-light 3D scanner and coordinate measuring technology. A CT scan makes use of computer-processed combinations of many X-ray images taken from different angles and allows a survey of undercuts and cavities but cannot be used for all component materials (e.g. lead).

It is common that a complex geometry is measured with several, different measurement technologies in many practical applications. The problem is that the obtained results cannot be compared to each other due to different technology principles. It is uncertain whether all three technologies provide a sufficient precision of the product geometry or not.

Therefore, a study based on the statistical comparison of the three different measurement techniques regarding various dimensions of the measured objects is presented in this paper. Due to the overall understanding, first the measurement methods are discussed regarding the applicability as well as their advantages and disadvantages. In the subsequent part, the measured part, the material it is made of as well as the measured points are presented. The statistical methods used for the comparison, in this case the non-parametric statistical tests are discussed in detail. For the purpose of a sensitivity study, Monte Carlo simulated values of various dimensions are analysed first. In other words, it is necessary to understand the sensitivity of the tests before presenting and discussing the real measured values. Finally, the results are discussed in detail and the study is concluded.

2 MEASUREMENT METHODS

The following measurement methods have various advantages and disadvantages. In general there are three measurement methods, which were also used in this work:

- Coordinate measuring machine (CMM)
- Structured-light 3D scan method (3DSM)
- Computer tomography (CT)

Coordinate measuring machine is based on a tactile measuring method. Main components are the measuring head with a touch sensor, the measuring table and the positioning system with an incremental sensor technology. The measurement object and the measurement head move relative to each other; therefore CMM is suitable to measure space coordinates. In comparison to 3DSM and CT, CMM provides the best measurement result with highest measurement precision at the touched measurement points. Due to the relative movement of measurement object and head, measuring an object point by point takes a lot of time. Furthermore, it is difficult to measure objects with freeform surfaces and it is impossible to measure objects with undercuts in a non-destructive way.

The structured-light 3D scan method is an optical, non-contact method and structured by a projector and two cameras on a tripod. Measuring result is a point cloud of the surface of the measurement object and needs to be mapped by computer algorithms subsequently. It is also possible to create a CAD model out of these points. A quick measurement of the entire object is the big advantage of 3DSM and provides a good alternative to measure parts in a production line. Disadvantages are big scattering effects regarding measurement result and precision due to the creation of shades. Furthermore, it is not possible to measure objects with undercuts in a non-destructive manner.

Computer tomography is also called imaging method. It is constructed similar to an X-ray machine, whereby the operating principle is slightly different in comparison to an X-ray machine. The difference is that during a measurement with a CT a lot of images, out of various angles and directions, are made and recorded in a systematic way. Subsequently, a computer composes the recorded images with the help of complex algorithms and map them to a CAD model. CT method does not work very fast but it has the ability of measuring undercuts without destroying the measured object. Therefore, it is well suitable to measure complex objects and geometries. The measurement result and precision is strongly influenced by the material of the measurement object and lots of setup parameters of the machine itself. The thicker and the denser is the material, the more the measurement result and precision will be affected in a negative way due to the scattering effects.

3 MEASURED PART—DTM INTAKE SOCKET

3.1 *Geometry*

The part, that has been chosen for the study is an aluminium intake socket out of the DTM (German Touring Car Masters). Since the material it is made of is very important for the CT-measurement, a spectral analysis has been undertaken in order to define the proper material composition. The results are described in the following section.

The overall geometry was considered to consist of various measured dimensions as well as geometric tolerances. Furthermore, it was considered to have a complex, though still manageable complexity for the measurements. The chosen intake socket, presented in the Figure 1 was a good compromise of all these attributes.

Further requirements on the object were different specifications of the measurement units (in millimetre or degrees). The object was considered to consist of various surfaces, curvatures, as well as cavities and undercuts. The material had to be measureable in a CT. Is shall be additionally stated, that the found part was prepared and refurbished for the purpose of the study. The exact composition of the material was unknown at the beginning and had to be analysed before starting the measurements.

3.2 *Material*

As already stated in the previous section, the material the part has been made of, needed to be an appropriate one in terms of the applicability for the CT-system. Therefore, the chosen part had to be analysed first regarding the material composition. For this purpose, a small splinter has been removed in the inner part of the socket (in the upper flange) for the material analysis. Subsequently, the splinter has been prepared for the analysis which has been performed with the energy-dispersive X-ray spectroscopy (Lipták 2003). The result of the spectroscopy is shown in Figure 2.

Figure 1. Measured object—intake socket out of the automotive engineering.

The abscissa of Figure 2 shows the energy in [keV], and the ordinate sows the intensity in counts per minute [cpm] of a certain element in the composition. The main peak of the diagram indicates an aluminium alloy. Though, the proper estimation of the material composition cannot be performed without a material expert. Therefore, the overall estimation of the compound was discussed with a material scientist and provided the result (with a high probability) of an AlMgSi—wrought alloy.

The small amounts of other various elements are impurities. The analysed material is well suitable for the CT-measurement, since it is the aluminium wrought alloy.

3.3 *Measured points*

The chosen 19 points for the measurement are presented in Figure 3. The precise description of all point is out of scope for the purpose of this paper as well as not necessary for the understanding of the performed research, and will be therefore omitted. Nonetheless, the chosen points represent a variety of different lengths and angles with various geometric tolerances and tolerance specifications.

Though, the chosen points can be considered as representative for all parts of similar dimensions.

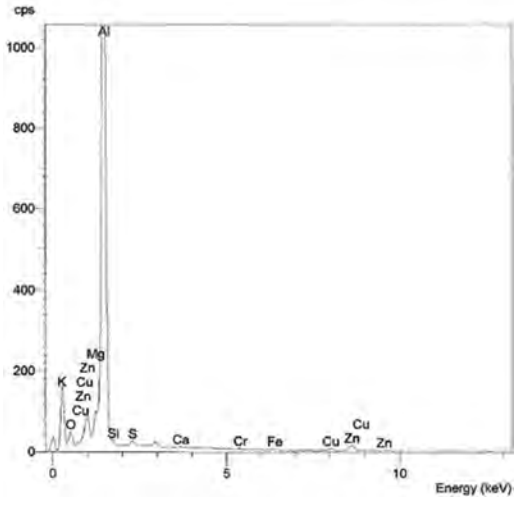

Figure 2. Spectral analysis of the material—intake socket out of the automotive engineering.

4 SAMPLE ANALYSIS BASED ON TEST STATISTICS

First step of the analysis of the measurements is the realisation of various hypothesis tests regarding the application of the proper analysis methods. Therefore, first the goodness of fit tests with the null (and alternative) hypothesis:

$$H_0 : F = F_0 \ \text{(and } H_1 : F \neq F_0\text{)} \tag{1}$$

that the sample data is distributed in a certain way (either normally or Weibull) has to be performed. For the normal distribution, Kolmogorov-Smirnov and Shapiro-Wilk (Hartung 1998) tests are common in use. Accordingly, Anderson-Darling, Kolmogorov—Smirnov and Chi-squared (Sachs 2009) tests can be applied for the Weibull distribution.

These testes are performed for two different tasks. First is the analysis of distributions regarding the measurement technologies itself, the second concentrates on the distributions of the measured points. The second analysis is mainly interesting for the different groups of geometric tolerances. In simple words, it shall be analysed, if e.g. the angles can be always fitted based on the same distribution function. The further purpose of the goodness of fit tests is the proper application of test statistics—parametric for the normal distributed samples and non-parametric in all other cases (Hinz 2014).

The goodness of fit tests applied for both cases provide heterogeneous results. It means, that no

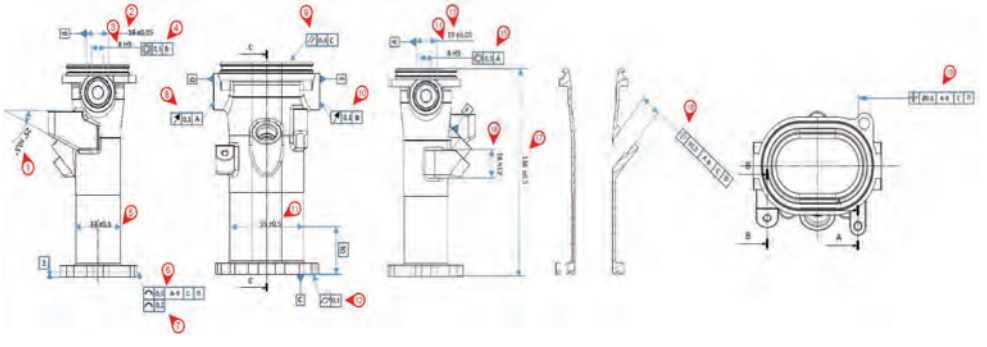

Figure 3. Measured points of the DTM socket.

specific distribution function can be fitted to all samples, either distinguished by the technology or by the measured points. Therefore, non-parametric statistics shall be applied for the further analyses.

For the comparison of samples, various significance tests according to different applications are available. Non-parametric significance tests do not require dependences on specific distributions. In comparison to similar application cases of parametric significance tests, further application cases and benefits such as simple calculation and detection of randomness of data are available.

For the purpose of this study, two nonparametric statistical tests were performed:

Mann-Whitney U test with the null (and alternative) hypothesis:

$$H_0 : F(z) = G(z) \quad (\text{and } H_1 : F(z) \neq G(z - \Theta)) \tag{2}$$

that the samples have the same focus, and

Levene's test with the null (and alternative) hypothesis:

$$H_0 : F(z) = G(z) \quad (\text{and } H_1 : F(z) \neq G(\Theta z)) \tag{3}$$

that the variances of the samples are equal.

A visual example of the statistical comparison based on the mentioned tests is shown in Figure 4.

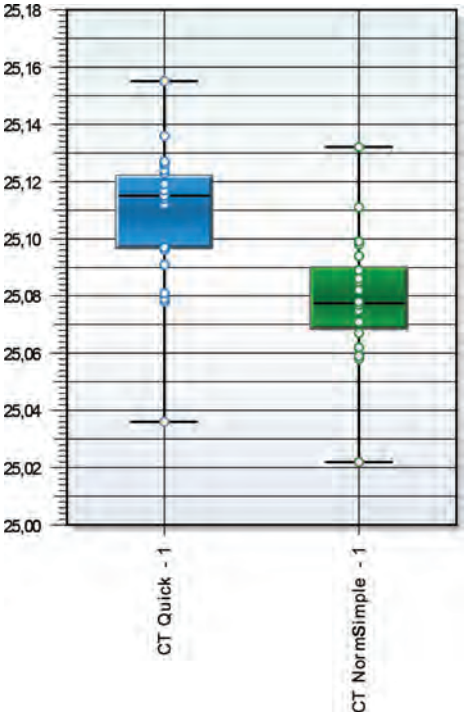

Figure 4. Boxplot—comparison of the samples.

Here, two different samples established with the CT-technology are statistically compared to each other.

5 SENSITIVITY STUDY

Preliminarily to the performed study based on real data, a sensitivity analysis was performed regarding the comparison of various samples based on simulated data. The main aim of the sensitivity analysis was the detection of critical boundaries, at which the test will distinguish the samples. In simple words, it shall be analysed when the samples can be defined as significantly different with regard to the measured value itself, the scattering of the value and the decimal digits with respect to the measurement technology.

For the purpose of the study, 27 various samples with sample size of 20 measurements were Monte-Carlo simulated according to the following conditions:

- All values are simulated with three decimal digits (due to the maximal resolution of the measured technologies)
- For every measured magnitude, three different values have been simulated: mean, upper specification limit, and lower specification limit
- All values were assumed to be normal distributed

Based on the given assumptions, different samples with different magnitudes has been simulated: 19 ± 0.05; 33 ± 0.5; and 136 ± 0.5, which provides all in all 27 samples. Note that all the values have no units, since the unit has no influence on the analysis itself and can represent any measurable value.

The simulated samples are analysed with both: Mann-Whitney U as well as Levene's test. Exemplary results are shown in Table 1. Here, the first column of the simulated value shows the simulated magnitude, the second shows the simulated scattering.

Table 1. Exemplary results of statistical analysis of simulated values.

Simulated value		U-Test	Levene's Test
$\mu = 19$	$s = 0{,}005$ vs. $s = 0{,}05$	$\mu_{005} = \mu_{05}$	$\sigma_{005} \neq \sigma_{05}$
	$s = 0{,}005$ vs. $s = 0{,}5$	$\mu_{005} = \mu_{5}$	$\sigma_{005} \neq \sigma_{5}$
	$s = 0{,}05$ vs. $s = 0{,}5$	$\mu_{05} = \mu_{5}$	$\sigma_{05} \neq \sigma_{5}$
$\mu = 33$	$s = 0{,}005$ vs. $s = 0{,}05$	$\mu_{005} = \mu_{05}$	$\sigma_{005} \neq \sigma_{05}$
	$s = 0{,}005$ vs. $s = 0{,}5$	$\mu_{005} = \mu_{5}$	$\sigma_{005} \neq \sigma_{5}$
	$s = 0{,}05$ vs. $s = 0{,}5$	$\mu_{05} = \mu_{5}$	$\sigma_{05} \neq \sigma_{5}$
$\mu = 136$	$s = 0{,}005$ vs. $s = 0{,}05$	$\mu_{005} \neq \mu_{05}$	$\sigma_{005} \neq \sigma_{05}$
	$s = 0{,}005$ vs. $s = 0{,}5$	$\mu_{005} = \mu_{5}$	$\sigma_{005} \neq \sigma_{5}$
	$s = 0{,}05$ vs. $s = 0{,}5$	$\mu_{05} = \mu_{5}$	$\sigma_{05} \neq \sigma_{5}$

The results of the statistical tests are shown in the columns U-Test (which is the short form of Mann-Whitney U Test) and Levene's test. It can be observed easily that only one hypothesis is rejected in case of the U-Test (seventh row) which means that the test statistics recognizes only one significant difference regarding the mean value. Though, it cannot be determined why this one particular test shows a significant difference. On the other hand, all test are rejected in case of the comparison of scattering of the samples. This means that independent on the magnitude of the simulated value, a factor 10 in the scattering will be always detected. This provides a very good detectability for the samples.

Since a detailed description of all results is out of scope for this paper, the most important results are summarized as follows: All 27 Levene's tests show a significant difference between the simulated scatterings. It means that a scattering with a difference of at least one magnitude can be always detected for such measured values. 26 of 27 U-tests (96.29%) show no significant difference between the samples regarding the focus of the sample. This means that a small scattering of the values has no influence on the detection of significance in the measured samples regarding the mean value. Furthermore, it means that once a significant difference will be detected in the measured samples, one can be sure that the technologies are significantly different.

Since no significant differences were determined in the scattering of the samples, a further analysis was performed. For this reason, further samples has been Monte-Carlo simulated based on the mentioned conditions with minor exception: The values are simulated with four decimal digits. Based on the assumptions, following samples has been simulated: 19 ± 0.002; and 19 ± 0.005.

All in all, 22 additional Mann-Whitney U and Levene's tests each were performed in the same manner. Once the scattering is much lower, the focus of the samples is much better differentiable. 18 out of 22 test show a significant difference regarding the focus of the samples. The variances are always differentiable based on the Levene's tests. This shows a very good applicability of the introduced hypothesis statistics.

6 ANALYSIS OF THE MEASUREMENTS

Based on the results and gained knowledge from the previous section, the measurements of the three described technologies shall be analysed. All measurements were performed 20 times for every technology each. Therefore, all discussed 19 measured points provide samples of 20 measurements. However, CT provides not the measured values itself, but.stl files which have to be additionally imported into a CAD program and processed. The.stl files are created based on the measurements and can be exported with very different qualities (the higher the number of elements in the.stl grid, the bigger the files). Therefore, different qualities of CT measurements were exported in order to analyse the quality of the mesh on the final results. The smallest.stl file was 120 MB and the biggest 3.5 GB big, which obviously determines also the export and calculation time.

The statistical test were performed exactly in the same manner as in case of the simulated values. All in all, over 250 statistical test were performed based on the measurements. The results provide the following conclusions:

- CMM has in 97.14% of all measurements a significant difference in the mean value
- CMM has in 98.85% of all measurements a significant difference in the scattering
- 3DSM has in 100% significant difference in both, mean and scattering, compared to CMM
- 3DSM has in 86.67% significant difference in mean value, compared to CT
- 3DSM has in 56.67% significant difference in the scattering, compared to CT
- CT has in 76.67% of all measurements a significant difference in the mean value

Basically, based on the gathered results, following statements are valid:

- CMM has a significant difference to the remaining technologies
- Based additionally on experience, it can be defined, that CMM is the most accurate technology
- The choice of the converting algorithm for the. stl files within the CT measurements has a significant influence on the quality of the results
- The difference between 3DSM and CT cannot be observed—both technologies has the same measuring accuracy

7 CONCLUSIONS

A very comprehensive study regarding the comparison of three different measuring technologies is presented in the present paper. For this purpose, an aluminium DTM socket has been measured on 19 different points. For the purpose of the comparisons, nonparametric test has been chosen and classified as suitable.

For the purpose of a sensitivity study, a number of samples has been Monte-Carlo simulated and analysed. It has been proven, that the chosen test

provide satisfactory results regarding the differentiability of the measured samples.

The analysis of the results show many significant differences, which means that the technologies itself are significant different, whereby the CMM is the most accurate one.

Based on the results of the analysed measurements as well as the advantages and disadvantages of the technologies, the decision about the application of the proper technology within a certain industry can be performed easily.

Machine learning modeling for massive industrial data: Railroad peak kips prediction

C. Contreras, M. López-Campos, P. Escalona, R. Stegmaier & T. Grubessich
Department of Industrial Engineering, Universidad Técnica Federico Santa María, Valparaíso, Chile

ABSTRACT: The exponential growth of industrial data being generated by sensors, modern equipment and devices is pushing the service sector to use more sophisticated analytics tools that can produce useful knowledge and predict certain events, especially for those which require reducing loss through preventive maintenance. This work presents the application of big data analytics for machine learning processing through a railway company problem approach, using one of the most powerful tools for large scale data management: the open-source Apache Spark platform. The practical implications of this, are in a reliable prediction of the condition of trains before being loaded and sent to a destination.

1 INTRODUCTION

The exponential growth of industrial data being generated by sensors, modern equipment and devices is pushing the service sector to use more sophisticated analytics tools that can produce useful knowledge and predict certain events, especially for those which require reducing loss through preventive maintenance.

However, processing large scale datasets and building predictive models with advanced algorithms, demands high efficiency in iterative computation tasks. In the last years, the open-source platform Apache Spark has experienced rapid growth due its outstanding performance and wide range of settings, which makes it well-suited for the development of machine learning (ML) applications using popular programming languages such as Java, Python, Scala and R.

This work shows how to build a predictive model in simple steps using the Spark environment for structured massive data manipulation. This model will consist of a decision tree for binary classification and a sensitivity analysis performance adjusting the main parameters. For academic purposes, the modeling will be set up on a pseudo-distributed single node cluster in Ubuntu 16.04, and the datasets loaded to Hadoop Distributed File System (HDFS), a reliable storage for large files that allows parallel processing, and Apache Spark 2.2.0 framework.

2 PROBLEM STATEMENT

In the railroad industry, the train wheels are critical components in terms of safety and one of the main priorities due their probabilities of failure, which may imply catastrophic consequences. One of the main concerns of the maintainers, is to be able to predict if according to several factors as the condition of the wheels, the size of the load to be transported, the distance to travel and the conditions of the road, the vehicle is suitable for go on a trip, ensuring its arrival on time and without problems to the destination. Otherwise, the necessary actions should be taken. The use of technology and especially counting on reliable databases, as well as mechanisms to provide intelligence and structure that data in predictive models, is relevant to support such decision-making.

Thanks to the development of new sophisticated sensors such as wheel impact load detectors (WILD) it is possible to monitor structural health trends and spot the critical wheels which need to be removed. However, setting out a car when it is loaded will cause a lot of loss to railroad companies, among other problems such delayed shipment and unnecessary disruptions in the network traffic. This situation urges the need of developing predictive models that can be used to project if a total vertical force imposed to the rails (denoted as peak kips) is above to certain values in the next loaded status. The WILD system scans millions of wheels per day throughout the international rail industry (Stratman, 2007), and it will provide us useful empirical datasets for training and testing for this endeavour.

3 PROPOSITION FOR METHODOLOGY

In real world applications, the data provided by different sources is not always structured. It needs to be preprocessed in order to generate the inputs to feed machine learning algorithms. In this particular case,

we propose the following framework for the creation and validation of a wheel peak kips predictive model.

3.1 *Machine learning data pipeline*

Data pipeline represents the flow of data for the machine learning process. This starts with a set of massive raw data which needs to be pre-processed and then fed to the machine learning algorithm. There are a large number of machine learning algorithms and different classifications, according to the type of problems they address (regression, classification, etc.), according to the data processing (linear, tree-based, neural network models) among others classifications. The ML algorithm learns, based on the fed data, to predict the future behavior of new supplied data. This is called "training" an algorithm. Subsequently, the data thrown by the ML algorithm need to be interpreted to finally obtain a diagnosis that is helpful in decision making. The entire process from the obtaining and pre-processing of raw data, to the interpretation and use of the predictions requested by the final users, is the called ML data pipeline.

The development and assembly of pipeline components need to support distributed computation and other requirements regarding data treatment, including fault tolerance, resource management, scalability and maintainability. This makes Apache Spark a very useful and reliable environment due its fundamental data structure for parallel processing (Resilient Distributed Datasets), and the Scala DataFrame API that allows to process from Kilobytes to Petabytes of data on a single node cluster and perform operations with only a few lines of code.

Figure 1 summarizes the steps followed by the ML data pipeline used in this work.

3.1.1 *Step 1: Data ingestion*

Data ingestion refers to the process of obtaining data to be used in the ML data pipeline. Data ingestion implies a non-trivial process of prioritizing data sources, validating the data obtained and sending them in an orderly manner to their next destination. All this must be done quickly and reliably so as not to lose information, especially when it is collected in real time. As previously mentioned, WILD system is the source of the two datasets used in this project: a training dataset and a testing dataset. These files contain the exhaustive information about a great number of variables monitored in relation to the performance of train wheels. It has very complete mechanical and physical information about the condition of each wheel, at each moment, corresponding to specific cars, trains and trips.

Data ingestion of the mentioned databases will be done using the Hadoop Distributed File System (HDFS), a reliable storage and highly fault tolerant for large files, and specially designed to be

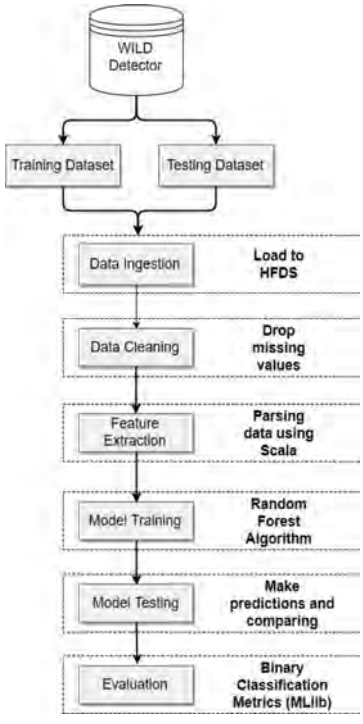

Figure 1. Machine learning data pipeline process flow diagram.

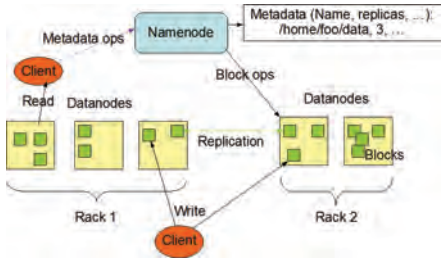

Figure 2. HDFS Archiquecture.

deployed on low-cost hardware. Its architecture is shown in Figure 2.

This distributed file system follows a master/slave architecture, the Namenode and Datanodes, respectively. For example, we have running five computers with 500 Gigabytes of storage each one with Hadoop environment installed. Accessing the storage from any of these five machines will work as a single large machine with total capacity of 2,5 Terabytes. This is when parallel processing can take advantage: if one single machine makes a task that takes 20 minutes with 500 Gigabytes of data, ten of them can complete such task in only 2 minutes.

In our particular case, the training and testing datasets consist in tabulated text files of 1.000

and 500 Gigabytes corresponding to 7 million and 2,5 million of rows, respectively. Both have headers with the name of the 22 features including the label, i.e. the values that we want to predict (peak kips). In our local machine terminal, the following commands are used to load these files:

```
>hadoop fs–put /localpath/training.tsv /training
>hadoop fs–put /localpath/testing.tsv /testing
```

3.1.2 *Step 2: Data cleaning*

Data cleaning is considered as a main challenge in the era of big data due to the increasing volume, velocity and variety of data in many applications (Tang, 2014). It is the process of detecting, fixing or removing incorrect and misleading records.

Having dirty source inputs is very likely and it can easily trigger runtime exceptions and therefore, terminate our whole process in Apache Spark.

There are several solutions and tools for data cleaning. In the Scala programming language, the main utility to achieve this task are the instances *Try*, *Success* and *Failure*.

```
> // Object to transform peak kips to binary
> def b(y: String): String =
> if (y.toDouble > = 90) "1" else "0"
>
> // Load from HDFS and clean data
> val file = sc.textFile("/training")
> val file2 = file
>      .map(_.split("\t")).
>      .flatMap(c = > Try{ b(c(1)+...)}.toOption)
```

3.1.3 *Step 3: Feature extraction*

Feature Extraction is a kind of dimensionality reduction that efficiently represents an initial set of data. The resulting reduced set is a non-redundant and good representation of the most relevant information of the entire data. Then, the following modeling training and testing processes can be executed over this reduced set of features (feature vector) instead over the complete initial database.

Since the incorporation of the Dataframe API to Spark in 2015, data processing and functional transformations have become much easier to code in general-purpose programming languages, and at the same time their performance have been improved. For the realization of this work, the selected features appear in Table 1.

3.1.4 *Steps 4 and 5: Model training and testing*

To train the data, we will use as ML algorithm, the Random Forest model for classification. One of the main advantages of this algorithm is that it does not require assumptions of normality of variables and it can deal with highly correlated and non-linear relationships between them.

Basically, the decision trees are built as it follows:

Table 1. Description of selected features.

Feature Name	Description
LOAD_EMPTY	Binary variable that indicates whether de equipment is loaded or empty
EQP_GRS_TONS	The tonnage of the equipment that the wheel is part of
EDR_EQP_SPD	The speed of the wheel at the time of the WILD measurement
TARE	Weight of the car when empty (in tons)
GRS_RAIL_WGT	The tonnage that the particular wheel type can sustain

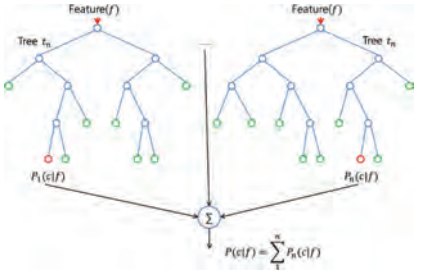

Figure 3. Graphical representation of a Random Forest decision tree.

- Randomly select *f* features from available features *F*
- Compute the best split point for tree *t* using the determined splitting metric (in our case of study, *Gini Impurity*), and split the current node into child nodes and reduce the number of features *f* from this node on
- Repeat steps 1 to 2 until either a maximum tree depth has been reached
- Repeat steps 1 to 3 in order to create a T number of trees

The result can be represented in Figure 3.

In the Spark platform, the generic code for building the model can be written as it follows:

```
> val model = Random-
Forest.trainClassifier (trainingData, numClasses,
categoricalFeaturesInfo, numTrees, featureSub-
setStrategy, impurity, maxDepth, maxBins)
```

3.1.5 *Step 6: Evaluation*

One of the most effective methods of evaluating the performance of a binary classifier system is the receiver operating characteristic (ROC) curve, which is defined as a plot of the true positive rate (y coordinate) against the false positive rate (x coordinate). Accuracy is measured by the area under the ROC curve (AUROC), and it's represented by the Equation (1)

$$AUROC = \int_0^1 \frac{TP}{P} d\left(\frac{FP}{N}\right) \quad (1)$$

This value fluctuates between 0,5 to 1, where 0,5 denotes a null prediction capacity, and 1 a perfect classifier.

To compute the raw scores on the test set, we can code the following lines:

```
> val predictionAndLabels = test.map {case
LabeledPoint(label,features)=>valprediction=
model. Predict(features)
 (prediction, label)}
> // Instantiate metrics object
> val metrics = new BinaryClassificationMet-
rics(predictionAndLabels)
> // Area under the ROC curve
> val auROC = metrics.areaUnderROC
> println("Area under ROC = " + auROC)
```

In addition, we can provide a simple sensitivity analysis by modifying the number of trees (numTrees) and maximum depth (maxDepth) to calculate the different values of AUROC (1).

4 RESULTS

As we can see in Table 2, the area under the receiver operating characteristic (AUROC) does not experience major fluctuations.

The most accurate model has 4 trees and maximum depth of 6. We can say that there is a 78% of probabilities that a defective train wheel will activate the alarm in the next loaded status predicted by the model (peak kips > 90) than a randomly chosen one. This represents the accuracy of prediction of the model.

5 DISCUSSION AND CONCLUSIONS

This work presents an application of big data analytics for machine learning processing with a railway company problem approach and using open-source tools. According to the obtained results, we can stand that the application of this methodology is adequate and valuable as a decision-making support, jointly used considering the experience of personnel, maintainers and technicians. At the same time, future analyzes can be tried to increase the predictive performance of the tool used in this project, for example, try to consider more features for the modeling, using a computer with more processing capacity.

We want to highlight the multipurpose Random Forest algorithm that can be used in many industrial sectors, in this case for preventive maintenance. Its outstanding performance is usable to get valuable predictive information that can be translated into new opportunities. However, due to limitations in hardware (settings on a single node cluster), training models with even larger input datasets may have a wide margin of improvement in terms of accuracy and processing speed.

Table 2. Area under ROC curve according to the parameters.

	Number of trees			
Max depth	3	4	5	6
3	0.7767	0.7708	0.7742	0.7702
4	0.7757	0.7828	0.7380	0.7812
5	0.7819	0.7632	0.7620	0.7622
6	0.7600	0.7864	0.7604	0.7622
7	0.7567	0.7660	0.7535	0.7622

ABSTRACT: The jacket structures are often employed in the range of shallow-moderate water depth. The bracing systems and jacket legs typically use the circular section in order to compromise the hydrodynamic resistance and high torsional rigidity However, under lateral impact, these tabular bracing members are susceptible to local denting due to ship collisions or through impact of falling objects and that can weaken overall performance of the entire platform. It is a great significance for forecasting dent depth of these members accurately. This paper investigates the use of adaptive meta-heuristics algorithm to provide an automatic detection of denting damage in an offshore structure. A model is developed combining with the percentage of the dent depth of damaged member diameter and is used to assess the performance of the method. It is demonstrated that the small changes in stiffness of individual damaged bracing members are detectable from measurements of global structural motion.

1 INTRODUCTION

Offshore jackets play an important role in the oil and gas industry. The risk of platform failure is a higher risk issue when operating an ageing platform. As a result, the need for the development of techniques necessary to assess platform integrity is clearly established. Several standards and recommended practices list a detailed inspection methods and requirements for the underwater, splash zone and topsides structures (May et al. 2008). For the oldest of operational ageing platforms, the assessment is quite challenging due to the existence of deterioration or dent-damage of structural elements due to collision or impacts. The change of dent depth can dramatically reduce the axial and bending capacities of the individual jacket leg members and weaken overall performance of the entire structure (Bruin, 1995). Therefore, accurate prediction of dent depth and dent direction angle would provide valuable information for the operations and maintenance operations at offshore platforms.

Karamanos and Andreadakis (2006) studied on denting of tubular members subjected to lateral loads. The loading condition is quasi static and the tubes are internally pressurized. The relation between denting force and displacements were evaluated through experiments and finite element simulations. Also relation between normalized forces and normalized denting displacements was deviated following both procedures. Wedge shaped denting tool was used in the experiment as well. Outcome of this research deliberates that the internal pressure in the tubular member increases the resistance against denting and reduce the denting length. Travanca and Hao (2014) discussed on the response of jackets on response to ship impact. Finite element formulations and calculations are derived to incorporate the dynamic aspects as well. The jacket was considered as a cantilever beam and the Degree of Freedom (DOF) was reduced for easiness of study. The outcome of the reduction of DOF was significant and showed similar outcome as from the FEM of original structure so far. Comparison of response time histories, deformation of modes, normalized deformation at different stages and the comparison of response histories from the original model and equivalent reduced SDOF model was contemplated for the parametric study. Moreover a four-legged jacket, a tripod jacket and a jack-up model were considered

for case study. Furthermore the effect of top mass are included and it is found that it is significant while the natural period has large value and the ratio of top mass and the jacket mass is high. Two stage dynamic analysis is also suggested to achieve more accuracy. Cosham and Hopkins (2004) illustrated on the dent effect on oil and pipelines which are especially used for oil and gas transmission. Different types of defects along with different types of dents are studied in this study. Burst strength and fatigue life are investigated for different types of dents. It was found that plain and smooth dent doesn't affect significantly on the burst strength but has effect on the fatigue life. Moreover, smooth dent reduces the fatigue life to a great extent. Kinked dents may be are dangerous for longitudinal cyclic stresses and are risky for external pressures with the internals. Moreover, it is noted that the smooth dent along with gouge is very unsafe considering both burst strength and fatigue which reduces considerably. Khedmati and Nazari (2012) explored the behavior of tubular members on response to impact loads. Strength and deformation characteristics are inspected in this work. Moreover the axial shortening behavior is also included. The effect of preloading and quasi static lateral load are also delineated. Storheim and Amdahl (2014) deliberates the design process of offshore platforms susceptible to ship collision. The ship-platform interaction is also represented. Four different collision contexts are incorporated. Force-displacements curves for different scenarios are interpreted. The outcome of the study suggested to revise the design specification for collision as the vessel size and bow configurations are changed a bit in recent years. Cerik et al. (2016) inspected denting damages in tubular members for low mass impact. Both experimental and numerical investigation was incorporated. It is observed that the numerical outcome has satisfactory similarity with the experimental test models. Local denting is considered along with the load-indenter displacements are also delineated. The deformation characteristics of single member with clamps are vastly studied. Cho et al. (2010) investigated the denting damage consequences of tubular members in offshore structures. Experimental denting test along with bending test was directed and a relation between dent depth and denting force was established. Moreover the residual strength of dented tubes can be predicted through the established equation which was derived from the relation of residual strength and bending moment. Cho et al. (2015) deliberated the response characteristics of impact loading in the context of tubular members in maritime structures. Drop test along with statistical analysis was carried out to predict the behavior against dynamic impact loading. Consequences of local denting and global bending were discussed elaborately from the experimental and numerical outcome. Minor dented damages due to ship collision could be the cause of major reduction of ultimate capacity and it was illustrated by Pacheco and Durkin (1988). Moreover, a geometrically ideal dent can represent the actual damage in case of finite element analysis and it is also delineated in this research. Li et al. (2013) focused on the ship collision consequences on the tubular members of Jacket structures. Both elastic and plastic behaviors are elaborated. Different scenario of ship collisions were assessed for substantial conclusions. It is reported that in case of larger deformation, the standard guideline underestimate resistance-indentation relationship. The elastic response from the vessel-platform impacts should be noted more carefully to comprehend significant effect of it in terms of energy absorption during impact.

The damage detection can be considered as a problem of system identification or an optimization inverse problem (Farrar and Worden, 2012). The optimization techniques can be used to quantify the unknown parameters of the damage. Over the last few decades, the adaptive meta heuristic and predicting control methods have become more widely used in several scientific research especially in the damage detection under ambient vibration (Miguel et al, 2012) and in the optimization design of fixed jacket offshore platform under environmental loads (Nasseri et al, 2014). Although much have been reported, very little have been done for the dent examination of circular member in the jacket structure which is the most common problem type to investigate the structural damage after ship collision. Intelligent computational techniques such as metaheuristics can be served to highlight areas where the sensor technologies and structural integrity monitoring techniques might be useful.

In this work, an optimization problem for offshore dent detection is posed to find percentages of dent in element diameters and impact angles. Five well established self-adaptive metaheuristics include JADE (Zhang & Sanderson, 2009), CMAES (Hansen, Muller et al., 2003), SHADE (Tanabe and Fukunaga, 2013), L-SHADE (Tanabe and Fukunaga, 2014), and ASCDE (Bureerat and Pholdee, 2017) are used to perform detection within a simulated damage scenario of a finite element reduced model of an offshore jacket platform. The efficiency and accuracy of each optimizer is discussed. Finally, the main conclusions and recommendations of future work are summarized.

2 DESCRIPTION OF AN OFFSHORE JACKET PLATFORM FOR THE ADAPTIVE META-HEURISTIC ANALYSIS

2.1 *Fixed offshore platform model*

The offshore jacket platform is modeled with the 3D frame elements to conduct the adaptive meta-heuristic analysis. The physical configuration of the jacket platform in side view along with the front view is available in Figure 1.

The offshore jacket platform is simulated to operate at the water depth 65.53 m. The topside of the jacket platform emerges above the sea water level 17.68 m. The bracing system of the jacket platform consists of two types (single bracing and the K bracing). The bottom bracing systems of the jacket structure is the K-bracing so as to compromise the connecting angle between chord and brace members more than 30 degrees to avoid the welding problem. The remaining of bracing systems is the single bracing to optimize the structural weight.

The top side of the oil and gas platform is simplified as a lumped mass for finite element analysis. The total weight of the topside is 2500 tons, which is equally distributed over four legs where each leg, is conveying 625 tons at the top connection of the jacket structures platform.

The structural members of the offshore jacket platform are utilized according to the design specifications (DNV-RP-C203, 2001). This jacket structure consists of 11 groups of tubular cross section. The element properties are listed in Table 1. All the structural members have the same material density and elasticity modulus. The location of structural elements with different colors for each groups are illustrated in Figure 2. The annotations of the colors are clarified substantially in Table 1. The formations of the groups are based on the outer diameter and wall thickness of the tubular section.

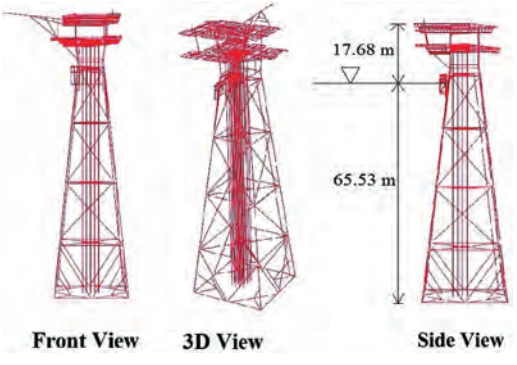

Figure 1. 3D and side views of offshore platform.

Table 1. Element properties.

Group name	Color indicator	Outside diameter	Thickness
G1		1.067	0.038
G2		0.457	0.010
G3		0.406	0.013
G4		0.356	0.010
G5		0.457	0.013
G6		0.356	0.013
G7		0.406	0.016
G8		0.324	0.010
G9		0.559	0.013
G10		0.559	0.019
G11		0.610	0.025

Modulus of Elasticity, E = 2.1 *10^{11} N/m^2;
Density of Steel = 7833 kg/m^3.

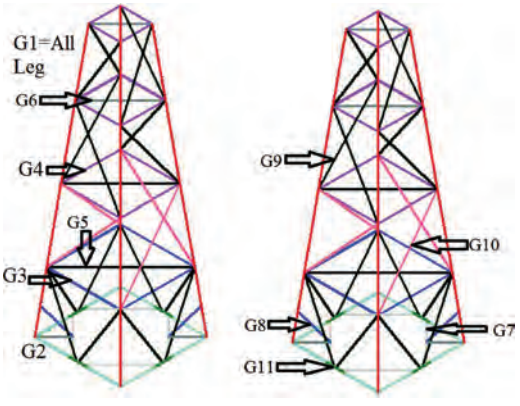

Figure 2. Member group specifications.

2.2 *Denting data and assumptions*

The assumption of denting members in the jacket platform comes from the consequences due to ship collision. There members from two different groups are assumed to be influenced due to ship collision. Member no 10 and 20 from G1 group and member no 88 from G9 group are the dented member. The vessel can impact to jacket platform in two directions either through bow or starboard direction. The location of dented members and impact direction are present in the Figure 3. Two members from leg and one bracing are impacted in according to the Figure 4. Denting is generally defined in terms of percentages of diameter reduc-

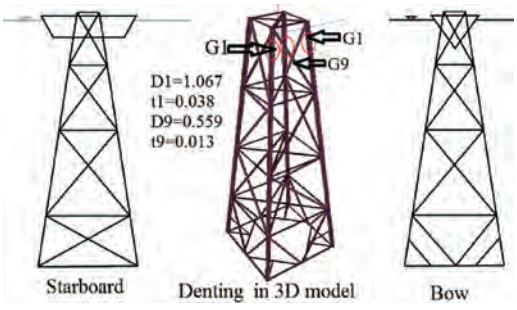

Figure 3. Ship collision and denting in members.

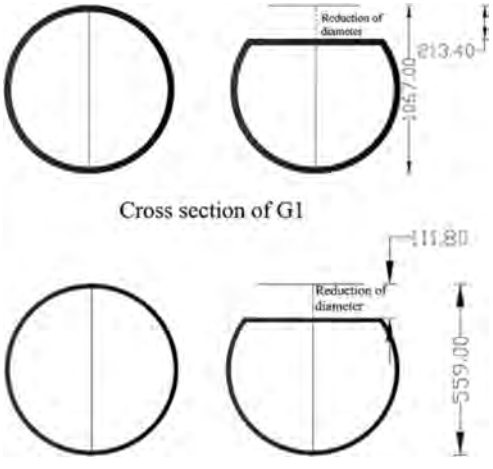

Figure 4. Denting sample in G1 and G9.

Table 2. Element groups of the jacket structure.

Group name	Element numbers	Outside diameter
G1	1–20	In element 10 & 20
G2	21–28	No denting
G3	29–32	No denting
G4	33–44	No denting
G5	45–52	No denting
G6	53–60, 117–120	No denting
G7	61–68	No denting
G8	69–72	No denting
G9	73–80, 85–92	In element 88
G10	81–84	No denting
G11	93–116	No denting

For members 41–44 and 57–60, are the members above the water level.

tion as per different code of practices (ISO 19901-3, 2014).

A sample of denting configuration for both type of members G1 and G9 are illustrated in Figure 4.

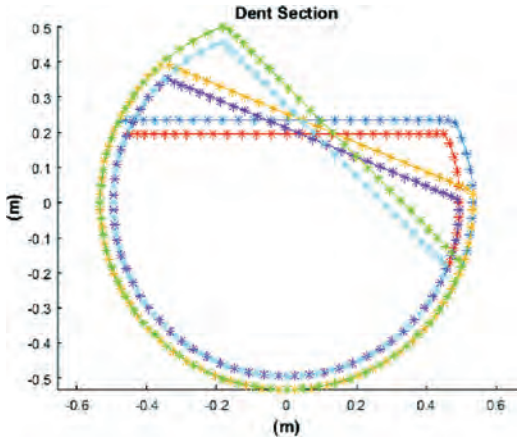

Figure 5. Denting of members for rotation of axis.

In this sample, 20% denting is contemplated. The diameters of the members as well as the dented length are identified in the following figure as well. Due to the denting effect, the stiffness of the member will be changed because of the changing of cross-sectional area and the moment of inertia but the mass will be unchanged.

It is assumed in this study that a single point of dented section will affect the whole member length. Moreover in reality, it is often not fixed whether the denting will occur along a certain axis or not.

As shown in Figure 5, the denting can occur in different angles if vessel impacts to the platform in the different direction of attack angle. The different local angle of denting member, as shown in Figure 5, can have different moments of inertia about two different axes. But the area will remain the same. For this reason, the angle for denting direction is also considered in this investigation and the range of the angle is between 0 and 360 degree. That is the ship can attack the offshore jacket platform from any direction and the denting can be occurred in any angles.

3 OPTIMIZATION PROBLEM OF OFFSHORE DENT DETECTION AND NUMERICAL EXPERIMENT SETUP

3.1 *Frequency and mode shape changes*

Dent detection of the offshore structure as detailed in the previous section is performed using vibration based damage detection. The main concept of vibration based damage detection is that updated mechanical properties of a mathematical model such as a finite element model and the modal data such as natural frequencies of the model agrees well the measured modal data. Damage of the

structure is identified by the detecting changes of the mechanical properties.

In this work, an optimization problem for offshore dent detection is posed to find percentages of dent in element diameters (P_d) and impact angles (θ) which consequently lead to the changes of mechanical properties (cross section area, second moment of area along y and z direction) and natural frequencies of the offshore structure. Since the natural frequencies can be accurately measured, an objective function in this case can be constructed in terms of changes in natural frequencies.

The percentage of dent damage in the tabular element can be found by solving an optimization problem to minimize the root mean square error (RMSE) between natural frequencies measured from the dented structure and natural frequencies computed by using the finite element model. The problem can be expressed as:

$$\text{Min: } f(\mathbf{x}) = \sqrt{\frac{\sum_{j=1}^{n_{mode}} \left(\omega_{j,damage} - \omega_{j,computed}\right)^2}{n_{mode}}} \quad (1)$$

where $\omega_{j,damage}$ and $\omega_{j,computed}$ are the structural natural frequency of mode j obtained from a dented structure and that from the finite element model respectively. A vector $\mathbf{x}$ is a set of design variables including percentages of dent in element diameters and impact angles ($\mathbf{x} = \{P_{d1}, P_{d2}, \ldots, P_{d,n}, \theta_1, \theta_2, \ldots, \theta_n\}^T$).

In this work, only element numbers 5, 10, 15, 20, 86, 88, 90 and 92 which are located at the sea level are set to have dent possibility. Therefore, the total number of design variables is set to be 16 (8 for percentages of dent in element diameters and other 8 for impact angles of the elements). The possibility of percentages of dent is set in rang of [0, 0.7] while impact angle is set in the set of {0, 22.5, 45}.

3.2 *Numerical experiment*

To investigate the search performance of optimization methods on solving the proposed problem of dent detection of the offshore structure, the percentage of dent in element diameter and impact angle are pre-defined while natural frequencies are simulated by means of finite element analysis instead of using real measuring data. The percentages of dent in element diameters and impact angles are set as 0.3 percent dent at elements 10, 20 and 88 with impact angles of 0, 22.5 and 45 degrees respectively. Natural frequencies for the first six modes of the dented and undented elements (as shown in Table 3) are used for the objective function calculation.

Table 3. Natural Frequency (Hz) up to six mode.

Modes	Undented	Dented
1	0.680	0.674
2	0.690	0.714
3	0.919	0.989
4	2.506	2.507
5	2.527	2.527
6	3.179	3.145

To minimize the objective function, five well-established self-adaptive meta-heuristics (MHs) are used. Details and notations of these methods are available in the literature in the corresponding references of the methods and will not be detailed here. The MHs used include:

- Adaptive Differential Evolution (JADE) (Zhang & Sanderson, 2009).
- Evolution Strategy with Covariance Matrix Adaptation (CMAES) (Hansen, Muller et al., 2003).
- Success-History Based Adaptive Differential Evolution (SHADE) (Tanabe & Fukunaga, 2013).
- SHADE with Linear Population Size Reduction (L-SHADE) (Tanabe & Fukunaga, 2014)
- Adaptive Sine Cosine algorithm with integrating Differential Evolution mutation (ASCDE) (Bureerat and Pholdee, 2017)

Each optimizer is used to solve the offshore structure dent detection test problem for 10 optimization runs. The population size is set to be 30 whereas the number of iterations is set to be 300. All methods will be terminated with two criteria: the maximum numbers of functions evaluation as 30×300, and the objective function value being less than or equal to 1×10^{-3}.

4 RESULTS AND DISCUSSIONS

After performing 10 optimization runs of all MHs on solving the offshore structure dent detection optimization test problem, the results obtained are given in Table 4. The mean of objective function are used to measure the algorithm rate of convergence in cases that the objective function threshold (1×10^{-3}) is not reached during searching. Otherwise, the mean number of FE runs is used as an indicator. The number of successful runs out of 10 runs is used to measure the search consistency. The algorithm that is terminated by the objective function threshold is obviously superior and any run being stopped with this criterion is considered a successful run (Bureerat and Pholdee, 2017).

Table 4. Comparison results among each optimizer.

Optimizers	Mean Obj.	Mean FEs	No. of successful run
CMAES	0.02428	8166	1
JADE	0.03626	8268	1
SHADE	0.03886	8367	1
LSHADE	0.02903	9000	0
ASCA	0.00095	2148	8

Table 5. The best results on finding the percentages of dent and impact angles obtained from all optimizers.

No	Simulated dent	CMAES	JADE	SHADE	LSHADE	ASCA
10	0.3	0.36	0.50	0.47	0.19	0.26
20	0.3	0.07	0.17	0.18	0.01	0.35
88	0.3	0.29	0.23	0.17	0.00	0.30
5	0	0.13	0.13	0.19	0.27	0.05
15	0	0.00	0.00	0.00	0.16	0.00
86	0	0.27	0.06	0.08	0.70	0.00
90	0	0.00	0.00	0.00	0.01	0.00
92	0	0.00	0.00	0.00	0.01	0.00
No	Simulated impact angle	CMAES	JADE	SHADE	LSHADE	ASCA
10	0	45	22.5	45	0	45
20	22.5	45	45	22.5	45	0
88	45	22.5	22.5	45	–	0
5	–	45	22.5	45	45	0
15	–	0	–	0	45	–
86	–	22.5	0	22.5	22.5	–
90	–	–	–	–	0	–
92	–	–	–	–	0	–
ω_1(hz)	0.674	0.674	0.675	0.673	0.672	0.673
ω_2(hz)	0.714	0.715	0.713	0.714	0.716	0.714
ω_3(hz)	0.989	0.989	0.988	0.989	0.988	0.989
ω_4(hz)	2.507	2.507	2.507	2.507	2.505	2.507
ω_5(hz)	2.527	2.527	2.527	2.527	2.527	2.527
ω_6(hz)	3.145	3.146	3.146	3.145	3.149	3.145

From Table 4, it can be seen that the best performer based on mean objective function values is ASCA while the second best and the third best algorithms are CMAES and LSHADE, respectively. When considering the number of successful runs, ASCA is said to be the most efficient optimizer which can detect the percentage of dent in element diameters and impact angles for 8 times out of totally 10 optimization runs with the average of 2,148 function evaluations.

Table 5 shows the best results on finding the percentage of dent and impact angles obtained from all optimizers. It was found that MHs will only detect impact angle values in the elements having percentage of dent higher than zeros. From Table 5, it can be observed that ASCA can correctly detect the percentages of dent in the offshore structure while the others failed to achieve such results. For the impact angles, the results of all optimizer are not accurate and need further improvement. One idea of such improvement is to introduce some nodal displacements that can be picked out of numerical mode shapes in the objective function, which will be explored and presented in future work.

5 CONCLUSIONS AND RECOMMENDATIONS

Five meta-heuristics optimizers were tested for the the dent damage of circular member in the jacket structure. The damage detection problems are based on vibration measurement and can be treated as an inverse optimization problem. The comparative results reveal that the ASCA is outstanding for predicting denting diameter but not denting angles. The results from ASCA could be use as the baseline for further improvement and investigation of dent damage examination using meta-heuristics.

Strategic view of an assets health index for making long-term decisions in different industries

A. De la Fuente, A. Guillén, A. Crespo, A. Sola, J. Gómez & P. Moreu

ABSTRACT: An Asset Health Index (AHI) is a tool that processes data about asset's condition. That index is intended to explore if alterations can be generated in the health of the asset along its life cycle. These data can be obtained during the asset's operation, but they can also come from other information sources such as geographical information systems, supplier's reliability records, relevant external agent's records, etc. The tool (AHI) provides an objective point of view in order to justify, for instance, the extension of an asset useful life, or in order to identify which assets from a fleet are candidates for an early replacement as a consequence of a premature aging. This paper develops a model applicable to different classes of equipment and industrial sectors. A review of the main cases where the asset health index has been applied is included. Likewise, advantages and disadvantages in the application of this kind of tools are revealed, providing a guide for a research line related to the general application of this tool.

1 INTRODUCTION

Nowadays, network operators are facing many challenges in their assets management. There is an increasing trend for stakeholders (safety, reliability, environment, and financial impact) while assets are aging, increasing the risk of failure. The need to estimate the expected time to failure becomes more relevant every day, and planning for an optimal replacement or maintenance program to renew assets becomes even more essential. By having a large amount of assets, the maintenance manager's challenge is to decide which assets require more attention and what actions should be taken. The complexity of this decision increases because each asset class has different failure modes, and each failure has different consequences in the asset network (Vermeer et al. 2015).

The objective of this contribution is to highlight the most relevant recent studies related to the asset health index. The concept of asset health index (AHI) and its application appear throughout this document. The different models will be divided into three parts. The first part deals with data gathering and their treatment, the second part corresponds to the index composition, and the third part is the output of results and recommendations related to the index value. As a final part of the contribution, limitations of the models and the future scope of asset health index are discussed.

2 CONCEPT OF AN ASSETS HEALTH INDEX

An Asset Health Index (AHI) is an asset score, which is designed, in some way, to reflect or characterize the asset's condition and thus, its performance in terms of fulfilling the role established by the organization.

AHI represent a practical method to quantify the general health of a complex asset. Most of these assets are composed of multiple subsystems, and each subsystem can be characterized by multiple modes of degradation and failure. In some cases, it may be considered that an asset has reached the end of its useful life, when several subsystems have reached a state of deterioration that prevents the continuity of service required by the business (Hjartarson & Otal 2006). Therefore, the health index, based on the results of operational observations, field inspections and laboratory tests, produces a single objective and quantitative indicator. It may be used as a tool to manage assets, to identify capital investment needs and maintenance programs (Naderian et al. 2008). In addition to condition and operation factors, the health index requires also to contain static factors linked to its location. That means, when environmental conditions are changed independently of the asset itself or the lack of any other change over time (Scatiggio & Pompili 2013).

The critical objectives in the formulation of a complex Health Index are as follows (Hjartarson & Otal 2006):

- The index should be indicative of the asset suitability for a continued service and representative of the overall asset health.
- The index should contain objective and verifiable measures of asset condition, as opposed to subjective observations.
- The index should be understandable and readily interpreted.

3 MODELS

Next, four different models from the literature (proposed for the calculation of an asset health index) will be studied. In general terms, they all have inputs to the model that can be data related to condition, equipment operation, the availability of spare parts used in the maintenance and, in some cases, information from the geographic location.

For the algorithms used in the index calculation, it will be seen how in the different models, all the information sources are integrated by weighting factors and depending on the maturity level of the model implemented in each sector. Likewise, the output study for each model and their recommendations is shown.

The following scheme (Figure 1) represents the concept of an AHI. It tries to compile the different inputs to the model from the literature consulted, and the different outputs for making long-term decisions (Azmi et al. 2017). It is important to highlight that this paper is focused on making long-term decisions. In any case, there are also AHI models that are used as tools in the field of Prognostics and Health Management (P.H.M.) (Ludovic et al. 2011) (Abichou et al. 2012; Abichou et al. 2015).

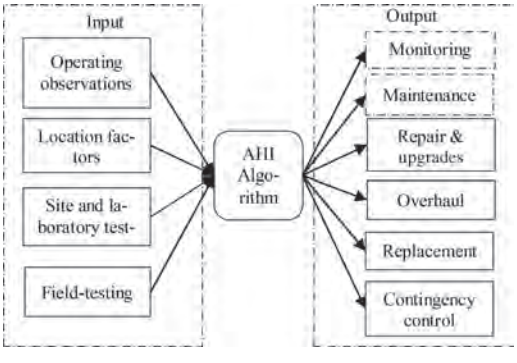

Figure 1. Concept of the health index within an asset management framework.

3.1 *Asset health index calculation model by Kinetrics*

The model developed by Kinetrics, Canada, proposes the overall assessment of transformers condition. The inputs to the model are data from different variables related to the operation and condition of the equipment throughout its useful life. The calculations for each variable, as well as detailed assessment are used to normalize the values, weighting them with corresponding weights and building a personalized asset health index.

3.1.1 *Inputs*

The inputs of the model, are the historical data of the variables of operation (load, number of operations, etc.), the results of oil samples labs tests (Oil quality, content in dissolved gases, acidity, etc.) and on-site tests carried out by technicians, such as insulation tests, thermography, corrosion status, etc.

3.1.2 *Index calculation methodology*

The methodology proposed for the index calculation is based on the normalization of each variable into a value between 0 and 4, together with a variable weight for the final composition in a single indicator.

As an example of standardization for the results obtained at a laboratory test, the following chart (Table 1) shows the link between concentration of dissolved gases in transformer oil and aging. In the table, concentrations of different dissolved gases are weighted, according to their relationship with the aging of the asset. Therefore, gases with greater weight are those that appear when the asset has reached a certain level of aging (Naderian et al. 2008).

Equation 1 below, calculated from the results of gases dissolved in oil, refers to the variable value which is one of the inputs to the AHI.

$$LTC\ Oil\ Quality = \frac{\sum_{i=1}^{4} S_i x W_i}{\sum_{I=1}^{4} Wi} \quad (1)$$

For the variables, the author proposes a weight between 1 and 10. Values close to 1 are assigned

Table 1. Concentration in ppm of gas dissolved in oil.

	Gas in oil concentration in tap changer				
Gas	ppm	ppm	ppm	ppm	W_i
CH_4	<50	50–150	150–250	≥250	3
C_2H_6	<30	30–50	50–100	≥100	3
C_2H_4	<100	100–200	200–500	≥500	3
C_2H_4	<10	10–20	20–25	≥25	3
Score (S_i)	1	2	3	4	

to variables whose relationship with the aging of the equipment is very small or null. On the other hand, for variables that take higher values (higher than 5 points), they are condition variables that more accurately reflect the aging of the equipment. The operating variables, such as the load factor of transformers and the power factor, are also related to the equipment aging speed, because they are good indicators showing when the equipment operates outside the design conditions.

3.1.3 *Model outputs*

For the model output, the author proposes a composition of all normalized variables in a single indicator ranging between 0 and 100. The value of 100 corresponds to a value of new equipment and the value of zero refers to a piece of equipment that has reached the end of its useful life, requiring to be replaced because it is already out of service. The following equation 2 is proposed by the author for calculating the health index (Naderian et al. 2008).

$$HI = 60\% \frac{\sum_{j=1}^{17} K_j HIF_j}{\sum_{j=1}^{17} 4K_j} + 40\% \frac{\sum_{j=18}^{20} K_j HIF_j}{\sum_{j=18}^{20} 4K_j} \quad (2)$$

The index value is related to a failure probability of the equipment, being divided into different ranges with their respective interpretations and recommendations. For the different index output ranges, some recommendations and measures are proposed in order to be taken into account for decision making in maintenance management. The following Figure 2 shows the relationship between the health index and the probability of failure (Naderian et al. 2009).

3.2 *Asset health index calculation model by DNV GL*

This model developed by DNV GL, Arnhem, the Netherlands, proposes a methodology for the calculation of a health index, calculated from the maximum admissible failure rates for the business, together with the asset criticality, in order to obtain an index to prioritize maintenance, overhaul and substitutions of parts. It uses as input variables the estimated useful life of the equipment, the current age and condition variables (load, on-site condition analysis, maintenance number, etc.). The output of this model is the remaining useful life of the equipment in years (Vermeer et al. 2015).

3.2.1 *Inputs*

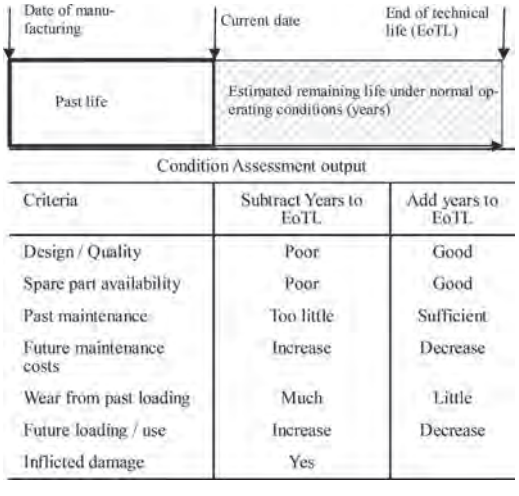
The model uses the useful life of the equipment as static data; this allows making a first estimation that will be corrected later with the information of the asset's condition and, at the same time, with the failure modes that appear throughout the asset life cycle.

3.2.2 *Index calculation methodology*

The methodology proposed by the author, is separated into three large blocks, depending on the type of data entry. The blocks are called as degradation function, static function and condition function. The model output is the relationship between the different functions for determining the health index, which is in this case the equipment remaining life.

The model application requires a previous estimation of the asset average age based on historical data. This average life becomes a technical life average that is later corrected with the specific condition data of the asset. In a simple way, the model increases or decreases the end of the asset technical life, depending on the real asset condition at the moment of its analysis, Figure 3, (Vermeer et al. 2015).

Figure 2. Asset health index ranges and the relationship with the probability of failure.



Condition Assessment output

Criteria	Subtract Years to EoTL	Add years to EoTL
Design / Quality	Poor	Good
Spare part availability	Poor	Good
Past maintenance	Too little	Sufficient
Future maintenance costs	Increase	Decrease
Wear from past loading	Much	Little
Future loading / use	Increase	Decrease
Inflicted damage	Yes	

Figure 3. Estimated remaining life corrected with the specific condition data of the asset.

3.2.3 *Model outputs*

Once calculated all proposed methodological functions, they are combined in order to provide the result of the asset remaining life. In order to make the calculation, first, the static function is calculated with condition function in series, while the degradation function is calculated in parallel with the others. Like the previous model, the index output provides an approximated value of the asset health status, which is in this case the equipment remaining life. In Figure 4, the combination between the different functions is observed for the calculation of the asset health index proposed by the author.

3.3 *Asset health index calculation model by TERNA*

This model developed by Terna Rete, Italy, proposes the calculation of the equipment health index based on static and dynamic parameters. Static parameters are associated with the location where the equipment is located, which are invariable in time and independent of the asset, for example, the recurrence of catastrophic phenomena, the probability of electrical storm, etc. Dynamic parameters are associated to the equipment and can be measured in situ by functional and visual tests, as well as in laboratory tests by analysis of oil samples, lubricants, etc.

The output of the model is an index between 0 and 0.5 which refer to the state as new and critical respectively. That is intended to justify technically and economically, making decisions for the investment of capital in replacement of equipment (Scatiggio et al. 2016; Scatiggio & Pompili 2013).

3.3.1 *Inputs*

The model author proposes static and dynamic variables for the model's inputs. Static variables do not depend on the asset itself but depend on the location (lightning frequency, catastrophic events, etc.). The dynamic variables proposed depend on the asset, and their value changes with the asset ages. Therefore, by capturing the change over time and comparing the maximum and minimum admissible for each kind of equipment, the condition status can be estimated at each moment of the asset life. The following condition parameters are those that are taken into account as inputs to the model (Pompili & Scatiggio 2015), each parameter is known as Health Index (HI).

- HI dielectric: parameters related to dielectric and thermal condition, as it may be obtained from dissolved gas analysis. These parameters are able to provide information on electrical (partial discharges, low energy discharges, arcing) and thermal problems (hot spots, overloads);
- HI thermal: parameters related to pure thermal condition of the insulating paper, as they may be obtained from the CO_2, CO and further periodical determinations;
- HI mechanical: parameters related to mechanical condition of the transformer, as they may be obtained from on-site electrical tests (inductance measurements, Sweep Frequency Response Analysis or SFRA, Frequency Domain Spectroscopy or PDC/FDS);
- HI oil: parameters related to insulating oil condition, as they may be obtained by water content, acidity, 50–60 Hz Breakdown Voltage (BDV) and Dielectric Dissipation Factor (DDF) determinations.

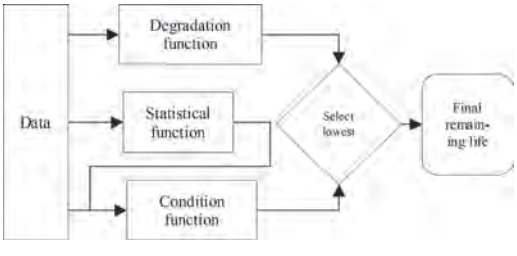


Figure 4. Schematic of how the functions are combined to give a health index.

3.3.2 *Index calculation methodology*

Due to the fact that different condition factors are very different from each other, they must first be standardized with their corresponding weights. In order to transform the value into a non-dimensional number, international guidelines and regulations (IEC, IEEE, CIGRE, etc.) are used.

Once the parameters have been standardized, from the following equation 3, the HI is calculated:

$$HI = \frac{HI_{dielectric} + HI_{thermal} + HI_{mechanical} + HI_{oil}}{HI_{MAX}} \quad (3)$$

where HI_{MAX} is a prefixed number and, as a consequence, the HI of each asset may be expressed per units (p.u.).

3.3.3 *Model outputs*

The model output is a HI value between 0 and 0.5. Higher and lower HI values are associated, respectively, to lower or higher levels of asset reliability.

In dependence on their HI, assets are classified in four classes. In Table 2, assets classified in "very good" and "good" condition may be managed following the common and standard maintenance practices, assets classified as "fair" or "doubtful" need an increase of analysis frequency or a deeper investigation (Scatiggio et al. 2016).

Table 2. Health Index (HI) evaluation.

Health Index (HI)	Condition
0–0,10	Very Good
0,10–0,20	Good
0,20–0,30	Fair
>0,30	Doubtful

The models that will be introduced in the paper are relevant, among other things, because:

- Asset managers need models to study options that maximise the value of an asset as it approaches the end of its useful life. Options may include (for example) changing the operating regime, partial asset replacement/refurbishment to extend useful life, or an indefinite ongoing 'patch-and-continue' programme, perhaps involving suppliers to provide necessary parts or services.
- Predicted performance supported by knowledge and asset information is available in many companies—normally based on good understanding of how assets degrade—but not incorporated in formal processes for capital investment. These models contribute to the decision process that seeks the optimal life cycle value.

4 CHALLENGES OF AHI APPLICATION

Currently, in order to respond the increasingly demanding requirements in terms of asset management, the application of AHI models offer the possibility to improve the process of decision making in maintenance situations. After a review of the literature, the best practices agree that using the asset health index offers the following advantages:

- Consolidate all information sources about the asset condition in a single integrated view of asset health.
- Provide an approaching indication of the asset at the end of its useful life.
- Condition assessment and asset performance.
- Report generation for maintenance attention.
- Needs identification at short and medium term for the replacement of individual equipment.
- Prediction of long-term needs replacement in large volumes of assets, identifying potential peaks with investment requirements.
- Identify problems, risks and opportunities for maintenance management.
- Provide information on asset deterioration trends that do not correspond to the rates of natural aging processes, which can be useful for planning appropriate maintenance strategies.
- Comparison between the assets condition by classes and locations, allowing taking actions in the operation and maintenance strategy of the organization.

On the other hand, any organization that decides to implement this tool in their strategic processes, with the purpose to improve its asset management, will have to take into account the below-mentioned considerations. Depending on the level of maturity of the organization, in some cases, they may be a challenge to overcome and, in others, an inconvenience to avoid or mitigate:

- The collection of data has a high cost. The capture of certain information requires a field technician in order to inspect and record the data.
- Uncertainty in evaluating asset conditions can create inconsistencies in the collection of data.
- Uncertainty about the return on investment, the valuation of costs and the financing of assets replacement or renewal, can make difficult to determine the information
- The lack of consistent and compatible methods to record, store and reference information can cause errors in the analytical phase.

Once these advantages and disadvantages have been seen, it's worth investigating the implementation of the AHI tool. The initial part of capture and processing of the data is critical; improving in this initial stage the assets management will ensure better results. For any organisation that decides to apply the AHI tools, its essential to incorporate in its asset management model, the condition study of the asset after replacement promoted by a decision based on the asset health. This will allow the learning and adjustment of the mathematical model based on their own experience, which will be benefited in better results in making long-term decisions.

5 CONCLUSIONS

Today, the use of tools for decision making about long-term renewal and replacement of equipment for organizations is quite extended. Thanks to Life-Cycle Cost analysis (LCC), it is possible to know from an economic point of view, the cost of an asset over its useful life and to estimate the time for replacement if needed. The disadvantage in many cases, is the large amount of variables that must be handled when estimating the real cost of an asset over its useful life, generating a scenario of high uncertainty (Durairaj et al. 2002). At that moment, it is where the AHI comes into play as a support tool, having a completely different calculation methodology, estimated from lab tests in order to know the asset condition, visual inspections,

operation and maintenance history and the age of the equipment and its components.

The roadmap for the definition of an AHI model is applicable to different kinds of equipment. It is currently under development and such development is generating the need to open new lines of research, in parallel to what is currently implemented in the field of electrical networks and more specifically in electrical transformers.

ABSTRACT: Acoustic Emission (AE) has seen increased popularity in applications involving machine condition monitoring. AE applications usually involve higher sampling rate than vibration signals, not rare reaching 2 MHz. One of the main challenges involving AE based fault diagnosis is the need of preprocessing massive amounts of data generated by this technique, including engineering of appropriate features and dimensionality reduction so to be able to handle such massive datasets. In this paper, we propose a novel method based on Deep Convolutional Neural Networks (CNN) to handle raw AE signals for diagnosis of a system's health states. This method is flexible enough to not only handle the massive amount of AE data, but also to provide the means for automatic feature extraction by applying various filters to the raw AE signals, and thus identifying relevant frequencies related to different faults. The proposed CNN method is applied to fatigue crack detection on blades of an experimental rotor.

1 INTRODUCTION

Unscheduled maintenance of mechanical systems leads to loss of production and might as well affect safety. There are many ways to minimize this effect, some of them are: increase redundancy, programed maintenance to identify problems that could incur in extended downtimes and, condition monitoring (Rabiei et al., 2016).

A popular approach to condition monitoring is vibration analysis. However, vibration monitoring is usually less sensitive to detecting damages already developed, which pose a significant limitation in sensitive systems. On the other hand, Acoustic Emission techniques are gaining grounds because they can identify damage at early stages, with the tradeoff of introducing higher sample rates resulting in massive and higher data dimensionality.

Moreover, both AE and vibration monitoring require signal preprocessing and interpretation such as wavelets, fast Fourier transform and band filtering among others (Riaz et al., 2017), a labor intensive and expensive endeavor requiring specialized engineering expertise.

Machine learning techniques have become a popular choice for fault diagnosis and prognosis. Most of these shallow models heavily rely on manual feature identification and extraction (Ruiz-Gonzalez et al., 2014; Kane and Andhare, 2016; Li et al., 2016).

As discussed in (Verstraete et al., 2017), the performance of these methods is dependent on the quality of the hand-engineered features, which obviously requires significant understanding of the system's degradation processes.

To tackle these challenges, we propose a deep CNN-based method for fault diagnosis that operates on massive raw acoustic signals and allows for the automatic hierarchical "layer to layer" feature extraction to learn complex representations of the data.

The remainder of the paper is structured as follows. Section 2 introduces deep learning and CNNs and their architectural building blocks. Then, Section 3 discusses the proposed method, application and validation for fault diagnosis of an experimental rotor and compares its performance to a fully optimized shallow neural network. Section 4 presents some concluding remarks.

2 CONVOLUTIONAL NEURAL NETWORKS

2.1 *Artificial neural networks*

Artificial Neural Networks (ANNs) are comprised of simple units called neurons. Each of these neurons creates a linear combination for an input (x) between a weight (w) and a bias (b) parameters that are learned by the ANN.

Also, an activation function (f) adds the nonlinear behavior that allows to compute nontrivial responses. Then, the output (O) of a neuron is computed by Equation (1):

$$O(x) = f(wx + b) \tag{1}$$

2.2 *Deep learning*

Simply put, deep learning is a branch of the Machine Learning that uses many hidden layers to perform the learning. The deep learning based networks learn multiple features over the features learned by previous layers, integrating the concept of hierarchy between features implying different levels of abstraction (Deng and Yu, 2014). This is important to achieve high accuracy in tasks that have complex relationship among data such as image recognition and signal processing.

2.3 *Convolutional neural network overview*

Convolutional Neural Networks (CNNs) are a type of Neural Networks that are specialized for processing grid-topology data (Goodfellow, Bengio and Courville, 2017). CNNs have been shown to outperform shallow architectures in many image recognition tasks and have been applied to vibration based fault diagnosis (Verstraete et al., 2017).

The main characteristics of the CNNs are that the layers have sparse connectivity and parameter sharing. The first characteristic means that CNNs use filters that are considerably smaller than the input implying that the filters store less parameters than a shallow neural network and detect important features of the input. The second one implies that the filter weights in a convolutional layer are used multiple times across the input resulting in computationally efficient matrix multiplication.

2.3.1 *Convolutional layer*

As we are dealing with raw AE data, the convolution operation in the proposed model is also 1D. This means that the filters (w(t)) learned by the network are in the time domain and generate a filtered signal of the input (x(t)) highlighting features that represent the system's health state. The output signal of a 1D convolution, s(t), is computed as shown in Equation (2):

$$s(t) = (x * w)(t) = \sum_{a=-\infty}^{\infty} x(a)\, w(t-a) \tag{2}$$

2.3.2 *Batch normalization layer*

Batch Normalization (BN) is a method for accelerating the learning of deep networks by reducing internal covariate shift of the data (Ioffe and Szegedy, 2015). This is achieved by performing a normalization for each mini-batch with the learning of new normalization parameters: scale parameter gamma (γ) and shift parameter beta (β).

Given the p-dimension input to a BN layer $x = (x^{(1)},...,x^{(p)})$, the transformation is made with Equation (3) and Equation (4):

$$\hat{x}^{(i)} = \frac{x^{(i)} - E\left[x^{(i)}\right]}{\sqrt{Var\left[x^{(i)}\right]}} \tag{3}$$

$$y^{(i)} = \gamma^{(i)}\hat{x}^{(i)} + \beta^{(i)} \tag{4}$$

where Var[X] is the variance and E[X] is the expectation and are computed over the training set. Equation (3) is used to standardize features and accelerate convergence and Equation (4) restores the representation power of the network.

2.3.3 *Pooling layer*

Pooling layers are used to reduce the dimension of the input and achieve spatial invariance. This is usually accomplished by taking the maximum value of a pooling window and switching it for all values in that window. This lowers the resolution but taking only the most important feature.

2.3.4 *Activation function*

As discussed before, activation functions add nonlinear behavior to the network. In the proposed CNN architecture, we employ the Rectified Linear Units (ReLUs) as activation function for the convolutional layers as they provide increased sparsity compared with Tanh or Sigmoid activation functions, thus decreasing computation time (Maas et al., 2013). The commonly used ReLU is shown in Equation (5):

$$g(x) = \max(0, x) \tag{5}$$

For the fully connected layers (see Section 2.3.5), the softmax activation function is used to quantify the probability of a sample to correspond to a given system's health state. This function is displayed in Equation (6):

$$f_k(z) = \frac{e^{a_k}}{\sum_{k=1}^{K} e^{a_k}} \tag{6}$$

2.3.5 *Fully-connected layer*

Finally, a couple of fully connected layers with same dimension are responsible for the classification based on the feature maps from the last convolution.

2.3.6 *Network optimization*

For supervised learning, the network learns by optimizing (minimizing) a loss function on the difference between the predicted and true labels. The selected loss function is the cross-entropy between the estimated softmax output $q(x)$ and target class $p(x)$:

$$Loss = -\sum_{x} p(x)\log\left(q(x)\right) \tag{7}$$

The network is optimized via ADAM (Kingma and Ba, 2014), an algorithm inspired in Stochastic Gradient Descent (SGD). This optimizer works with adaptive estimates of lower-order moments and performs well with noisy and sparse gradients. This method combines two extensions of SGD: Adaptive Gradient Algorithm that improves performance on problems with sparse gradients by maintaining a learning rate per parameter. The other one is the use of Root Mean Square Propagation, which adapts the learning rate as a function of the magnitude of the gradients for the weights, improving the performance with noisy data.

2.3.7 *Regularization*

To tackle the CNNs tendency to overfit during training and to improve generalization performance, regularization is implemented by means of the following two approaches. First, we employ L2 regularization by adding a term to the loss function that penalizes high weights over the network (Peng *et al.*, 2015). Second, we use dropout, which consists of disconnecting some neurons during training to prevent co-adapting (Srivastava *et al.*, 2014), is implemented in the fully connected layer with 50% drop probability.

3 PROPOSED CNN METHOD

3.1 *Dataset*

The proposed CNN based method is conducted on a dataset generated from AE monitoring of an experimental rotor, as shown in Figure 1.

The setup is comprised of:

1. Mistras, Micro 30 Acoustic Emission sensors
2. Rotor and blades
3. DC Motor MY-1016, 24[V] 13.7[A]
4. MCP Q10-QS305 Power Source.

The rotor has 8 blades with one of them notched according to size and position in Table 1.

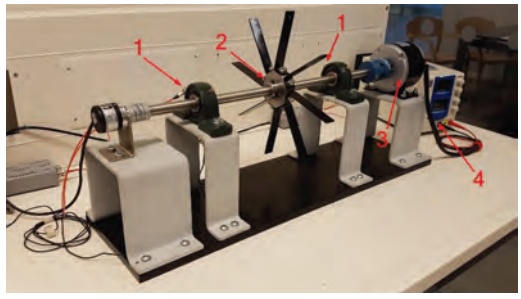

Figure 1. Experimental rotor setup.

Table 1. Size and position of notches.

Position [mm]	Size [mm]
5	3
20	6
	10

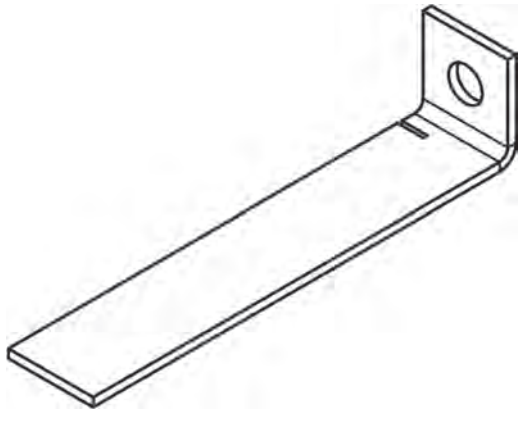

Figure 2. Sketch of a blade with a 6 mm notch at the 5 mm position.

A sketch of a blade is displayed in Figure 2.

The acquisition rate is 500 kHz and each combination between position and size of the notches are measured for 176.16 s divided in 168 files of 524,288 data points each.

In this dataset, there are seven health conditions: undamaged; 3 mm, 6 mm and 10 mm cracks at the 5 mm position; 3 mm, 6 mm and 10 mm cracks at the 20 mm position. For each health state, there are 53,477,376 data points and the CNN is fed with samples composed by slices of 49,152 points (1.77 rotor turn) of the raw signal with 50% overlap. Note that the proposed CNN method is trained for a 3-health state scenario corresponding to: (1) Undamaged, (2) Damage at 5 mm position obtained by combining the 3 mm, 6 mm and 10 mm cracks at that position; and (3) Damage

at 20 mm obtained by combining the crack sizes 3 mm, 6 mm and 10 mm at the 20 mm position.

Data augmentation is also implemented to enforce network generalization, thus improving the accuracy on unseen samples. The dataset has a total of 548,458,432 data points that are split into 80–20 proportion for training and testing, respectively.

Figure 3 shows examples of raw AE signals for each of the three health conditions. Notice that the signals have a significant amount of noise mainly because the rotor system is not perfectly balanced and has some degree of misalignment. In addition, vibrations from the bearings, coupling and motor add additional noise to the response.

However, the implementation of de-noising methods incurs in loss of information and encompasses pre-processing time that we want to avoid and handle with the proposed architecture.

Moreover, based on the raw signals and the amplitude spectrums shown in Figure 3, the health conditions are remarkably similar that, coupled with the signal noise levels, makes this dataset a significant challenging diagnosis task.

3.2 *Proposed deep CNN architecture*

The proposed CNN architecture, processing batches of 256 samples, consists of five convolutional layers as follows (see Figure 4): the first convolutional layer has 32 oversized filters of 128×1 designed to tackle background noise in the acoustic emission raw signal; this is followed by four convolutional layers with 32, 32, 64 and 128 filters of size 3×1, respectively, which are designed to automatically and hierarchically extract features from the AE data. The last convolutional layer's output is reshaped before being fed to the last two fully connected layers, each with 1024 neurons, that are responsible for processing the features obtained from the convolutional layers to perform fault diagnosis.

The proposed CNN method is trained for 15000 epochs, where one consists of all training samples. The CNN is regularized via dropout for the fully connected layers with 50% of keep probability and L2 regularization (see Section 2.3.7) as well as early stopping by saving the best epoch in terms of accuracy and generalization capability (train loss remaining low as test loss decreases).

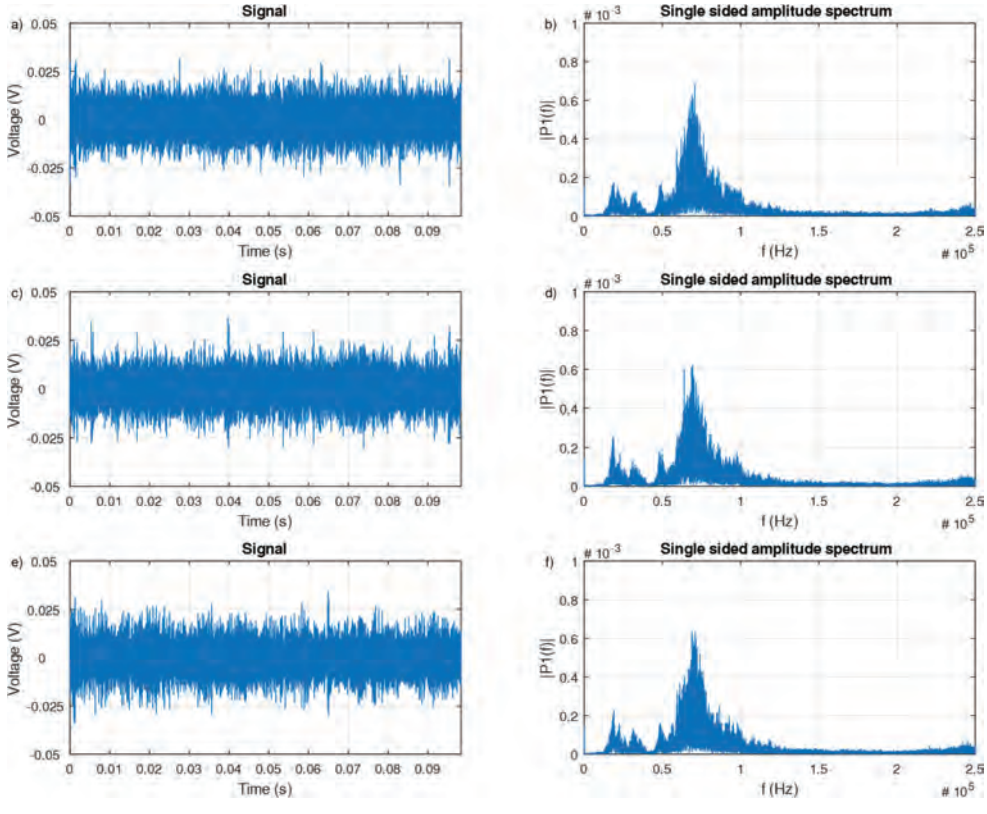

Figure 3. a) 5 mm sample signal, b) 5 mm amplitude spectrum, c) 20 mm sample signal, d) 20 mm amplitude spectrum, e) Undamaged sample signal and f) Undamaged amplitude spectrum.

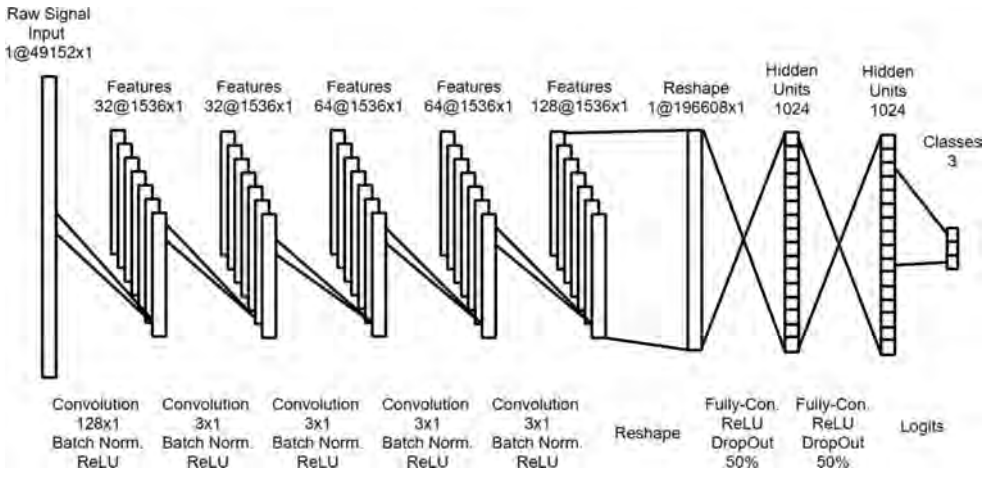

Figure 4. Architecture of the CNN.

Also of note is that the proposed CNN architecture does not have pooling layers. There are two underlying reasons: firstly, the proposed CNN method is not required to achieve spatial invariance as it deals with raw acoustic emission signals; secondly, the CNN marginally improved (in terms of accuracy and generalization) by the reduction in size of the feature maps resulting from the polling layers or, conversely, its performance deteriorated due to the loss of information incurred by the implementation of pooling layers.

In terms of activation functions, the fully connected layers use softmax, whereas ReLU is implemented in all five convolutional layers (see Section 2.3.4 for details). The CNN weights are initialized by Xavier Normal Initialization, a Normal Uniform distribution normalized by the size of the previous and next layer (Glorot and Bengio, 2010) and bias as 0.1 constant in all layers.

3.3 *CNN implementation*

All the results shown in the next section were obtained using the following hardware configuration at Smart Reliability and Maintenance Integration Laboratory (SRMILab) in the University of Chile: Intel® Core™ i7-6700 K CPU with 32 Gb RAM and a NVIDIA Titan XP GPU.

3.4 *Results and discussion*

The proposed CNN method is compared with a shallow ANN that has the same two fully connected layers, but lacks the convolutional layers. This allows us to assess the impact on the fault diagnosis performance of the convolutions as signal filtering and de-noising tool as wells as the quality and robustness of the extracted features. This ANN is fully optimized with ADAM adaptive gradient-based optimization algorithm and regularized via dropout (with 50% keep probability), weight regularization for both hidden layers and early stopping.

Table 2. Accuracy for health state of the system.

	Test accuracy (%)
ANN	33.7
CNN	93.0

Table 3. Performance measures in percentages [%] for the proposed CNN method.

	5 [mm]	20 [mm]	Undamaged
Sensitivity	89.77 ± 1.70	91.50 ± 1.48	97.65 ± 0.36
Specificity	94.69 ± 0.80	95.93 ± 0.62	99.04 ± 0.46
Precision	89.22 ± 1.62	91.53 ± 1.22	98.18 ± 0.92
F1 Score	89.48 ± 0.98	91.51 ± 0.88	97.91 ± 0.57
Accuracy	93.06 ± 0.80	94.50 ± 0.42	98.56 ± 0.39

Table 2 shows the overall test fault diagnosis accuracy. The proposed CNN method significantly outperforms the shallow ANN in terms of accuracy and generalization capacity, with the ANN barely learning from the complex AE dataset.

To corroborate these results, we collect the average values and corresponding standard deviations per health state from multiple runs for different performance metrics as shown in Table 3.

Table 4. Confusion matrix for the proposed CNN method.

	5 [mm]	20 [mm]	Undamaged
5 [mm]	363	35	6
20 [mm]	28	382	0
Undamaged	8	0	402

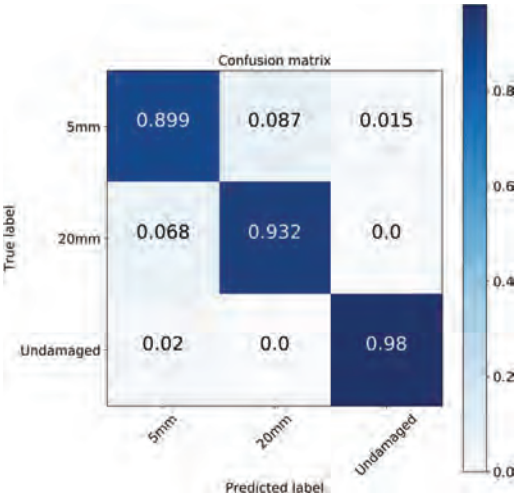

Figure 5. Normalized confusion matrix for the proposed CNN method.

Moreover, the unnormalized and normalized confusion matrices are shown in Table 4 and Figure 5, respectively.

Based on these results, the proposed CNN method outperforms the shallow ANN for the rotor's fault diagnosis based on acoustic emission monitoring. This is corroborated by observing Figure 6a) and c) that the CNN presents a monotonically descendent testing loss behavior that leads to improvement in the fault diagnosis accuracy. But, it should be observed that that the accuracy improvement to time ratio for the CNN is very low for the last epochs even though the network still learns. This could be driven by a very low learning rate for these epochs as ADAM adapts this hyperparameter.

However, as shown in Figure 6b) and d), the ANN barely learns from the raw AE data, which could be attributed to the complexity of the data as well as the meaningless features that the ANN extracts by treating the signals as independent points, problem that seems to be compensated by the convolutional filters in the CNN.

However, the superior performance achieved by the proposed CNN method comes at a much higher computational cost due to the significant number of learnable parameters and hyperparameters leads to extended training times.

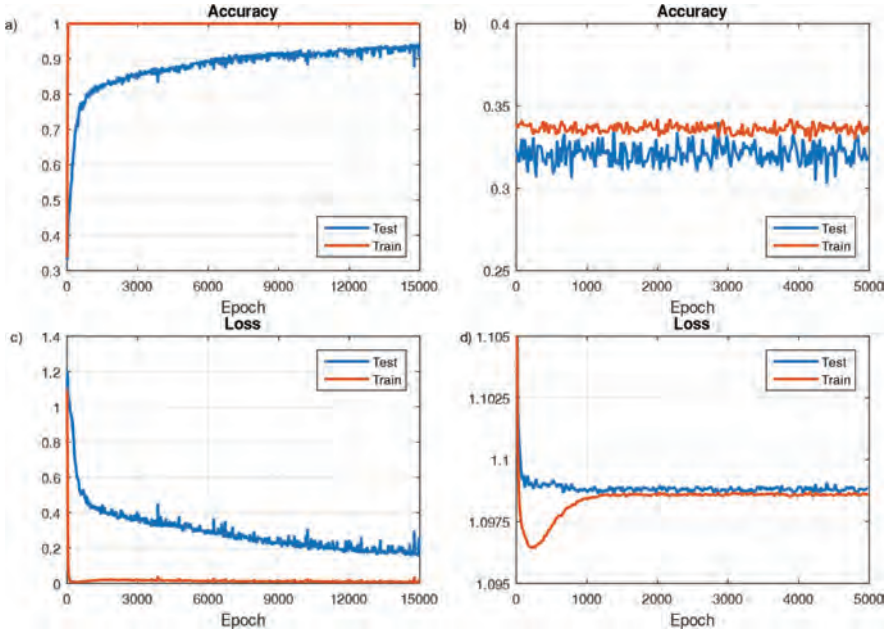

Figure 6. a) Accuracy behavior of the CNN, b) Accuracy behavior of the ANN, c) Loss behavior of CNN and d) Loss behavior of the ANN.

4 CONCLUSIONS

This paper has introduced a new deep CNN-based method for fault diagnosis using raw acoustic emission signals. The application of this method to an experimental rotor has shown that the proposed method delivers satisfactorily performance metrics for health state diagnosis. The CNN method was also compared to a fully optimized ANN, with the former significantly outperforming the shallow method.

These solid results in fault diagnosis are mainly due to the CNN's ability to automatically extract features from and efficiently handle the noisy acoustic emission signals. This also brings major advantages to the development of automated monitoring and fault diagnosis tools such as the possibility to bypass the intervention of the human element in the labor-intensive feature engineering process and reducing the need for preprocessing and de-noising of acoustic emission signals. Based on these preliminary results, the proposed CNN method is a promising tool for fault diagnosis.

Best practices to improve public private people partnerships in the city resilience-building process

P. Marana, L. Labaka & J.M. Sarriegi
TECNUN, University of Navarra, Donostia-San Sebastian, Spain

ABSTRACT: Population is increasingly urban settled. Ensuring the welfare of society against upcoming crises derived from emerging challenges such as climate change, social dynamics and critical infrastructure dependencies within cities is seen as a priority for both scholar and practitioners. In this context, the concept of city resilience gains relevancy. Moreover, the task of ensuring the well-being of society increasing city resilience cannot completely rely on public entities; the contribution of private companies and citizens is also needed. There is a need to develop effective mechanisms such as Public Private People Partnerships (4Ps) to support the city resilience-building process. In order to develop effective and long lasting 4Ps that contribute to the city resilience building-process it is important to consider three dimensions; stakeholder relationship, information flow and conflict resolution. The aim of this paper is to present and describe a repository of best practices gathered from real city resilience-building processes that are currently taking place in different cities all over the world that contribute to the development of these three important 4P dimensions.

1 INTRODUCTION

According to the United Nations by 2030 more than 60% of people living in the world will be settled in urban areas (WHO 2017). Moreover, cities are currently at cross roads of challenges like climate change, social dynamics and the increasing dependence on the correct functioning of critical infrastructures that affect directly to the welfare of society (Gonzalez et al. 2017, Schauppenlehner-Kloyber & Penker 2016, Toubin et al. 2014, Elmqvist et al. 2013). Therefore, crises affecting cities derived from these challenges will potentially affect the welfare of citizens. This is why ensuring effective crisis management within cities will be increasingly important in the upcoming years in order to ensure the wellbeing of society (Toubin et al. 2014).

It is also important to bear in mind that the nature of the striking events that generate crises could be predictable or unpredictable. Moreover, predictable crises can also have unpredictable consequences due to potential cascading failures that may occur between complex interconnected systems (Pyrko et al. 2017). Therefore, a risk management approach that only consider predictable risks and consequences is not enough to deal with nowadays crises (Boin & McConell 2007). The resilience concept seems promising to address the need to deal with unexpected crises (FCOP 2011). Therefore, efforts are being made in promoting resilience in order to be able to face upcoming unpredictable crises that could potentially affect the welfare of society.

City resilience is an emerging concept that has been gaining popularity in the last few years. However, there is still a lack of consensus on its definition and has different approaches (Bång & Rankin 2016). Within this research, city resilience is defined as "the ability of a city or region to resist, absorb, adapt to and recover from acute shocks and chronic stresses to keep critical services functioning, and to monitor and learn from on-going processes through city and cross-regional collaboration, to increase adaptive abilities and strengthen preparedness by anticipating and appropriately responding to future challenges" (Hernantes et al. 2016).

Therefore, increasing city resilience will be a priority to ensure the welfare of society in the upcoming years (Toubin et al. 2014). In fact, ensuring the well-being of citizens in times of crisis is not a mission that can be delegated to public entities. In order to successfully fulfil this mission; the collaboration of additional city stakeholders, like private companies and citizens, is required (Kapucu 2012, Oxley 2013). While public entities should be the ones in charge of coordinating all the efforts being made to increase city resilience, it could also be beneficial to involve private companies and citizens (Gimenez et al. 2016). Private companies could contribute with technical expertise and additional resources in case the damage caused by an unpredictable event exceeds the capacities of public entities to deal with the crisis. Moreover, citizens could use their specific knowledge about the local community to better understand the needs of local

people regarding city resilience (O'Sullivan et al. 2015, Scolobig et al. 2015). Therefore, addressing unpredictable events affecting cities requires letting aside a silo-thinking mentality by involving different city stakeholders and coordinating their efforts to increase the city resilience level.

In light of this situation, developing meaningful public private people partnerships (4Ps) at the city level for strategic decision-making regarding city resilience could have a significant positive impact (Boyd & Juhola 2014, Ng et al. 2013). We define 4Ps as partnering arrangements, both formal and informal, that are developed between public entities, private companies and citizens with the aim of improving the city resilience-building process.

It is important to bear in mind that the objective of developing 4Ps is to foster meaningful collaboration among city stakeholders rather than to develop agreements per se. Rigid agreements have proven to be suitable for addressing expected crises, but trusting that rigid predetermined agreements can address unexpected events is not always effective (Stewart et al. 2009). Developing meaningful and long lasting 4Ps in which all the city stakeholders are represented enables to increase the adaptability and the improvisation capacity in times of crisis.

In order to develop effective 4Ps it is important to consider three dimensions; stakeholder relationship, information flow and conflict resolution (Marana et al. 2018a). The aim of this paper is to present and describe a repository of best practices (projects, strategies, activities, policies, methodologies and tools) gathered from real city resilience-building processes that are currently taking place in different cities all over the world that contribute to the development of 4P dimensions.

2 STATE OF THE ART

2.1 *Fragmented efforts between city stakeholders*

Emerging wide scope complex challenges like climate change, socio-political issues or critical infrastructure dependency, cannot be addressed by a single institution on its own.

The awareness regarding the importance of addressing the effects of these challenges is increasing among most city stakeholder groups (Gonzalez et al. 2017). For instance, the local government is developing and implementing climate change adapting plans; critical infrastructures are investing resources on understanding the existing interdependencies between them in order to prevent cascading failures that end up affecting several services, NGOs are focused on developing programs to reduce inequalities that affect vulnerable population and so on.

Each city stakeholder group can contribute to the city resilience-building process in different ways. Public companies (local, regional and national government, emergency services and so on) can contribute with their decision-making experience and capacity as well as with material resources. Private companies (Critical Infrastructure providers, businesses, insurance companies and so on) can contribute with technical and operational expertise as well as with additional material resources. People (citizens and NGOs) can contribute with knowledge of social, behavioral, economic and environmental issues (Scolobig et al. 2015).

All the approaches are equally valuable and require to create a holistic city resilience-building process. The key is not to consider them as isolated efforts but to integrate all of them in an effective way. Therefore, aligning the efforts of all the city stakeholders using mechanisms like 4Ps should be considered as a priority in order to improve city resilience.

2.2 *Dimensions of public private people partnerships*

Collaboration enables partners to share their knowledge, skills, resources and perspectives to use them in alternative and complementary ways (Gagnon et al. 2016, Jones & Barry 2011). Fostering 4Ps within the context of city resilience enables each stakeholder to contribute in the most appropriate way to the resilience-building process. In order to develop 4Ps in the most effective manner, the following dimensions should be considered (Marana 2018a) (Figure 1).

2.2.1 *Stakeholder relationship*

This dimension is related to the attributes and attitudes stakeholders must possess to work together successfully. We highlight the importance of promoting commitment of the city stakeholders to be

Figure 1. 4P dimensions.

active part of the city resilience-building process assuming that mutually beneficial goals could be achieved. Coordination and trust not only among city stakeholders but also with other systems and institutions with similar or complementary purposes are also considered within the scope of this dimension. It also embraces the need to increase adaptability of the partnership in the face of upcoming challenges. Finally, this dimension also considers the relevance of involving representatives of all the city stakeholder groups within the city (public institutions, private companies and citizens).

2.2.2 *Information flow*

This dimension is related to the communication channels and protocols that stakeholders must use to invest resources in the most effective manner. When we refer to this dimension we are highlighting the need to ensure the timeliness, accuracy and relevance of the shared information. Active participation of city stakeholders in planning, goal setting and execution of tasks are also considered within this dimension. This dimension also embraces how quickly information is available to relevant city stakeholder and the ease with which partners understand the information provided. Finally, it also considers to what extent critical and sensitive information is shared with other authorized partners.

2.2.3 *Conflict resolution*

This dimension is related to the techniques used to solve problems related to the correct functioning of the partnership. It highlights the importance of finding solutions to solve conflicts between city stakeholders in a constructive way in which the interests of all the involved partners are represented. This dimension also refers to the ability of the partnership to use lessons learnt in the past and to increase the effectiveness of future decisions. Finally, it also considers the importance of aligning the self-interests of each partner into a mutually beneficial goal.

3 METHODOLOGY

This research consisted of two different stages. The first stage consisted of an academic literature review and the second stage consisted on a revision of existing city resilience strategies.

3.1 *1st stage: Academic literature review*

A literature review was conducted in the Scopus database, in order to find best practices that contribute to the development of 4Ps in the city resilience-building process. This literature review enabled to find articles focused on the dimensions of multi-stakeholder collaboration in the context of city resilience.

The query used in the search in order to find relevant articles was the following: *"city resilience" OR "community resilience" OR "urban resilience" AND partnership OR collaboration.*

In order to ensure a more standard set quality only academic papers published in scientific journals were considered in this research. Although conference proceeding usually present interesting research projects, generally the main outcomes are published in scientific journals. Therefore, the type of publications was limited.

After conducting the search in the Scopus database a total amount of 96 articles were obtained. After reading the title and the abstracts a total amount of 52 research articles were analysed in full detail.

The aim of this academic literature review was to gather information about projects, strategies, activities, policies, methodologies and tools that have proven to be effective in the development of 4Ps in the city resilience-building process.

3.2 *2nd stage: Revision of city resilience strategies*

A revision of city resilience strategies was conducted in order to identify what cities are currently doing and planning to do in order to improve the effectiveness of 4Ps and consequently, increase city resilience.

City resilience strategies were obtained from the 100 City Resilience webpage (100 Resilient Cities, 2016c). 100 Resilient Cities is an initiative funded by the Rockefeller foundation whose aim is to help cities around the world to become more resilient to the physical, social and economic challenges that are a growing part of the 21st century.

The 36 city resilience strategies available in the 100 Resilient Cities website at the moment when this research was carried out were revised in order to find projects, strategies, activities, policies, methodologies and tools that contribute to improve each of the three dimensions of 4Ps in order to develop effective 4Ps in the city resilience-building process.

4 RESULTS

In the following section, the most important results obtained after reviewing scientific papers as well as city resilience strategies will be presented. Considering their final aim, the best practices gathered from the literature review have been classified into the three 4P dimensions.

4.1 *Stakeholder relationship*

Improving the interaction among stakeholders representing different city sectors is key for developing effective 4Ps that contribute to the city resilience-building process.

Representing the interests of all the city stakeholders when developing the basis of the city resilience-building process is key so that everyone accepts it and feels part of it.

The empowerment of citizens is key to foster engagement and a sense of belonging to the city. The city of Christchurch is developing alternative forms of public participation to promote awareness of issues and engage citizens in resilience related decision-making (100 Resilient Cities 2016d). The creation of community boards, advisory groups and working parties will enable that city stakeholders are more informed about the issues that community leaders have to make decisions.

The involvement of city stakeholders is not sufficient to ensure the effectiveness of resilience-building processes. There is a need to coordinate all the efforts being made by all the different groups. The city of Glasgow is conscious of this and has started to develop an integrated resilience plan for critical services in the face of long-term stresses in order to ensure the wellbeing of its citizens (100 Resilient Cities 2016b). The interdependencies among cross-sectoral critical services within Glasgow are identified with the objective to ensure that critical services remain functional and accessible regardless of the upcoming challenges.

Moreover, it is also important to realize that the resilience level of the city does not only rely on the city itself. Due to the increasing interconnection among cities throughout the world, learning from what others are doing is also key to address the challenge of developing resilience in cities. For instance, Bangkok is one of the cities that has addressed this challenge and is now interacting with different cities around the world with the support offered by the 100 Resilient Cities network (100 Resilient Cities 2017a). The city of Bangkok is currently working together with the city of Jakarta and Mexico City. The three of them are rapidly developing in mega cities where the challenge of efficient mobility exist. Therefore, they are working together to find solutions to this challenge.

4.2 *Information flow*

Improving the information flow among different stakeholder groups is key to improve the decision making process in the context of the city resilience-building process.

Developing communication channels to share information with city stakeholders is required to increase city resilience. The municipality of Dakar is aware of this fact and therefore is currently working on implementing tools and services to provide its city stakeholders with access to information on imminent crises in real time (100 Resilient Cities 2016a). These tools will enable that, a few months before a rainy season or time of high tides, the municipality could start communicating on disturbances observed to anticipate and reduce eventual damages caused by flooding. They realized that although public entities keep track of natural events preceding major disasters, such information is not actively used to the best advantage of the city. In light of this situation, they are working on creating a database of current data on the city's vulnerability state and they are establishing a network of community resilience champions.

This last initiative includes the integration of real-time information to the city's mobile application NAVIGEM in order to advise people when imminent risks are detected. However, communication with city stakeholders should be done not only using social media and apps. Usually, the most vulnerable groups in society like elderly people and children are not users of these communication channels. In order to reach to those groups alternative tools to proactive communicate upstream periods of vulnerability, like daily/weekly radio programs are being developed.

The timeliness, accuracy and accessibility of information is another key issue when talking about information in the context of city resilience.

Due to the technological updates conducted in cities in the last years, local governments are now increasingly considering to leverage the internet of things (IoT) to gather timely and accurate data that can enable to improve resilience related decision-making processes. Using the most current technology could help them to address disasters more efficiently and safely. However, this type of progress will require more than just employing the IoT to improve emergency preparedness and response; city stakeholders need to be ready to receive, interpret, and use the data in an effective manner. IoT sensors can be critical for urgent decisions like whether to evacuate an area at risk of earthquake, or how to guide residents to the safest exit routes ahead of an emergency. For instance, Santiago is working on applying sensors to improve the early warning systems as well as to use that information to design more effective evacuation protocols (100 Resilient Cities 2017b). In San Francisco, an early warning system called ShakeAlert has been started to be implemented in order to detect the first wave sent by an earthquake and to report is to citizens using this system (100 Resilient Cities 2016f).

Public entities must also know which communication channels work best to reach the affected city

stakeholders. For instance, if the at-risk population is predominantly Spanish-speaking, then the messages should be sent in Spanish. When dealing with an elderly population, the outreach can be done through television, newspapers, and radio rather than tech-driven channels like text alerts and apps. This targeted communication is a shift from the conventional "one size fits all" approach.

4.3 *Conflict resolution*

Improving conflict resolution to enable perspective alignment among stakeholders representing different interests will contribute to have a holistic view of city resilience.

Not only the involvement and contribution of all the city stakeholders is required to develop an effective city resilience-building process, an alignment on their perspective about resilience is also need. The city of New Orleans is aware of this need and is currently working on establishing a resilience center (100 Resilient Cities 2015). The aim of this center is to provide a space to build awareness and expertise of city stakeholders to develop projects and coalitions and to exchange ideas and practices both locally and globally. This space will enable to create synergies between different city stakeholders to work on initiatives that benefit all.

In order to increase the city's resilience level, the experience and lessons learnt by all the city stakeholders should be considered. The city of Melbourne is very aware of this need and is currently working on an initiative called (Monash University Disaster Resilience Initiative (MUDRI)), which explores how different stakeholders prepare to effectively response to crises and develops a Resilience Compendium that identifies leading practices that facilitate the sharing of best practices among different city stakeholders (100 Resilient Cities 2016e). This initiative enables to have a centralized resource for sharing and accessing information on resilience-building activities undertaken at the city. Consequently, this will prevent duplication of efforts and will promote a more efficient use of available resources.

In Rotterdam, the local government is also very aware of the need to empower all city stakeholder groups and has developed an action called the integration tours (100 Resilient Cities 2016g). In fact, talks and events aimed at encouraging cooperation and fostering dialogue between public entities, private companies and people are organized. These actions make citizens aware of their own roles in society and how they can better contribute to city resilience. Talks seek to break down the barriers created by self-interests to enhance effective dialogue among city stakeholders. These tours bring groups from different backgrounds and roles in society together to discuss different issues that are important for increasing the city's resilience level. Activities like this support knowledge sharing, strengthen mutual understanding, and enable the alignment of the different perspectives.

5 INTERCONNECTIONS BETWEEN 4P DIMENSIONS

This paper has presented the three different dimensions that should be considered when developing effective 4Ps that contribute to the city resilience-building process. However, it is important to bear in mind that all this dimensions are closely related among each other. The literature review has shown us that improving one 4P dimension has co-lateral effects on the other dimensions.

For instance, improving the relationship of different city stakeholders will have a potential impact on the amount and quality of the information they share between them (O'Sullivan et al. 2015). When a sense of belonging and trust among different entities exists, there is a bigger chance to improve the information flow among the partners. Improving the quality, accessibility and sharing of information also improves the coordination of city stakeholders and the sense of inclusiveness (Davenport et al. 2010).

Moreover, an improvement of the stakeholder relationship and of the information flow within the partnership has also an impact in the conflict resolution dimension (O'Sullivan et al. 2015). The better the relationship among city stakeholders and the more information is shared the easier to solve potential conflicts among city stakeholders will be.

Although all the best practices could have been classified within one 4P dimension, the effects of their implementation are usually transversal and affect not only to the improvement of their own dimension but also to the others. Therefore, further research should be conducted to better understand which the priority implementation order of these best practices should be in order to use the available resources in the most effective manner.

6 CONCLUSIONS

Although practitioners and academics are aware of the importance of improving collaboration between all the city stakeholders (public entities, private companies and citizens) to increase the resilience level of a city, there is not a concept to refer to this idea. This paper has presented the concept of public private people partnership (4P) as a new mechanism to foster collaboration through

formal or informal arrangements between city stakeholders in the city resilience building process.

This research has presented relevant best practices that are currently being implemented in certain cities all over the world. However, it is important to consider the limitations of the work presented. The best practices presented in this paper to illustrate how each dimension can be developed have been chosen in a pragmatic manner, without following a concrete methodology. The relevancy of these examples, will also decrease as available knowledge about city resilience building process increases and technology improves.

The efforts and resources dedicated to develop and implement an effective city resilience-building process are limited. Therefore, there is a need to set a priority order when implementing the resilience building best practices depending on the strengths and weaknesses of each particular city. Moreover, it is important to bear in mind that some cities could find easier to develop one dimension rather than other due to a cultural aspect. For instance, in some countries, like the ones in northern Europe, more attention is paid to the standardization of information sharing procedures. Therefore, these countries may find easier to improve the information flow dimension. However, other countries with a different cultural background, for instance the countries in the Mediterranean Sea, may find easier to establish informal relationships among stakeholders due to their feature of being more sociable. All these aspects should be addressed in future researches.

Checklist for judgement of technical facility safety level and results obtained by its application in practice

D. Procházková & J. Prochazka
Faculty of Transportation Sciences, Czech Technical University in Prague, Czech Republic

ABSTRACT: Technical facilities safety is fundamental issue for human society and its development. It is reality that it is broken by many known and newly cognized risks that are related to forever grooving complexity of technical facilities and whole world. Today, we know that it is also necessary to consider the risks that are connected with interfaces among their subsystems and components. With regard to the world dynamic development, it is necessary to monitor the priority risks and to cope with them during the time. The measure of safety level is performed by help of logically arrangement of requirements of individual techniques used at work with risks in technical facilities, fragmented to 7 domains and Maximum Utility Theory principle. The paper also shows the results on safety levels for 5 technical facilities.

1 INTRODUCTION

On the basis of present level of knowledge that is e.g. represented by publications from the ESREL conferences (Ale et al. 2010, Bérenguer et al. 2011, Briš et al. 2009, Cepin & Bris 2017, Nowakowski et al. 2014, Podofillini et al. 2015, Steenbergen et al. 2013, Walls et al. 2016), which is summarized in (Procházková 2015, 2017), we perceive each technical facility as open complex system of systems, i.e. as several open systems that are mutually penetrated and are interfaced with vicinity.

The interfaces ensure the fulfilment of important operations and services, and simultaneously they cause the dependences that are the roots of specific vulnerabilities. Under specific conditions they originate highly unfavourable interfaces that lead to technical facility failure, which at certain circumstances distinctly also damage the technical facility vicinity. Therefore, at ensuring the technical facility safety it is necessary to consider that technical facility has various assets that are altered in dynamically variable world. The multiplicity and variability of assets cause that under certain conditions, the measures ensuring the safety of individual assets are conflicting, which means that methods using at risk management aimed to technical facility safety need to be multi criterial (Procházková 2017).

2 SAFETY AND RISKS OF TECHNICAL FACILITIES AND PRODUCTS

At present in advanced engineering disciplines described in works (Ale et al. 2010, Bérenguer et al. 2011, Briš et al. 2009, Cepin & Bris 2017, Novakowski et al. 2014, Podofillini et al. 2015, Steenbergen et al. 2013, Walls et al. 2016, Procházková 2015, 2017), the safety is understood as the attribute that emerges on the system level. The safety shows the quality of set of human measures and activities, which ensure that system is safe. Among the important quantities the following relations are valid: *dependable (reliable) system* is a system that performs required functions in a given place, a given time and a given quality during the whole life cycle; *secure system* is the dependable system that is protected against to internal and external disasters of all kinds; *safe system* is the secure system that does not endanger itself and its vicinity under all conditions; and *risk* je is understood as the probable size of losses, damages and harms on protected assets in real system that is calculated for unit of space and unit of time. It is dependent on the disaster size and on the local assets vulnerabilities. Safety and risk are in certain relation, but they are not complementary quantities. The risk reduction means the safety increase, but it is not always valid inversely (Procházková 2015). The complementary quantity to safety is the criticality; in some legislation, e.g. in the SEVESO directive, it is used the term recklessness instead of criticality. *Criticality* denotes the limit (boundary) from which the risk impacts are significant up to eliminative for followed system, which means that appurtenant risk needs to be always mastered.

3 DATA USED AT CHECKLIST FORMATION

On the basis of data given in publications (Ale et al. 2010, Bérenguer et al. 2011, Briš et al. 2009, Cepin

Figure 1. Items that influence the result of work with risks of technical product.

& Bris 2017, Novakowski et al. 2014, Podofillini et al. 2015, Steenbergen et al. 2013, Walls et al. 2016, Procházková 2015, 2017), and in Archives (ČVUT 2017), it is necessary to consider seven items (Figure 1) that influence the result of work with risks of technical facility, i.e. its safety, namely:

1. Context in which the risks, inherently connected with technical facility, are inserted.
2. List of considered sources of risks.
3. Type of risk form.
4. Ways of mastering the risks.
5. Process model of work with risks, application of the TQM and Coase theorem.
6. Technique of management and coping with risks of technical facility.
7. Way of management of risks in time.

Ad 1. It holds that the most general context to which the risks of technical facility are inserted has the assets: human life, health and security; property and public welfare; environment; and technologies and infrastructures. The process model ensuring the human security and development is in (Procházková 2015). On the basis of results in (Procházková 2015, 2017) and data obtained directly in practice (ČVUT 2017), in the technology sector it is often considered only the context of technical facility or context of enterprise that administrates the technical facility, and in many cases only the context of production facility or its part. It is understandable that the use of more limited context means the higher default of reality.

In practice, it means that the appurtenant solution does not consider some sources of risks and the impacts of risks´ realization on all public and enterprise assets. They are neglected: harmful phenomena from technical facility vicinity and phenomena induced by bad decisions of management of enterprise or administrative bodies; and the impacts of risks on humans, properties and environment in technical facility vicinity.

Ad 2. With regard to results in (Procházková 2011a, 2015, 2017) and data obtained directly in practice (ČVUT 2017), it holds that in practice there are used the following choices of sources of risks:

1. Sources of risks determined either by legislative, or by experiences of worker who solves the task.
2. Only technical sources of risks in a given technical facility. Usually, it goes on risks connected with: material (fulfilment of required parameters, supplier relations—alternative material etc.); construction and interfaces of components and facilities (free procedures, presence of unstable hazardous substances….); production procedures, e.g. at welding, specific works with millers, lathes etc.; and conditions that are necessary pro production of quality product, e.g. certain pressure, certain temperature or certain humidity of surrounding medium etc.
3. Technical sources of risks and human factor. To items given in point 2, they are added the risks connected with false operations of workers.
4. Technical sources of risks and human factor in the broadest interpretation. To items given in point 3, they are added risks connected with sources of organizational accidents (i.e. bad decision-making, using the false procedures etc.).
5. Technical sources of risks, sources of risks threatened the workers lives, health and safety, sources of organizational accidents and sources of risks in working environment.
6. The sources of risks given in point 5 plus external sources of risks.
7. The sources of risks given in point 6 plus sources of risks from interfaces of facilities, components and system that disturb the technical integrity, the originators of which are in automatization, education and good skill.
8. All Hazard Approach in the form described in (Procházková 2011a). This selection considers risks from the five basic domains (ca 77 sources).

The last set of risk sources is complete, but it is challenging on data, methods, knowledge, experience and time period. It requires the strategic, systemic and proactive approach and it has according the results of FOCUS project (Procházková 2015) a lot of deficits at use in present practice.

Ad 3. On the basis of results in (Procházková 2015, 2017) and data obtained directly in practice (ČVUT 2017), it holds that in technical practice, there are used the partial, integrated and integral

(systemic) risks. Partial risk is the risk connected with one asset. The partial risks are various, e.g. health risks, technological risks, risk of fire etc. For their determination, many legal rules and supporting software exist (Procházková 2011a). Integrated risk represents the sum or other aggregation of partial risks. It is used e.g. in protection of workers lives, health and safety (Procházková 2011a). Integral (systemic) risk is based on system concept of entity and it also includes the interfaces among the assets and components of technical facility (Procházková 2015, 2017). It is given by relation

$$R(H) = \left[\sum_{i=1}^{b} A_i(H) Z_i(H) + \sum_{i=1}^{n} \int_0^T \int_s F(H, A_i, Pi, 0, t) dS dt \right] \cdot \tau^{-1}$$

in which $\boldsymbol{H}$ is the hazard connected with given disaster in site of technical work; $\boldsymbol{A_i}$ are values of followed assets for i = 1,2,…, n; $\boldsymbol{Z_i}$ are vulnerabilities of assets for i = 1,2,…, n; $\boldsymbol{F}$ is the loos function; $\boldsymbol{P_i}$ are the occurrence probabilities of damage of assets for i = 1,2,…, it goes on conditioned probabilities; $\boldsymbol{O}$ is vulnerability of protective measures; $\boldsymbol{S}$ is the size of followed space; $\boldsymbol{t}$ is time measured from the disaster origin; $\boldsymbol{T}$ is the time period of losses origin; and $\boldsymbol{\tau}$ is the disaster return period.

It is evident that for long-term ensuring the safe technical facility, it is necessary to consider the integral risk. Because in above given formula, the loss function is not known, so in (Procházková 2015, 2017) there are given procedures used in practice for estimation of integral risk; they are based on the analysis of real and simulated disasters´ scenarios and expert judgement.

It is necessary to note that determination of individual types of risks also differ in exactingness on data and methods of their processing (Procházková 2011a, 2017); the lowest challenging is the determination of partial risks, and therefore, these are mostly used in practice, although their validity with regard to total technical facility safety is very limited.

Ad 4. On the basis of results of investigations given in (Procházková 2015, 2017) and data from practice (ČVUT 2017), three cases are found. In the first one, there are used the risks, which are determined and mastered only after the technical facility construction (Prochazkova 2015); this way is danger because some of important risks, which could be only mastered by specific technical measures in assignment of technical facility, can be only reduced by organizational measures that are lower effective than technical measures (ČVUT 2017, Procházková 2015, 2017). In the second one, the risks are considered from beginning the technical facility design up to its termination from operation. This way depends on requirements of legislation, knowledge and skill of designers, constructors and operators, which does not guarantee the consideration of all sources of risks. In the third one, risks are considered from beginning the technical facility design and at trade-off with them, it is used the Defence-In-Depth approach, which requires system thinking, multi sectoral and transdisciplinary knowledge and experiences (ČVUT 2017, Procházková 2015).

The ensuring the safety of technical facility and its vicinity depends on quality of work with risks and on accessible possibilities of both, the technical facility management and personnel, and the public administration (ČVUT 2017).

Ad 5. The risk mastering in given time and given site requires: knowledge; capabilities; competences, finance; material, technical and human sources. Therefore, in next we deal not only with alone work with risks, but also with practical procedures that are used at decision-making on the risk mastering. On the basis of results of investigations in (Procházková 2015) and data obtained directly in practice (ČVUT 2017), it holds that in technical practice it needs to use the process model shown in Figure 2.

It is evident that if we are not able to identify and analyse some risk, so we are not capable effectively to defend the followed entity against it. The error, which we do at risk analysis, is transferred to emergency, continuity and crises plans, and it reduces their value in relation to planned measures directed to protection of human lives and health, and also to operational capability of rescue units participating in performance of rescue operations.

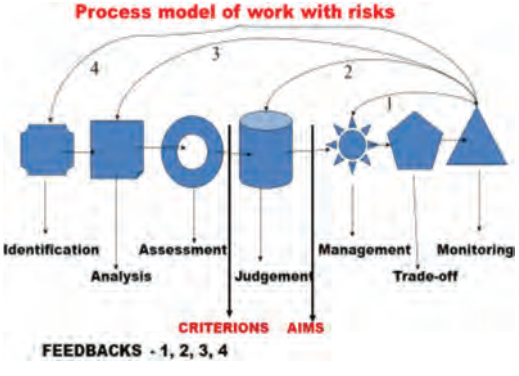

Figure 2. Process model of work with risks. Criterions = conditions that determined when the risk is acceptable, conditionally acceptable or unacceptable. Aims denote required states. Numbers 1,2,3,4 denote feedbacks that are used if the monitoring shows that followed requirements on safety are not fulfilled.

The aim of risk management is to find the optimum way, how to reduce the founded risks to required socially acceptable level, possible to keep up on this level. The risk engineering aim is then to find the way, how under available options, the risk management proposed measures and activities for risks mastering to realize and to ensure their reliability and function. The risk reduction is almost always connected with increase of expenses and claims on knowledge. The risk management is led by effort to find the boundary to which it is endurable the risk reduction, so the spend expenses would be socially acceptable.

In harmony with the public interest it is necessary so the risk acceptability might have the social dimension. Therefore, it is necessary to consider:

1. For whom the risk could be acceptable; for risk originators, for politicians or for public?
2. Who determines the risk acceptability; politicians adjudicate on that, which is legal, and so they could not adjudicate on that, which is acceptable.
3. If at risk determination there were discussed actually permitted risks, intolerant threshold values and attitudes of public to risks.

Risks are inherent factors of human system, i.e. they were, are and will be, and besides they will occur new ones. Therefore, the management of risks requires risk dimension and measurement of risk, which consider not only the physical damages, harms, victims and economic losses bulk, but also the social, organizational and institutional factors.

The outputs from risk management process for needs of good governance according to TQM are: *Risk assessment document* – records on all appurtenant risks; *Top risks list* – list of selected risks, the mastering with them has the highest claims on sources and time; *Retired risk list* – serving as the historical reference for future decision-making.

Technique of alone risk management from the point of provident handle with forces, sources and means, formally reviews before at each phase of work with risks the results of management and mastering the risks in the context of profits and expenses on outputs. The Coase theorem (Coase 1960) is used for determination of economic optimum in expenses on mastering the risks.

Ad 6. On the basis of results in (Procházková 2015, 2017) and data obtained directly in practice (ČVUT 2017), it holds that in technical practice it needs to understand that technical facility risk management and risk mastering are not the task of individual, not one organisation or one sector. It goes on the collective effort of all participants. It is evident that: professionals who have knowledge, data and capability to apply suitable methods can only determine the risk; and only persons who have appropriate competences can decide on handling with risk, i.e. legally determined representative of public administration or technical facility; and risk mitigating and control could be performed only by professionals who have appropriate knowledge, capabilities, skill, equipment, sources and means. The public is lawful participant at risk mastering because it goes on its security and quality of life. Because there are many risk sources, and countermeasures for their mastering are very often conflicting, it is necessary to use the risk management aimed to safety (Zairi 1991).

The negotiation with risks goes from present possibilities of human society and it lies in splitting the measures and activities for risk mastering into: prevention, mitigation, response and renovation.

So the executive body of organisation could effectively work with risks, it is necessary to determine the procedure for risk determination by legal rule, and simultaneously to determine the value scales by which the outputs of tools for determination of risks in organization are interpreted; i.e. it is necessary to determine which risk value is acceptable, which one is conditionally acceptable and which one is unacceptable. In tools for risk determination, it is necessary to distinguish the sophisticated tools for professional sphere and tools for administrative bodies for which the checklists are the most suitable.

Ad 7. On the basis of results in (Procházková 2015, 2017) and data obtained directly in practice (ČVUT 2017), it holds that in technical practice it needs to understand that from system viewpoint the ensuing the technical facility safety is the requirement on the complex system, not on its components.

Risks are inherent attribute of human system and each technical facility, and therefore, they need to be managed during the whole technical facility life time. The aim of risk management is to ensure the safe technical facility, i.e. also its competitiveness today and in future, i.e. it goes on determination the priority risks and their correct management. The risk management needs to ensure the technical facility safety at conditions normal, abnormal and critical.

On the basis of present knowledge given in (Procházková 2011a, 2015, 2017), the Safety Management System (SMS) of complex object is built on principles of process management and it includes the organization structure, responsibilities, practices, regulations, procedures and sources for determination and assertion of prevention of disasters or at least the mitigating their unacceptable impacts. Usually, it deals with many questions, apart from also the organisation, workers, identification and assessment of hazards and risk that follow from them, organization management, change

management in organization, emergency and crisis planning, safety monitoring, audits and review.

The process safety management is concentrated to six processes: concept and management; administrative procedures; technical matters; external co-operation; emergency preparedness; and documentation and investigation of accidents. These processed are further divided into sub processes that are in detail described in (Procházková 2015, 2017).

The processes coordination is aimed to ensuring the safe facility at conditions normal, abnormal and critical. The coordination in this context is understood as the controlled process, the aim of which is to create and to operate the technical facility in required quality; it follows the processes in spheres as: space and time, personnel, material, finance and documentation (Procházková 2015, 2017).

For support of safety management system, it is necessary to process the series of remedial tools as: security plans; on-site and off-site emergency plans; continuity plans; crisis plans; in practise the risk management plans for priority risks have been very came in useful (Procházková 2017). The most important is safety culture as it is stressed in fundamental work (Kongsvik, Almklov, & Fenstad 2010).

4 METHOD FOR CHECKLIST MAKE-UP AND METHOD OF ITS USE IN PRACTICE

Data and experiences from work with risks are given in (Procházková 2011a, 2015, 2017) and in works that are cited in them. They clearly show that the facility risks are pulled off, the better level of facility safety is reached. From this reason, we used at construction of tool for judgement of technical facility safety: the final judgement of used risk engineering methods quality (US EPA 2008), i.e. we compile the checklist; and the maximum utility theory principles (Keeny & Raiffa 1993). The checklist was proposed by procedure described in (Procházková 2011b) so the question answer "YES" in each aspect given in Chapter 3, belongs to the best way of aspect solution on the basis of present knowledge and experiences. The scale for judgement of total result is selected in agreement with recommendation in (Procházková 2017).

For real judgement of safety of technical facilities, we used the safety audit method (Procházková 2011a, b). At safety audit, the answer to each question is always separately formulated by 5 evaluators (technical director, security expert of technical facility, security expert of local public administration, security expert of regional public administration, authors) according to documentation of technical facility. The final evaluation of each question is made as median from partial evaluations. In case of significant doubts at certain real question judgement, the note was given in special column of check list; and the final results in these cases are finally obtained by panel discussion of experts.

5 CHECKLIST

Specific checklist compiled by procedure described in foregoing chapter is in Table 1. It contains 72 questions. The scale for its final evaluation (i.e. the determination of safety rate) is in Table 2.

Table 1. Check list for judgement of technical work safety according to judgement of work with risks. Answers: Y – YES, N – NO; R – Remark.

Question	Answer Y	N	R
Are in technical facility documentation distinguished the terms danger, hazard and risk?			
Is technical facility documentation based on context that considers only the technical work assets?			
Is technical facility documentation based on context that considers technical work assets and selected public assets (employee, contractors, and visitors, humans in work vicinity, working setting and environment)?			
Is technical work documentation based on context that considers technical facility assets and all public assets?			
Are only considered risk sources that are determined by expert experience?			
Are only considered only risk sources that are determined by legislative and expert experience?			
Are only considered risk sources that are connected with technical facility alone?			
Are considered risk sources that are connected with technical facility alone and human factor connected with badly performed working operation?			

(*Continued*)

Table 1. (*Continued*).

Question	Answer Y	N	R
Are considered risk sources that are connected with technical facility alone and human factor in the broadest concept?			
Are considered risk sources that are connected with technical facility alone, human factor in the broadest concept, workers health jeopardy and threatening the working environment?			
Are considered risk sources that are connected with technical facility alone, human factor in the broadest concept, workers health jeopardy, threatening the working environment and environment outside the technical facility?			
Are considered risk sources that are connected with technical facility alone, human factor in the broadest concept, workers health jeopardy and threatening the working environment in system context, i.e. also risk sources connected with linkages and flows in technical facility?			
Are considered risk sources according to All-Hazard-Approach?			
Are only considered partial risks?			
Are considered partial risk and integrated risk?			
Are considered partial risks, integrated risk and integral risk?			
Are risks in technical facility systematically followed?			
Are risks in technical facility systematically followed only after technical facility building?			
Are risks in technical facility systematically followed for its whole life cycle, i.e. from its design?			
Are risks in technical facility systematically followed for its whole life cycle, i.e. from its design and in its design and operation used the Defence-In-Depth approach?			
Is at work with risks in technical facility systematically used the process model of work with risks?			
Is at work with risks in technical facility systematically used the process model of work with risks that possesses clearly determined criterions for risks acceptance?			
Is at work with risks in technical facility systematically used the process model of work with risks that possesses clearly determined criterions for risks acceptance, which respect public interest (i.e. they have social dimension)?			
Is at work with risks in technical facility systematically used the process model of work with risks that possesses clearly determined criterions for risks acceptance and aims of risk management?			
Is at work with risks in technical facility systematically used the process model of work with risks that possesses clearly determined criterions for risks acceptance with regard to public interest?			
Is at work with risks in technical facility systematically used the process model of work with risks that possesses clearly determined criterions for risks acceptance with regard to public interest and corrected measures in monitoring for the case that risk will happen unacceptable?			
Is at work with risks in technical facility systematically determined and followed the set of priority risks?			
Does technical facility risk management technique ensure in each phase of work with risks the review of profits and costs connected with measures for risks mastering, so economical handling with forces, sources and means might be ensured in technical work?			
Does technical facility risk management technique ensure in each phase of work with risks the review of profits and costs connected with measures for risks mastering, so economical handling with forces, sources and means might be ensured in technical work and in public administration?			
Are in technical facility systematically performed the preventive measures for reduction or avert of some risks?			
Are in technical facility systematically performed the preventive measures for reduction or avert of all priority risks?			
Are in technical facility systematically performed the preventive measures for reduction or avert of all risks that have potential to cause important losses to technical facility?			
Are in technical facility systematically performed the preventive measures for reduction or avert of all risks that have potential to cause important losses to technical facility and unacceptable impacts on surrounding environment?			
Are in technical facility systematically performed preventive measures for reduction or avert of all risks and prepared the mitigating measures for reduction of some highest risk impacts?			
Are in technical facility systematically performed preventive measures for reduction or avert of all risks and prepared the mitigating measures for reduction of all priority risks impacts?			
Are in technical facility systematically performed preventive measures for reduction or avert of all risks and prepared the mitigating measures for reduction of all risks impacts that can cause the significant losses to technical facility?			

(*Continued*)

Table 1. (*Continued*).

Question	Answer Y	N	R
Are in technical facility systematically performed preventive measures for reduction or avert of all risks and prepared the mitigating measures for reduction of all risks impacts that can cause the significant losses to technical facility and unacceptable consequences for surrounding environment?			
Is technical facility insured against risks?			
Does technical facility possess the finance, material, technical, personal and organisational measures for response to important risk?			
Does technical facility possess the finance, material, technical, personal and organisational response for renovation after important risk realisation?			
Does technical facility possess the finance, material, technical, personal and organisational measures also for response and renovation after extreme unexpected realisation?			
Are at work with risks in technical facility only considered the results of preliminary risk analyses?			
Are at work with risks in technical facility preferred the results of standard, fast and low precise risk analyses before results of preliminary risk analyses?			
Are at work with risks in technical facility preferred the results of detailed risk analyses in synoptic concept before the results of preliminary risk analyses and standard, fast and low precise risk analyses?			
Are at work with risks in technical facility preferred the results of individual and specific risk analyses before the results of detailed risk analyses in synoptic concept, preliminary risk analyses and standard, fast and low precise risk analyses?			
Are at work with risks in technical facility determined the criterions for assessment?			
Are at work with risks in technical facility determined the criterions for assessment technical and economical items?			
Are at work with risks in technical facility determined the criterions for assessment technical and economical, external and internal items?			
Are at work with risks in technical facility determined the criterions for assessment technical and economical, external and internal and socially political items?			
Are at work with risks in technical facility determined the requirements for ensuring the safety?			
Are at work with risks in technical facility determined the requirements, standards and norms for ensuring the safety?			
Are at work with risks in technical facility determined the requirements, standards and norms for ensuring the safety and partial aims?			
Are at work with risks in technical facility determined the requirements, standards and norms for ensuring the safety, partial aims and methods and procedures?			
Are at work with risks in technical facility determined the requirements, standards and norms for ensuring the safety, partial aims, methods and procedures, and also limits and conditions?			
Are at work with risks in technical facility determined the requirements, standards and norms for ensuring the safety, partial aims, methods and procedures, limits and conditions and also the authorizations of persons or institutions?			
Does the technical facility administrator hold the safety management system that is compiled on the principles of process management and systemic work with risks?			
Does the technical facility administrator hold the safety management system (SMS) that contain the organizational structure, responsibilities, practices, rules, procedures and sources for determination and enforce of disaster prevention or at least for mitigating the unacceptable disasters impacts in technical facility and in its surrounding?			
Does the technical facility administrator hold the safety management system (SMS) that contain management of six processes: concept and management; administrative procedures; technical matters; off-site co-operation; emergency preparedness; and documentation and accident investigation?			
Does the technical facility administrator hold the SMS that contains the concept and management process with sub-processes for: overall concept; reaching the safety partial aims; safety governance; alone safety management system; personnel—human sources management, education and training, internal communication, working environment; audit and assessment of performance of safety aims?			
Does the SMS technical facility contain the administrative procedures process with sub-processes for: hazard identification from possible disasters and corresponding risk assessment; documentation of procedures (including the work permits); changes management; safety connecter with contractors; surveillance under products safety?			

(*Continued*)

Table 1. (*Continued*).

Question	Answer Y	N	R
Does the SMS technical facility contain the technical matters process with sub-processes for: research and development; design and montage; inherently safer processes; technical standards; storage of hazardous substances; and integrity maintenance and maintenance of equipment and buildings?			
Does the SMS technical facility contain the off-site co-operation process with sub-processes for: co-operation with public administration; co-operation with public and other involved (including the academic institutions); and co-operation with other enterprises?			
Does the SMS technical facility contain the emergency preparedness process with sub-processes for: on-site planning; facilitation of off-site planning (for which the public administration is responsible); and co-ordination of activities of resort organisations at ensuring the emergency preparing and the response?			
Does the SMS technical facility contain the documentation and accident investigation process with sub-processes for: processing the reports on disasters, accidents, near misses and other instructive experiences; investigation of damages, losses and harms and their causes; and response and consequential activities after disasters (including the application of lessons and information sharing)?			
Does the SMS technical facility contain the program for safety improvement in which there are given: roles of stakeholders; rules for safety culture improvement (golden rules); and relevant responsibilities?			
Does the SMS technical facility contain the program for safety improvement in which there is given: security plans (on strategic, tactical, functional and technical levels); on-site and off-site emergency plans; continuity plans; and crisis plans?			
Does the SMS technical facility contain the program for safety improvement in which there is given the risk management plan with clearly determined countermeasures and responsibilities?			
Does the SMS technical facility contain the program for safety improvement in which there is given the risk management plan with clearly determined countermeasures and responsibilities that only contains the technical risks?			
Does the SMS technical facility contain the program for safety improvement in which there is given the risk management plan with clearly determined countermeasures and responsibilities that only contains the technical and organisational risks?			
Does the SMS technical facility contain the program for safety improvement in which there is given the risk management plan with clearly determined countermeasures and responsibilities that contains the technical, organisational and external risks?			
Does the SMS technical facility contain the program for safety improvement in which there is given the risk management plan with clearly determined countermeasures and responsibilities that contains the technical, organisational, and external and cyber risks?			
Does the SMS technical facility contain the quality monitoring the both, the integral risk and all important partial risks and the corrective countermeasures for occurrence of unacceptable risks?			
Total			

Table 2. Value sale for safety level determination.

Safety level	Values v%	Number of answers "YES" in Table 1
Extreme high – 5	More than 95%	More than 68
Very high – 4	70–95%	51–68
High – 3	45–70%	33–50
Medium – 2	25–45%	19–32
Low – 1	5–25%	4–18
Negligible – 0	Lower than 5%	Lower than 4

6 RESULTS OF JUDGEMENT OF SAFETY LEVEL FOR SELECTED COMMON TECHNICAL FACILITIES AND DISCUSSION

For judgement of safety levels, it was selected 5 common technical facilities that do not belong to the critical objects in the Czech Republic; they belong to Small and Medium Enterprise (SME); specifically: chemical plant; machine plant; thermal power plant; airport; highway (ČVUT 2017). In all cases, the access to the facility documentation was regardless conditioned by agreement that real data on technical work will not be published. Therefore, it is only given the final result of investigation in the form:

1. Number of answers YES moves in interval 20–29 with mean value (median) 24.
2. The highest reached validities of work with risks:
   - there are only followed assets of technical facility,
   - there are only followed the risk sources that are in technical facility and human factor connected with wrongly performed operations,
   - there are considered partial risks and mostly integrated risk connected with workers´ health threatening,

– risks are followed only after technical facility building,
– at work with risks of technical facility it is used the process model of work with risks that has only clearly determined the acceptance criteria for risks inside, and sporadically for risks outside,
– there are performed the preventive measures only for reducing or averting the priority risks,
– it is ensured the insurance of technical facilities for case of realisation of famous risks,
– there are preferred the results of fast and less precise risk analyses,
– at work with risks there are only determined the criterions for technical and economical assessment,
– there are applied demands, standards and norms for ensuring the technical safety,
– the technical facility administrator has the safety management system based on principles of process management.

Comparison of number of answers YES with the scale in Table 2 shows that the safety level is medium in the followed SME. The judgement of level of reached validities of used techniques for work with risks shows that in practice, the system approach is missing and that in common technical facilities there are only respected the demands given in legislative and own experience with risks.

From the viewpoint of human system security, the obtained finding is not too comforting. Results of detail long-term research of technological facilities and infrastructure accidents, summarized in (Procházková 2017), fully agree with outcomes that are in many papers published in journal *Safety Science,* which are perfectly expressed in work (Konsvik, Almklov & Fenstad 2010). Structure of safety culture needs to start on top management level and to spread to lower management levels.

However, the safety culture is not all-powerful tool. Therefore, it is also necessary, so: the technological facility owner may not prefer the profit prior to human system security; and the tools used for safety formation need to correspond to present level of cognition. In these cases, the state government and legislation play important role. The government needs to ensure the corresponding education level, high qualified supervision and inspection under the technological facilities behaviour, namely starting from sitting, over building and operation up to decommission and decontamination of territory.

Subsidiary product of study of documentations of mentioned technical facilities and others (ČVUT 2017) is the detection that experts from different domains connected with technical facility do not co-operate; it is proved by records in documentations on conflicts that had not originated if expert communicate together.

7 CONCLUSION

An overview of areas that affect the selection of individual techniques work with the risks shows that where it comes on ensuring the safe technical facilities, it is a need to use the techniques for working with risks, which are based on the system concept and critical evaluation of all influences that can act on the technical facility, now and in the future.

The investigation of problems related to the work with risks of technical facilities showed that at common technical facilities, is the medium level of safety. It reflects low level of work with risks; i.e. low safety culture and weak power of government in formation of territory safety.

The judgement of validity of methods and procedures of work with risks, which are used in practice in the Czech Republic, shows that they still predominate the techniques that do not respect the system nature of technical facilities and the dynamics of development. From the study of followed technical facilities documentations, it is obvious that at formation of their safety, the experts from different fields work separately, which of course cannot guarantee optimal safety and optimal costs.

The Kursk submarine disaster in view of resilience assessment

A. Leksin & U. Barth
University of Wuppertal, Wuppertal, Germany

R. Mock
Zurich University of Applied Sciences, Winterthur, Switzerland

ABSTRACT: In August 12, 2000, the Russian Oscar-class submarine Kursk (K-141) sank during a navy manoeuvre in the Barents Sea killing all 118 personnel on board. The vessel was powered by two nuclear reactors and carry nuclear missiles which can be armed. The disaster is well documented and encompasses many socio-technical elements influencing the sequence of events finally leading to wreckage. For this, the disaster is considered as an archetypical event which might highlight the advantages as well as the limitations of resilience assessment approaches, e.g. in comparison with established risk assessment methodology. For this the paper starts with results of a literature survey with resilience metrics and areas of technical applications. The Kursk disaster is reviewed by available literature and research reports by Root Cause Analysis. The causing aspects (events, procedures, human factors, etc.) are then structured and classified according to their relevance and impact on vessel's resilience. In a next step, these aspects are contrasted to the risk assessment approach as defined, e.g. by ISO 31000. The methodological juxtaposition is intended to characterize the maturity level of resilience analysis in a real world framework as well as to elaborate major differences in validity of the underlying system analysis concepts. Finally, the pros and cons of the reviewing approach are discussed.

1 INTRODUCTION

In the context of risk analysis, the term resilience is often used nowadays. It is noticeable that both a generally accepted definition of this term and consequently a metric of resilience are missing. The differences between risk and resilience assessment often remain unclear, e. g. in connection with related terms such as availability, vulnerability, and Business Continuity Management (BCM). To a certain extent, this follows a tradition of dealing with indefinite terms such as, risk, which in turn is based on other terms that are not always clearly definable. For instance, there is a risk if several factors coincide: danger, exposure and vulnerability (cf. (Lenz 2009)).

The paper is an attempt to work out the differences and similarities between the two concepts of risk and resilience, where the approach follows the idea of "learning by doing" system assessments. An archetypical case was selected for this: The Kursk submarine disaster in 2000. On the one hand, a submarine is a self-contained socio-technical system, which simplifies considerations. The case itself, in turn, can be presented from a variety of sources. One of us (A. Leksin) can refer to less well known Russian literature as well as on feedback of one Russian accident investigator. The case was dealt with a root cause analysis (RCA), which was then used for the discussion on risk and resilience assessment.

The remaining paper is structured as follows: Chapter 2 compiles definitions of risk, resilience and the comparison of major system management terms. Chapter 3 describes the chronology of major events and causative aspects of the Kursk disaster and present a part of the resilience identification. Based on sequence of major events differences in risk and resilience assessment are elaborated in chapter 4. The results are discussed in chapter 5.

2 TERMINOLOGY

There is extensive literature research on the definition of the term resilience, e. g. (Husseini et. al. 2016, Francis et al. 2014). There is a consensus that resilience is concerned with socio-technical systems and their ability to respond to disturbances in order to maintain the specified performance. This paper follows the definition of (Lay et al. 2015) who defines resilience by a set of system abilities:

Resilience: System abilities to respond to disturbances, to monitor, to learn, and to anticipate developments.

Table 1. Comparison of major system management terms.

Term	Connotation	Intrinsic system property	Management	Focus
Risk	negative	no	external interference	(undesired) events
Resilience	positive	yes	Intrinsic	System performance
Vulnerability	negative	yes	external interference	(undesired) flaws
BCM	positive	no	external interference	(undesired) events
Availability	positive	yes	external interference	failures

Responsiveness considers all kind of disturbances into account, all deviations from specified performance levels, both positive and negative impacts. The term "disturbance" indicates that point of view is dominated by negative impacts.

Furthermore, responsiveness indicates systems immediate response to disturbances. Hence resilient systems are designed to react on disturbances in a self-managing way.

Looking at socio-technical system, humans are the carrier of its learning and anticipating abilities as covered by system management processes. Monitoring can be done both automatically/technically and by humans also depending on surveillance level.

The concept of risk is assumed to be known to the reader. The paper follows the well-established definition of risk of (Kaplan & Garrick 1981):

$\{Risk_i \mid s_i, f_i, c_i\}$,
where:
S_i: scenario identification or description
F_i: probability (or frequency) of that scenario
C_i: consequence or evaluation measure of that scenario, i.e., the measure of damage.

The frequency/consequence concept of risk is also along to common risk management standards, e.g. (ISO 31000 2009). Risk figures are usually computed by $f_i \cdot c_i$. Note, that scenario is not defined by (Kaplan & Garrick 1981) and (ISO 31000 2009). The authors will use it in terms of (imagined) sequence of events. Probability is a measurement of uncertainty of (future) events based on (statistical) data. As a consequence, risk becomes a concept of proactivity and finally preparatory by management.

Vulnerability is a well established term in IT security which is easily adaptable to any other engineered systems. According to (NIST 2012), the definition is:

Vulnerability: Weakness in an information system, system security procedures, internal controls or implementation that could be exploited by a threat source.

For this, the understanding of vulnerability follows the keyhole principle and is an intrinsic system property. Vulnerability management is then to reactively plug flaws.

However, the limits of the concepts are not always clear: According to (Lenz 2009:38–43.69), risk always coincides with danger, exposure and vulnerability. Additional components such as coping capacity and criticality (meaning and consequences upon entry) can be added to this assumption.

The concept of Business Continuity Management is a related system maintaining process to risk, resilience and vulnerability management, as defined by (SBA 2013):

Business Continuity Management (BCM) is a company-wide approach designed to ensure that critical business processes can be maintained in the event of major internal or external incidents.

The view is the management of single (major) undesired events in order to minimise their impacts. The management objective is to maintain the specified business performance level.

3 THE SUBMARINE KURSK (K-141) DISASTER

The Kursk submarine disaster took place in the Barents Sea on 12 August 2000, killing all 118 personnel on board. In this paper, the course of the disaster, if publicly known, serves as a test case for the methods of system analysis listed in chapter 1. The detailed description of the disaster is a significant part of the resilience identification step which is explained in chapter 4.2. The authors process the Kursk catastrophe on the basis of publicly available information and present a possible sequence of events. Further discussions will then be held on this basis. The case covers all elements that make an analysis interesting from very different perspectives, i.e. the interaction of people and technology in a stressful overall situation. However, the basic system performance remains simple: *ensuring the safety and health of the crew*. The question is to what extent the system analysis methods listed above would have been suitable for recognizing this accident in advance.

3.1 *Event of the Kursk disaster*

There are about 18 different disaster versions of the Russian Oscar-class submarine Kursk (K-141).

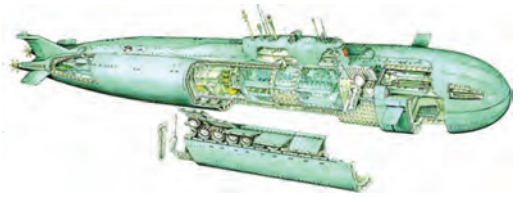

Figure 1. Example of the inner and outer hull construction with P-700 Granit "Shipwreck" cruise missiles on the bow side (Militaryarms 2017).

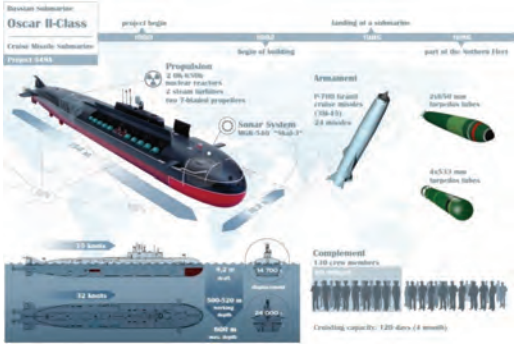

Figure 2. Characteristics of Oscar class submarine (Defending 2015).

This paper considers one of the official versions—an explosion of a torpedo but due to the influence of a second submarine. The chronology of major events and causative aspects (events, procedures, human factors, etc.) are structured and classified according to their relevance to give a better overview for the reader by describing only the important steps of the disaster. The RCA breaks down a complex scenario into individual steps (black boxes in the RCA diagram of Figure 3), which ultimately indicate a cause-effect chain. Secondary event chains can be added (grey boxes). For better understanding the boxes are numbered. The event numbers can also be found in the case description.

The description of the significant factors which had a strong influence on the worst case scenario can be traced back to 1999. Kursk was on the military mission in the Mediterranean Sea to monitor the United States Sixth Fleet responding to the Kosovo crisis. *(1)* After the successful mission the submarine returns into the stationing port of Vidyayevo. After a longer down time due to financial reason the commissioning of the submarine by the crew was under time pressure towards the end of May 2000 because of the Russian Navy large scale naval exercise planning for August 2000. Therefore the crew had a shortage of lack of planned training activities in the last approx. 9 months *(2)*. But due to the last successful mission in the Mediterranean Sea, it cannot be ruled out that part of the crew was self-confident. Either because of time pressure and/or the incorrect planning of the Marine areas by the Military-Maritime Fleet of the Russian Federation *(3)*, the way to the naval exercise area was over "underwater mountains" *(4)*. Such manoeuvre through areas of not deep-water sites of the sea can be dangerous for an Oscar-class submarine and other submarines because it is difficult to manoeuvre due to radar shadows of sonar and magnetic interference. The threat obviously increases with the condition that other countries submarines are always present in such naval exercises.

Table 2. Explosive characteristics of USET-80 and VA-111.

USET-80 (warshot torpedo)	Total weight – 2000 kg explosive weight – 200/300 kg
VA-111 (warshot torpedo)	Total weight – 2700 kg combat unit – 200 kg explosive weight 200 kg

On August 10th, 2000 the Kursk had begun the planned activities in the naval exercise near the Kola Bay. On August 12th, 2000 at 11:28 local time, two explosions were detected by various seismologists and hydroacoustics. The first explosion corresponded for ≈500 [kg] TNT equivalent and after 135 seconds the second explosion with ≈5000 [kg] TNT equivalent. Unfortunately the exact number of armed cruise missiles at the Kursk varied depending on references. Typical armament consist 24 of SS-N-19/P-700 Granit "Shipwreck" cruise missiles that were designed to defeat the best naval air defences. The missile containers are located on both sides of the deckhouse, outside the rugged boat hull. Based on the most references, photographic material and video footage the Kursk had during this naval exercise 24 of P-700 Granit "Shipwreck" cruise missiles on board. Due to the double hull construction of the Oscar-class submarine, the second explosion of the P-700 Granit "Shipwreck" cruise missiles did not initiated. Constructors considered such worst-case scenario and reinforced the inner hull with high content stainless steel about 45–68 [mm] thick. There is 200–350 [cm] gap to the 5–10 [mm] thick outer hull.

Therefore both detected explosions were in the 1st torpedo compartment. As before the exact number of dummy and warshot torpedos varies from 8 to 18 and even 24. Weapons included 18 of SS-N-16 "Stallion" (РПК-6 "Водопад"), hydrogen peroxide-fueled Type 65 torpedo (65–76A), USET-80 (УСЭТ-80) and their different types. Kursk was armed at that moment with dummy (65–76ПВ and USET-80) and warshot (65–76A, USET-80) as well as torpedo VA-111 Shkval.

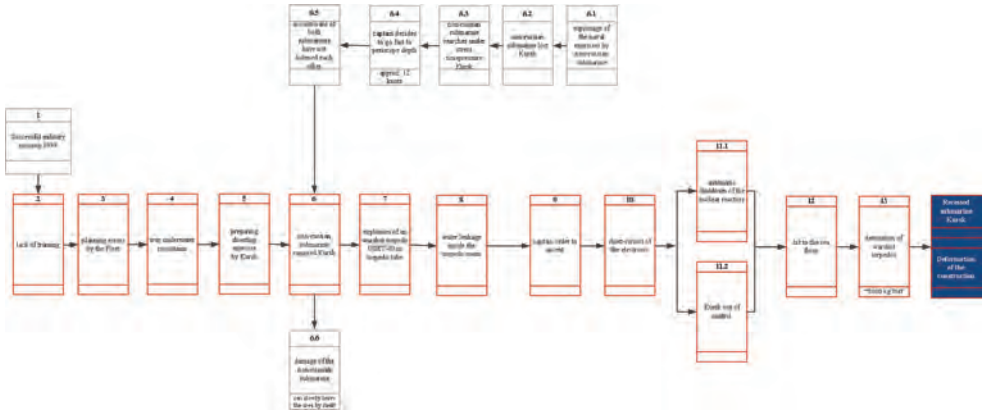

Figure 3. Sequence of events in form of RCA.

Although it was an exercise, Kursk loaded, as mentioned before, also with combat capable weapons. This means that some of the torpedo tubes are constantly in combat readiness with an armed warshot torpedo. Warshot torpedo which was used by Kursk in military mission is typically the torpedo USET-80. Table (2) shows short characteristics of the torpedoes USET-80 and VA-111 Shkval.

Based on these characteristics, the possibility of an USET-80 in the torpedo tube is very high and its TNT equivalent is near to 500 [kg] *(7)*. Also it was planned to launch the USET-80 torpedo as secondary in this naval exercise.

However, all versions of disaster reports agree on one—the first explosion was an explosion of a torpedo in a torpedo tube. As mentioned before, by all naval exercises other countries submarines are always present at the naval area as well as near main marine ports during the year. The history of underwater incidents between submarines is well known and documented in different languages and countries (Drew et al. 1998). "Among the specified accidents there are several tens of collisions of submarines, including 20 underwater collisions of Russian Navy submarines with foreign submarines. From these 20 examples 11 were in grounds of combat trainings (naval exercises) on the way to the main stationing sites of the Northern and Pacific fleet, including 8 in the north and 3 in the Pacific Ocean in a short time period from 1968 till 1993" (Aleksin 2001, Viperson 2001). Several accidents have also been registered since 1993 till nowadays. On August 12th, 2000 Kursk prepares for shooting practice in the predetermined and surveyed area radio and radio engineering investigation of surface forces of "opponent—Kirov-class battlecruiser Pyotr Velikiy" *(5)*. Due to force 3 at sea the speed of Kursk was approx. 8 knots. The Kursk had changes the depth level many times according to typical exercise. A second non-Russian submarine which monitors Kursk the last two days *(6.1)* has lost the contact *(6.2)* and couldn't find the Russian submarine *(6.3)*. They decided to emerge on periscopic depth *(6.4)* to explain this situation in order to prove if Kursk has also surfaced. On the way to periscopic depth the non-Russian submarine unexpected struck *(6.5)* with the lower cornice of a bow part from a high angle of attack to the top area of the right bow side of Kursk where were torpedo tube was charged with the warshot torpedo USET-80. Both submarines continue to move with a former speed (5.5 [m/s]), destroying each other's hulls *(6)*. Nuclear submarines of US and UK Navy are build only one 35–45 [mm] thick stainless steel hull. Thus Kursk damage was much higher. In a second after the struck with the torpedo tube located to the right board of Kursk it was crumpled on a half of the length which caused a detonation of the warshot torpedo USET-80 *(7)*. This detonation was on a line of least resistance to the hatch of the torpedo tube, destroying this and created a hole more as half a meter in diameter. Water flows inside the torpedo compartment and causes trim to the bow side *(8)*. The captain of Kursk order to ascent and increase the speed *(9)*. However short circuits of electrical networks happen because of water penetration *(10)* and due to this the emergency system block both nuclear reactors *(11.1)*. The Kursk was out of control *(11.2)* with a strong trim to the bow side and hits the seafloor *(12)*. The second explosion was initiating with the impact on the floor *(13)*. This explosion killed many crew members in the conning tower and control room (2 compartment), radioelectronics room (3 compartment), living room (4 compartment), room with diesel-generator, electrolysis installation for air regeneration, compressors of high pressure etc. (5 compartment). Although Kursk was designed

to withstand external pressure of depths of up to 1.000 [m], the second internal explosion destroyed the bulkheads between the compartments (probably till the compartment 5) which are calculated for only 10 atmospheres.

The inner hull is designed for 60 atmospheres, which prevented the explosion of the P-700 Granit "Shipwreck" cruise missiles as mentioned before in this paper.

Based on the RCA and literature statistics on similar incidents, the catastrophe must be considered by the submarine Kursk as an archetypal event. Next chapter discusses how such scenario could be implemented in the prospective of classical risk analysis as well as the possible approach of a resilience concept and its implementation problems.

4 RISK AND RESILIENCE ASSESSMENT

The established system assessment process can be summarized by three steps: *identification, analysis, evaluation*. These processes are well defined in risk assessment while there are methodological gaps in resilience assessment.

The following subsections outline these gaps and point to differences in risk and resilience assessment by exemplary application to the Kursk disaster.

4.1 *Risk assessment*

The established approaches and concepts of risk assessment are presumably known to the reader (i.e., how to perform Failure Mode and Effects Analysis (FMEA), Fault Tree Analysis (FTA), and others).

Also in risk assessment, a study starts with determination of system boundaries. When following the risk management process of, e.g., ISO 31000, then risk assessment includes the (technical) system, where the remaining risk managing processes are beyond. With regard to resilience assessment (cf. chapter 4.2), risk studies are based on a restricted system definition. As a consequence, some boxes of RCA in Figure 3 are excluded (the results of all selection criteria as compiled in this chapter are applied on RCA of the Kursk disaster and summarized in Table 3).

There are studies of navy available to support out established risk assessment approaches, e.g., (Holmboe et al. 1992) on likelihoods of threats, maturity of technologies, systems potential to develop a threat scenario.

The identification process starts with the specification of hazards and threats as well as vulnerabilities of the system and system components.

Hazard is commonly defined as a condition, circumstance or process what can cause damage. Furthermore, hazard is limited to accidental, undesired and sudden events.

Risk analysis needs the quantification of frequency and likelihood of an undesired event. Figure 5 shows the risk analysis model as applied by the authors.

The terms in Figure 5 are specified by:

- hazards are characterised by possibilities,
- results of threat factors. Scenario analysis used to anticipate how threats and opportunities might develop and are used for all types of risk with short and long term time frames,

Figure 4. Compartments of Kursk (Naked-science 2017).

Table 3. Risk analysis relevant actions according to RCA.

RCA steps	Action	*H*	*T*	*V*	*S&S*	*C*
2	negative	+	–	+	n.r.	–
3	negative	+	–	+	n.r.	–
4	negative	+	+	–	n.r.	+
5	n.r.	n.r.	n.r.	n.r.	n.r.	n.r.
6	negative	+	+	+	+	+
7	negative	+	+	+	+	+
8	negative	+	+	+	+	+
9	n.r.	n.r.	n.r.	n.r.	n.r.	n.r.
10	negative	+	–	+	+	+
11.1	positive	n.r.	n.r.	n.r.	n.r.	+
11.2	negative	+	–	–	–	+
12	negative	+	+	–	+	+
13	negative	+	+	+	+	+
End	negative	+	+	+	+	+

+: relevant impact regarding risk analysis; –: no-impact on defined system; n.r.: not relevant for risk analysis.

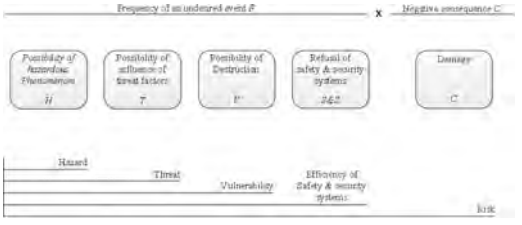

Figure 5. Risk analysis model.

- destruction of objects as a result of hazards are characterized by conditional probability,
- unavailability of safety and security systems because of combinations of non-reliability, human factors among others, are quantified by probabilities of scenario development from emergencies towards accident.

Depending on analysis goals (quantitative or qualitative) different approaches are in use. The Russian Army carries out FTA (personal communications with Saint Petersburg State Institute of Technology). However, FTA does not consider positive events and an analysis of top event *Recessed submarine* is then incomplete. The failure analysis based on qualitative approaches, as FMEA, could be added.

Within this defined framework for risk analysis Table 3 shows the relevant boxes of the RCA.

The selection process for identifying the RCA boxes relevant to risk analysis bases on the following rules:

Rule 1: The box event is within the defined system boundary.
Rule 2: The hazard is relevant within the defined system boundary.
Rule 3: If a threat (from outside) exists, it is taken into account.
Rule 4: Searching for vulnerabilities in the system.
Rule 5: Investigation of safety and security systems is a special task of risk analysis.
Rule 6: Negative consequences are always relevant for risk analysis independent from threats and vulnerabilities.

Thus, step *preparing shooting exercise (5)* is not relevant from the view of risk assessment. The *order by the captain (9)* is a positive measure and, thus not relevant for the defined scenario. The *automatic shutdown of the nuclear reactor (11.1)* is not part of the risk analysis because it is a planned safety process. Steps *(2)* and *(3)* are only considered in human reliability analysis. Finally risk is often evaluated by risk matrix. However, the risk evaluation process is not subject of this paper.

4.2 *Resilience assessment*

As mentioned in chapter 2, resilience considers extended socio-technical systems where (human as well as automated) actors are responsible for actions to positively or negatively affect system responsive-ness. Applied resilience assessment by case study brings further differences to risk assessment in understanding to light. The system assessment processes (i.e. aspect identification, analysis and evaluation) structures the following discussion.

System performance is a matter of documented system design specifications and other characteristics of embedding system entities. Then, resilience assessment of the Kursk disaster comprises all involved submarines and crews as well as the entire Northern Military-Maritime Fleet of the Russian Federation at the moment of the exercise and impacts from sea environment. The impact on the environment is not relevant. Hence, you can easily define actions, actors, and system boundaries in Kursk example in contrast to, e.g., infrastructures. Within this framework, the identification process starts with the specification of system performance P. For this, two approaches are common in resilience assessment (cf., e.g., Mock 2018): either the analysts decide to model time-depending performance $P(t)$ or they compile a set of n resilience impacting aspects $P = \{a_1; a_2; \ldots; a_n\}$. $P(t)$ can be easily defined (e.g. safe and secure transport of crew and cargo during mission time) but finding a corresponding measurement is not always as straightforward as, e.g. oxygen content of the breathing air during mission time. Note, that availability, as shown in Table 1, is a performance model $P(t)$ showing the probability course of operability of a system. Maintenance and repair are considered as activities to keep the system resilient, and are actions of responsiveness.

The identification process by compilation of a set of aspects influencing resilience appears plain, e.g. the number of redundancies of life supports systems, educational level of crew, repair, etc. However, time dependency and the representation of systemic relationships are lost then.

The resilience analysis process by $P(t)$ follows the common processes of formal mathematical/physical of system modelling and simulation and will not be discussed here. However, the RCA presentation of the Kursk disaster in Figure 3, which follows a timeline of succeeding events, is considered as a simple representor of $P(t)$ after revision towards resilience (see Table 4). $P(t)$ analysis needs the specification of normal operation bandwidths of total system performance. For instance, the oxygen content on a submarine can be above or below a lethal threshold. The life support system may be able to provide a breathable atmosphere again, but this can be too late for the crew. In terms of resilience analysis, the responsiveness of the entire submarine system is lost as safe transport has ended. These points to specific views in resilience analysis: Total loss of performance or functionality (worst case) is excluded from analysis ("If dead you are not resilient any longer"). The analysis of impacting aspects $\underline{P}$ needs the definition of a resilience metric which is still under discussion in academia. Table 4 summarises the findings in resilience identification and analysis by the Kursk example as represented in Figure 3.

Table 4. Resilience assessment for performance "safe and secure transport of Kursk crew and cargo during mission time".

RCA	Sub-system	*P*	Action	Actor(s)
1	fleet	+	success	Kursk crew, fleet
2	Kursk	–		Kursk crew
3	fleet	–	preparedness	Kursk crew, fleet
4	environment	–		
5	Kursk	+	exercise	Kursk crew
6	Kurs, other sub.	–	ram	Both crews
7	Kursk	–	explosion	
8	Kursk	–	leakage	
9	Kursk	+	order	Kursk's captain
10	Kursk	n.r	short-circuit, loss of control	
11.1	Kursk	n.r	shutdown reactor	
11.2	Kursk	n.r	loss of control	
12	Kursk, environment	n.r	grounding, loss of control	
13	Kursk	n.r	detonation, loss of control	
End	Kursk	n.r		

+/–: positive/negative impact on resilience; n.r.: not relevant for resilience assessment purposes.

As figured out in Table 2, resilience assessment ends with the loss of control of the Kursk ("If faint, then you are no longer resilient"). Step *(6)* can be similarly analysed by considering RCA steps *(6.1)* to *(6.6)* which introduces the second submarine into analysis. The marine environment (step *(4)*) has been identified as challenging for submarines which does not support safe transport.

Resilience evaluation is the process of assessment. Again, the analyst depends on how resilience analysis been performed. In case of modelling *P(t)* a characteristic value needs to be defined, e.g. the ratio of resilient operation mode to total mission time. This is equivalent, e.g. to reliability and availability analysis. The evaluation of the set of impacts *P* needs the definition of a resilience metric comparable to risk prioritisation value RPV in risk analysis and provided by FMEA. Evaluation criteria of acceptance/non-acceptance of resilience analysis results still needs to be defined (a resilience priority value is introduced in (Mock 2018)).

13	*Y*	*N*
Summary	Y: 10 of 19	Y: 13 of 19

4.3 *Synopsis*

Based on RCA every single step is discussed from the side of resilience assessment in comparison to the risk assessment. Table 5 differs between the selections of *yes (Y)*, *no (N)*.

Avoidance of worst case scenario or disaster is the aim of a risk assessment. Therefore, positive or neutral (from the view of risk analysis) steps such *(1)*, *(3)*, *(5)*, *(6.1)*, *(6.2)* are not considered. But e.g. step *(9)* could be considered if the order of the captain is incorrect. Step *(2)* can be also considered only in case of human reliability analysis. Equivalent to a worst case scenario "meltdown of nuclear reactor", step *(13)* must be take into account by this disaster. Similar, step *(6)* could correspond to a "plane crash on nuclear power plant" scenario (external event). Step *(5)* is not a malfunction or optimization, but an important point in the overall process. Due to the defined performance indicator step *(6.2)* must be considered too (the second submarine is part of the whole system). As mentioned before, with defined performance indicator—safe implementation of the naval exercise for the crew—the resilience analysis ends with the step *(10)*. As mentioned in chapter 2, risk assessment often uses the basic frequency/consequence definition to get calculation values. However, the next step after description of the RCA from the side of resilience

analysis is complicated due to absence of any useful values and equations which could be support the calculations and as a result the evaluation of the defined system and performance indicator.

5 CONCLUSIONS

Resilience assessment should be different from risk assessment and other related concepts and approaches. For instance, risk assessment is basically restricted to undesired events and does not cover the extended view of technical systems. On the other hand, event identification highly depends on the definition of system performance indicating resilience as a measurement of system quality.

The issue of applied resilience assessment is shown by considering the archetypical case of Kursk submarine disaster. The detailed description of sequence of steps by Root Cause Analysis shows that a precious accident analysis is significant for identification of aspects which have impacts on resilience. The specification of system performance and the view of extended socio-technical systems increase resource requirements (time, expertise, etc.) of auditing. This way of thinking definitely uncovers additional elements of system disturbances.

However, resilience analysis is still in its beginnings and there is no commonly accepted methodology and metric. In summary, resilience assessment is different to risk assessment in some ways and shows promising aspects in extended system analysis. However, further steps towards operationalisation of the resilience concept are needed.

A quantitative approach for applied resilience assessment audits

R. Mock
Institute of Sustainable Development INE, Zurich University of Applied Sciences, Winterthur, Switzerland

ABSTRACT: Today's infrastructural systems are expected to be safe and resilient. In this context, assessment of such systems faces two principal challenges: common approaches in risk assessment have reached their limits in methodology and feasibility in assessing complex and interconnected systems. On the other hand, resilience assessment is in its beginnings and lacks, e.g., a commonly accepted resilience metric. The paper starts to specify a practical definition of resilience and assigned metric: Resilience is characterised by influencing recovery properties of a socio-technical system. Actors and actions are carriers of these properties. This corresponds to the views of system representation by Use Case Diagrams (UCD). In order to quantify an UCD, actions are validated by assessing their compliance level L. Actors are associated with their abilities to respond, monitor, learning, and to anticipate developments. The result is given by the Resilience Priority Value REPV = $L \cdot I$ of actors and overall system. The resilience assessment process is exemplified by a case study of a car park guidance system.

1 INTRODUCTION

Current infrastructural systems show a high level of complexity and technical development will further strengthen this trend. As consequence, such systems will become increasingly difficult to handle for system operating organisations (private and non-private) and managers involved. It already looks as that methodological or practicable limits of, e.g., established risk assessment approaches have been reached. New terms reflecting newly desired system properties (e.g., resilience, smartness) are emerging too. However, the methodology of resilience assessment is in an early stage of development and not (yet) in the focus of most organisations. This is also due to the lack of a practicable, quantitative metric of resilience. In this context, the paper presents an approach to facilitate applied resilience assessment audits. Following the concept of system representation and resilience quantification, the remaining paper is structured as follows: Chapter 2 defines resilience and terms in use. The results of a literature survey on resilience definitions in specified engineering domains are given in Chapter 3. In Chapter 4, resilience assessment is utilised by using quantified Use Case Diagrams (UCD). The case study presented in Chapter 5 serves to proof the concept. The paper closes with discussion of pro and cons of approach and context.

2 TERMS

The view in applied research and development in resilience analysis covers the requirements of users in organisations and enterprises (mainly small to mid-sized enterprises SME). Hence, any resilience assessment approach needs to cover additional demands (cf. (ISO-31010 2009)), which might be unimportant to basic research. A major concern of organisation is method efficiency. Thus, the resilience assessment approach as introduced in this paper aims to finally reach practicability as known in basic risk assessment audits, fire and explosion inspections, annual tests of vehicle safety (Ministry of Transport (MOT) test), among others. According to the author's experience, such a system analysis must be typically performed from one person in about one day.

There are already exhaustive literature surveys on terminology of resilience, where the most common understanding of resilience is exemplified by Scholz et al. (2012): Resilience is the ability of the system to adjust its functioning […] following changes and disturbances, so that it can sustain required operations.

Hosseini et al. (2016) also consider system recovery abilities as crucial part of resilience, where recovery is the capability of a system to absorb and adapt to disruptive events.

Lay et al. (2015) labour characteristics and abilities of resilient systems in more detail, which is finally the definition as used in this paper:

DEFINITION 1 (RESILIENCE) *characterises the abilities of a system to respond to disturbances, to monitor, to learn and to anticipate developments.*

With this, resilience belongs to a set of related engineering terms characterising system capabilities by attributes or system performance function $P(t)$, e.g., availability $A(t)$:

Definition 2 (Availability) *is the probability of finding an unit in an operational condition at time t.*

This definition of availability follows, e.g., DINEN61703 (2002). Note that $A(t)$ encompasses maintenance, which is a system ability to respond to disturbances (failures, incidents, over-fulfilment, etc.), to monitor them (failure identification) and to learn (optimising maintenance processes) and anticipate trends (expected failures). The latter is covered by reliability management processes and preventive maintenance. So far, resilience looks like the generalisation of availability towards the analysis of extended socio-technological systems. Furthermore, management and associated processes are considered as an integral part of such a system in resilience assessment (cf. (Leksin et al. 2018)). By contrast, management tends to play the role of an external controller in risk assessment. Business continuity (BC) also follows the concept of system recovery but concentrating on business impacts:

Definition 3 (Business Continuity) *is a corporate capability. This capability exists whenever organisations can continue to deliver their products and services at accep*table *predefined levels after disruptive incidents have occurred (cf. ISO 22301: 2012).*

Resilience is in line with established approaches to manage deviations, e.g., risk management according to ISO-31000 (2009). Note, that any system assessment approaches cover the subprocesses of event identification, analysis and evaluation. The view of resilience, availability and business continuity is to describe system capabilities with associated performance functions where risk relates to (undesired) events.

3 STATE OF THE ART

The following results of a survey on resilience definitions concentrates around engineering domains which are then used to reason the way of utilisation of resilience assessment as proposed in Chapter 4. Hosseini et al. (2016) give an extended review of definitions. They state that the engineering domain "includes technical systems designed by engineers that interact with humans and technology, such as electric power networks". There, engineering resilience is defined in various points of views:

- Sum of the passive survival rate (reliability) and proactive survival rate (restoration) of a system.
- "Intrinsic ability of a system to adjust its functioning prior to, during, or following changes and disturbances, so that it can sustain required operations under both expected and unexpected conditions" (Hollnagel et al. 2010).
- "Infrastructure resilience is the ability to reduce the magnitude and/or duration of disruptive events. The effectiveness of a resilient infrastructure or enterprise depends upon its ability to anticipate, absorb, adapt to, and/or rapidly recover from a potentially disruptive event" (NIAC 2009).
- Factors, e.g., minimisation of failure, limitation of effects, administrative controls/procedures, flexibility, controllability, early detection.

Furthermore, Hosseini et al. (2016) state that:

- Many definition focus on the capability of system to *absorb* and to *adapt* to disruptive events, and *recovery* is considered as the critical part of resilience.
- For engineered systems, reliability is considered to be an important feature (e.g. nuclear power systems).
- Returning to steady state performance is needed for resilience; some definitions do not impose that the system returns to the pre-disaster state (e.g. infrastructure).
- Multidimensionality and threat-dependency of resilience definitions.

These lists and the findings of Chapter 2 substantiate: Resilient systems show abilities to preparedness and recovery in general. Then, preparedness is typically covered by a descriptive (i.e. qualitative) and case specific set of attributes $\max_{\bar{x}\in(0,\infty)} f(\bar{x}) - g(\bar{x}) - h(\bar{x})$. System performance $P(t)$ uses various modelling and simulation approaches to model system dynamics and performance $P(t)$ according to the resilience triangle concept. Definition of preparedness attributes follows methods to design and evaluate questionnaires, check lists, etc., and graphs represent relationships of system abilities. This notation is useful to characterise the common approaches of resilience system analysis:

- *Attributive*: Starting point is the compilation of system specific attributes $\mathbb{A} = \{a_1, a_2, \quad, a_n\}$, which characterises the presence of or impact on resilience properties, e.g., awareness, flexibility, risk management, competence, and redundancy. Then, analysis follows methods to evaluate questionnaires, check lists, etc. or uses any graphs to represent relationships.
- *Performance*: System performance modelling needs the specification of time dependent and system specific performance measurements, e.g., availability (i.e. function showing the alternation of operation and maintenance), returns (money), among others. Note that $P(t)$ already comprises the recovery properties. Modelling parameters of might base on $\mathbb{A}$. Hence, $P(t)$ can be modelled by graph theory, (e.g. Markovian

models, system dynamics, state diagrams), classical mechanics considering damped harmonic oscillation, (i.e., spring model) as well as control theory using proportional–integral–derivative controller (PID controller).

The definition of resilience performance $P(t)$ results in generic system statements:

- $max\left\{\left|\Delta P(t)\right|\right\} \leqq b$: There is a specified band width b (i.e. defined upper and lower performance levels) which defines system operability (Mock and Zipper 2017).
- $P(t) = 0$: Total system failure (worst case) which ends reparability. Recovery is not possible and system re-construction is equivalent to a different and thus new system. Reconstruction is only possible by supporting measures of the superior system (cf. definition of disaster). Hence, $P(t) = 0$ is associated with fully operable (new) system which is a common boundary condition in reliability analysis.
- $P(t) = k$ and $\dot{P}(t) = 0$: Nominal operation on constant performance level k.
- $\dot{P}(t) \neq 0$: System is in resilience mode.
- $\ddot{P}(t) \neq 0$: Acceleration of performance alteration is an indicator of resilience request.

In summary, there is no common understanding of resilience and how to model resilience. Many authors define key abilities of resilience by their own. The lowest common denominator is the ability of a resilient system to respond to disturbances and, hence, functional preserving capabilities (i.e. recovery). In order to verify these findings, Table 1 uses Def. 1 of resilience to allocate the specified attributes of resilience for infrastructure systems as named in references.

Table 1 also shows that "respond" to disturbance is the main property of a resilient system. The remaining properties are less frequently listed. From the author's point of view, this table exemplifies the uncertainty of how to deal with resilience key capabilities other than "respond", and that it is still necessary to utilise the resilience concept for concrete applications.

Table 1. Key abilities of resilience for infrastructure systems.

System	Respond	Monitor	Learn	Anticipate	Reference
System homeland security	robustness, consequence mitigation	threat and hazard assessments	adaptability, harmonisation od purposes, comprehensive of scope	risk-informed planning and investment	(Hosseini et al. 2016)
Telecommunication network	maintainability	reliability, safety, confidentiality, availability, integrity performance	–	–	(Hosseini et al. 2016)
Communication network	defend, remediate, recover	detect, diagnose	refine	–	(Hosseini et al. 2016)
Infrastructure system	absorb, recover	–	adabt	anticipate	(Lay et al. 2015)
Critical infrastructure	responsiveness, timely recovery, minimum level of service while undergoing changes, flexibility	–	–	coordinated planning	(Lay et al. 2015)
Infrastructure network	ability to regain a previous state	–	adopt the stress–strain model	–	(Bergström et al. 2015)
Infrastructure	recovery (bouncing back)	–	–	–	(Lundberg and Johansson 2015)
Critical infrastructures	robustness, (availability of redundancy, resourcefulness and efficiency of supporting measures)	–	–	–	(BABS 2013)

4 UTILISATION

Chapter 4 identifies the interrelationships among system elements by UCD and how to quantify system resilience by attributes as given in Def. 1.

4.1 *Use Case Diagram UCD*

The Unified Modeling Language (UML) is a quasi-standard of system representing diagrams offering conformance in syntax and semantics. UML 2.5 defines thirteen types of diagrams, divided into three major categories: Structure Diagrams, Behaviour Diagrams, and Interaction Diagrams (cf. www.uml.org) UML diagrams are standardised by (ISO-19501 2005), where UCD is the most simple structure diagram in UML. This Chapter gives a short introduction into the concept of UCD by referencing to the mentioned standard unless otherwise stated.

Definition 4 (Use case) *is a kind of classifier representing a coherent unit of functionality provided by a system, a subsystem, or a class as manifested by sequences of messages exchanged among the system (subsystem, class) and one or more outside interactors (called actors) together with actions performed by the system (subsystem, class).*

A use case is shown as an ellipse containing the name of the use case which characterises activities of actors.

Definition 5. *"An [actor] defines a coherent set of roles that users of an entity can play when interacting with the entity. An actor may be considered to play a separate role with regard to each use case with which it communicates".*

The standard stereotype icon for an actor is a "stick man" figure with the name of the actor.

There are three types of relationships among use cases (actions) and association

- *Association*: The participation of an actor in a use case. In Figure 1, associations are shown by solid lines.
- *Extend*: An extend relationship from use case A to use case B indicates that an instance of use case B may be augmented (subject to specific conditions specified in the extension) by the behaviour specified by A.
- *Include*: An include relationship from use case E to use case F indicates that an instance of the use case E will also contain the behaviour as specified by F.
- *Generalisation*: A generalisation from use case C to use case D indicates that C is a specialisation of D.

The author considers UCDs as especially useful for resilience assessment purposes in order to depict actors and associated actions on technical and organisational level (i.e., modelling socio-technical systems).

4.2 *Semi-quantified resilience assessment by UCD*

Establishing the resilience assessment audits at organisations needs an approach which is resource saving and follows established ways of system representation, e.g., by UML. In a first step, it is suggested to use the interrelationships among system elements by UCD and to assess system resilience by means of the resilience attributes as given in Def. 1. As mentioned above, the UCD differentiates between actors and actions. In engineering terms, actions can be evaluated by assessing their level of compliance with standards, best practices, etc. It is assumed that a high compliance level has a positive effect on the system resilience. Actors are the carriers of system resilience where their impact on recovery abilities is evaluated. For this, the Resilience Priority Value *REPV* of an actor is introduced, which uses the definition of resilience as given in Def. 1:

$$REPV = L \cdot I(d,m,l,a), \tag{1}$$

where

- *REPV*: Resilience Priority Value of an actor
- *L*: compliance fulfilment level of an use case (action)
- *I*: impact of recovery ability of an actor
- *d*, *m*, *l*, *a*: actor's abilities to respond disturbances, to monitor, to learn and to anticipate.

All assessments use ordinal scales of range [1, 2, …, 10], where 1 indicates best and 10 worst cases. The concept follows the familiar idea of estimating risk priority figures, even if resilience is understood as a positive system property.

So far, the assessment of *L* is the result of audits and expert judgement about the proven record of reached compliance levels of actions or associated technology, e.g., the operation of IT security management. In the best case, the rating of *L* bases on already available reports of compliance certifications, e.g., according to ISO/IEC-27002 (2005).

Actors are considered as the intrinsic carriers of resilience. As mentioned above and following Def. 1, the impact of recovery ability *I* depends on four attributes, which are rated by ordinal scales of range [1, 2, …, 10]. *I*(*d*, *m*, *l*, *a*) of an actor is assessed by the mean value of these abilities. The abilities of learning *l* and anticipation *a* are currently covered by humans. However, trends in smart manufacturing and artificial intelligence blur this classification.

The analysis of system resilience needs rules to make use of UCD. For a very first proof of concept, the following procedural steps are defined:

1. An estimated compliance fulfilment level $L_{i,e}$ of $i = 1,2, \quad ,k$ is assigned to each use case U_i.
2. Considering relationships for assessing L_i of U_i
   – Apply the mean value of all *incoming* extend associations
   – Apply the mean value of all values assigned to *outgoing* include associations
   – Compute the mean of both values
3. Rounded off to the next integer
4. Repeat the process until all use cases (actions) are assessed.

In summary, every use case (action) U_c is characterised by a number of extend and include relationships R (i.e., edges): $U_c\left(R_{c;ext};R_{c;inc}\right)$. For further resilience computation, only subsets of relationships are needed. For this, every U_c is assessed by the mean values $\bar{x}$ of compliance levels L of associated incoming extend relationships and outgoing include relationships, i.e. $U_{c;L}\left(\bar{x}_{c;L_{in-ex}};\bar{x}_{c;L_{out-incl}}\right)$. The mean of both values finally gives the looked for compliance level L_{U_c} of an action.

Next, every actor $A_j, j = 1,2, \quad ,k$ is evaluated by the following rules:

1. Assign values of $I_j\left(d_j,m_j,l_j,a_j\right)$
2. Compute the mean of assigned values in I_j which is the looked for impact value of recovery ability of an actor $I_{j,a}$.

Then every actor shows an impact value $I_{j,\,a}$ and is assigned with a use case value L_i (if there are more than two associations use the mean value of L_i's). With that, all values are given to compute $REPV_J$ as defined in Eq. 1. System resilience is estimated by the mean value of all actors' *REPV* and again rounded of to next integer.

4.3 *Proposed audit process*

The utilisation process of resilience assessment is finalised by auditing a system. The following steps roughly structure such an audit:

– Step 1 – Drafting use cases and actors of socio-technical system to be audited
– Step 2 – Transfer of use cases and actors into the UCD
– Step 3 – Quantification of UCD
– Step 4 – Evaluation of results and *REPV*.

Steps 1 and 2 follow the basic steps of creating any UCDs. In terms of risk and resilience assessment Step 1 covers the identification process and Step 3 the analysis process. The resulting REPVs might be evaluated by a matrix or threshold approaches as known in risk assessment. However, this step is not elaborated in this paper.

The suggested resilience audit process opens developments towards semi-automated processes to support auditors. The generation of UCDs is a well-known activity in software engineering and there are many tools available to do that (cf. Chapter 5). The computation process of UCDs follows ideas of using complexity metrics as common to characterise computer codes and associated UMLs (cf. (Mock et al. 2015)). Altogether, it is intended to develop the following audit supporting steps: The auditor has to identify actions and actors for UCD generation. Both aspects are plant or system specific. However, there are repetitive elements, e.g., associated with IT security, fire and explosion protection, and occupational safety. These elements are typically standardised and subject of compliance checks. Frequently occurring or, e.g., industry branch specific actions and actors can thus be deposited in a tool library. An auditor then selects the appropriate ones by a drop down menu.

In a next step, the auditor has to identify and create the relationships among actions and actors. This step is tool supported too.

Finally the auditor needs to input the estimated impact values *I* for every action with only one relationship and to assign $I_j\left(d_j,m_j,l_j,a_j\right)$ for every actor. The remaining computations will be done by the tool.

In the end, the auditor needs more knowledge in system relationships as, e.g., for filling check lists or to perform an FMEA. On the other hand, the usual actions and actors as well as associated $I_{j,\,a}$ and L_i ratings should be known by an experienced auditor as they are close to common checks and results of site-specific compliance checks.

5 CASE STUDY: CAR PARK GUIDANCE

The audited system in this case study is a car park guidance system as implemented in a Swiss city. The system is designed to manage and optimise car traffic flow between a parking lot outside town ("Castle") and a car park building in city centre. ("Town"). All parking spaces are equipped with sensors, networked and controlled by a Supervisory Control and Data Acquisition system (SCADA). Parking space allocation is visible for drivers by displays in "Town".

Step 1 – Drafting actors and use cases

The actors are defined by

– Driver (Family): The family is on a getaway. The Driver (Family) speaks German and strictly follows the parking guiding displays in

order to avoid looking for parking space. The DRIVER (FAMILY) first drives to the display at the car park in the city.
- DRIVER (TOURIST: The foreign DRIVER (TOURIST does not understand German and feels unconfident with display symbols. Hence, this driver ignores the parking guiding displays and makes ad-hoc decisions where to park.
- CAR PARK OPERATOR (TOWN): There are no specifications about sensors. CAR PARK OPERATOR (TOWN) is assumed to be responsible for car park and system operation. The operator might start parking place managing activities.
- PARKING LOTS OPERATOR (CASTLE): There are no specifications. PARKING LOTS OPERATOR (CASTLE) is assumed to be responsible for 84 parking lots and system operation. The operator might start parking place managing activities.

Actions (use cases) are defined as

- *Display:* The only car parking display is located at the car park "City" in town and shows the number of free parking spaces at "City" (max. 340) and "Castle" (two parking spaces small and big: 10 + 74 = 84) nearby the Castle. It is assumed that display hardware does not fail at any time within the observation period of 4.5 years of operation. The associated system software is remotely updated and patched via Internet.
- *Gateway*: Kerlink LoRa IoT Station (2 identical stations) "is an industrial solution suitable for people who want to mount the gateway outside and who have sufficient technical skills to connect, mount and maintain the device themselves. … somewhat older software, that is being used, [and] this device will do the job. A trained software engineer will be able to update the device using the [firm] software" (source: thethingsnetwork.org). The Gateways link the 84 *Sensors(Castle)* with the Internet by the Swisscom Mobile network.
- *Sensors (Castle)*: The "Fastpark Flush-Mounted Sensor" (in total 84 sensors) are part of Parking Management System (PMS). "The wireless system uses smart sensors installed in parking spaces and guides drivers to areas with vacancies via electronic panels …" (source: www.worldsensing.com). The *Sensors(Castle)* are linked with associated Gateways and Parking Management System PMS(Castle). Sensors might fail but are not maintained in observation time. The sensors are battery operated and uses the novel Low Power Wide Area (LPWA) technology for gateway communication.
- *PMS Operation*: PMS operation and associated data storage is done by a separated EU computing centre.
- *Sensors (Town):* There are no specifications about sensors of car boxes. It is only assumed that there are sensors which provide display data.
- *PMS (Castle)*: SCADA device in order to process and monitor data from *Sensors(Castle)*. The SCADA serves as Human Machine Interface (HMI). The operator is considered as an integral part of *PMS (Castle)* who then might startparking place managing activities.

Step 2 – Creating UCD

Information on actors and actions is used to build up the UCD of Figure 1. The software tool PlantUML (www.plantuml.com) creates UCDs from textual inputs. It is a plug-in, e.g., of Eclipse. The possibility of integrating PlantUML into various software development frameworks is considered as pre-condition for further resilience software tool development.

Step 3 – Quantification of UCD

Table 2 shows the quantification of UC as given in Figure 1.

Computation in Table 2 is exemplified by considering the Action U_8: The auditor estimates and

Figure 1. UCD of case study.

Table 2. Estimation of compliance fulfilment level L_i by use case (actions) U_i.

i	Action Ui	Li, e	L_i

3	Driver (family)	9	7	6	5	6	6
4	Driver (tourist)	7	5	2	1	3	3

Table 4. Resilience priority value REPV of actors.

j	Actor A_j	L_i	I_j	$REPV_j$	Comment
1	Car par operator (town)	9	7	63	
2	Parking lot operator (castle)	9	8	72	
3	Driver (family)	10	6	60	$L_3 = \frac{10+9}{2}$
4	Driver (tourist)	10	3	30	

assigns a compliance fulfilment level of $L_{8,e} = 8$ to the action "operates PMS". This action points to three other actions by include relationships associated with (8+9+9). The mean value including $L_{8,e}$ gives 9. There is an input of an extend relationship $L_{4,e} = 8$ which then gives the final mean value of $L_8 = \frac{9+8}{2} = 9$ (rounded off to the next integer).

Every actor is assigned to an impact value of recovery ability using I_j d_j, mj, l_j, a_j.

Step 4 – Evaluation of results and REPV

As a result from Table 4 the actor Driver(Tourist) shows lowest resilience properties. The overall resilience value of the car park guidance system is the mean of all REPV's, i.e., $REPV_{syst} = 56$ indicating a system with medium resilience.

6 CONCLUSIONS

In view of extended socio-technical system analysis, developing a closed resilience assessment approach is subject of research (cf. (Mock and Zipper 2017). However, this research only makes sense if the understanding of resilience finally results in a different approach as already established by the concepts of, e.g., risk, BCM and availability. From the author's experience, discussion about resiliency often follows synonymous paths as already given by these established concepts (cf. (Leksin et al. 2018)).).

On the other hand, resilience assessment methodology is in its beginnings and still beyond entrepreneurial interests and has not fixed as state of technology yet. Thus, the paper is understood as a step toward utilisation of resilience assessments of complex systems. For this, a simple REPV is defined and the assessment process uses standardised system representation by UCD, which properly differentiates between actions and actors. This property covers well the inclusion of socio-technical aspects, where actors are carriers of major properties of resilience (e.g., learning). They are integral parts of the audited system, which is then becomes describable as a socio-technical system. By defining rules to quantify UCDs, the proposed resilience assessment approach opens paths for software tool development in order to support resilience assessment audits of, e.g., infrastructural systems. The case study serves as a proof of concept.

Discussions at ESREL conference in 2017 have given rise to fears that the inclusion and detailed understanding of the technical functioning of (infrastructural) systems could be neglected in resilience assessments. The use of UCD provide a practical way out of this situation, since UCDs are based on comprehensive descriptions of actions, actors and their relationships supporting a systemic analysis approach.

The proposed concept of system assessment supports auditors to check to what extend infrastructural systems are resilient. However, the approach still needs verification of quantification rules, which are presumably too simplistic. The approach also needs an extended review based on a broader application example. Further developments consider the inclusion of complexity measures in order to increase the meaningfulness of UCD quantification.

Enhancing metro system resilience after signaling perturbations by bus bridging service: The case of Beijing

Q. Wei, R. Niu, T. Tang & S. Su
State Key Laboratory of Rail Traffic Control and Safety, Beijing Jiaotong University, Haidian District, Beijing, P.R. China

L. Yue

ABSTRACT: Signaling system is a typical safety critical system aiming to enhance the safety and efficiency of train operation. Any signaling failure or abnormity will force a fallback to the safe side (stop), causing the drop in driving efficiency. Therefore, a fast and efficient way to replace the metro system after signaling failure is of great significance for passengers. Considering the road traffic conditions, a method for generating emergency metro-bus bridging plan is presented to improve the metro system resilience by assessing the satisfied passenger travel demands. The plan is implemented by generating the bus bridging routes based on the constructed metro-bus network and allocating the limited bus resources to the generated routes optimally. The approach is applied to Beijing Metro Line 5 coping with high signaling failure probability and the simulation results show that the system resilience is significantly enhanced about 21%–43% with metro-bus bridging service.

1 INTRODUCTION

Nowadays, the operation of metro system relies more and more on signaling system with the increasing of the degree of automation. Any disruption in signaling system may cause the trains and passengers to be late, even more, resulting in the chaos of public traffic. In August 18, 2016, the Beijing Metro Line 1 was suspended for more than 2 hours during evening peak hours due to a 3 min interruption of signal transmission network. Coupled with the bad weather, thousands of people were trapped in the downtown area. Therefore, compared with the frequency of failures, metro operators are more concerned about the impact of signaling failures on train headways and passenger transport. However, RAM (Reliability, Availability, Maintainability), the commonly used performance indexes, are always assessed by the average data with a period time, and cannot clearly show the reduction and recovery of train passing efficiency. Therefore, the concept of resilience is introduced to measure the impact of failure to metro system.

The first systematic definition of resilience is represented by Holling (1973) in ecological system almost 40 years ago. He thinks "resilience determines the persistence of relationships within a system and is a measure of the ability of these systems to absorb changes of state variables, driving variables, and parameters, and still persist." Since that time, researchers covering numerous fields have gradually realized the advantages of resilience in system design and management. For social domain, US Department of Homeland Security (2006) tend to view social resilience in terms of the ability of system or asset to maintain its function or recover from attack or incident. When in economic system, Rose & Liao (2005) characterize dynamic resilience as the speed of which an entity or system recovers from a severe shock to achieve a desired state. In railway system, Adjetey-Bahun et al. (2016) state that the concept of resilience has been introduced to measure both the ability to absorb perturbations and rapidity recover from perturbations. Throughout all the definitions, all of them are emphasizing the ability of system to absorb the perturbation and adapt to it changes, as well as recover from it quickly. The most quoted concept of resilience is from Bureau et al. (2003), they state that the seismic resilience of a system can be achieved by reducing failure probabilities, reducing consequences from failures and reducing the time to recovery. Furthermore, it can be defined as four characteristics: robustness, redundancy, resourcefulness, and rapidity and a broad measurement of resilience capturing these features is proposed as a resilience triangle model.

Combining the characteristics of metro system, the resilience of metro system can be introduced as: the ability of system to reduce the probability of failure, adapt to the impact of failure and recovery

from the failure. In this point, Vugrin et al. (2010) define three capacities to quantify and design for a better resilience of system, these capacities are:

- Absorptive capacity:
  It mainly reflected before or the time perturbation intervention, when the system can automatically withstand the perturbation and minimize the consequence of failure, it's an endogenous feature of system. In metro system, it can be reflected as reducing the probability of system to failure through the reliability design. For example, the redundancy of the onboard wireless unit to make the system immediately switch to the rear one when the front unit failures, so that the train can normally receive the Movement Authority with no impact on the train operation.
- Adaptive capacity:
  During the disruption and recovery period, through ingenuity or extra efforts to deal with the impact of disruption, is a set of actions of self-organization to response to the perturbation. One example is during the signaling perturbations, the operation order of the metro system relies upon the command of the dispatcher in the degraded model.
- Restorative capacity:
  The ability of system to quickly recover back to its original or expectation state by maintenance management and the ability of system to be repaired easily. For example, training and testing of the maintenance plans of general failures to improve the human maintenance ability so that the system can be recovered quickly.

As quick and efficient substitution of metro service is necessary for accommodating metro passengers during signaling perturbations. Thus, an ad-hoc bus bridging service is set up after signaling perturbations to enhance the metro system resilience of adaptive capacity by transferring the passengers to the nearest or destination metro stations in the shortest time.

The reminder of the paper is organized as follows. Section 2 reviews the quantitative measurement methods of resilience as well as the strategies to enhance the resilience of system. Section 3 introduces the proposed metro-bus bridging emergency plan to enhance the system resilience. The plan is applied to Beijing Metro Line 5 in Section 4 and Section 5. And we end this paper with two conclusions in Section 6.

2 LITERATURE REVIEW

2.1 *Quantitative measurement of resilience*

The quantitative measurement of resilience proposed by Bureau et al. (2003) (shown in Figure 1.)

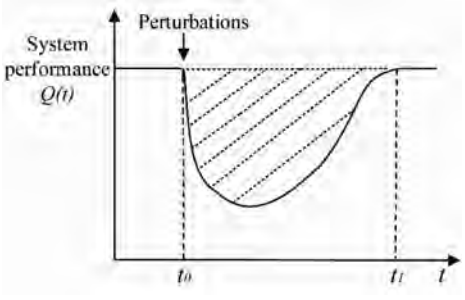

Figure 1. Resilience triangle model proposed by Bureau et al.

is extended and improved by many ways. Reed et al. (2009) propose the resilience of a system can be assessing by the ratio of the resilience triangle curve area to the time interval. Besides, Vugrin et al. (2013) proposed the system resilience can be assessed by resilience costs within systemic impact and total recovery effort. Where the systemic impact can be evaluated by the size of the resilience triangle curve, and the recovery effort is represented by the area of recovery effort curve.

Except for the size of resilience triangle, the important points of the triangle curve can also be used to measure the system resilience. Dorbritz (2011) puts forward the disaster resilience of transportation system can either be quantified by the resilience triangle area or three values: (1) the initial impact of the disaster; (2) the minimum value of system performance; (3) the time system get recovery. Nan et al. (2016) present an integrated metric for system resilience quantification, the metric combines three resilience capabilities in four phases based on resilience curve and is dimensionless and useful to compare different system resilience.

In addition to the traditional numerical methods used above, a stochastic method can also be used for assessing the resilience of system. Based on the resilience triangle, Chang & Shinozuka (2004) developed a probabilistic method for assessing system resilience. Where the resilience is defined as the probability of the system performance after the disruption lesser than the accepted performance. The proposed framework is applicable to both the infrastructure system and community, but the acceptable standard of the system is difficult to standard. Ouyang et al. (2012) introduce a time-dependent expected resilience metric as the mean ratio of the area between the real and target performance curve. The resilience metric is a stochastic one as the perturbation is modeled as Poisson distribution process and the resilience of system can incorporate one or multiple related hazards.

The above general resilience evaluation methods are concentrated on the resilience triangle model,

besides, the mathematical optimization models are also proved to be effective for assessing the resilience of system based on the network topologies structure of the system with one or more objective. As the scale-free graph nature of the system makes it easy to quantify the system resilience, especially for transportation system. Ip & Wang (2011) represent the transportation networks by an undirected graph with nodes as cities and edges as traffic roads, and the resilience of the network can be assessed by the feasible links between each node after disruption. Follow that, a multi-objective optimization model is proposed to evaluate the efficient edges and nodes to improve the network resilience. Beyond that, fuzzy logic is also used to quantify the resilience of system when involves several variables which are all important to the system.

2.2 *Strategies to enhance resilience in transportation system*

The definition and value of the system resilience can become useful and meaningful when used to devise effective resilience strategies for the system of interest. In transportation system, two ways are summarized to enhance the system resilience. On the one hand, it can be enhanced based on the definition of resilience expounded as the three capacities. As resilience is the embodiment of a variety of capacities, enhancing a specific capability contributes to enhance the resilience of system. Nan et al. (2016) test the strategies in an electric power supply system, where the resilience enhancing strategies can be interpreted as: (1) increasing the capacity of the battery to improve the absorptive capability during the disruption phase; (2) the improvement of human operators' ability to enhance the adaptive capability during the recovery phase; (3) the improvement of the efficiency of line operation to enhance the restorability capacity during the recovery phase.

In this point, organizational and management plans can be implemented to enable the system quick recovery and minimum the impact of disruptions. Adjetey-Bahun et al. (2016) propose a crisis management plan addressing the system capacity in order to assess the extent to which they increase the resilience of mass railway transportation system during perturbations, i.e. setting up temporary train services on part of the impacted line during perturbations can enhance the resilience of system effectively and decreasing the repair time of fault equipment contributes to the restorative capacity.

The same way also can be found in Chan et al. (2016) when assessing transportation system resilience with weather disruptions. Three common strategies are defined and offered for making transportation system more resilient: (1) hardening: building levees and floodwalls to prevent floodwaters; (2) redundancy: power distribution is a redundant system that provides a backup path between points; (3) elasticity: holding the aircraft on the ground to protect the fleet and passengers and taking off again quickly after the storm. Three aspects of resilience can work in combination to enhance the transit system resilience and support system management decisions.

On the other hand, pre- and post-disruptions actions are also impactful for system resilience improvement. After metro system disruption, an integrated local bus services and metro system to enhance metro network resilience is introduced by Jin et al. (2014), where a two-stage stochastic process model is presented to evaluate Singapore public transit network resilience and to optimize bus service routes that run in parallel with the metro lines. For more comprehensive, Faturechi & Miller-Hooks (2014) clearly address the pre-event mitigation and preparedness and post-event response in the disaster management life cycle are three decision process to the system resilience and a three-stage program is proposed to quantifying and optimizing the roadway network resilience.

3 METHODOLOGY

As the metropolises with large population and complex road conditions, the road congest conditions and the metro station exports are considered in the metro-bus bridging methodology to allow the passengers to reach their destinations in an available and quick way. In order to enhance the metro system resilience after signaling perturbations, the proposed bus bridging plan can be divided into three steps: (1) to the failure metro station as the endpoint, combined with the actual topology of the roadway to construct the metro-bus network; (2) generating the bus bridging routes between each O-D pair to avoid the congestion sections with minimum travel time; (3) allocating the limited bus resources to the bridging routes to increase the number of passengers demands that can be satisfied.

3.1 *Metro-bus network*

The metro-bus bridging network is modelled by a directed graph $G = (V, A)$, illustrated in Figure 2. In order to avoid passengers get stranded at the metro station during signaling perturbation, not only the disruption metro stations, the other metro stations which directly connected with the disruption metro stations are also considered to be bridged. Where set V is the set of nodes in the network, including metro station nodes and roadway nodes. The metro station nodes are the bus bridging stations and the roadway nodes are the end of roadways modelled according to the actual road network. Set A is the set of arcs in graph G, which is the connection of roadway

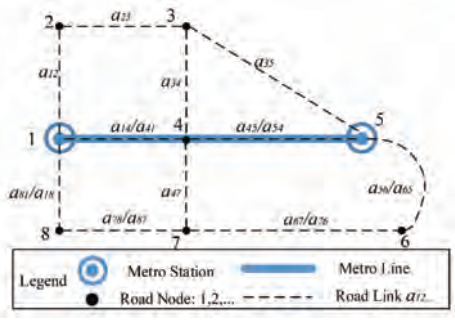

Figure 2. Metro-bus bridging topology network.

Table 1. Classification of roadway congest conditions in Beijing.

Congest conditions	h_{ij}
Smooth	0
Basically smooth	0.2–0.5
Mild congestion	0.5–0.8
Moderate congestion	0.8–1.1
Serious congestion	>1.1

node with metro node, or roadway node, labelled as $a_{ij}(i,j \in V)$. Based on the metro-bus network, the bus-bridging route can be modelled as the link of several arcs between origin nodes and destination nodes.

3.2 *Generation of bus bridging route*

Go through all the alternative routes, the shortest path may not be able to meet the constraints of actual demands, like route length constraints and road capacity limit. Thus, in the plan, Yen's (1971) *k*-shortest path algorithm is used to explore the feasible bus bridging routes under certain constraints.

Different from other research, the real-time traffic conditions $h_{ij}(i,j \in V)$ is considered in the plan, known as Traffic Performance Index (TPI) in Beijing, means the average travel time on a_{ij} is more than h_{ij} times as much as usual under congest conditions, for details shown in Table 1.

According to the real-time traffic conditions h_{ij}, the travel time $t_{ij}(i,j \in V)$ on each a_{ij} is calculated as:

$$t_{ij} = \frac{l_{ij}}{v} \cdot (1 + h_{ij}) \tag{1}$$

where v is the average travel speed of the bus, $l_{ij}(i,j \in V)$ is the length of a_{ij}.

The route constraints in the plan include two components: the minimum route travel time T_{min} and the maximum route travel time T_{max}. The final feasible generation route $b \in B$ between each O-D can be formulated as $f(w, k)$:

$$b: f(w,k) = min\{t_w x_w^k\} \tag{2}$$

subject to:

$$T_{min} \le t_w \le T_{max} (w \in W) \tag{3}$$

$$x_w^k = \{0,1\} \ (w \in W) \tag{4}$$

objective function (2) minimize the travel time of each O-D route, where route $w \in W$ is defined as all the available routes between each O-D and t_w is the travel time of route w. Constraint (3) is the travel time constraints for each route . In constraint (4), x^k_w is a binary decision, if $x^k_w = 1$, means the route w belongs the k-shortest path. Table 2. describes the process of generating the bus bridging route $b \in B$.

3.3 *Bus resource allocation*

According to Reed et al. (2009), the system resilience can be quantitative as (shown in Figure 3.):

$$R = \frac{\int_{t_0}^{t_f} Q(t)dt}{t_f - t_0} \tag{5}$$

Table 2. Steps of generating the bus bridging routes.

Input: $G = (V,A)$, T_{min}, T_{max}, k.
Output: $b \in B$.

Step 1	All the alternative routes are generated using k-shortest path algorithm between each O-D.
Step 2	Check all the generated routes for the minimum and maximum route constraints, if the route satisfied, then the route is accepted as a candidate route. Otherwise, it is removed.
Step 3	For all candidate routes, find the shortest one for each O-D, and kept in the set B as the final generated bus bridging routes.
Step 4	Output the set of B.

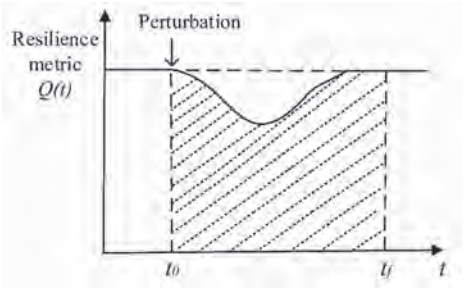

Figure 3. Resilience quantitative model proposed by Reed et al. (2009).

where R is the system resilience, can be calculated as an integral of the normalized resilience metric $Q(t)$ within an interval time, t_0 is the time perturbation intervention and t_f is the fixed time window. As the time interval $(t_f - t_0)$ can be defined flexibly, in the metro system, it can be varied with different types of signaling failure or defined as a fixed value. When resilience metric $Q(t)$ is a discrete value, the system resilience R can be defined as:

$$R = \frac{\sum_{i=1}^{i=N} Q(i \cdot \Delta T) \cdot \Delta T}{N \cdot \Delta T} \tag{6}$$

let N be a number such that:

$$\left(t_f - t_0\right) = N \cdot \Delta T \tag{7}$$

Mathematically, according to Chen & Miller-Hooks (2012), the metro system resilience metric $Q(t)$ can be expressed as the passenger travel demands between each Origin-Destination (O-D) pair that can be satisfied during the signaling perturbation, which known as Travel Demand Satisfaction Rate (*TDSR*) in the following.

Since the Genetic Algorithm (GA) provides a robust search as well as a near optimal solution in a reasonable time, the approach is employed to obtain an optimal system resilience accomplishing by allocating the limited bus resources to the generated bus bridging route $b \in B$ and the resilience metric (*TDSR*) of metro system is proposed as:

$$f(TDSR) = max\left\{\frac{\sum_{b \in B} n_b \times C}{\sum_{b \in B} d_b}\right\} \tag{8}$$

subject to:

$$0 \le n_b \le N (b \in B, n_b \text{ is integer}) \tag{9}$$

$$\sum_{b \in B} n_b = N \tag{10}$$

objective function (8) is to maximum the total number of passenger Travel Demands Satisfied Rate (*TDSR*), where d_b is the passenger demands for each O-D route $b \in B$ and obtained with fixed intervals Δt. An integer variable n_b indicates the number of buses allocated to each O-D route $b \in B$. C is the capacity of the bus and N is the total number of buses that available in the bus depots.

Hence the GA chromosome consists of integer gene values represents one solution of the bus allocation and is as follow:

$$[n_{b1}, n_{b2}, \ldots, n_{bm}] \tag{11}$$

where m is the total number of generated routes from set B. The objective of GA model presented here is to scientifically guide the bus resources allocation and select an optimum solution with the satisfied passenger travel demands being maximum. The implementation of the GA is shown in Table 3.

Table 3. The process of bus resources allocation.

Input:	$G = (V, A)$, d_b, B, N, C, m, Genetic Algorithm setting parameters.
Output:	$f(TDSR)$, $[n_{b1}, n_{b2,\ldots,} n_{bm}]$
Step 1	Input all the GA related parameters.
Step 2	Generate the GA population formulation for the current O-D pair set size m and initialize each chromosome randomly.
Step 3	Set generation = 1.
Step 4	According to each O-D pair passenger demands d_b, evaluate each chromosome by the objective function.
Step 5	Keep the current solution.
Step 6	Generate next generation. • Rank. • Selection. • Crossover. • Mutation.
Step 7	If the generation ≤ Max_Generation, increased generation by 1 and go to step 4; else update the current best solution if improved.
Step 8	Output the best bus-allocation solution from the best solution found, and its performance $f(TDSR)$.

4 CASE STUDY

According to the actual signaling system fault records, typical trackside signaling perturbations are summarized and the impact of different conditions to system resilience is discussed.

4.1 *Background of case study*

The model is applied to generate metro-bus bridging plan for Beijing Metro Line 5, whose average number of passengers on weekends can reach one million. The signaling failure data is provided by Communication and Signaling Branch Company Affiliated with Beijing Mass Transit Railway Operation Corp. Ltd. According to the statistics of the failure record in the past four years, the main trackside signaling equipment with high failure probability are summarized as: (1) WESTRACE TCOM system used to produce carrier frequency of track circuit; (2) track circuit transmitter or receiver; (3) the trackside APR used to send position information to the trains. Once the equipment fails, signal or multiple track sections will be affected and impact will last one or two hours.

Through the analysis of historical fault records, the failure of TCOM system has the most influence in the trackside equipment as the TCOM system failure will affect multiple sections for few hours. In this way, four typical areas with high failure rate of TCOM system are enumerated (shown in Figure 4.) and the bus bridging area is tabled in Table 4.

Due to the large passenger flow in Line 5, great disturbance to passenger travels will be caused when the signaling failure happens. Therefore, we assume the operators will call for bus-bridging if the perturbation lasts ten minutes. The parameters

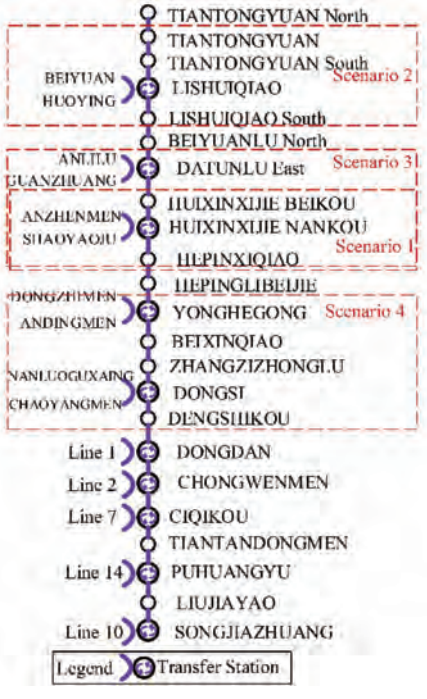

Figure 4. Typical areas with high failure rate of TCOM system in Beijing Metro Line 5.

Table 4. Four typical bus bridging scenarios.

Scenario NO.	Bus bridging areas
Scenario 1.	Huixinxijie Beikou-Huixinxijie Nankou-Hepingxiqiao-Anzhenmen
Scenario 2.	Tiantongyuan-Tiantongyuan South-Lishuiqiao-Lishuiqiao South-Huoying
Scenario 3.	Datunlu East-Huixinxijie Beikou-Huixinxijie Nankou-Hepingxiqiao-Anlilu-Anzhenmen
Scenario 4.	Yonghegong Lama Temple-Beixinqiao-Zhangzizhonglu-Dongsi-Dengshikou-Nanluoguxiang

related to the proposed bus-bridging plan are set as follow:

– The perturbation occurs at 7:00 am and lasts 2 hours.
– The average bus speed of bus: $v = 18$ km/h.
– Feasible bus resources: $N = 15$ during each time interval, $C = 80$ person/bus.
– Time constraints: 1 min–20 min.

4.2 *Modeling and bus-bridging strategy*

The path network models between metro stations are built based on google map. And then, shortest bridging route are selected with the improved k-shortest path algorithm. For example, in Scenario 1, set $k = 4$. Under the constraints of time conditions and passenger travel demands, there are 9 bus bridging routes are generated (shown in Figure 5.). And the bus bridging plan avoids the congestion section {*v7-v12-v15, v27-v28*} from Huixinxijie Beikou to Huixinxijie Nankou. But from Huixinxijie Nankou to Hepingxiqiao, the congestion section {*v15-v18-v27*} is still in the plan, as the other way cost too much travel time.

The travel demands for each O-D route are collected from the AFC (Automatic Fair Collection system) during 7 am to 9 am in the workday. The available bus resource in each time interval is 15. The *TDSR* of Scenario 1 with bus bridging plan is shown in Figure 6. And the resilience of the metro system is 0.80, improved by 29% than normal condition.

Figure 5. The bus bridging routes in Scenario 1.

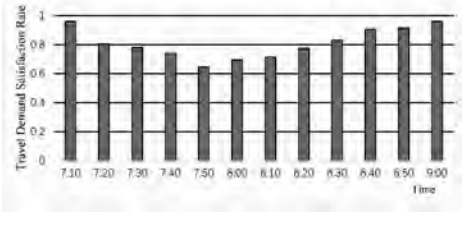

Figure 6. *TDSR* with bus bridging plan in Scenario 1.

5 DISCUSSION

5.1 *The influence of bus resources on bus bridging plan*

The system resilience metric (TDSR) can be calculated by the O-D demands that the bus bridging plan can satisfy in perturbation scenarios and shown in Figure 7. At the beginning of the implementation of the plan, as a large number of passengers stayed at the station, the TDSR presents a trend of decreasing due to the start of the failure. About half an hour later, the passengers are gradually evacuated with the bus bridging plan, and the resilience metric of system begins to recover. However, the time with the lowest TDSR is varied with the passenger travel demands delay at each metro station. In Scenario 2, the system is less resilience at the outset due to the greatest passenger demands at the time perturbation occurs. And in Scenario 3, the TDSR of the system has changed little because of the stable passenger demands during the perturbation.

According to Formula (2), the system resilience in the four scenarios with or without the bus bridging plan are shown in Table 5. It can be seen that with the proposed bus bridging plan the system resilience can be increased by 21%–43%.

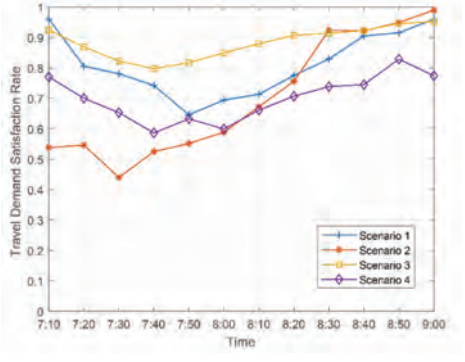

Figure 7. TDSR in different scenarios with bus bridging plan.

Table 5. The comparison of the metro resilience before and after the implementation of the bus bridge scheme.

Scenario NO.	System resilience (R1)	System resilience with bus bridging (R2)	Improvement (R2-R1/R1)
Scenario 1.	0.62	0.80	0.29
Scenario 2.	0.58	0.70	0.21
Scenario 3.	0.70	0.88	0.26
Scenario 4.	0.49	0.70	0.43

5.2 *The influence of bus resources*

In order to minimize the impact on normal bus transit system, the buses that can be used to the metro-bus bridging plan are limited. As the amount of buses will directly affect the improvement of system resilience, it is necessary to weight the bus transit system with the metro system resilience enhancement. Figure 8 shows the *TDSR* of system with different bus resources in Scenario 2. When the bus resources get 25 each interval time, the system resilience can get 0.91, up to 30% compared to M = 15. And from 7 am to 8 am, about 25 buses are needed at each time interval so that the *TDSR* of system can reach 0.8, and from 8 am to 8:30 am 20 buses are required, and from 8:30 am to 9 am, 10 or 15 buses are enough to make the *TDSR* to 0.8. It is provided a reference for the metro operator and the bus transit operator to design the bus bridging emergency plan adjusting the number of buses in different time periods to meet the needs of passenger demands without affecting the bus transit system.

5.3 *The influence of tidal flow*

For Beijing Metro Line 5, its northern end to Tiantongyuan, an important office worker residence, the flow of people in working days during morning and evening peak has obvious tidal trend (shown in Figure 9.). Therefore, in the bus bridging plan, the bus routes on the up and down lines will be reduced to one-side route according to the direction of passenger flow in order to support the specific passenger demands. In Scenario 2, before 8:30 am, the *TDSR* is about one third higher than that of the two-sides bus bridging and the *TDSR* of system are above 0.7 (shown in Figure 8.). There is an obvious improvement of system resilience as the bus bridging plan only considers one-side (uplink) passenger flow and it can be improved about 21%.

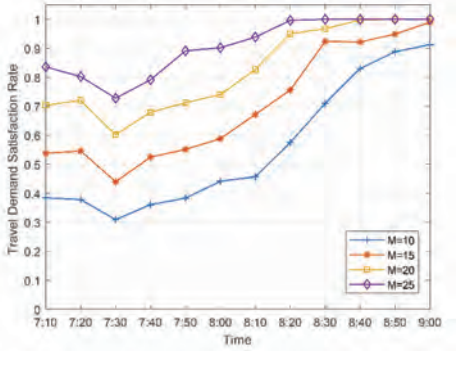

Figure 8. *TDSR* in different amount of buses over time in Scenario 2.

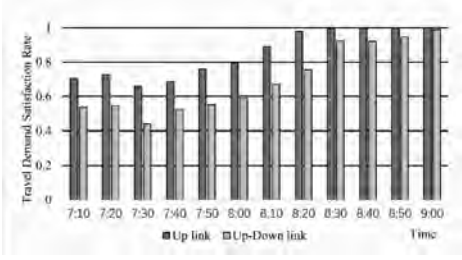

Figure 9. *TDSR* in uplink and up-down link bridging routes in Scenario 2.

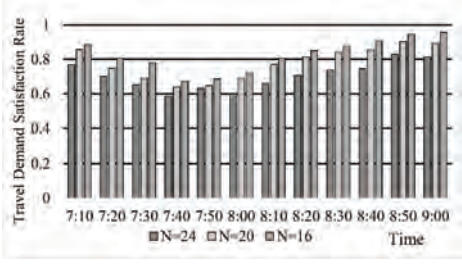

Figure 10. *TDSR* improvement from different bridging routes in Scenario 4.

Also, in Scenario 4, when removing part of the bridging routes that the system *TDSR* also get improvement (shown in Figure 10.). When the total bus bridging routes are 24, the system resilience is 0.7, when the total number of bridging routes streamlined to 16, the system resilience can be 0.83 improved by 19%. For general scenarios, with the limited bus resources, the metro operator can adjust the bus bridging routes appropriately according to the distribution of passenger flow in each time period and arrange the limited buses to the stations with most demands so as to meet the bridging routes with more demands and prevent the accumulation of stranded passengers in stations.

6 CONCLUSION

The resilience of metro system is mainly manifested as absorptive capacity, adaptive capacity and recovery capacity, and we focus on the adaptive capacity which can be enhanced with external bus bridging services after signaling failure. According to the above, the main conclusions are as follow:

1. In metropolis, urban rail transit system is the most important way for people's traveling, once the signaling system failures, a large number of passengers will be accumulated at the station in a short time during the peak period. With the bus bridging plan, the metro system resilience can be improvement about 21%–43% compared to the normal situations. And the bus bridging plan can be used to slow down the pressure caused by the passengers. The results show the passenger flow will return to normal state about an hour later without other actions taken by the metro operators. Therefore, we suggest that during the perturbations, except for the bus bridging plan, operators shall inform the passengers about the signaling failures with network or other media in time so as to avoid excessive passenger stranded at stations.
2. The trend of morning and evening tides of passenger flow is obvious in Line 5, the generated bus bridging routes can be properly adjusted to the change of passenger flows and the priority of the routes with more demands to enhance the metro system resilience. The results provide reference for the metro operator in daily disposal after signaling failure.

Further improvements of the metro-bus bridging plan, we are interested in the exits of the bridging metro stations, as the wide distribution of the metro exits will influence the bus bridging routes especially in transfer stations. In addition, further work can be carried out on the commands of the dispatcher during the perturbations, optimizing the strategy of dispatcher to restore the normal operation order of the train as soon as possible to enhance the resilience of the metro system.

ABSTRACT: Resilience of Critical Infrastructure (CI) has been a research focus for several years now, with efforts being made to develop methods for the analysis and assessment of CI resilience. However, these efforts are often carried out without consideration of enriching societal risk or resilience assessments with knowledge of the resilience of CI. Bearing in mind that the definition of CI according to the EU reflects the fact that it exists to deliver vital societal functions, the consideration of its resilience in isolation of the community it serves is only addressing part of the problem. The Horizon 2020 project IMPROVER has already developed methodologies for assessing and managing CI resilience. This paper proposes an evolution of the management framework for CI resilience which enriches societal resilience assessment with knowledge of the CI resilience. The framework and societal resilience analysis methodology are both described along with an application of the analysis method.

1 INTRODUCTION

In recent years, increasing resilience of Critical Infrastructures (CI) has been a major objective of the EU as well as worldwide. Disruptions of critical infrastructures, caused by natural or man-made events, are increasingly affecting today's society as the reliance on infrastructure systems to provide vital societal functions increases (Rinaldi et al. 2001). As one of the main purposes of CI is to deliver services to the society, resilience assessment of CI should be closely linked to the study of societal resilience. Societal resilience refers to "the ability of social groups or communities to cope with external stresses and disturbances as a result of social, political and environmental change" (e.g. Adger 2000, Folke 2006, Furedi 2007, Marshall 2010, Voss 2008). As being able to tolerate a reduction in the quality, quantity, or availability of a service provided by a CI demonstrates coping capacity, it can therefore be seen as a key component of societal resilience. Thus, CI resilience and societal resilience are closely linked, with each influencing the other. Indeed, many existing societal resilience analysis methodologies include indicators relating to critical infrastructure (e.g. Michel-Kerjan 2015, Boon et al. 2012, Cutter et al. 2010, Renschler et al. 2010). As such, increasing CI resilience also serves to increase societal resilience, creating a positive feedback loop between the two. The societal domain mainly becomes of interest when considering a higher level; regional or national, where several CI operate.

To that end, the EU Horizon 2020 project IMPROVER (Improved risk evaluation and implementation of resilience concepts to critical infrastructure) has developed the IMPROVER Societal REsilience Framework (IS-REF), which maps resilience management onto common risk management frameworks and includes aggregated CI resilience assessments as an input to the societal resilience analysis (Fig. 1). The IS-REF is an evolution of ICI-REF (IMPROVER Critical Infrastructure Resilience Framework), which is developed for managing CI resilience, and has a similar structure.

The initial step in IS-REF is to establish the context for societal resilience management. This includes the gathering of CI resilience assessments, which may have been conducted by using the ICI-REF framework with methodologies developed within IMPROVER, designed for CIs to manage

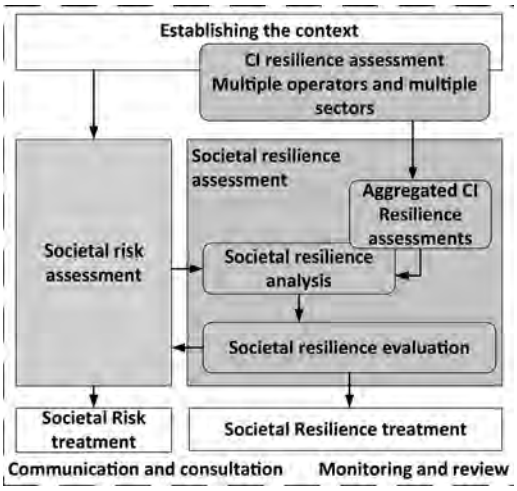

Figure 1. The structure and process of the IMPROVER Societal REsilience Framework (IS-REF).

Table 1. Success factors for IMPROVER's resilience management frameworks, with requirements to analysis methodologies.

System dimension	Success factor
Goal	Applicable to all types of CIs
Environment	Easy to use
	Effective and coherent crisis and disaster resilience management
	Provide relative resilience measurements
Structure	Supplements existing practice
	Taking into account public communication
Evolution	Arranged for being revised continuously
	Learning capabilities
	Willingness of utilisation

their technological and/or organisational resilience. In the next step of IS-REF, as a complement to societal risk assessment, a societal resilience assessment is undertaken. The results of such a resilience analysis shall be evaluated against previously decided upon criteria, and if necessary, a societal resilience treatment plan is devised. Throughout the entire IS-REF framework, communication and consultation as well as monitoring and review take place. For more details on the framework see IMPROVER's deliverable 5.1 (Lange et al. 2017).

Within both the ICI-REF and IS-REF, the resilience analysis can be performed using existing methodologies. However, IMPROVER has designed success factors for the performance of the resilience management frameworks and their content. Those of the success factors which generate requirements to resilience analysis methodologies are presented in Table 1. The success factors were designed to meet requirements from stakeholders and end-users, and have their basis in the Horizon2020 call text. With the background in systems theory (Roux-Rouquié & Moigne 2002), the success factors are categorised according to four fundamental system dimensions: goal, environment, structure and evolution, and are described in detail in IMPROVER's deliverable D6.1 (Reitan et al. 2017).

For the purpose of fulfilling the success factors, a well-defined methodology which is highly suitable for analysing societal resilience within the context of CI is currently being developed; the IMPROVER Societal Resilience Analysis (ISRA) methodology. This paper describes the background and structure of ISRA which is still in an early phase. Pilot tests, giving insight in how the methodology can be used, will aid the further development and optimisation of the methodology. A societal resilience analysis of one of the living labs in IMPROVER was conducted and is presented in this paper.

2 ANALYSING SOCIETAL RESILIENCE

Assessing and enhancing the resilience of critical infrastructures will not automatically result in a resilient society, since social and human dimensions have a strong influence in the achievement of a resilient society. Indeed, it is important to consider the link between physical and human systems to understand and enhance societal resilience (Chan et al. 2014). However, the concept of resilience is not yet fully operationalized, and many different approaches have been developed to achieve a measurement of resilience (e.g. Frankenberger et al. 2013, Boon et al. 2012, Cutter et al. 2010, Norris et al. 2008). While there are no generally agreed upon metrics, indicators can be an effective tool to help decision makers understand where their community stands in terms of resilience and as a base for developing plans and strategies to enhance resilience. Furthermore, for CI, a societal resilience analysis based on indicators provides a holistic picture of a community's strengths and weaknesses in times of disasters, offering an understanding about what kind of society the critical infrastructure operates in.

2.1 *Resilience capacities and dimensions*

In the field of societal resilience, the concept of coping capacity, adaptive capacity and transformative

capacity are common denominators that are used to categories capacities needed to achieve resilience (Keck & Sakdapolrak 2013). Coping capacity refers to the ability to respond, absorb and recover from a disruptive event and is generally related to a time frame close to the event. Adaptive capacity includes the ability to plan for and adjust to future challenges, which is related to a longer time-frame both before and after an event. Resilience is not only about quick recovery and adjusting to new circumstances; the aspect of transformation must also be taken into account. Transformative capacity refers to the ability to transform the stability landscape in order to create new, better, pathways for the system and is thus related to major changes in the long-term.

Resilience is by definition a complex and multi-dimensional topic, and a resilience assessment should ideally include all of these dimensions and their interdependencies (Sharifi & Yamagata 2016). However, to be able to operationalize the resilience concept, some trade-offs are necessary. From literature, six major societal resilience dimensions were identified as physical, social, human, natural, economic and institutional capital. Each of these dimensions has influence on the resilience capacities discussed above.

3 THE ISRA METHODOLOGY

3.1 *Overall structure*

The objective of the methodology is that the analysis should be able to inform a community on how to enhance coping, adaptive and transformative capacities. The starting position is to analyse a community's perceived capability to react, adapt and recover from a shock. Based on the resilience dimensions, a set of indicators has been identified to analyse societal resilience. Within ISRA, detailed individual assessments of CI resilience are used to provide an input to the physical dimension.

The indicators are further categorized by which capacity they mainly have influence on (Table 2). The indicators and their parent resilience dimensions can, in reality, influence more than one capacity, but in this first development phase, they are categorized according to the capacity they are assumed to have the most effect on. The proposed aim of using the methodology is to i) develop a common understanding of societal resilience, and ii) establish the current position (the result of the analysis).

However, it is important to keep in mind that ISRA is only a part in an overall resilience management strategy, the results of which need to be used in the resilience evaluation part of the framework to ensure sense making, before deciding how to go about improving resilience in the resilience treatment part of IS-REF. In this early development phase, the focus was to identify relevant indicators from literature and create a holistic picture of the societal resilience domain. Thus, at this stage, interdependencies or conflicting goals among the indicators were not taken into account.

3.2 *Aggregation of the indicators*

The assessment is performed by qualitatively scoring a set of indicators on a scale from 1 to 5. The indicators are categorized according to the six resilience dimensions at Level 2 of the ISRA structure (Fig. 2). The score for each resilience dimension is achieved by aggregating the indicators under each dimension and capacity to a single measurement, and thereafter aggregating the three capacity scores into one score for each resilience dimension. In this early development phase of ISRA, all indicators and subcategories are weighted equal, but one might want to weigh the importance of the capacities and dimensions in order to capture subjective resilience aspects. The indicators are aggregated by the weighted arithmetic mean (Eq. 1)

$$Level\ k\ indicator = \sum_{i=1}^{n} w_i x_i \quad (1)$$

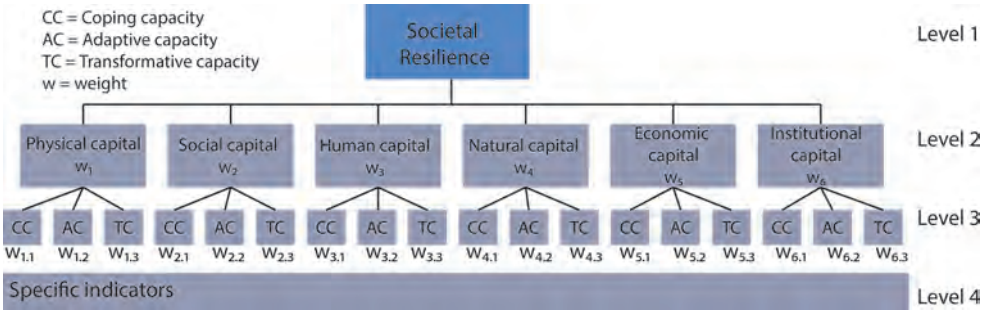

Figure 2. Structure of the ISRA methodology.

where n is the number of Level $k+1$ indicators, w_i the weighting coefficient for the individual Level $k+1$ indicator and x_i the scoring of the individual $k+1$ indicator. The aggregation can be done all the way up to Level 1 (see Fig. 2) resulting in a global score for societal resilience. However, a lot of information can be lost by doing that, so presenting the resilience dimensions in Level 2 provides a more detailed result.

4 PILOT DEMONSTRATION OF ISRA

4.1 *Case study*

The *Port of Oslo* has been one of the living labs in IMPROVER from the start of the project. The relevance of the Port of Oslo from a CI resilience perspective can be traced back to 2014, when the Norwegian Directorate for Civil Protection published an overall assessment of the management of the safety conditions in Sydhavna, and pinpointed improvement measures for the enterprises, the City of Oslo, the Port of Oslo and central government authorities.

In the wake of the report, the extensive exercise *HarbourEx15* was carried out at Sydhavna from 28 to 29 April 2015. The scenario for the exercise was an explosion and fire in containers with hazardous substances in the container area, fire in the fuel depot, evacuation of smoke-filled areas in parts of Oslo, and the grounding of a vessel and subsequent oil spill in the Inner Oslo Fjord.

The goal of the exercise was to improve emergency planning and rescue operations in the event of a major accident in Oslo. The exercise involved a total of ca. 40 participating organisations, including the rescue agencies, public authorities with responsibility for emergency planning, international rescue services and private actors at Sydhavna and in the City of Oslo.

In the evaluation of HarbourEx15, nine proposed initiatives were described, among these some of relevance to societal resilience, including population alert (acute alert) and providing information to the public (DSB 2016). Based on this work, a well-defined approach for societal resilience assessment is of interest to the area.

4.2 *The pilot test approach*

4.2.1 *The focus group*

In the development of ISRA, which is an operational methodology, users (authorities) were included at an early stage of the work to ensure that the methodology is fit-for-purpose. The focus group consisted of 5 relevant representatives from the HarbourEx15 evaluation. The participants were chosen to represent different parts of the community, as well as for their ability to provide insight and experience in areas connected to societal resilience. Their task was to evaluate the methodology from the perspective of the HarbourEx15 based on their expert knowledge about Sydhavna and the surroundings.

4.2.2 *Approach*

The exercise was in the form of a questionnaire. This was considered a sufficient method to combine a societal resilience analysis of the case study, and simultaneously receive the focus group's spontaneous evaluation of the indicators, as well as the quality of the questions that were designed to provide measures to the indicators. The questionnaires were designed as follows:

The focus group was asked to decide on a geographical area to perform the evaluation on. They were subsequent asked to evaluate the area according to the 56 societal resilience indicators. The indicators were evaluated according to a symmetric Likert scale from 1–5. To facilitate the self-evaluation, each indicator was described by a statement to which the respondents can specify their level of agreement from Strongly Disagree (corresponding to 1 on the scale) to Strongly Agree (corresponding to 5 on the scale). To support their evaluation, they were asked to provide evidence and support for their answers, along with a summary of the discussions that led to the response. Finally, they were asked to give their opinion about each indicator's relevancy and understandability. The feedback was then analysed using thematic analysis (Braun & Clarke 2006).

4.3 *Results*

In this section, general comments from the focus group and evaluations of the specific indicators are described.

4.3.1 *Comments and input*

Three main themes were identified from the comments and input regarding the chosen indicators and statements: lack of clarity, more than one question, and overlap.

For several of the indicator statements, focus group participants expressed the need for several clarifications. For example, one comment stated, "Unclear what it is you are looking for here." Another way to express lack of clarity was by asking directly for clearer definitions for the following words: Cooperation, Coordination, Community, Crowdsourcing, Community based, Actor, Stakeholder, Public, People in the community and Trust. Other times, there was uncertainty about which actor the methodology was asking about (e.g. "unclear if referring to decision making structures

Table 2. Societal resilience indicators according to their resilience dimension and supporting capacity, and scores from the pilot self-evaluation exercise. CC = Coping capacity, AC = Adaptive capacity, TC = Transformative capacity.

in administrative decision-making systems or in civil society") or the scope of the question (e.g. "should we refer to the South Harbour and industrial duty, or should we refer to the community at large"). This theme appeared 18 times in the comments.

Another theme was that several indicator statements are actually comprised of multiple statements, showing up 11 times. This comment illustrates well the participants' views: "The statement contains two different elements/issues that can have different answers." There were also a few (five) comments with regards to certain indicators overlapping with one another. One such comment, "there is an overlap here with several of the other indicators," demonstrates well this theme.

Of special importance, though only mentioned once, was a comment related to the entire methodology instead of a single indicator or indicator statement. The participants asked, "How close should we attach the response to events in Oslo harbor?" This comment also shows a lack of clarity in how to use the method.

While the participants of the focus group had helpful critiques of the methodology, they also stated that while they found the exercise challenging, they also perceived it to be interesting and relevant to the assessment of societal resilience.

4.3.2 *Self-evaluation*

The preliminary scores from the pilot self-evaluation are shown in Table 2. Since there is no analysis made within IMPROVER project on the critical infrastructure in Sydhavna, there are no scores for the indicators under physical capital.

The focus group were also asked to provide evidence and discussion in regards to the self-evaluation score given for each indicator. However, evidence and discussion were provided for only 18 out of 56 indicators. Evidence and discussion provided ranged from very relevant and specific, for example for indicator 2.12 (see Table 2), "Emergency services and the municipality use social media, and have a large number of followers (c.f. HarbourEx15)", to relevant but lacking in empirical support, for example for indicator 2.3 Trust between citizens, "Based on the generally high level of trust in Norway, we answer that we agree," to suppositions, as for example indicator 6.7 Usage of ICT for public awareness of disasters, "we don't think so".

4.3.3 *Presentation of societal resilience*

The societal resilience of Sydhavna and its surrounding neighbourhoods is preliminary illustrated by the radar chart in Figure 3. All dimensions except physical capital are represented by aggregated scores from the self-evaluation, and the physical capital is purely fictively scored by the authors of this paper. Note that the radar chart does not represent absolute measurements of the societal resilience in Sydhavna, but is rather a way to show how the output from ISRA may be presented.

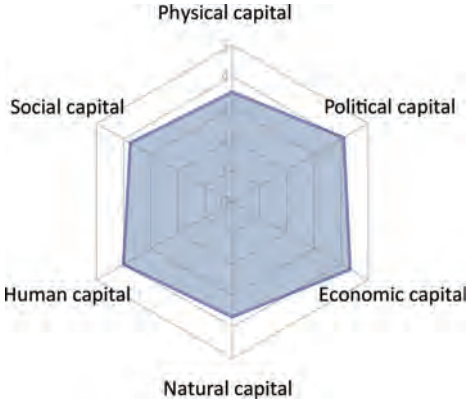

Figure 3. Presentation of the result from the pilot self-evaluation of societal resilience using ISRA.

4.3.4 *Sensitivity analysis of indicator weights*

At this early development phase, the indicators were weighted equally due to lack of information about relative importance of the indicators and dimensions. A simple sensitivity analysis was performed to study if, and how, different weightings would affect the results. The sensitivity analysis was performed by assigning the Level 3 indicators a weight of 0.5 one at a time, and assigning the remaining two Level 3 indicators a weight of 0.25. The resulting scores were compared to those obtained with equal weighting. The result from the sensitivity analysis is shown in Table 3.

5 DISCUSSION

5.1 *The outcome of the pilot test*

The methodology was perceived as valuable in terms of creating an overview of aspects that can affect coping, adapting and transforming capacity. However, the self-evaluation scores given to the indicators need to be supported by evidence or references. In the pilot test, only 18 out of 56 indicators were supported with evidence. This means that the output of the analysis should not be considered a realistic result in terms of maturity of societal resilience. In general, the focus group scored themselves high on the indicators and the resulting aggregated scores for each resilience dimension was around 4 on a scale from 1–5. This could mean that the studied area is mature regarding societal resilience, but since the evidence provided in the analysis were weak, strong conclusions should not be drawn from these results.

5.2 *Limitations of the study*

At this stage, the indicator hierarchy that ISRA is constructed of does not consider interdependencies

Table 3. Level 2 scores aggregated with equal weights, and w = 0.5 for each Level 3 indicator (capacity) by letting the rest of the weights remain equal (w = 0.25).

	Equal weights	Coping w = 0.5	Adaptive w = 0.5	Transform. w = 0.5
Physical capital	3.500	3.375	3.625	3.500
Social capital	3.802	3.768	3.744	3.893

Institutional capital	3.944	3.875	4.125	3.833

and correlations between different resilience dimensions. However, as the socio-ecological system is a very complex system, there is a need to consider how the different parts interact and affect each other. Moreover, there is no consideration of conflicting goals among the indicators or if there are synergies that could result in emerging properties.

These limitations need to be explored, and the effects need to be evaluated, to further improve ISRA and produce valid results from the analysis.

5.3 *Going forward: Ways to improve the method*

The sensitivity analysis showed that weights can affect the end result, although neither a statistical sensitivity analysis was made, nor an analysis of weighting on each indicator. To further develop ISRA there is a need to investigate if and how to assign weights to the indicators.

One limitation of the indicator hierarchy that ISRA is constructed of is that it does not consider interdependencies and correlations between different resilience dimensions. As the socio-ecological system is a very complex system, there is a need to consider how the different parts interact and affect each other. This would increase the validity of the analysis.

The thematic analysis of the participants' comments identified three main areas for improving ISRA indicators. These are the need to clarify not only the definitions of words but also the scope and actors associated with the statements, ensure that each statement is only presenting the respondent with one question, and that the statements do not overlap with other indicator statements. As such, for future iterations of the methodology, we propose to add in a definitions section that clearly defines commonly used terms, as well as define certain terms that are used only once within the Statement provided. When operationalising the indicator into a statement, care needs to be taken to ensure that each indicator statement is indeed composed of only one question, thus a review of the statements to include only the most applicable question to the indicator will be done. Lastly, overlapping indicators will be evaluated to see if the overlap is necessary. If so, the statements will need to be rephrased in order to put the accent on the differences between the indicators and ensure they do not overlap. The focus group also demonstrated the importance of including ISRA in the IS-REF framework, and better explaining how these two work together. Indeed, the comment relating to the scope of the methodology demonstrates that the fact that the context was meant to be identified before ISRA was used was unclear to the participants.

Furthermore, the level of detail required for the evidence and discussion part of the methodology should be clearly defined, and more emphasis should be put on the importance of providing evidence to support ones self-evaluation. In this first pilot study, the scoring was, in general, not underpinned by strong evidence, and thus the results in terms of societal resilience maturity are not reliable. Indeed, the evidence allows future users of the evaluation to understand why the indicators were scored as they were, and also provides good input for the resilience treatment part of IS-REF.

While improvements need to be made, the overall feeling shared by the participants was that ISRA provides a novel approach on disaster risk management and may be useful for evaluating societal resilience, thus demonstrating the success of the method.

6 CONCLUSIONS

This paper has presented the Improver Societal Resilience Analysis (ISRA) and demonstrated the methodology. The methodology is being developed to enrich societal resilience with the knowledge of critical infrastructure resilience on a regional or national level. To ensure operability of the methodology, a focus group consisting of potential future users were involved from the start of the development process. Their feedback provides a basis for further development of the methodology, including increasing clarity, removing overlap and multiple statements, better explaining how ISRA fits into IS-REF, and putting more emphasis on the collection of evidence. These improvements will ensure that ISRA meets the needs of the intended user and is providing a useful process as well as valid results.

The ISRA methodology draws on existing indicators and frameworks for societal resilience analysis; however it introduces the results of critical infrastructure resilience evaluations to the societal resilience analysis as an overall high level indicator of the physical capital of a community. In combination with the IMPROVER IS-REF, as proposed in the introduction to this paper, ISRA is a tool which could be used to enrich societal risk assessments by providing an overview of the capacity of a society to cope with, adapt to and transform in the aftermath of a disaster or emergency. This information, while not necessarily adding value for a risk assessment addressing the frequency of an incident and the immediate consequences of an incident would add significant value and help to evaluate risks by providing an overview of the medium and long term ability of a community to cope with the incident.

ACKNOWLEDGMENT

We would like to thank the focus group participants for their time and valuable input. The IMPROVER

project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement no. 653390.

ABSTRACT: In the field of Critical Infrastructures (CI), both policy and research focus has shifted from protection to resilience. The IMPROVER project has developed a CI resilience management framework (ICI-REF), applicable to all types of CI and resilience domains (technological, organisational and societal) allowing operators to understand and improve their resilience. IMPROVER has also developed methodologies to be used within the framework, accompanied with resilience indicators for operators to assess their technological and organisational resilience. The framework allows CI operators to incorporate resilience management as part of their risk management processes. The ICI-REF, the resilience analysis methodologies and indicators have been optimised, applied and demonstrated in a pilot implementation, focusing on the potable water supply in Barreiro, Portugal. Conclusions from the operators so far are that the indicators, well-defined and unambiguously described, are crucial for monitoring resilience activities, to ensure objective, consistent, repeatable and representative results from the assessed processes.

1 INTRODUCTION

Increasing Critical Infrastructure (CI) resilience is one is one of the main objectives for the European strategy towards a more secure Europe (COM, 2010). Through the Program for Critical Infrastructure Protection (EPCIP), issues and approaches to focus on are defined, where measures to facilitate implementation of resilience concepts to CI are identified (SWD, 2013). The concept of resilience has evolved from ecological resilience, via psychology, engineering to the disaster risk reduction field. There is thus a range of definitions of the concept of resilience and for this context we use that of UNISDR *"The ability of a system, community or society exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions"* (UNISDR, 2009). In EU, CI is defined as: "*an asset, system or part thereof located in Member States which is essential for maintenance of vital societal functions, health, safety, security, economic or social well-being of people, and the disruption or destruction of which would have a significant impact in a Member State as a result of the failure to maintain those functions*" (Council, 2008).

An overall goal of the EU-funded Horizon 2020 project IMPROVER is to improve European CI resilience to crisis and disasters, through the implementation of technological, organisational and societal resilience concepts. To that end, the IMPROVER Critical Infrastructure REsilience Framework (ICI-REF) was developed. The framework is supported by resilience analysis methodologies and indicators, also developed in IMPROVER. It is inspired by existing stand-

ards and frameworks e.g. ISO 31000, ISO 22301, ISO 22316, Org. Resilience HealthCheck (Austr. Government, 2017), Benchmark Resilience Tool (Resilient Organisations, 2014) and Resilience Measurement Index (Petit et al, 2013).

To ensure that the developed ICI-REF framework, with supporting methodologies and indicators, is fit-for-purpose, it is optimised in pilot implementations, by application to relevant scenarios in semi-real environments at several living labs. One pilot implementation has recently been conducted, focusing on potable water supply in Barreiro, Portugal.

This paper describes structures and processes of the ICI-REF and resilience analysis methodologies, including preliminary results of the pilot implementation at the Barreiro living lab, Portugal.

2 IMPROVER CRITICAL INFRASTRUCTURE RESILIENCE FRAMEWORK (ICI-REF)

2.1 *The ICI-REF structure and process*

ICI-REF is a general and well-defined framework for managing the technological, organisational and societal resilience of CI (Lange et al., 2017a; 2017b). It includes the flexibility to account for the unique features of the various types of CI, giving CI operators an understanding of, and a capability to improve, their resilience. The framework extends standard risk procedures (ISO 31000) and considers resilience assessment as complementary to risk assessment. The framework is constructed such that it is easily incorporated within existing risk management processes by CI operators. Initial feedback by CI operators (Theocharidou et al., 2016) indicated this approach as the most feasible one, as it can improve their current practices and allow for risk and resilience management decisions to be taken based on the results of both assessments. ICI-REF allows operators to perform self-assessment or focused analysis of technological/organisational aspects in order to either monitor resilience over time, or compare to similar CI within the same sector. The ICI-REF structure is depicted in Fig. 1.

The ICI-REF process starts with *establishing the context*, implying the gathering of information, defining the resilience domain(s), etc. The defined context, risk identification and risk analysis are then fed into, and complemented by, the resilience assessment process. *Resilience assessment* comprises of *resilience analysis* and *evaluation* against pre-defined criteria. Three different resilience analysis methodologies have been developed (described in 2.3). The results from risk and

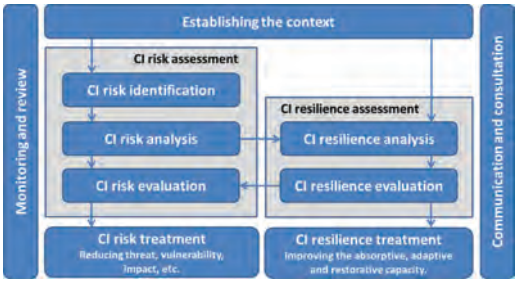

Figure 1. Structure of the IMPROVER Critical Infrastructure REsilience Framework (ICI-REF).

resilience assessments constitute the basis for designing treatment plans, describing how to both mitigate risk and improve resilience. This parallel process allows decision makers to select risk and resilience measures in a cost-effective way, especially when a measure can be implemented to address both risk and resilience objectives. Throughout the ICI-REF process, *Monitoring and review* as well as *Communication and consultation* are continuous background processes (see Lange et al., 2017).

CI resilience analysis can be performed by implementing existing methodologies, or by methodologies developed in IMPROVER. This paper focuses on technological and organisational resilience analysis, for which resilience assessments are performed at the CI level. Assessment and management of societal resilience shall instead be conducted on regional or national levels, using CI resilience assessments as input. A modified version of ICI-REF is developed for this purpose (Rosenqvist et al., 2018).

2.2 *Resilience indicators*

In the context of IMPROVER, the term "resilience indicators" is related to variables that can be used, either alone or in combination, as a representation of resilience. Qualitative, semi-quantitative or quantitative indicators are analysed and, when sufficient, aggregated to a measure of resilience.

The resilience indicators should be clearly defined, in order to ensure objectivity and a proper balance between generality and specificity. To monitor resilience over time or comparing to similar CI, the indicators must also provide reproducibility and repeatability. Measurement scales for the indicators and their possible weight factors should ideally be benchmarked at a sectoral level.

Based on literature and defined requirements from CI operators associated with IMPROVER, the resilience indicators to be included in the resilience analysis step of ICI-REF are developed and optimised. They relate to the various resilience

analysis methodologies used for different resilience domains.

2.3 *Resilience assessment*

As a first step, the CI operator may want to conduct an initial self-assessment to indicate strengths and weaknesses in its resilience; i.e. in which areas or domains a more in-depth assessment is required. For this purpose, the operator may find a resilience analysis methodology with high flexibility useful, such as the Critical Infrastructure Resilience Index (CIRI) developed in IMPROVER (Pursiainen et al., 2017).

This process may be sufficient, but if required, operators can perform re-assessment by using analysis methodologies which goes more into details. For this purpose, two different methodologies have been developed: the IMPROVER Technological Resilience Analysis (ITRA) and IMPROVER Organisational Resilience Analysis (IORA) for analysing technological or organisational resilience, respectively (Bram et al., 2017; Mindykowski et al., 2016). CIRI, ITRA and IORA methodologies are briefly described below.

2.3.1 *Critical Infrastructure Resilience Index (CIRI)*

Critical Infrastructure Resilience Index (CIRI) is a holistic and easy-to-use self-assessment methodology. It is applicable to all types of infrastructures, and built on a four level hierarchy of indicators, focusing mainly on the technological and organizational domain. The backbone for CIRI is the crisis management cycle (OECD, 2011; Pursiainen, 2017). The different phases in the cycle corresponds to the seven Level 1 indicators: Risk assessment, Prevention, Preparedness, Warning, Response, Recovery, and Learning, Fig. 2. Under each Level 1 indicator there is a subset of given generic indicators (Level 2).

Further, for each Level 2 indicator there is a new subset of mainly given, measurable indicators. However, as sectors use different metrics and measures (quantitative/qualitative) the exact measurement depends on the sector, referred to as Level 4 indicators, the bottom of the hierarchy.

For a common viewpoint, Level 4 indicators are transformed to qualitative maturity scale, scaling, from 0 to 5. At Level 3 and 4, the operator has the possibility to assign weight to the indicators according to their importance. After assessing the Level 4 indicators, results are aggregated up the hierarchy, and each Level 1–3 indicator get a score from 0 to 5. The result is presented in a radar chart with all the seven Level 1 indicators.

In addition, to present a more detailed analysis, it is possible to construct charts for all Level 1 over their respective Level 2 indicators, see Fig. 3.

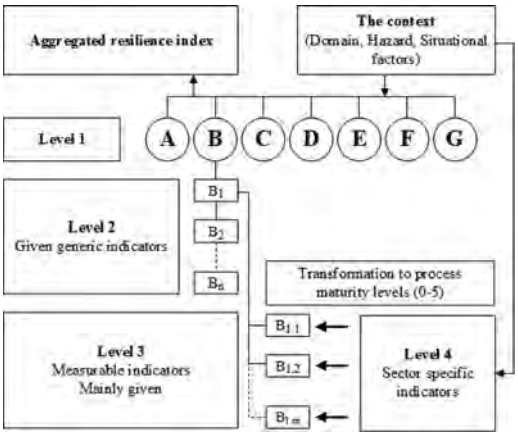

Figure 2. The hierarchical structure of Critical Infrastructure Resilience Index (CIRI). The Level 1 indicators, representing different phases in the risk management cycle, are here denoted (A) Risk assessment, (B) Prevention, (C) Preparedness, (D) Warning, (E) Response, (F) Recovery and (G) Learning.

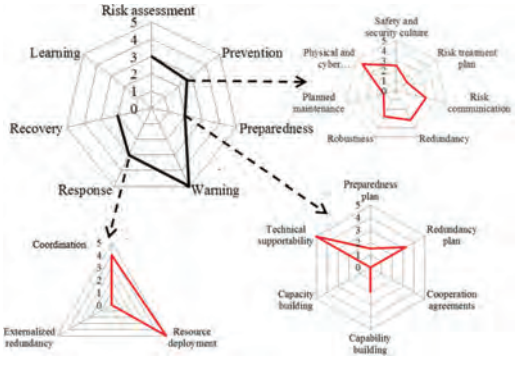

Figure 3. Analysis results for most Level 1 indicators, and Level 2 indicators under Prevention, Preparedness, and Response.

It should be noted here that this is a self-assessment methodology and thus not fully objective. However, the result is indicative of the CI's resilience level and highlights strengths and weaknesses of the infrastructure, both from the technological and organisational perspective. It can be used as the basis for further detailed analysis, using methodologies like IORA and ITRA.

2.3.2 *IMPROVER Technological Resilience Analysis (ITRA)*

Technological resilience is often visualised using the performance loss and recovery function or the area between the function and an uninterrupted capacity/performance. From the risk identification,

Fig. 1, a prioritised list of possible hazards which could impact the CI is used as input to the technological resilience analysis, which aims at quantifying the performance loss and recovery of the CI service. Thus, technological resilience is conditional on the occurrence of a specific hazard, following the procedure of the risk management of ISO 31000.

Estimating the functionality needs therefore suitable *intensity measure* of the hazard to which the vulnerability of the system's subparts can be evaluated through their *fragility.* Combining this information gives a measure of the *damage* to the system which should be transformed into one or several *performance measures* in order to focus on the core aspect of resilience: functionality of the system.

Once the performance measures loss and recovery functions are estimated they should be evaluated against other CI, historical performance or the needs and expectations of the infrastructure's end-users. It is therefore of vital importance to choose the performance criteria keeping in mind that: (i) they should be possible to translate from estimated damages, with sufficient accuracy and (ii) they should be constructed such that they can be compared to other CIs, historical performance or (preferably) the needs and tolerances from the end-user (Petersen, 2018).

2.3.3 *IMPROVER Organisational Resilience Analysis (IORA)*

IORA follows a similar structure to other organisational analysis methods. The purpose of the analysis is promoting resilient performance. Subsequent levels are functions, forms and processes which contribute to this purpose. The functions required to achieve this are: design of tasks and roles; design of the framework and its content, goals, rules, processes and procedures; strengthening collaboration; learning and redesign; underlying values and interpretations, Fig. 4.

Organisational resilience analysis process requires collection and processing of information about how the organisation's processes contribute to this. For the Barreiro implementation this is done via in-depth interviews based on a narrative of a historical event (saline intrusion in a fresh water well). Functions, forms and processes during this event form the basis for the analysis and the subsequent evaluation.

3 PILOT IMPLEMENTATION ON POTABLE WATER SUPPLY NETWORK

3.1 *Test object*

The object to be tested in the pilot implementation, comprises of the ICI-REF, its supporting methodologies for resilience analysis (CIRI, IORA and ITRA) and the developed resilience indicators. The test object will be denoted as ICI-REF in the remainder of the document for simplicity.

3.2 *Living lab: The potable water supply system of Barreiro*

Barreiro's municipality, with an area of 36.41 km^2, has, according to the Census 2011, a population of 78,764 people. It has 17 km river front to Tagus and Coina rivers and an important road-rail-river terminal. It is located about 40 km from Lisbon to which it is linked by two bridges, and about 35 km from Setúbal, the district capital. Barreiro's potable water supply system consists of 11 licensed ground-water intakes from a semi-confined aquifer, 7 reservoirs for treated water storage with the total capacity of 12.750 m^3, 7 treatment installations, for disinfection with the addition of sodium hypochlorite, 3 pumping stations, 5 blowers, 16.1 km of main ducts, and 308 km of meshed distribution pipes.

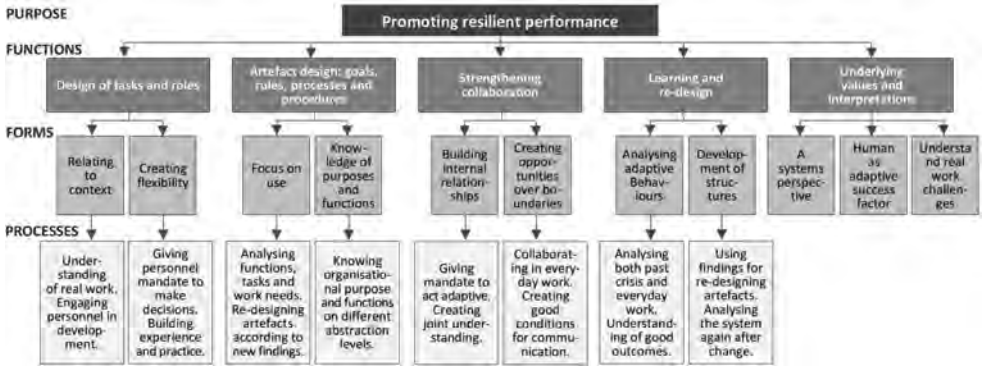

Figure 4. Indicators on different abstraction levels in the IMPROVER Organisational Resilience Analysis methodology (IORA).

The municipality has a remote management system that allows real time monitoring of pressure and flows in the water supply (and waste water) systems. The pilot implementation focuses on three pressure zones in the north, which combined account for 60% of the total water supply in the municipality.

Fig. 5 shows the area subject to the assessment.

3.3 *Systematic approach for testing and evaluating the performance of ICI-REF*

To make the pilot implementation robust, a triangular approach was used for testing and evaluating the performance of ICI-REF. Triangulation is the combination of two or more data sources, investigators, methodologic approaches, theoretical perspectives or analytical methods within the same study (Denzin, 1970; Kimchi et al., 1991). Using multiple methods decreases the "deficiencies and biases that stem from any single method" (Mitchell, 1986) creating "the potential for counterbalancing flaws or the weaknesses of one method with the strengths of another." Therefore; focus group, documentation, field studies and surveys were used to collect data for the critical evaluation of the performance of ICI-REF. The IMPROVER project embraces all these approaches in several steps and iterations for optimising ICI-REF.

3.3.1 *Collection of data*

A *focus group,* consisting of representatives from the operator at the Barreiro living lab, was selected based on their insight into current processes and methodologies for risk assessment at the Barreiro living lab. There has been close cooperation between the focus group and the project team throughout the project via continuous communication, and workshops. These were invaluable in addressing strengths and weaknesses of ICI-REF before the final pilot implementation. The focus group, as a qualitative, exploratory research method, has aided the understanding about not only the operators' opinions, but also how and why they think the way they do.

Field studies were performed for testing the application of ICI-REF in a semi-real environment. Field studies require detailed observation and evaluation, allowing conclusion of understanding and comparisons of the information generated from each site (Burgess, 1984; Denzin & Lincoln, 2011; Rossman & Rallis, 2011). An advantage of field studies is that they give better external validity than in laboratory experiments because a field experiment takes place in typically occurring social settings.

The field study relied on application of ICI-REF to a relevant hazard scenario. A scenario with high disaster risk was prioritised by structured expert judgement elicitation by the stakeholders. Fig. 6 shows a hazard map for the Barreiro living lab.

The hazard chosen to assess the resilience of the water supply system was an earthquake with liquefaction, which is considered the highest disaster risk for the water network combining consequence and probability. The assets susceptible to the hazard are:

- The reservoir, pipe system, pumps and the critical users being the hospital and the health centre.
- All technical equipment used to repair and to distribute redundant functionality.

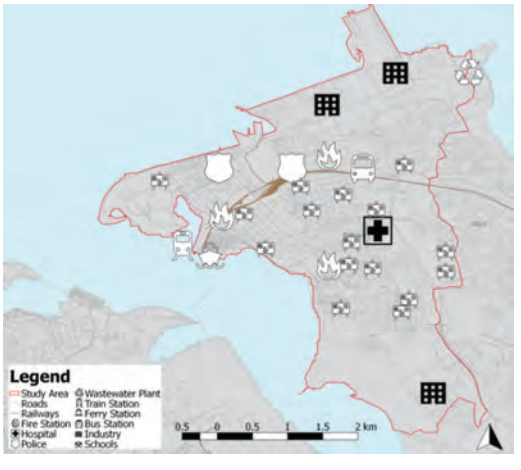

Figure 5. The northern part of the Barreiro municipality subject to the pilot implementation.

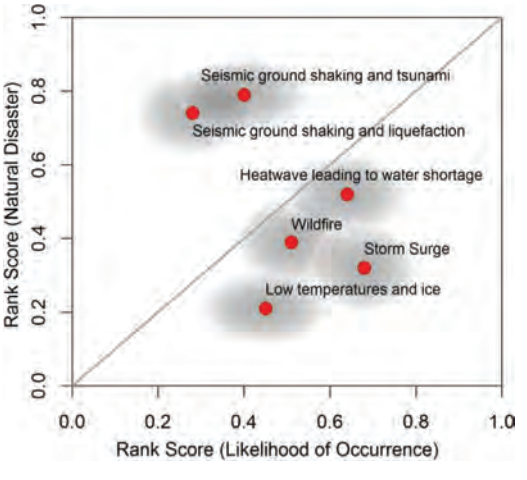

Figure 6. Plot of rank scores of six natural hazard scenarios based on their likelihood to cause disaster and to occur at Barreiro's water network in the next 5 years. (Pursiainen et al., 2015).

All staff and the entire organisation and the processes used in the preparatory, functional and administrative work.

Documentation was collected in order to analyse vital data from the CI. For example, the safety plans, and organisation chambers. These documents were used to assess the as-is situation of the CI. Typically, the analysis aims at visualising the current state process to clarify how the CI process works today, and what can be done to improve the current situation.

Different forms of *surveys*, aimed at the operator, project team members and other stakeholders were used in advance, during and after the pilot implementation. By using surveys, a broad range of data has been collected, e.g. tolerance levels; attitudes; opinions; beliefs; values; behaviour and factual. The surveys were used as basis both for defining performance criteria for resilience assessment and for the critical evaluation of the performance of ICI-REF.

3.3.2 *Critical evaluation*

Eighteen success factors were developed for the critical evaluation of the performance of ICI-REF. These ensure that ICI-REF meets stakeholders and end-users needs and are designed based on continuous input from the living labs during the project. The design science research methodology (Hevner et al., 2004) is used for the critical evaluation process in which the success factors are evaluated based on demonstration results and applications of ICI-REF.

The defined success factors of the project are primarily designed for critical evaluation of the overall ICI-REF framework, but they also implicitly set requirements to the relevance and quality of the tested analysis methodologies with indicators. Examples of success factors related to indicators are shown in Table 1.

Table 1. Examples of success factors for critical evaluation of the relevance and quality of resilience indicators.

The framework shall be easy to use	Guidance on how framework indicators can be interpreted in relation to resilient performance
The framework shall provide effective and coherent crisis and disaster resilience management	Resilience indicator follow-up should promote a shared view within the organisation on real work challenges.
The framework is arranged for being revised continuously	Existence of a system for recurring analysis, criticism and revision of the indicator framework and implementation

Table 2. Scale for analysing perception of indicators by the Barreiro operator.

Rating	Definition
A	The indicator was perceived, and there is evidence of the indicator
B	The indicator was perceived, but there is no evidence of the indicator
C	The indicator was not perceived
D	Not applicable

3.4 *Results from initial demonstrations*

CIRI, IORA and ITRA were all applied in the initial demonstrations. Evaluation from ITRA showed that the system most probably will meet the expectations of end-users for reasonable scenarios of damage. Also, despite being highly dependent on key personnel resources the flat organisation helps in fast recovery in times of crises, as shown in IORA evaluation.

A set of resilience indicators was tested within the CIRI methodology and assessed, using a software tool developed in IMPROVER (accessed at: http://improver-inov.herokuapp.com/). The indicators were discussed and evaluated by the operator according to the indicators' relevance and comprehensibility as means of assessing their resilience.

The operator was asked to assign resilience measurement scores to the indicators, and to rate them on the perception scale, according to how well they were understood by the operator. The scale for the perception ratings is presented in Table 2.

The structure and processes of resilience analysis methodologies proved functional in the demonstration. Based on the feedback from the operator, only minor modifications of the methodologies were required to optimise the relevance of the analysis results towards the main pilot implementation. The operator expressed the need for user-friendly, clear and not too complex assessments. They further concluded that the structure is not the main point of interest to the living lab, but the functionality of the assessment process, and the questions and goals related to the indicators. An issue pointed out by the living lab is which resources are required to perform the assessment; i.e. whether they need to employ external resources or can train internal resources.

The operator emphasised the crucial role of resilience indicators in the monitoring of resilience activities. However, to ensure objective, consistent, repeatable and representative results, the indicators and their designed questions must be defined using unambiguous terms. As long as the indicators are well described and leave little room for subjectivity, the high number of indicators is not a problem. The need for guidelines was also expressed.

Challenges related to the definitions of measurement scales and assignments of weights for qualitative or semi-quantitative indicators were pinpointed. E.g. the measurement scale used to assess the indicators should be well-defined since it is mandatory to understand the differences between the different measurement scales to perform benchmarking. It was also discussed how flexible the indicator structure should be; e.g. if CI operators shall be allowed to define their own scales and weights, and how this will affect the assessments and limit their relevance.

The perception of the operator that some of the indicators were too vague, needed to be better explained and that some were difficult to point out evidence for, led to adjustments and development of the overall set of indicators and how they are presented.

To address the need for proper descriptions and definitions of sector-specific indicators, "indicator cards" were developed for the complete developed set of technological and organisational resilience indicators at the lower CIRI level. Each individual resilience indicator card provides a detailed description of the sector-specific indicator subject to assessment as exemplified in Fig. 7.

The indicator cards consist of the following information:

- The assessed indicator and its parent indicators are listed.
- Detailed information about the context is given. The resilience domain (technological or organisational), hazard types (natural, non-malicious man-made, malicious man-made and multi-hazards) and situational factors (e.g. temporal, geographical or conceptual considerations for taking such an indicator into account) are indicated. Finally, the applicable sector (in this case potable water supply) is pointed out and if the indicator is generic or scenario specific.

A description of the indicator and guidance for assessing the maturity level is provided through a rationale of why this indicator is justified. Moreover, a question is provided, which can be asked to the operator for measuring the indicators in a clear and explicit manner with the 6 different maturity levels described (scale 0–5) and a reference for describing the indicator.

3.5 *Results from pilot implementation*

Based on the feedback from the initial demonstrations, ICI-REF was optimised, and the pilot implementation was conducted.

The resilience assessments resulted in suggestions for resilience treatment. Raising public awareness as well as training were pinpointed from the three tested methodologies. Application of CIRI resulted in recommendations to prevent silos, i.e. to have quick and easy cooperation between management and people in the field and to have structures in place to ensure this. Application of IORA actually identified that such a characteristic existed in the Barreiro organisation however more as an unofficial way of working. This demonstrates the ability of the different methodologies to bring up different levels of details and different perspectives.

The performance of ICI-REF in the pilot implementation is currently being critically evaluated with regards to the success factors. Generally, indicators were perceived by the operator as clearly described and easy to interpret, hence the adjustments made after the initial demonstrations had

improved ICI-REF significantly. When weighting the indicators, information from the operator could be valuable with regards to the importance of an indicator, but at the same time, it is important that the indicators are not biased towards the operator. The operator was of the opinion that ICI-REF can be valuable both as an internal audit tool and also in everyday work, and that it was useful in promoting reflection around resilience of the organisation and resilience treatment. The ability to compare results with other operators in the same sector outside of Portugal would also be useful for benchmarking purposes.

In order to provide an overall resilience score, all relevant indicators must be assessed. Although the pilot implementation assessed only a sample set of all the defined indicators, the operator found the results valuable for prioritising future work and development within their organisation.

4 DISCUSSION AND WAY FORWARD

After the initial demonstration of ICI-REF at the Barreiro living lab, the operator was of the opinion that indicators are crucial for monitoring resilience activities. However, to ensure that the assessment results are objective, consistent, repeatable, and representative of the assessed processes, the indicators should be defined using unambiguous terms. It was strongly suggested that clear questions should be asked for the operator to better understand what the indicator is assessing. The main potential for improvements of ICI-REF therefore lies in the design of sector-specific resilience indicators.

The indicators must not only be comprehensible and clear, but also at the same time leave some room for site-specific information. The degree of indicator specificity has been discussed with several living labs through the project, and the need for a balance between generality and specificity has been emphasised. If an indicator is too general, this may reduce the ability to detect details or new areas of resilience improvements. On the other hand, information about the specific CI can also be lost if the indicator is too detailed, which can make a further comparison with similar CI less relevant.

Regarding the measurement scales for the sector-specific indicators, it is not only challenging to define the scales, but it may also be challenging to assign quantitative value to a qualitative indicator without introducing subjectivity. The operator should therefore provide evidence and comments to support their assigned values for each indicator.

Despite the challenges in defining the indicator scales, weights and degree of specificity, the need for including sector-specific indicators are unquestionable. It should be described in terms of guidelines or references, at which level the indicators' scales and weights should be defined to ensure legitimacy. Benchmarked indicators exist within certain CI sectors. Although it may not be a requirement for a CI to compare to similar CI's, the living labs have expressed the wish to perform such a comparison at a regional level. However, for indicators that are not benchmarked, the comparison between similar CI will not be applicable if the operators, themselves, define scales and weights.

The indicator cards for the Barreiro living lab were successfully tested in the pilot implementation, as the indicators were considered well described and easy to assess and respond to. Indicator cards are now being developed for application in the next pilot implementation at another of the living labs in IMPROVER; the M1 highway in Budapest, Hungary.

5 CONCLUSION

The ICI-REF, technological and organisational resilience analysis methodologies and indicators have been applied and demonstrated in a pilot implementation, focusing on the potable water supply in Barreiro, Portugal. These have been developed with the aim to smoothly extend current risk management practices into a resilience management framework. A set of technological and organisational resilience indicators has been designed and described in "indicator cards". Efforts are made to improve the clarity of definitions and descriptions of resilience indicators, since unambiguous description of indicators is crucial for monitoring resilience activities. Based on the feedback from the Barreiro living lab during the project, initial demonstrations and a pilot implementation, the ICI-REF and the developed resilience analysis methodologies proved functional based on preliminary results.

They are now ready to be fine-tuned towards the next pilot implementation in IMPROVER. This focuses on the M1 highway in Budapest, Hungary, covers several scenarios and will be finalised in 2018. Combining results from the two pilot implementations allows evaluating the performance of the ICI-REF framework, methodologies and indicators to different CI sectors and contexts. Based on this, European guidelines for the resilience management to CI will be developed, addressed both to CI operators and policy makers.

ACKNOWLEDGEMENTS

Barreiro Municipality are acknowledged for valuable feedback and active participation in the

pilot implementation. This work is funded by the EU's Horizon 2020 research and innovation programme, grant agreement No 653390. It does not reflect the official opinion of the EU. Information and views expressed therein is the responsibility of the authors.

ABSTRACT: No consensus currently exists on how to measure and evaluate Critical Infrastructure (CI) resilience. Attempting to use the public's declared coping capacity as a target for CI resilience, this paper explores how to develop relevant resilience performance measurements that enable comparison to the tolerance levels of the general public. To do so, one must first establish the normal performance of the system and the applicable performance measures. Then, a survey is used to convert public perception into these measures as to enable comparison with the technical resilience performance. The CI resilience will be presented through a family of so-called resilience triangles which will illustrate the evolution of the performance, before, during and after a crisis event. A case study of the Municipal Water Network of Barreiro, Portugal, is used. The overall performance is preferably described with the categories quality, quantity and delivery. In quantifying the performance the importance of what is being assessed, to what hazard and for which end-user became evident.

1 INTRODUCTION

Critical infrastructure (CI) resilience is often defined as the ability to maintain a minimum acceptable level of service and the ability to rapidly restore full service in relation to a crisis event on the CI system. However, no consensus currently exists on how to measure these elements. Furthermore, most existing methodologies do not take into account human factors arising from the society which the CI serves. Since the general public, end users of CI services, appear to have reasonable expectations of CI operators in crisis times (Petersen et al., 2017), we suggest using their declared coping capacity as a reference for CI resilience measurements. In order to do so, one must convert public perception into measurable indicators, which can be comparable to the technical performance of the service, and examine how these indicators can be measured, forecasted or assessed over the course of an event. Thus, this paper explores how to identify relevant comparable performance measurements for the CI case of a water distribution network. The methodology will present the resilience measures through a family of so-called resilience triangles, which will illustrate the evolution of the performance, before, during and after a crisis event. A resilience triangle (Bruneau et al., 2003) is shown schematically in Figure 1.

The performance, Q, quantifies the performance of the system. For many CI systems, it is normal that the system performance decays slowly over time as a result of aging, reflected in by the difference between Q_0 and Q_1. A sudden drop in the performance represents the effect of a sudden shock to the system. How deep the drop goes and the steepness of the drop depends on how well the sys-

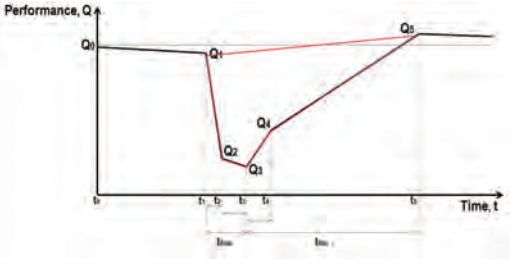

Figure 1. A schematically drawn "resilience triangle" illustrating the performance of a system over the course of a crisis event.

tem is able to absorb the initial shock (minimizing the impact) (Q_1 to Q_2) and respond to it (Q_2 to Q_3). The size of the triangle (marked in red) further depends on the system's capacity to recover (Q_3 to Q_5). The total performance loss of the system over the duration of the initial incident and recovery is however, partially an indirect result of how well the system has earlier targeted the measures of risk assessment, prevention and preparedness. The gain in performance over time after the performance loss reflects how well the system recovers from the shock and eventually learns from the shock. The learning phase enables and could likely lead to increased system functionality compared to before the shock, due to the renewal in restoration of the system, but also from the learning experience itself.

A case study of the Municipal Water Network of Barreiro, Portugal, is used to illustrate the development of the performance measuers needed to create the resilience triangles and is subject to a pilot implementation of a CI resilience management framework developed within the IMPROVER (Improved risk evaluation and implementation of resilience concepts to critical infrastructure) project, funded under the Horizon 2020 program. The implementation explicitly investigates public tolerance levels through a survey. The overall performance is well described and categorized in terms of quality (suitability for drinking and cooking), quantity (the amount of water accessible to the public) and delivery (the amount of water delivered to the tap) of water. In order to quantify these, the importance of understanding what is being assessed, to what hazard and for which end-user became evident. After describing the Municipal Water Network of Barreiro, Portugal the paper describes the development of performance measures, followed by a first look at the preliminary results of the resilience assessment through the resilience triangles.

2 BACKGROUND ON THE BARREIRO LIVING LAB CASE STUDY

The city of Barreiro is part of the Lisbon metropolitan area, located on the south bank of the Tagus River estuary, about 40 km from the city of Lisbon. It has a population of almost 80 000 people with an area of 36.41 km^2. Ferries and two bridges connect Barreiro to Lisbon.

2.1 *The municipal water network*

The Barreiro Municipal Water Network delivers potable water to the municipality of Barreiro and serves all its inhabitants and industries. It has an annual water flow of 6,200,000 meters cubed. The drinking water comes exclusively from an underground aquifer (Barreiro Municipality, 2009). The water supply system in Barreiro is constructed by 11 licensed ground-water intakes from a semi-confined aquifer, 7 reservoirs for treated water storage, 3 pumping stations, 5 blowers, 16.1 km of main, 263 km of ordinary pipes and a considerable amount of service connector pipes. The pipe system is made out of mostly fibre cement (FC) and some parts of PVC (polyvinyl chloride) and PE (Polyethylene).

The Barreiro municipality is divided into 7 different pressure zones. This study is limited to look at the resilience of 3 of these water supply zones that together serve about 60% of the population. Within the three pressure zones considered for this study there are three water storage units, including one high storage tank: Alto da Paiva high tank (SNZM Reservoir), and 2 semi-buried tanks: Alto da Paivo (SNZB1 Reservoir) and Sete Portais (SNZB2 Reservoir). The reservoirs have a reserve capacity of 12 750 m^3, which supplies the population for about 24 hours based on volume.

Several hazards may influence the water network in Barreiro including earthquakes (leading to sever ground shaking or liquefaction), droughts and heatwaves. A historical example can be found in 1969, when Barreiro's water network endured moderate damage due to a 6.8 Magnitude earthquake event which led to the unavailability of potable water for 24 hours. More recently, in 2012, rice and cereal agriculture in Setúbal were affected by a water shortage (Ioannou et al., 2016).

3 DEVELOPMENT OF THE METHODLOGY

3.1 *Interview with living lab*

The first step in developing a methodology to measure resilience was to interview the living lab. Semi-structured interviews were held with employees from the Municipal Water Network in order to further the understanding of the system function as well as how they would act in the case of a crisis. Specifically, questions were posed in regards to the technical details of the system, recovery time estimates, and emergency/contingency plans.

3.1.1 *Results*

The Barreiro Municipal Water Network operators provided models of their different pressure zones where all the details of pipes, valves, reservoirs and tanks are stored. The model can solve the hydraulic flow through the whole system using the EPANET freeware (Rossman, 2000), provided by the United States Environmental Protection Agency. The operators of Barreiro especially pointed out two

assets that are crucial for the overall supply of water in the system: a supported, semi-buried reservoir and one critical pipe, the General Distributor Conduit (DN350). The supported reservoir of Alto da Paiva supplies the zones, Zona Baixa 1 (SNZB1) and Zona Media (SNZM), while the General Distributor Conduit DN 350 mm in fiber cement supplies the Zona Baixa 2 (SNZB2). Figure 2 shows these assets including the water network in the study site.

When discussing recovery times and actions, the operators informed us that if there is a water outage longer than 24 hours, regardless of the cause, they intend to use two water tanks of 80 m^3 capacity provided by the Barreiro Firefighters to provide water to the public. However, the water will need to be boiled. They estimate that within 30 minutes they would be able to make the tanks available to the public if using their own water sources. However, if the crisis was larger and water would have to come from neighboring municipalities or elsewhere, it could take a few hours, depending on road accessibility. They also have the possibility to request assistance to the district civil protection command and to be able to have a collaboration between the firefighting corporations of the district, a total of 25 teams with about 1500 to 2000 m^3 (estimated values) of total water supply capacity. However, these resources are pending other duties for the firefighting corporations. If an earthquake also affects the neighboring municipalities, the assistance could come from either the north bank of the Tagus River, Lisbon, or even further south, using the same means. They are currently in the process of developing their Water Safety Plan that will include both emergency and contingency plans.

Based on the hazard assessment and interest of the operators, a scenario of liquefaction following a severe earthquake is considered for this study.

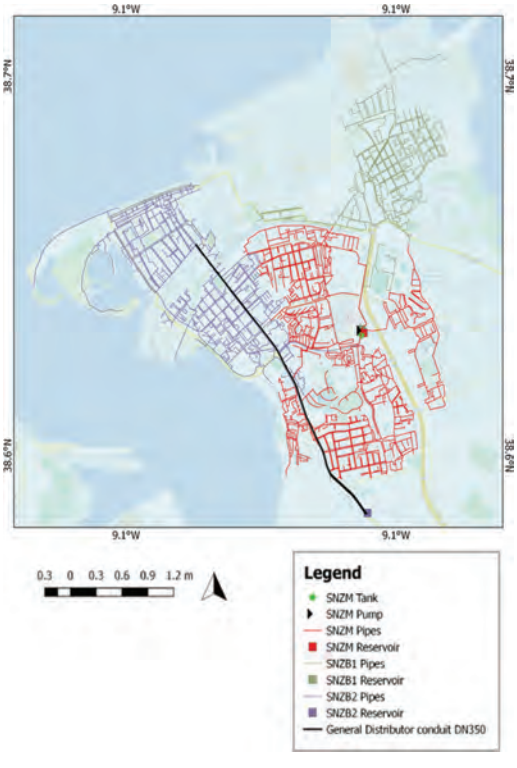

Figure 2. Barreiro Study Site Pipe network and Reservoir.

3.2 *Performance measures*

In order to define the performance measures, the first step was to define the normal performance. For this case, normal performance was considered as the normal domestic water use, covering consumption (drinking and cooking), hygiene (both personal and domestic cleanliness) and amenity use (i.e. watering plants, washing bikes) as listed by WHO (Howard & Bartram, 2003). In Barreiro the average water consumption to cover this is about 200 L/person/day. For survival and to avoid an outbreak due to lack of sanitation, the lowest acceptable quantity of water for survival is approximately 20 L/person/day (Cousins, 2013; Kameda, 2000; Mowll, 2012). In this study we have assumed that this is the minimum requirement for the first 3 days and that the requirement thereafter is increased to 50 litres per person per day, on account of the WHO recommendations.

A quantitative assessment of the performance of the water system was in this study measured as the percentage of the population that receives the services with the same performance as of a "normal day" before the earthquake for each performance measure. A similar study on the Los Angeles Water Service Restoration Following the 1994 Northridge Earthquake (Davis et al., 2012) defines five performance measures of the system: quality, quantity, delivery, firefighting and functionality. While the first three are measures directly impacting the public, functionality describes how the system performs its function in terms of efficiency, durability, sustainability and economics. This measure is not dealt with in this study. The availability of extinguishing water for firefighting is assumed covered by the abundant access to water around the municipality by the Targus River and is not covered here. Thus, the three performance measures in this study are:

1. Water delivery: Percentage of the population served by the pipe system through water on tap

(the water delivered may not meet the quality or quantity requirements).
2. Water quality: Percentage of population that have access to water at drinkable standards (not needing to boil the water).
3. Water quantity: Litres of water available per person per day.

3.2.1 *Estimating the performance measures*

First, an estimated time for service restoration is needed. To do so, the repair time was divided into two groups: emergency response time and recovery time. The emergency response time covers the period in which search and rescue is highly prioritized. This also includes work for road accessibility etc. Recovery time covers the period from when the repair starts until the entire network is repaired. These two times overlap and this is dealt with according to prioritizations inspired by the Oregon resilience plan (OSSPAC, 2013) and from literature on experiences and lessons learned from previous earthquakes (Bragado, 2016; EERI, 2007; Eidinger & Davis, 2012; Pedroso et al., 2013; Mowll, 2012). Based on this, a simple spreadsheet model is built which can estimate the emergency response time. The recovery time is estimated from simulations of perturbed EPANET models, as well as historical data for repair times for different pipe materials. These combined methods allow us to measure the water delivery and water quantity. The water quantity is defined as the total volume of water delivered on tap or to community service points for the public to carry home. This water is delivered either through tanks or, at later stages, also through pipes connected to these service points. At even later stages, the quantity also includes water being delivered to homes through the water distribution pipe system. Water delivery is calculated through the total amount of water that can be extracted from the network through nodes connected to households or other buildings as the system is repaired. Nodes that are somehow connected to a water source can often deliver the capacity prior to the incident. We assume that the "normal" delivery at each node is proportional to the number of people served at this point. Thus the relative delivery at all nodes to the delivery prior to incident is assumed equal to the fraction of people being served by the connected nodes. Based on the interview with the operators, the water quality indicator will need to remain at 0% of normal performance (i.e. water needs boiling before consumption but is suitable for washing) until the system has been repaired and thoroughly flushed.

3.3 *Public expectations*

Previous research on expectations/satisfaction of water service disruptions have shown that attitudes are not very strongly held on this subject matter (Vloerbergh et al., 2007). Most previous research does not deal with expectations/tolerances/satisfaction during times of crisis, but instead with "normal times" or planned works (Speers et al., 2002). As mentioned above, previous work within the IMPROVER project has found that the general public, end users of CI services, appear to have reasonable expectations of CI operators in crisis times (Petersen et al., 2017). As such, we suggest using their declared coping capacity as a target for CI resilience. In order to do so the public perception must be discovered in a way that is comparable to the technical performance measures of the service. To our knowledge, no studies comparing expectations to performance measures currently exist.

A common way to evaluate public expectations/user satisfaction for water operators is using a "willingness to pay" model. However in a disaster situation, this is not an appropriate measurement method as people need to have access to water, being a basic human need, regardless of the cost. As such, we propose to use a questionnaire in order to determine the public's coping capacity. Indeed, people themselves have been found to be good judges of their ability to deal with disturbance and change (Nguyen et al., 2013) and the idea of people being able to accurately judge themselves has been used in other domains, ranging from psychology to well-being and climate change adaptation (Jones & Tanner, 2015). Furthermore, previous research into water customer preferences has also used questionnaires to establish coping capacity in times of water shortage (Vloerbergh et al, 2007; Speers et al., 2002).

3.3.1 *Development of the survey*

The survey was developed with a view to real world performance capabilities of operators that were established in the interview. The performance measures were not asked about directly, meaning we did not use the terms delivery, quality or quantity. Instead, situational, laymen's terms were used to increase understanding of the survey (for more on the importance of the understandability of questionnaires, see OECD, 2013). The following paragraphs describe the questionnaire.

The respondent is presented with the following scenario: "*Imagine that a high magnitude earthquake occurs, where a large part of the population is left without access to potable water on tap without any previous warning*". Next, the respondent is reminded of the various needs for water following an earthquake (drinking, hygiene (showering, flushing toilet), cooking and cleaning). Then, the same measures as used for technical performance are used to create questions to find public expectations/tolerance levels for reduced service. This took

the form of three questions. The first question deals with the tolerance for recovery times of delivery by asking how long the respondent is willing to tolerate water being delivered via tanks (*Water would have to be delivered in tanks. How long would you tolerate these conditions?*). The next question addresses the recovery time tolerance level for quality by asking how long the respondent would be willing to boil water before drinking (*How long would you tolerate having to boil the water before drinking it?*). Lastly, to address the quantity indicator, respondents are asked how long they will tolerate having only X amount of water (going from 10 L to 100 L) per person per day (*How long will you tolerate having only the following amount of water per person per day?*). Respondents were also presented with some examples of water consumption (washing dishes by hand uses about 25 L, taking a 5-minute shower uses about 35 L). The time frame proposed to the respondent comes from not only historic examples and satisfaction surveys, but also realistic time frames for operators given in the interview. The proposed times are <12 h; 12–24 h; 1–2 days; 3–4 days; 5–6 days; 1 week; 2 weeks; 2 weeks – 1 month; More than 1 month. The questionnaire also asked about respondent's demographics and satisfaction levels with the current water service.

3.3.2 *Dissemination plan*

The questionnaire was designed as a telephone questionnaire. A representative sample of 1,005 (with a confidence level of 95.5% and an error value of +/–3%) based on age and gender of Barreiro residents was interviewed. The questionnaire was carried out by Pitagórica – Investigação e Estudos de Mercado SA. Respondents were interviewed in Portuguese. A few face-to-face interviews were also held, as there were issues finding enough young adults to answer the questionnaire via the telephone. Data collection was from 11 October 2017 to 5 November 2017.

4 APPLICATION OF THE METHODOLOGY

4.1 *Technical resilience analysis: performance measures resilience triangles*

The performance is briefly described below. The details of the models and assumptions involved will be further described in future publications of the same authors. Here, we show the result of one event only, a magnitude 7, peak ground acceleration 0.21–0.36 g shaking, which has a probability of 4–10% in 50 years for the specific location. It should be noted that the results shown here are preliminary and the final results will be subject to review throughout the complete pilot implementation. They serve, nevertheless, as a good example of how to compare estimated performance and public expectations.

The quantity of water during the response phase, in which resources are focused on rescue, clearing roads and electricity, is left to what is in tanks and what is stored in people's homes and stores. It is conservatively set to 5 L/day/person, assuming that all water in the storage tanks can be placed at community service points to reach the full population. After 24 hours water will be transported from adjacent regions via eight tank trucks of 40 m^3 to service points (~40 L/person). Since it is difficult to carry more than 20 L of water long distances, also considering that people have to carry for others (children, elderly etc.), a reasonable estimation of water availability when it's not delivered on tap, based on previous experience, is 20 L per person for the first days and twice that as needs become more pressing. When the network is being repaired the performance of the system is modelled using modifications and repeatedly running EPANET. By using fragilities of ductile and brittle pipes based on historical seismic events (Eidinger et al, 2001; Shih & Chang, 2006) we assigned a fragility of each pipe to liquefaction following earthquakes, describing the number of breaks in a pipe of certain material and size per unit length. The probability of a pipe breaking due to an event is given as, where is the breaks per unit length of the pipe and its length.

The pipes are then removed from the EPANET model using random numbers in comparison to the probability of failure. The flow in nodes connected to removed pipes are set to zero. Large negative pressures at nodes as a result of the perturbed network also results in the removal of nodes and any connected pipes. Running the model for the pressure and flow in the new system yields e.g. the demand (water extracted) at each node, which is summed up over all nodes. This is interpreted as a measure of the delivery of water. The pipe model just takes into account mains and not service lines from the street to the tap, which usually are the responsibility of the property owner.

Starting with the pipes of high priority (serving the hospital and community service points) and then according to their distance to reservoirs and tanks, the pipes are then replaced in the model, running it repeatedly to investigate the performance of the network until the network is back at original shape (note that other strategies of repair are being considered in the ongoing full study). The time to replace a pipe is treated as a function of its material and size based on empirical data (Porter, 2016) as well as the interviews with the operators. All in all several hundred of models are run controlled from Matlab. The result presented here in Figure 3 is very preliminary.

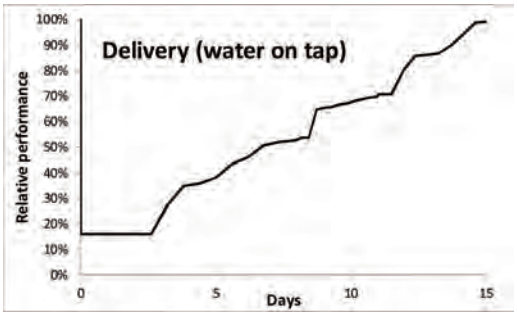

Figure 3. A simulation of the delivery to tap after the event using analytical models and EPANET modelling using fragilities of each pipe.

For the magnitude of earthquake considered here the response phase takes 2 days after which the repairs on the network start. After 48 hours some parts of the network distributed water will add to the water delivered at service points. As the network is repaired and additional nodes become connected, water is not uniformly distributed throughout the municipality. Instead water is delivered with close to normal service to a limited amount of people with access to it. There is likely a higher quantity capacity in the system than can be delivered.

It will be recommended that all water collected from service points or extracted from tanks should be boiled before consumption and, as such, the quality will not meet the drinkable water standards until the complete network is properly flushed.

4.2 *Evaluation criteria: tolerance triangles*

Preliminary results from the survey have been used to create tolerance triangles. Quantity is described as an average of the amount of water accepted weighted by the lowest fraction of population tolerating this (people tolerating 20 L also tolerate 40 L), Figure 4. Quality and delivery are defined as percentage of the population tolerating the action (boiling and collecting from service point, respectively). The expectations resilience triangles are thereafter created by the accumulated percentages of respondents willing to tolerate a given time frame.

4.3 *Technical resilience evaluation: performance vs tolerances*

To determine if the operator currently meets public expectations for service restoration time the tolerance and performance triangles are compared. The comparison of delivery tolerance against performance is shown in Figure 5.

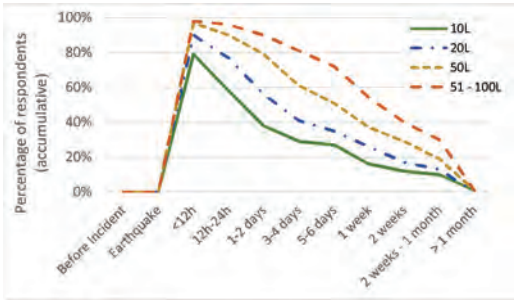

Figure 4. Percentage of respondent that tolerate a certain quantity of water per day and person after an earthquake.

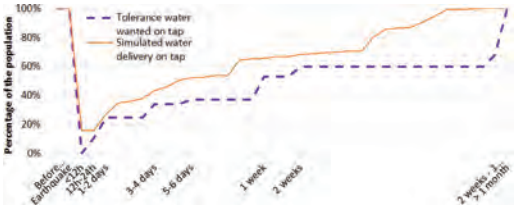

Figure 5. Resilience evaluation for delivery.

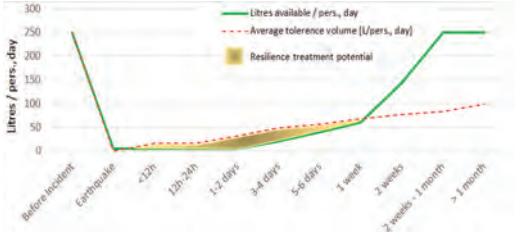

Figure 6. Resilience evaluation of quality.

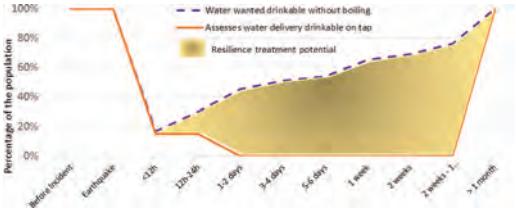

Figure 7. Resilience evaluation for quality.

The weighted average of the tolerance quantity at each moment in time is compared to the total quantities from our performance models, Figure 6. Advice to boil the water for everyone is considered the zero level for quality. The advice will be told until the whole network is restored. Clearly that does not meet the tolerances of the public, Figure 7.

5 DISCUSSION

5.1 *Meaning of the resilience evaluation*

The expectations of the public seem to be nearly met by the technical performance in terms of quantity, Figure 6. At the beginning the tolerance is somewhat below the performance, however, it seems that the endurance of the citizens is longer than the time needed to restore full capacity in terms of quantity. A month after incident the tolerances are for much lower quantities than expected performance. Also the simulated performance level during the first days is very conservative. This is because it is very difficult to assess road accessibility and to estimate the stored water capacity. We chose to ignore larger water storages in stores or homes. These can be significant and the resilience of the society might be much higher than the resilience of the specific infrastructure itself. Nevertheless, facing the mismatching identified, one way to close the resilience treatment potential could be to lower the expectations of the public during the initial stage and to increase the capacity through communication campaigns highlighting the need to store water for emergency situations.

Furthermore for delivery the performance is within a good range of the tolerances; the performance seems better than the tolerance for the entire time period studied. This is also in line with the previous findings in this project (Petersen et al., 2017).

One aspect where the public tolerances do not meet the performance is the quality. Apparently, boiling water for more than two days is too long of a time as it appears to constitute a major impact on many people's lives. The treatment to close this gap could be to use antiseptic tanks, which there is access to, but structures and practices of the usage are lacking. Also, quality of tap delivered water could possibly be guaranteed earlier by flushing separate areas of the system once they are repaired. Public campaigns could again be useful for changing the public's perception of and the need for boiling water.

5.2 *Performance measures chosen based on comparability of results*

In developing these performance measures the importance of what is being assessed, for which end-user and to which hazard became evident. The need of water could e.g. be larger in a heat wave and dry spell compared to an earthquake. The perception of the service provided to the public is not always measurable in technical evaluation of the system. From a personal perspective, it can be difficult to know how many liters of water one can tolerate to get by with. It is even harder to relate this to pressure or head in the system, parameters that are actually measured. Indeed, general performance indicators do not take into account the service that is provided to the public by a given infrastructure. Thus, by focusing on the normal performance of the service, the tolerance levels of the public to the change of service are able to be taken into account. Uncertainties in the modelling are found in the estimates of accessible resources and time efficiency of restorative capacity for the damage itself is done based on likelihood of exceeding a break probability. A natural way to solve this is to run the model in a probabilistic methodology to identify the spread in the result based on the random numbers. This is currently being done as this article is being written. One aspect is that the performance is here measured as a scalar number. It might not be the people of least tolerance who gets access to water first. Instead, even if the tolerance and performance curves matched perfectly a portion of the population would consider the system to underperform whereas another portion would consider the opposite. In addition, the tolerances are naturally a function of the magnitude of the event, something which is very difficult to identify in a survey. Previous findings show, however, that communication and information of the situation and the reasons for performance drops is vital to keep the public content during crisis events. Lastly, while the performance measures suggested could be used for almost any hazard, a scenario is necessary to be able to measure them effectively (for both technical performance and the survey).

5.3 *Survey limitations*

When responding to questionnaire surveys, people often respond by providing snap judgments based on available information and may be influenced by emotional or contextual factors (Schwarz & Stack, 1999). Also, question wording could affect stated tolerance levels, as research has demonstrated that when asked if they care about a given issue, people state concern for issues that do not exist (Herrmann et al., 1994). Further, respondents may choose to answer in their own self-interest, claiming to tolerate less so as to not give the CI operators an excuse to perform any lower than absolutely necessary. The opposite may be true, reporting that they are willing to tolerate more than they actually could handle in order to appear heroic. This is furthered by the fact that research has also shown that disaster victims rarely passively wait around for someone else to take care of their needs (Quarantelli, 1998), and having high expectations towards CI operators to act in a disaster may indicate a gap between expectations and the ability of citizens in responding to crisis situations. Lastly, expectations have been

found to be influenced by demographic factors, previous disaster experience and information provision (Petersen et al., 2016). However, with purposeful survey design and adequate sampling methods such as the one used here, many of these limitations are reduced and even overcome (Jones & Tanner, 2015).

5.4 *Success of the method*

These preliminary results show that public tolerance and technical performance of a critical infrastructure can be evaluated and compared to each other in the case of a drinking water distribution network. It seems from this case study that reasonable comparable performance measures have been found. The operators of Barreiro have expressed positive feedback to the methodology and think that the results provide relevant knowledge. However, a more descriptive resilience treatment where strategies of closing the gaps between expected performance and public tolerance are formed is currently work in progress during the writing of this article. The success of the method, pending on the usefulness to the operators, is not yet entirely apparent. However, this work shows that tolerance and performance can be compared if the survey asks the right questions and the right modelling work is conducted.

6 CONCLUSIONS

This paper describes the preliminary results of evaluating the expected performance of a critical infrastructure, in the form of a water distribution network, to the public tolerances of the service that the infrastructure provides. It is suggested that this comparison is a valuable measure reference of evaluating the performance compared to an otherwise arbitrary scale of performance. It is shown that comparisons can be done and that the chosen performance measures must be clearly defined prior to evaluating both performance and tolerances. When doing this, the different aspects of the service provided must be considered as the perception of the service usually is multifaceted and not necessarily directly linked to the scalar which might be the most straightforward to assess technically. The results of the resilience analysis that are presented here are based upon an initial study of the Barreiro municipality's potable water network. As such there are a number of simplifying assumptions and changes which are made which mean that the performance shown is not the true performance of the system (such as it being based on only one earthquake scenario). Nevertheless the results are useful as an illustration of the resilience evaluation methodology shown.

ABSTRACT: Resilience Engineering is an original approach on safety management considering the development of agent's adaptive capacities to the diversity of situations that can occur, as the main target of safety management practices. The Resilience Analysis Grid aims supporting the assessment of key capacities of a resilient organisation. A specific instance is developed for supporting railway safety management. It is composed of a set of key indicators and a methodology to collect and analyse information. Application of the prototype to study trains station resilience capacities demonstrate its potential to understand resilience capacities with deducting resilience and fragility factors.

1 INTRODUCTION

Resilience Engineering is considered by Borys, Else and Leggett (2009) as the fifth age of safety following an age of integration age (Glendon et al. 2006) where safety management aims integrating technical, human, managerial and cultural factors in risk management practices such as risk analysis, barriers management and accident analysis (Hale and Hovden 1998) (Hudson 2007). Resilience Engineering perspective on safety management considers that the dynamic of evolution of safety practices doesn't provide to workers capacities to cope with the complexity of their environment and that theoretical and methodological innovations are necessary endowing systems the requisite imagination to respond and overcome to the diversity of situation that can possibly occur (Adamski and Westrum 2003, Woods and Hollnagel 2006). Safety evolves reactively after each event questioning the relevance of models structuring safety theories, methods and tools. The new factor or element founded that support the explanation of the event and the failure of safety management system is theorized and integrated in safety management practices (procedures, indicators, etc.). Then safety management system tries to constraint system dynamic in order to minimize the occurrence of such factors. The development of "human error", "organisational failures", "safety culture" theories, method, tools and operational practices illustrates this dynamic. The complexity of a system is associated among other properties, to non-linearity and to difference between reality and artifice (Chandlers 2014). Consequently, the Resilience Engineering perspective on safety aims to change the main focus of safety management from risk prevention to workers adaptive capacity to respond and overcome unwanted situations. This perspective considers that the absence of unwanted consequences is not caused by the efficiency of risk barriers but by the capacity of the system to be in control despite the variability and the complexity of situations and the lack of time, knowledge, competence or resources (Hollnagel and Woods 2006). The Resilience Engineering perspective on safety management considers resilience of a system as it's "ability to recognize and adapt to handle unanticipated perturbations that call into question the model of competence, and demand a shift of processes, strategies and coordination" (Woods 2006) and "the intrinsic ability of a system to adjust its functioning prior to, during, or following changes and disturbances, so that it can sustain required operations under both expected and unexpected situations" (Hollnagel 2011).

Aims of this paper are to firstly present indicators defined to assess the resilience of an organisation, then associated method for assessing resilience performance and finally results of its application to a train station.

2 PERFORMANCE INDICATORS

According to the resilience engineering perspective on safety management, organisation can be con-

sidered as resilient if they are able: 1) to respond and overcome to the diversity of situations that may arise; 2) to monitor that which changes, or may change in the near term that it will require a response; 3) to learn from both positive and negative experience of the past; 4) to anticipate development, threats, and opportunities further into the future (Hollnagel 2011). A first set of indicators, the Resilience Analysis Grid, has been proposed to support the assessment of these four dimensions (Hollnagel 2011). Starting from resilience engineering concepts and models and the Resilience Analysis Grid, a process of contextualisation to the railway domain has been conducted. Results from this process are nine indicators to be used to assess the resilience of railway systems. For each indicator, four rules are defined for supporting the evaluation. A system is evaluated with five stars if the four rules are true, four stars if the first three rules are true, etc.

2.1 *Capacity to respond and overcome to the diversity of situations that may arise*

Two indicators are related to the capacity to respond and overcome to the diversity of situations that may arise. The first one is related to routine situation and the second situations that are considered as abnormal. The definition of the indicators considers tasks related to the adaptive process (detect, recognize, decide to change behaviour, define behaviour, mobilise resources), the existence or not of procedures or good practices associated to the situation, the difference between the context of action (competence, knowledge, resources and time) available and the context required to respond to the situation, and the different dimensions of performance of the system (quality, reliability, safety, security, sustainability, etc.).

1. The first indicator is related to the capacity of operational agents to adjust their procedural and/or methodological framework or to be creative in order to carry out their normal activity in spite of the variability of their environment while respecting the temporal, economic and activity specific performance criteria. The four rules associated to the indicator are:
2. Agents know their work and associated performance criteria
3. They have the skills or know the procedures to follow and have the resources, time and information to carry out their work in accordance with the different performance criteria.
4. If they lack skills, resources, time or information they are able to be creative in carrying out their work according to performance criteria.
5. If the situation changes and the procedural framework is no longer applicable, they are able to be creative enough to carry out their work in accordance with performance criteria and have the necessary margins of maneuver.

The second indicator is related to the capacity of operational agents to adjust their normative and/or methodological framework or to be creative in order to face and overcome the occurrence of an urgent and/or unexpected situation, anticipated or not, while respecting the temporal, economic and activity specific performance criteria. The four rules associated to the indicator are

1. Agents are aware of the abnormal situations, the behavior to adopt when they occur, or what document to consult to know.
2. They have the skills, resources, time and information to respond to the situation in accordance with the different dimensions of performance.
3. If they lack skills, resources, time or information they are able to be creative in responding to the situation in accordance with the different dimensions of performance.
4. If the situation changes and the procedural framework is no longer applicable or there is no procedural framework, they are able to be creative in responding to the situation.

2.2 *Capacity to monitor that which changes, or may change in the near term that it will require a response*

Three indicators are related to the capacity to monitor that which changes, or may change in the near term that it will require a response. They are related to the capacity to evaluate and exploit retrospective safety performance, actual safety performance and prospective safety performance. The four rules associated to the three indicators are:

1. The system has indicators for measuring retrospective/actual/prospective performance
2. Retrospective/actual/prospective safety performance indicators are consistent with the system and are properly and regularly reviewed.
3. The nature, period, frequency of the measurement (qualitative or quantitative) of the indicators and the time between measurement and exploitation are correct
4. There is no conflict between safety performance indicators production performance indicators

2.3 *Capacity to learn from both positive and negative experience of the past*

Two indicators are related to the capacity learn from both positive and negative experience of the past. They are related to the capacity to acquire, disseminate and use experience in the occurrence of unwanted situations (incident, accident, etc.)

for the first one and of gained during the observation of daily operations for the second.

The four rules associated to the first indicator are:

1. The occurrence of an abnormal situation (non-compliance, incident, accident, disaster, etc.) is detected, listed, investigated and the results disseminated within the organization.
2. Criteria for identifying a situation to be investigated are clearly identified, shared and appropriate by the system. The direct and indirect causes sought and the reaction of the system are investigated.
3. Necessary skills for conducting the investigation are available, necessary information can be accessed and the study carried out independently of the stakeholders.
4. Lessons learned information are processed, capitalized and proactively transmitted to the other entities of the system.

The second indicator is evaluated with these four rules:

1. Audits are carried out to understand the real functioning of the system
2. Competences necessary to realise audits are sufficient
3. Audits results are used and capitalized by the station
4. Results are proactively transmitted to others stations

2.4 *Capacity to anticipate development, threats, and opportunities further into the future*

Two indicators are related to the capacity to learn from both positive and negative experience of the past. They are related to the capacity to identify, use and disseminate information about the consequences of a change of a component of the system for the first indicator and of a change in the environment of the system on safety performance for the second indicator.

The four rules associated to the first indicator are:

1. Anticipating the consequences of internal changes on safety is a dimension of the culture of the organisation.
2. The methodological approach for conducting the study of consequences of change is clearly formulated and based on adequate expertise
3. The anticipation of consequences of the change is carried out with sufficient time so that the consequences identified can be taken into consideration.
4. Outcomes relating to potential sources of threats or opportunities are shared within the organisation.

The second indicator is evaluated with these four rules:

1. Anticipating the consequences of external changes and of trends is a dimension of the culture of the organisation.
2. The methodological approach for conducting the study of consequences of external changes and trends is clearly formulated and based on adequate expertise
3. The anticipation of consequences of the external changes and trends is carried out with sufficient time so that the consequences identified can be taken into consideration.
4. Outcomes relating to potential sources of threats or opportunities are shared within the organisation.

3 METHODOLOGY

In order to assess and enhance the resilience of socio technical system resilience, a four phases method is proposed:

- Phase 1. Definition of the context of the diagnostic. System representative defines scope, schedule, working team and stakeholders of the diagnostic process.
- Phase 2. Performance assessment. Working team collects data necessary to evaluate performance indicators and write assessment report validated by stakeholders.
- Phase 3. Actions plan definition. Working team collects data necessary to define with stakeholder's actions plans aiming to improve gaps and preserve good practices.
- Phase 4. Conclusion of the study. Working team writes and presents final reports to system representatives.

In the perspective to experiment it, the method has been applied to the study the management of departures and arrivals of train processes of a train station. Accordingly, the following four paragraphs are outlining results of the application of these four phases in detail.

The study conducted aims studying both the resilience of the train management activities of the station and the relevance of the method. The scope will be operational activities dedicated to the management of departures and arrival of train in the station. Operational trains departure and arrival functions are relevant to study resilience because they involved technical agents, proximity managers, safety and production services, they are shape by schedule, procedures and time constraints, injuries may occur and they are sensitive to events occurring in the station and in the network.

The second phase of the process consists of the organisation of data collection. A set of workshops has been scheduled. First workshop was dedicated to a global presentation of the organisation of departure and arrival operational functions from schedules design to effective realisation of the tasks, observation and informal interview techniques were used. Results of this first workshop support the definition of a questionnaire. This questionnaire has been applied to interview twelve representative agents of the system (operation, technical manager, proximity manager, safety manager, head of the safety service). Data collected with interviews support the assessment of the different indicators. These results were discussed in a group workshop.

Next section is dedicated to the presentation of the results.

4 RESULTS

Data collected during interviews support the assessment of the different indicators that constitute the resilience performance. For each indicator rules, an evaluation is proposed and a set of fragility and resilience factors are proposed. Results for the indicator related to the capacity to respond and overcome to the diversity of situations that may arise are discussed in this section.

4.1 *The capacity to respond and overcome to the diversity of routine situations that may arise*

Results of the analysis of data collected related to the first indicator support the assessment of adaptive capacity of operational agents and of margin of manoeuver provided by the system to the variability of routines situations.

Agents know their work and associated performance criteria.

The assessment of the rule is based on the comparison of the description of the different tasks to be performed between both operational and managerial agents, procedures and observations.

According to the results of the analysis, the part of the rule dedicated to the knowledge of the activities is judged satisfactory. Agents seems to have a quite good perception of the reality of their tasks.

According to the results of the analysis, the part of the rule dedicated to the knowledge of the performance associated to the activities is judged satisfactory. Agents seems to know the different performance associated to their activities and aims satisfying safety and punctuality issues. Proximity managers aims finding the good trade-off between the satisfaction of objectives associated to their position and the management of the human dimension of their team.

They have the skills or know the procedures to follow and have the resources, time and information to carry out their work in accordance with the different performance criteria.

The assessment of the rule is based on the analysis of agent's testimonies about their work environment and their relation with competences, resources, procedures, time and information.

Operational work environment is judged maladjusted to work conditions such as winter and summer temperature, workplaces are not ameliorated and cleanness is judged insufficient. Moreover, they have the feeling that working in difficult condition is considered as normal and that budget is use for other issues than improving work conditions.

A period of empowerment is necessary for operational agents before they can overcome fear feelings to hazards associated to the tasks, during this one-two month period they can make mistakes. This time is longer for the traffic manager not caused by hazards buy by the complexity of the management tasks. Moreover, it is very difficult allocating training period to agent due to workforce issues and unplanned absence. These difficulties are compensated by initial training, the accompaniment of experimented agent during their first interventions, the vigilance of the hierarchy and mutual assistance between agents.

Procedures are learned in initial training by agents, monitoring achieved by proximity managers and their hierarchy helps check that they are fully known and understood. In case of doubt, agents ask their managers who are able to answer them. Agents used to mentally remind the procedure to be followed before performing critical and hazardous tasks. Agents consider that some tasks planed by procedure don't impact safety and consequently might don't apply them if they have constraints. This fragility is compensated by the monitoring by the hierarchy of the correct application of all the tasks of procedures. When a procedure is modified, each agent concerned have to attest he has considered the change. Due to the multiplication of changes, sometime minor, agent known that a change occur but don't take the time to study the change. Proximity managers compensate this issue with teaching and monitoring the correct understanding of changes that affect the work of the operational agents.

There is a difference between technical and human resources necessary to achieve goals in term of number of daily trains negotiated with stakeholders and resources available inducing recurring problems. There is a feeling that solutions provided to solve them by operational agents are not considered by the hierarchy. When tools are not available, exchanges are organized between agents. Agents absenteeism is important it is compensated by the

capacity of proximity managers and the hierarchy to perform operational tasks.

Work schedule is planned so that time is not a constraint for operational agents achieving tasks and time margins are planned between two work activities. The hierarchy considers that safety is the priority and don't put pressure on agents. A point of fragility is that agents enchain short period of activity and period of inactivity causing issues related to activation and concentration.

Information management is a major for all agents involve in the management of trains departures and arrivals. The use of information systems and informal communication networks helps manage constrains during both design and production phases. Information systems and communication protocol aims considering the constraints of each agents. Operational and proximity managers are continuously looking for information about the state of activities and of the network in order anticipating potential issues. For that they try to find information system and create a personal communication network. In case of lack of information operational agent don't hesitate to ask their managers who are responsible to find solution. Information systems may be saturated by the multiplication of message. Managers have to be careful delivering the good message to the right person at the right time in order to not induce perturbation in the system. Conflicts may arise caused by absence of answer or because of the tone or the type of message exchanged.

Related to all these positives and negatives factors the rules has been evaluated as medium.

If the situation changes and the procedural framework is no longer applicable, they are able to be creative enough to carry out their work in accordance with performance criteria and have the necessary margins of manoeuvre.

The assessment of the rule is based on the analysis of agent's testimonies about complicated and complex situations that can occur in routine situations.

Many situations related to incidents, delays, malfunctions require an adaptive response from agents and from the system. A routine situation may cause blockages due to its failure to be taken into account by procedures or by the definition of agent's roles. Some agents demonstrate initiative during such situations in order to insuring the train to be able to start on time and safely. They have margin of maneuver from hierarchy to take the time necessary to perform work safely for insuring safety even if it creates some delays for the train.

Based on all the fragility and resilience factors identified, the evaluation of the indicator is Acceptable for agents capacity to adapt to the variability of routines situation and the contribution of the organization as medium.

4.2 *The capacity to respond and overcome to the diversity of abnormal situations that may arise*

Results of the analysis of data collected related to the second indicator support the assessment of adaptive capacity of operational agents and of margin of manoeuver provided by the system to abnormal situations. A typology of abnormal situation has been firstly deduced and for each, factors of fragility and resilience has been identified.

Four abnormal situations have been studied:

- Situations caused by an increase of agents workload of agents resulting from the absence of two to three operational agents.
- Situations resulting from a safety incident occurring on one of the place of the station.
- Situations resulting from an incident occurring at the station or on the network which disrupts the production, where the management is under the responsibility of the train station.
- Situations resulting from an incident occurring at the station or on the network which disrupts the production, where a crisis management room is open under the responsibility of an authority external of the station.

Situations caused by an increase of agents workload of agents resulting from the absence of two to three operational agents.

When such a situation occurs, agents must perform the same tasks as in routine situations but in a different context. They may be required to perform more during the same service, to carry out them on numerous trains consecutively, to carry out them in a crisis atmosphere with many passengers seeking information to see in a hostile situation with aggressive and violent passengers. Agents adaptation is promoted with their acceptance that some days they must performed more activities than originally planned, with the ability of management to perform operational tasks and agent's knowledge on know how to prioritize their work with managing their production tasks as a priority and trying to find a solution for the passengers.

Situations resulting from a safety incident occurring on one of the place of the station.

When such a situation occurs, potential consequences of the psychological impact of the event on agent's activities in the short and medium term has to be considered as impact of the consequences of the absence of one or more agents for injuries, rest or suspension on the production capacity of the station. Ability of management supporting agents to overcome the event, the possible consequences (suspension, etc.) and to make the incident a source of awareness of risks not taken into account and of learning performing activities in compliance and safely.

Situations resulting from an incident occurring at the station or on the network which disrupts the production, where the management is under the responsibility of the train station.

When such a situation occurs, delays may affect the following services that need to be refined, Supervisors may have to leave the site and oversee operational activities to manage the crisis situation as a strain, the, some tasks that have to be carried out quickly in order to solve the situation may not be possible due to unavailability of technical resources or difficulties in setting up the stopover (access to storage areas, etc.). Culture of mutual assistance between services and agents in disturbed situations, the "Pride of the railway man", facilitate adaptation need to overcome such situations.

Situations resulting from an incident occurring at the station or on the network which disrupts the production, where a crisis management room is open under the responsibility of an authority external of the station.

When such a situation occurs, agents and managers have the feelings to not to be listened by the crisis management unit when they propose solutions appearing effective to them and that they undergo the decisions and their negative consequences on production and on customers. Moreover, there is a risk of chilliness caused by the fear of the perception and reaction of general headquarters. Culture of mutual assistance between services and agents in disturbed situations, the "Pride of the railway man", facilitate adaptation need to overcome such situations.

Based on all the fragility and resilience factors identified, the evaluation of the indicator is medium for agents capacity to adapt to the variability of abnormal situation and the contribution of the organization as medium.

5 DISCUSSION

Resilience can be perceived as a process, a set of properties, results of a dynamic of development, results of the response of a system to a situation, a combination of all the above. Resilience assessment is a complex process requiring to consider the system studied, a set of situations of adversity and a set of values.

As other equivalent work (Patriarca et al. 2017), a phase of translation of the initial RAG grid (Hollnagel 2011) is necessary to address concrete topics of the system studied.

The overall process is complicated to apply. Firstly, because topics studied are related to the system as he is and not as it should be, consequently conditions have to be favorable in order to have people accepting to describe their working conditions. Secondly, resilience performance is related to situation that don't occur frequently and for some situation they never occur. Consequently, it's difficult to collect relevant data allowing to predict how the system will respond to such a situation.

Results of the application are mainly qualitative because they aimed to promote dialog between actors of the organization and to support the definition of plan of actions for improving the system.

6 CONCLUSION

Application of the method to the train station demonstrates the potential of indicators and method to collect and analyse data on the resilience performance of an organisation. Fragility and resilience factors has been identified. If some topics where familiar with agents, others where more difficult to study, such as learning from normal situation, actual and prospective safety performance indicators or change management with operational agents.

Resilience factors have been identified, nevertheless the success of such factors are dependant of the availability and motivation of operational and managerial agents performing tasks that are not relevant to their duties, good cohesion of team and of vigilance on maintaining margins of manoeuver available.

Lessons learned from this experiment will structure the refinement of indicators and methodology in order to produce an operational method. The new method will be applied to other systems to continue validating its performance.

Simulating the world described with the functional resonance analysis method

P. Smoczyński, A. Kadziński & A. Gill
Poznan University of Technology, Poznan, Poland

ABSTRACT: In the recent years there is a constant growth of interest in Resilience Engineering. According to its approach, accidents in complex socio-technical systems happen due to 'functional resonance' of many underdefined system functions. The resonance is often analysed and presented with help of Functional Resonance Analysis Method (FRAM). However, in many reported research, the analysis is limited to a separated group of functions and describes a process rather than a system as a whole. Contrary to this common practice, we assume that the processes are 'looped' and the system functioning—infinite. In the paper, we introduce a concept of a novel computer software which can demonstrate such systems described with FRAM models. The prepared software has been used for simulating a moving tram. Several simulations with different parameters have been compared to show the possible use of this software in further investigating of systems described with help of FRAM.

1 INTRODUCTION

The issues of safety have probably accompanied humankind since the very beginning of its existence. However, the need for a more formalised approach to this subject matter did not appear until the industrial revolution in the 18th century (Hollnagel 2014). Scientific research came even later—the essential book by Heinrich (Heinrich 1931) dedicated to work safety is worth mentioning here (Lundberg et al. 2009). In the period after World War II, reliability engineering developed, thanks to which many tools still in use today, such as the FMEA or FTA methods, were introduced.

Along with the noticeable improvement in the reliability characteristics of technical objects, undesirable events increasingly resulted from the errors of machine operators. In consequence, the models in use were supplemented with the so-called human factor. However, it turned out relatively quickly that an attempt at attributing responsibility solely to operators of technical objects does not bring the expected effect. It therefore became necessary to also include the organisations for which these operators worked in the analyses, which gave rise to safety management systems (Hollnagel 2014).

The results of scientific research translated into legal regulations concerning safety, in which departure from the focus on the technical details towards ways of making decisions and management could be observed since the 1970s (Hale et al. 1997). This trend was additionally reinforced by the results of studies on disasters from the 1970s and 1980s, such as the Piper Alpha oil platform disaster of 1988 (Paté-Cornell 1993), as well as the governments' will to withdraw from direct responsibility for the level of safety. Since the announcement of the results of the investigation of the causes of the Chernobyl disaster of 1986, also the need to enhance the culture of safety has been the topic of discussion (Wang & Liu 2012).

Experience in implementing safety management systems revealed a number of problems, however. Already in the 1990s, it was observed that people's behaviour changes under the influence of the ubiquitous procedures. Power (Power 1997) called this phenomenon the formation of an 'audit society', in which more emphasis is put on obtaining another certificate than on the actual effects of work. Forcing compliance with procedures does have certain positive effects, e.g. makes cooperation more predictable (Jeffcott et al. 2006), but it also leads to the marginalisation of the significance of the employees' knowledge and experience (Almklov et al. 2014).

The problems mentioned above are the reason that changes and additions to the approach to safety management are currently proposed. They concern changes in the manner of formulating safety procedures (Hale & Borys 2013) and moving from searching for the causes of undesirable events to searching for the causes of correct execution of system tasks (Hollnagel 2014). As a result, system resilience to unexpected changes in the manner of their operation is expected to increase.

One of the methods used for modelling of complex socio-technical systems in order to find the

resilience mechanisms is Functional Resonance Analysis Method (FRAM), proposed by Hollnagel (Hollnagel 2012). It has been applied in a variety of organisations and industries. The most recent papers describe e.g. sinter plant (Patriarca, Di Gravio, Costantino, et al. 2017), air traffic management system (Patriarca, Di Gravio, & Costantino 2017, Yang et al. 2017) or application in medical care (Pickup et al. 2017).

Most of the authors, however, tend to use the FRAM to analyse separated processes in the complex systems, from the beginning to the end of such a process. In our opinion, the FRAM can also be used to describe systems as a whole, where the processes are 'looped' and the system functioning—constant and infinite. The article aims to present an early version of a simulation software which can be used for this purpose, basing on a simple example of a moving tram.

In Section 2 we have presented the way how the approach to safety has changed over years to better and described the foundations of the FRAM. In Section 3 we have shown how these foundations are transformed into the proposed software. In Section 4, we show results of a tram ride simulation. The paper ends with conclusions in Section 5.

2 FUNCTIONAL RESONANCE ANALYSIS METHOD

Recently, a considerable increase in the complexity of systems, caused by the possibilities offered by new technologies and pressure to introduce changes as soon as possible and for as low a price as possible, could be observed. The consequence of this situation is often the lack of complete understanding of the processes occurring within the systems, which leads to their sudden failures. Since 2000, a rapid increase in the number of publications on this topic, dedicated to the issues of resilience engineering from the point of view of e.g. safety, system complexity, organisation or ecology, has been observed. The term 'resilience' is understood in four ways in these works (Woods 2015):

- As rebound – how a system rebounds from disrupting or traumatic events and returns to previous or normal activities.
- As robustness – expanding the set of disturbances the system is prepared for.
- As graceful extensibility – how a system extends performance or uses extra adaptive capacity in case of unpredictable events.
- As sustained adaptability – a policy making it possible to continue proper operation in the long term as external conditions change.

It is sometimes believed (Woods 2015) that only the latter two approaches are justified. Research of the sole process of returning to the initial condition is considered to be incomplete, as its course is determined by activities undertaken before the disturbance (which corresponds to increasing resilience as defined in no. 3 and 4). Preparing the system for the previously predicted events in turn corresponds to the phase of reacting to risk in the classic form of the hazard risk management process.

A different attempt at taking a complete look at the issue of resilience was made by Lundberg and Johansson, whose work (Lundberg & Johansson 2015) presents a resilience model including six functions: anticipation, monitoring, response, recovery, learning, and self-monitoring. An in-depth analysis of various definitions of resilience can also be found in (Adjetey-Bahun et al. 2016). In principle, resilience engineering is supposed to be as universal as possible (Haavik et al. 2016), and research on the topic has been carried out in many different areas of human activity, including medicine, aviation, and nuclear power stations (Le Coze 2016).

The Functional Resonance Analysis Method (FRAM), has been proposed by Hollnagel (Hollnagel 2012) for modelling how complex socio-technical system work. The method is based on four principles (Patriarca, Di Gravio, & Costantino 2017):

- Equivalence of failures and successes. Equivalence and successes come from the same origin, i.e. everyday work variability. This latter allows both things go right, working as they should and things go wrong.
- Principle of approximate adjustments. People as individuals or as a group and organizations adjust their everyday performance to match the partly intractable and underspecified working conditions of the large-scale socio-technical systems.
- Principle of emergence. It is not possible to identify the causes of any specific safety event. Many events appear to be emergent rather than resultant from a specific combination of fixed conditions. Some events emerge due to particular combination of time and space conditions, which could be transient, not leaving any traces.
- Functional resonance. The function resonance represents the detectable signal emerging from the unintended interaction of the everyday variability of multiple signals. This resonance is not completely stochastic, because the signals variability is not completely random but it is subject to certain regularities, i.e. recognizable short-cuts.

The principles constitute a new approach for understanding safety, called 'Safety-II' (Hollnagel 2014). In brief, the steps for safety system analysis using FRAM are (Patriarca, Di Gravio, & Costantino 2017):

– Identification and description of system's functions
– Identification of performance variability
– Aggregation of variability
– Management of variability.

The distinctive feature of the FRAM is the way how the functions are represented. The graphical form of this representation is shown in Figure 1.

As shown in Figure 1, each function is characterised through six aspects (Yang et al. 2017):

– Input (I): what the function transforms or processes or what starts the function
– Output (O): the result of the function, either an entity or a state change
– Preconditions (P): conditions that must exist before a function can be executed
– Resources (R): what the function needs when it is carried out (Execution Condition) or consumes to produce the Output
– Time (T): temporal constraints influencing the function (with regard to starting time, finishing time or duration)
– Control (C): how the function is controlled.

The definition of aspects is intuitive, but often too general for creating a consistent procedure of choosing them in particular circumstances. Anvarifar et al. (Anvarifar et al. 2017) notice that further work is required to test the applicability of the FRAM for detailed risk analysis in more complicated and data demanding case studies. Patriarca et al. (Patriarca, Bergström, et al. 2017) add that a comprehensive FRAM analysis might generate a representation, which is impressive in terms of its sheer number of functions and couplings, but hard to make interpretive sense for further analytical purposes. The solutions used to overcome this problem consists of decomposition schemes and various original computer software based on Monte Carlo simulation.

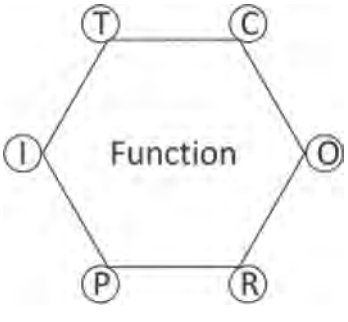

Figure 1. A hexagon characterising function in FRAM (Hollnagel 2016).

3 THE SIMULATION SOFTWARE

With our software presented in this paper we would like to simulate 'looped' systems described with FRAM models. It has been prepared using Microsoft Visual Studio Community 2017, which is available for free i.a. for academic purposes, enriched by a demo version of NMath library from CenterSpace. The program has been written with Visual Basic.NET programming language as a Console application and is running in the text mode only. It allows to focus more on the algorithms than on the visual part of the software. Following assumptions have been made for assuring consistency of FRAM-based models used as simulation basis:

– All the functions use information of generic type provided through their Input aspects to produce results of generic type, which are made available through the Output aspects
– The Control aspect is an input of generic type for information used by the function in order to minimise its own variability
– The Timing aspect is an input of date/time type that provides the earliest time when the function can be activated
– The Preconditions and Resources aspects are inputs of 'true' or 'false' type; the first aspect is checked whether it equals to 'true' at the activation of the function and the second aspect – constantly throughout its realisation.

The assumptions have been shown graphically in Figure 2.

With the assumptions (Fig. 2), the aspects have been effectively divided into two groups:

– Aspects responsible for determination if and when the function is performed: Timing, Preconditions and Resources
– Aspects responsible for how the function is performed: Input, Output and Control.

For the first group of aspects, it was possible to determine the type of variables used for communication between functions. The types correspond

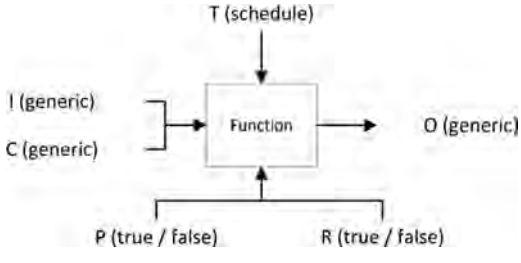

Figure 2. Interpretation of FRAM's aspects used in the proposed simulation software.

to the description in Fig. 2, i.e. Date for the Timing aspect and Boolean for the Precondition and Resources aspects. The second group of aspects is of generic type, as it depends on what the function actually does. The implementation of the 'inside' of the function has to be written manually directly into the program's code. However, in the future it is possible to introduce an interface similar to the LabView from National Instruments. It would allow to 'construct' the functions graphically from a set of predefined instructions (loops, conditions, etc.).

All the functions identified during the FRAM and present in the model are put by the software at the beginning of the simulation simultaneously in a 'stand-by' mode. Their actual activation depends on the respective Timing, Preconditions and Resources aspects an can be repeated throughout the simulation time. This approach makes the simulation never ends, just as the modelled systems never 'stop' their existence.

4 PERFORMANCE VARIABILITY OF A MOVING TRAM

For the testing purposes of the simulation software, we have decided to simulate a simple system of a tram moving through a city. The respective FRAM model has been presented in Figure 3.

The schemes as in Figure 3 can be created with help of specialised software, called FRAM Model Visualiser, which is available free of charge (Hollnagel 2016). Following two foreground functions have been considered in the model:

– *Exchange of passengers*, a function encapsulating the boarding activities between opening and closing doors
– *Move tram*, a function of keeping the vehicle running.

In addition, following background functions have been considered:

– *Prepare timetable*, giving the earliest time of moving away from a tram stop
– *Passenger flow*, a function that represents the passengers waiting for the tram on the tram stop
– *Traffic lights*, a technical function that periodically prevents the driver from leaving the tram stop
– *Produce electricity*, a technical function that supplies electricity which is inevitable for performing the function *Move tram*.

In the model, the Gauss distribution has been used for generating random numbers that describe the timing of traffic lights, producing energy, and the travel time between stops. The number of passengers increases with time and, when more boarding is needed than the schedule allows—the Exchange of passengers function uses warning signal to speed up the process. The warning signal device works with average efficacy of 1/*e*, i.e. in average one out of *e* signals lowers the remaining time of boarding by some value, that depends on the device type.

The sample simulation record has been shown in Figure 4. The simulation software allows to save the simulation record in form of a text file, which can be further elaborated with e.g. Microsoft Excel.

In the case study we have assumed that the departure time from stop $i + 1$ is 40 seconds later than the departure time from stop*i*. For the Gauss distributions determining the timing of background functions Produce electricity and Traffic lights (Fig. 3), we have used the following parameters:

– For Power = true: $\mu = 35$, $\sigma = 5$ [s],
– For Power = false: $\mu = 10$, $\sigma = 3$ [s],
– For Green light = true: $\mu = 4$, $\sigma = 4$ [s],
– For Green light = false: $\mu = 8$, $\sigma = 2$ [s].

In case that the time were negative, it is changed into zero. Additionally, the travel time is drawn

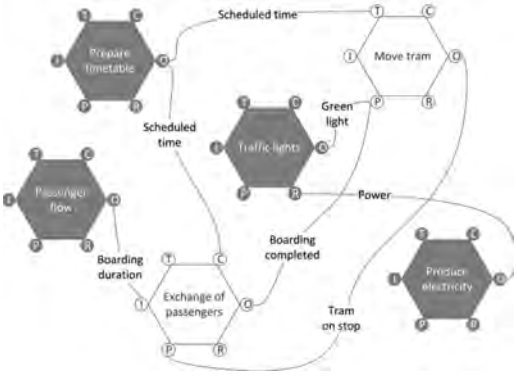

Figure 3. FRAM model of a tram moving through the city.

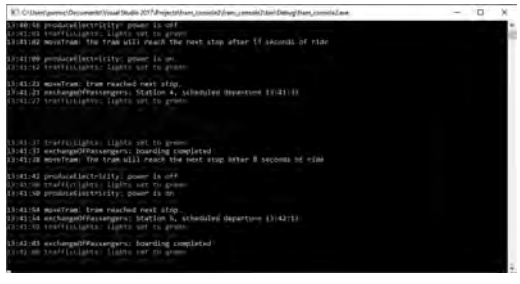

Figure 4. Sample record of a simulation performed in the software.

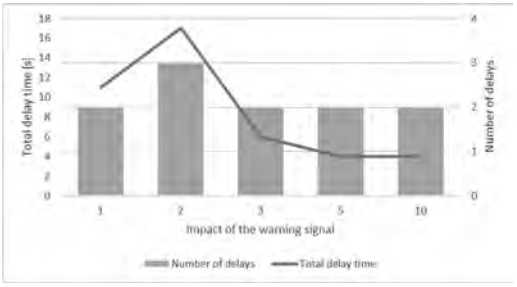

Figure 5. Total delay time and number of delays in respect to the impact of the warning signal.

according to the Gauss distribution of $\mu = 10$, $\sigma = 3$ [s]. The *Passenger flow* output is the boarding time that equals to the time between closing the doors at stop i and opening it at stop $i + 1$. Boarding time at the beginning of the simulation equals to 10 s.

The aim of the case study is to determine which one of five possible warning signal devices should be used in the tram after its renovation. The devices have the same efficacy $e = 0.4$, but differ in terms of their effectiveness in speeding up the boarding. Each time the signal is taken into consideration by the passengers (what happens with average probability 0.4), the signal lowers the remaining boarding time by 1, 2, 3, 5 or 10 seconds. This timespan will be called 'impact' of the device. For each of the warning signal device, a 10-minute simulation has been made. The results are summarised in Figure 5.

The number of delays during the simulation amounts to 2 in four cases and 3 in one case. Due to the different number of delays, the total delay time increases for impact 2 and then decreases and remains at the same level for impact 5 and 10. The results, although should only be considered as estimates, allow to opt for the device with impact 3 or 5 and suggest that investing in the device with impact 10 is not justified.

5 CONCLUSIONS

Models prepared with the FRAM can be used not only for description of processes, but also for simulating systems throughout their lifetimes. Models used as a basis for this kind of simulation will often be complex and, therefore, a strict and consistent understanding of the functions' aspects is needed. A proposal for such understanding has been presented in this paper together with an early version of a dedicated simulation software. Its applicability has been shown on an example of warning signal devices installed in a tram. Further work is needed to make the software fully intuitive and to integrate it with the official FRAM editor (Hollnagel 2016).

Technical safety and reliability methods for resilience engineering

I. Häring & P. Gelhausen
Fraunhofer Ernst-Mach-Institut, EMI, Efringen-Kirchen, Germany

ABSTRACT: Resilience of technical and socio-technical systems can be defined as their capability to behave in an acceptable way along the timeline pre, during and post potentially dangerous or disruptive events, i.e. in all phases of the resilience cycle and overall. Hence technical safety and reliability methods and processes for technical safety and reliability are strong candidate approaches to achieve the objective of engineering resilience for such systems. This is also expected when restricting the set of methods to classical safety and reliability assessment methods, e.g. classical Hazard Analysis (HA) methods, inductive Failure Mode and Effects Analysis (FMEA), deductive Fault Tree Analysis (FTA), Reliability Block Diagrams (RBDs), Event Tree Analysis (ETA) and reliability prediction. Such methods have the advantage that they are typically already used in industrial research and development. However, improving the resilience of systems is usually not their explicit aim. The paper covers how to allocate such methods to different resilience assessment, response, development and resilience management tasks when engineering resilience from a technical perspective. In particular, the resilience dimensions of risk management, resilience objectives, resilience cycle time phases, technical resilience capabilities and system layers are used explicitly to explore their range of applicability. Also typical system graphical modelling, hardware and software development methods are assessed to document the usability of technical reliability and safety methods for resilience analytics and technically engineering resilience.

1 INTRODUCTION

As the number of applications of the concept of resilience to (socio) technical systems in mainly academic research and development rises, the question of how to successfully implement these approaches in the private sector, industry and small and medium enterprises is getting more and more prominent. The present paper addresses this challenge by surveying the suitability of classical, mainly analytical system analysis methods for assessing and improving resilience of (socio) technical systems.

The wording resilience analytics has been used recently quite general in the sense of resilience assessment in the societal-technical domain, see e.g. (López-Cuevas et al. 2017; Linkov, Florin 2016; Thorisson et al. 2017). However, the present use of the term analytical is to relate to classical system analysis methods, such as hazard analyses (HAs) including Hazard Lists (HLs), failure mode and effect analyses (FMEAs), fault tree analysis (FTA), event tree analysis (ETA), reliability block diagrams (RBD) and double failure matrix (DFM).

The application of established system modelling, analysis and simulation methods for resilience analysis covers Bayesian networks (e.g. Yodo et al. 2017) and Markov Models (e.g. Zhao et al. 2017). Fault propagation in a hazard and operability analysis (HAZOP) context for resilience assessment is described in (Cai et al. 2015). Also first approaches have been reported to use FMEA for resilience assessment with the aim of applying the functional resonance analysis methodology (FRAM) to a smart building (Mock et al. 2016). However, for instance fault tree analysis has not yet been used for resilience analysis.

First attempts of an evaluation of the suitability of system analysis, simulation and development methods including some selected classical system analysis methods for resilience assessment have been conducted in (Häring et al. 2016c; Häring et al. 2016b). In contrast to (Häring et al. 2017), the present approach does not provide generic considerations of the suitability of methods for technically driven resilience assessment and development process steps.

The present approach focuses on determining which contributions to resilience assessment can be expected from mainly analytical system analysis methods and their extensions. To this end, it resorts to already often used resilience dimensions such as resilience or catastrophe response phases, system management domains or resilience capabilities.

By resorting to 5 such resilience dimensions as detailed and motivated below, the expected relevancy of mainly analytical system analysis methods is assessed from different and complementary perspectives. Using the resilience dimensions, the suitability of method assessment is resolving the expected benefit in respective phases or resilience

aspects rather than aiming at an overall applicability scoring.

This is conducted based on expert judgement (Meyer, Booker 2001) and consensus feedback of scientists related to the research field of technical safety and risk analysis. Also groups of almost finished master students in security and safety engineering of an applied science university contributed, mainly trained in tabular system analysis methods.

Key motivations for focusing on classical system analysis methods include:

- Analytical system analysis methods are established and accepted by practitioners in industry;
- Expectation that resilience analysis can in parts be delivered with extensions of classical methods;
- Expected efficiency of semi-quantitative methods compared to quantitative approaches;
- Identification of implicit resilience activities within current existing risk analysis and management practice;
- Clarification of resilience concepts by specifying methods supporting their fulfillment;
- Identification of critical resilience aspects that need to be analyzed with more effort, i.e. going beyond classical system analysis methods.

The paper is structured as follows. In section 2, the approach is described how to assess the suitability of mainly classical analytical system analysis methods for resilience analysis by employing resilience dimensions suitable for technical resilience understanding. Section 2 also details the methodology. It illustrates the need of going beyond classical risk assessment with the help of resilience event propagation through logic and assessment layers.

In the following sections 3 to 7, for each of the listed resilience concepts, possible contributions from the methods are discussed. For each resilience dimension a matrix is filled with assessments of the suitability of the method for contributing to each of the resilience dimension attribute. Also, recommendations for the extension of the methods are given.

In section 8, the overall suitability of each method is summarized and conclusions regarding adaptations and further developments are drawn.

2 APPROACH TO ASSESS THE SUITABILITY OF METHODS

Before detailing the approach of suitability assessment of classical system analysis methods, the paper gives some general considerations on the necessary extension of methods for resilience assessment when compared to classical risk assessment.

Conditional probability expressions based and extending classical notions of risk have recently been used to quantify key objectives of resilient response (Aven 2017). This shows that resilience analysis may benefit from the application of traditional and more modern risk concepts.

The idea used as starting point in (Aven 2017) is that resilience behavior can be defined to occur post disruption events. Thus resilience event B, e.g. "system stabilizes post disruption", "system recovers", "system bounces back better", "recovery time shorter than critical time" or "sufficient system performance level reached within t" are always conditional previous events,

$$P(B \mid A), \tag{1}$$

where A is a "disruptive event" or equals a chain of events,

$$A = A_1, A_2, \cdots, A_n. \tag{2}$$

This approach relates with the often used definition of conditional vulnerability in risk expressions, see e.g. (Daniel M. Gerstein et al. 2016),

$$R = P(E)\, P(C \mid E)\, C, \tag{3}$$

where E is a threat event and C the consequence.

However, the classical vulnerability approach of (3) focuses on the quantification of the conditional consequence probability, whereas (1) refers to resilience behavior post disruption events.

As the vulnerability including risk definition of (3) is already an extension of the classical definition of risk

$$R = P(C)\, C, \tag{4}$$

and typical resilience expressions are further extending the definition of (1) and (3), it is expected that classical system reliability and safety approaches are challenged when used for assessing resilience. In particular (very) simple tabular approaches resort to risk concepts as described by (4) when applied in a traditional way, i.e. they focus on avoidance of events and system robustness in case of events only.

Generalizing (1), resilience expressions of interest typically are of the form (Häring et al. 2016a)

$$P(B \mid A) = \sum_{i=1}^{N} P(B \mid D_i) P(D_i \mid A), \tag{5}$$

where $D_i, i = 1,2,...,n,$ form a complete set of expansion events. Equation (5) uses the law of total probability and can be understood as an insertion of unity of all possible intermediate states

$$\sum_{i=1}^{n} P(\bullet \mid D_i) P(D_i \mid \bullet) \tag{6}$$

between any two known states. Equation (5) can also expresses the idea of possibly unknown transition states or disruptions which are included in the set D_i. In this case, A is just a system initial sate.

Of course, (5) can be generalized to consider multiple resilience layers or response and recovery phases, see (Häring et al. 2016a). Along the lines of interpretation given for (1), an interpretation of (5) reads for instance

$$\begin{aligned} &A = \text{“Disruption event”},\\ &\{D_i\}_{i=1,\ldots,n}, \text{Set of possible response and recovery events/Set of transition states},\\ &B = \text{“Final state of interest”}. \end{aligned} \tag{7}$$

When comparing risk and vulnerability expressions of the form (3) and (4) with resilience expressions of the form (1) and (5), it becomes obvious that it is not straightforward to expect that classical analytical system analysis methods can deliver assessment results regarding resilience. This motivates the question how such methods can contribute to resilience assessment.

For focusing the research question, the following system modelling, classical system analysis and system development methods are considered regarding their suitability for resilience assessment:

- SysML, UML;
- HL, PHA, HA, O&SHA, HAZOP;
- FMEA, FMECA, FMEDA;
- RBD;
- ETA;
- DFM;
- FTA, time-dependent FTA (TDFTA);
- Reliability prediction with standards;
- Methods for HW and SW development;
- Bit error correction methods.

To assess the suitability of methods for resilience engineering, the following resilience dimensions are used:

- 5-step risk management process (AS/NZS ISO 31000:2009), for review: (Purdy 2010), (Luko 2013), for critical discussion mainly regarding the coverage of uncertainty (Aven 2011);
- Resilience time-phase cycle, based on (Thoma 2014);
- Technical resilience capabilities, based on (Häring et al. 2016a);
- System layers, based on (Häring 2016a);
- Resilience criteria (Bruneau et al. 2003) (Pant et al. 2014);
- Resilience analysis and management process (Häring et al. 2017);

For the first 5 resilience dimensions, each combination of system analysis method and resilience dimension attribute is assessed using the three equivalent semi-quantitative scales

$$\begin{aligned} &\{1,2,3,4,5\},\\ &\{--,-,o,+,++\},\\ &\{\text{not suited (adaptation useless)},\\ &\ \text{rather not suited (or only with major modifications)},\\ &\ \text{potentially suited (after adaptation)},\\ &\ \text{suited (with minor modifications)},\\ &\ \text{very well suited (straightforward/no adaptions)}\}. \end{aligned} \tag{8}$$

Typical examples read as follows: (i) The identification of potential disruption events of systems can be supported by using the classical system analysis methods hazard list (HL) and preliminary hazard analysis (PHA). Hazard lists are very well suited for identifying hitherto unknown events when used as checklists of potential disruptions and asking the question “what if?”. Regarding the identification of possible disruptions for a system under consideration, the overall rating of HL could be “++” or “+” for PHA. This example shows that rather than assessing the generic suitability of a method, its use within a certain resilience assessment process or conceptual structuring is addressed.

(ii) Fault tree analysis (FTA) allows to consider combinations of events by using the AND gate. When only a known sequence of events is possible, the sequencing AND gate can be used, which enforces an order of occurrence of events. Such a sequence might be first “detection of threat”, second “decision to start counter-measure” and third “activation of counter-measure”. This order is then used for assessing the probability of success of a technical prevention measure. Sequential events can be analyzed with time-dependent Boolean differences to analyze sequential structure functions rather than classical combinatorial Boolean structure functions (Moret, Thomason 1984). Hence, FTA and even more TDFTA can be expected to cover after modifications also the response and recovery phase, resulting in a “+” assessment, respectively.

3 SUITABILITY ASSESSMENT WITH FIVE-STEP RISK MANAGEMENT SCHEME

The 5-step risk management scheme is only a very generic framework for identifying risks on resilience objectives. As discussed in the introduction, objectives in the case of resilience analysis are more second order (e.g. “fast recovery in case of disruption”) when compared to classical risk analysis and management (e.g. “avoid disruption”).

Table 1 assess the suitability of analytical system analysis and some development methods for resilience analysis sorted along the 5-step risk management scheme using the scale of (8).

Understanding the system sufficiently for resilience risk analysis is supported with graphical/semi-formal Unified/Systems modelling languages (UML/SysML) modelling, see the first two lines of Table 1.

The initial hazard analysis methods HL and PHL support the identification of possible disruptions. They are considered as a starting point. Refined analyses can be supported with SSHA, HA, O&SHA, and HAZOP, the differences of which are typically small and depend on the application; for small systems they can be summarized in one analysis.

Approaches that need substantial system knowledge include RBD, the inductive approaches ETA, FME(D/C)A and deductive approaches (TD) FTA, which are often summarized in a bow tie analysis. The success of FMEA variations is expected to be more efficient when depending on system functions (or services) as inductive starting points rather than system components or subsystems.

In the case of (TD) FTA, the success of application will strongly depend on the definitions of the top events, which should cover main resilience objectives.

Table 1. Suitability of analytical system analysis and HW/SW development methods for resilience analysis sorted along the 5-step risk management scheme.

Method\ 5-step risk management process steps	(1) Establish context	(2) Identify risk/ hazards	(3) Analyze/ compute risks	(4) Evaluate risks	(5) Mitigate risks
SysML	+	++	++	o	++
UML	+	+	+	o	+
HL	+	++	+	o	-
PHA	+	+	++	+	+
SSHA, HA	o	+	++	++	++
O&SHA, HAZOP	o	+	++	++	++
FMEA, FMECA	–	o	++	+	++
FMEDA	–	–	++	+	++
RBD	o	+	++	+	++
ETA	+	+	++	+	++
DFM	–	o	++	+	++
FTA, TDFTA	–	o	++	+	++
Reliability prediction with standards	–	–	++	+	++
Methods for HW and SW development	–	–	–	–	++
Bit error correction methods	–	–	–	–	++

4 METHOD USABILITY ASSESSMENT USING RESILIENCE RESPONSE CYCLE TIME PHASES

The catastrophe management cycle in 4 steps (e.g. preparation, prevention and protection, response and recovery, learning and adaption) as well as in 5 steps as used in Table 2 take advantage of a logic or time ordering of events with respect to disruption events (Häring et al. 2016a): (far) before, during, immediately (after). Another typical timeline as well as logic sequence example was given in section 2.

The first observation in Table 2 is that the analysis methods should be conducted, if considered relevant, mainly in the preparation phase. However, especially fast analytical simple methods can also be applied during actual conduction of response and recovery. For instance, during and post events, a PHA scheme could be used to identify further possible second-order events given a disruption.

The second observation in Table 2 comprises the coverage of resilience cycle phases. The suitability of method assessment stems from the fact that classical analytical approaches by definition cover prevention and protection when identified with frequency of event assessment and immediate (first order) damage assessment.

Table 2. Suitability of system modelling, analytical system analysis and selected development methods for resilience analysis along the 5 phases of the resilience cycle: Resilience event order logic or timeline.

Method\ Resilience timeline cycle phase	(1) Prepare	(2) Prevent	(3) Protect	(4) Respond	(5) Recover
SysML	++	++	++	++	++
UML	++	+	+	+	+
HL	++	++	++	++	++
PHA	++	++	++	+	+
SSHA, HA	++	++	++	+	+
O&SHA, HAZOP	++	++	++	+	+
FMEA, FMECA	++	++	++	+	+
FMEDA	++	++	++	+	+
RBD	++	++	++	+	+
ETA	++	++	++	+	+
DFM	++	++	++	+	+
FTA, TDFTA	++	++	++	+	+
Reliability prediction with standards	++	++	++	+	+
Methods for HW and SW development	++	++	++	+	+
Bit error correction methods	++	++	++	++	+

If system failure, in case of variations of HA, FMEA and FTA, is defined as failure of adequate response (e.g. absorption and stabilization), of recovery (e.g. reconstruction and rebuilding) or even of improving or bouncing forward using damage as optimization opportunity, these methods can be used with adaptions also for these resilience timeline phases. Similarly, RBD and ETA are assessed.

The system modelling and development methods for hardware and software (HW/SW) can be used for all resilience cycle phases. As in the case of classical system analysis methods, adaptions up to major new developments are believed to be necessary.

Even if especially the classical tabular system analysis methods were assessed as very relevant for resilience assessment, it is noted that they are part of established processes in practice. Therefore, even when adding only some additional columns, their modified best practice of use is expected to be challenging in company development environments. In this sense, Table 2 is a guideline for the expected usability of the listed methods.

5 METHOD USABILITY ASSESSMENT USING TECHNICAL RESILIENCE CAPABILITIES

Sensor-logic-actor chains are basic functional elements used for active safety applications in safety instrumented systems, especially within the context of functional safety as governed by (IEC 61508 Series). The technical resilience capabilities can be considered as a generalization of such functional capabilities.

They can also be related to the much more abstract and generic OODA (observe, orient, decide, act) loop, which has found much application also in the catastrophe response arena, see e.g. (Lubitz et al. 2008; Huang 2015). The technical resilience capabilities are also very close to capabilities to be expected from a general artificial intelligence (Baum et al. 2010) and related possible architectures (Goertzel et al. 2008).

Table 3 assesses the suitability for use of the selected methods along each technical resilience capability dimension attribute. Since the technical resilience capabilities are generic properties of (socio) technical systems, the realization of the properties in systems is prone to risks: e.g. external and internal; accidental and intentional; safety and security related; systematic (by construction) and statistic.

In Table 3, the more generic system modelling methods SysML and UML are rated better when compared to more specific methods. Table 3 expresses with the uniform distribution of "+" that any resilience analysis conducted using the methods has to take into account all the technical resilience properties. This shows that major adaptations and further developments are necessary to apply classical methods, since a cross-cutting task has to be covered by the methods.

Table 3. Suitability of system modelling, analytical system analysis and selected development methods for resilience analysis along the technical resilience capability dimension attributes.

Method\ Technical resilience capabilities	(1) Observation, sensing	(2) Representation, modeling, Simulation	(3) Inference. decision making	(4) Activation, action	(5) Learning, modification, adaption, rearrangement
SysML	++	++	++	++	++
UML	+	++	++	+	++
HL	+	+	+	+	+
PHA	+	+	+	+	+
HA	+	+	+	+	+
O&SHA, HAZOP	+	+	+	+	+
FMEA, FMECA	+	+	+	+	+
FMEDA	+	+	+	+	+
RBD	+	+	+	+	+
ETA	+	+	+	+	+
DFM	+	+	+	+	+
FTA, TDFTA	+	+	+	+	+
Reliability prediction with standards	+	+	+	+	+
Methods for HW and SW development	+	+	+	+	+
Bit error correction methods	o	o	o	o	o

For instance, columns or labels could be added to assess to which type of system resilience function a system failure belongs in case of HA, FMEA and ETAs. Also FTAs top level event formulations either have to address the functional steps separately or find sufficient generic top level formulations allowing for combinations of top events.

6 METHOD USABILITY ASSESSMENT USING SYSTEM LAYERS

Table 4 assesses the potential of application of the representative methods of section 2 with the help of system layers for socio technical systems. The often used 4 layers physical, information, cognitive, social, see e.g. (Fox-Lent et al. 2015), have been refined in the physical-technical domain and more specified in all attributes when compared to (Häring et al 2016a).

The strength of the selected representative very specific methods is in the domain of hardware and data integrity as well as HW/SW development. Also the classical tabular methods focus somewhat on electronics, especially FMEDA.

Table 4. Suitability of system modelling, analytical system analysis and selected development methods for resilience analysis along system layers or generic management domains.

Method\ System layer, Management domain	(1) Physical	(2) Technical, hardware	(3) Cyber, software-wise, protocols	(4) Operational, organizational	(5) Societal, economic, ethical
SysML	++	++	++	+	+
UML	++	++	++	+	+
HL	+	++	+	o	o
PHA	+	++	+	o	o
HA	+	++	+	o	o
O&SHA, HAZOP	+	++	+	+	+
FMEA, FMECA	+	++	+	o	o
FMEDA	+	++	+	o	o
RBD	+	++	+	o	o
ETA	+	++	+	+	+
DFM	+	++	+	+	+
FTA, TDFTA	+	++	+	o	o
Reliability prediction with standards	–	++	–	o	o
Methods for HW and SW development	+	++	++	o	o
Bit error correction methods	–	+	++	o	o

Table 5. Suitability of system modelling, analytical system analysis and selected development methods for resilience analysis along modified resilience criteria.

Method\ Modified resilience criteria	(1) Robustness: low initial damage	(2) Redundancy: system property of overall damage tolerance	(3) Resourcefulness: fast stabilization and response	(4) Rapidity: fast recovery and reconstruction
SysML	+	++	++	++
UML	o	++	+	+
HL	+	o	–	–
PHA	+	+	–	–
HA	+	+	–	–
O&SHA, HAZOP	–	+	–	–
FMEA, FMECA	+	o	–	–
FMEDA	o	–	–	–
RBD	+	++	–	–
ETA	+	+	–	–
DFM	o	++	–	–
FTA, TDFTA	+	++	+	+
Reliability prediction with standards	–	–	–	–
Methods for HW and SW development	–	–	–	–
Bit error correction methods	–	–	–	–

The general purpose methods ETA, DFM, RBD and FTA require educated application, often out of their classical domain of application, especially HAZOP. RBD diagrams and SysML/UML methods are expected to be of use for acquiring and documenting sufficient system understanding.

HA-type methods are well suited but need to be applied out of their typical technical domain also to operational and societal system layers.

7 METHOD USABILITY ASSESSMENT USING RESILIENCE CRITERIA

Table 5 assesses the potential of application of the representative methods of section 2 with the help of the often used 4 resilience criteria introduced by (Bruneau et al. 2003) and technically refined by (Pant et al. 2014). For the suitability of method assessment, the following modified working definitions are used in this paper:

1. Robustness: measure for low level of damage (vulnerability) in case of event; 'good' absorption behavior; 'good' protection.
2. Redundancy: measure for low level of overall system effect in case of local (in space, in time, etc.) disruption event; system disruption tolerance.
3. Resourcefulness: measure for capability of successful allocation of resources in the response phase to stabilize the system post disruptions.
4. Rapidity: measure for fast recovery of system.

The results are similar to the suitability assessment along the logic or timeline resilience cycle phases as conducted in section 4: classical analytical approaches do not focus beyond the damage events. Robustness, resourcefulness and rapidity are according to the working definitions strongly related to the resilience cycle phases absorption/protection, response and recovery.

Redundancy is understood in the classical way as an overall system property. Hence in all cases sufficient system understanding is required, which is supported by graphical modelling.

The (also) graphical approaches RBD, ETA and FTA are strong for redundancy and resourceful-

ness assessment. Especially time dependent FTA and underlying time dependent Markov models are believed to be key for resourcefulness and redundancy assessment, nevertheless with major adaptations.

8 SUMMARY AND CONCLUSIONS

In summary, each of the representative analytical system analysis methods as well as HW/SW development methods (techniques and measures in the sense of (IEC 61508 Series)) showed potential for resilience engineering, i.e. resilience assessment and development and optimization as defined in the introductory sections.

The classical tabular approaches HA and FMEA are assessed to be suited with minor up to major modifications for resilience analytics. Major advantages are expected by redefining and adding dedicated columns to cover resilience aspects. Also graphical methods like RBD, ETA and FTA are tools that by definition cover at least technical aspects of resilience of systems in case of very informed application.

In all cases, the extensions and adaptions need to carefully consider the initial background and application context of the methods. Therefore, in case of technical resilience engineering contexts, it is expected that the methods have to be newly established. This holds since all these methods are prone to routinely use, which is often very contrary to the out-of-the box thinking necessary for resilience engineering. For instance, established hazard lists for an application domain will not contribute to an as complete as possible disruption threat list.

The different resilience dimensions used for suitability assessment exhibited strengths and weaknesses for exploring the methods' potentials:

- The risk management cycle is a very generic process, allocating most analysis methods in the risk analysis step. Resilience objectives formulation is key and challenge.
- Resilience cycle (time or logic) phases allow to spread out assessments and activities. However, they are prone to 'divide et impera' effects of losing the overall picture.
- Technical resilience capabilities need to be covered for the operation of typical system (service) functions on overall system level allowing a technical approach. It is deemed challenging how to modify and extend classical methods to cover them.
- Traditional resilience criteria ("Resilience Rs") can be nicely linked to timeline/logic concepts as well as system redundancy assessments. They also link with performance-based resilience curve assessments. Challenges are expected when trying to translate the more abstract concepts into system analysis and development requests.

In summary, future work is expected to benefit from informed further development of classical system analysis methods for resilience analysis. Such resilience analytics is believed also to strongly support the development of resilient systems, in particular in industrial environments. Such informed applications are expected to ripe many of the benefits listed in the bullet list of the introduction.

ACKNOWLEDGEMENTS

This research has been conducted in the context of the Freiburg Sustainability Center of Excellence, a cooperation of the Fraunhofer institutes in Freiburg and the Albert-Ludwigs-University Freiburg. It is supported by grants from the Baden-Württemberg Ministry of Economics and the Baden-Württemberg Ministry of Science, Research and the Arts. In parts, the work has also been supported by the German BMBF Project "Windows for continuous academic education" within the Sub-Project "Resilient Technical Systems". Thanks goes also to master students of security and safety engineering of the Hochschule Furtwangen University.

Interdependent infrastructure network restoration from a community resilience perspective

K. Barker, D.B. Karakoc & Y. Almoghathawi
University of Oklahoma, Norman, OK, US

ABSTRACT: Many critical infrastructure networks that dot the global landscape often rely on each other in different ways for each to be functional. Government planning documents around the world recognize the interdependence of these infrastructure networks. But naturally infrastructure networks do not exist for their own operation but because society relies upon them for convenience, productivity, and health, among others. Recent large-scale disruptions to critical infrastructure, primarily due to natural disasters whose frequency appears to be increasing, have left communities devastated for extended periods. As such, planning for the resilience of critical cyber-physical-social networks should emphasize the social aspects of disruptions. In this work, we study the problem of the restoration of interdependent infrastructure networks after the occurrence of a disruptive event with a focus on the vulnerability of the society that interacts with the networks. We integrate (i) a resilience-driven multi-objective mixed-integer programming formulation that schedules the restoration of disrupted demand nodes in each network with (ii) a geographically distributed index of social vulnerability that measures the impact to the community surrounding the disrupted demand nodes. This model integration is illustrated with an example of community resilience in Shelby County, Tennessee.

1 INTRODUCTION

A *critical infrastructure network* is defined as a network of independent, mostly privately-owned, human-made systems and processes that function collaboratively and synergistically to produce and distribute a continuous flow of essential goods and services (The Report of the President's Commission on Critical Infrastructure Protection 1997). Such infrastructure networks, such as electric power, water distribution, natural gas, transportation, and telecommunications, operate on a daily basis to maintain the functioning of modern societies and to provide their essential needs.

With the continuous technological developments, infrastructure networks and their distribution systems become more dependent on each other's functionality to perform with higher efficiency (Rinaldi et al. 2001). However, this type of a complex coordination and interconnection on various aspects such as sharing components, utilizing one's output as another's input, transmitting information and much more, make critical infrastructure networks more vulnerable against possible disruptive events (Rinaldi et al. 2001). This (often bi-directional) relationship among these networks enhances the possibility of chain reactions between the disrupted and undisrupted components where one infrastructure network might lead the failure of another one due to their high interdependency (Little 2002, Wallace et al. 2003, Buldyrev et al. 2010, Eusgeld et al. 2011, Ouyang 2014, Danziger et al. 2016, Wu et al. 2016). Therefore, resilience planning in the form of restoration scheduling of these potentially highly vulnerable networks becomes more challenging especially when the increasing frequency of man-made or natural disruptive events considered.

In the literature, many different approaches have been introduced to quantify the resilience of a network where the ability to withstand, adapt to, and recover from a disruption is referred as resilience (Barker et al. 2017). As shown in Figure 1, consider two primary dimensions of resilience: vulnerability and recoverability (Henry and Ramirez-Marquez 2012, Barker et al. 2013). The vulnerability of a network is defined as the magnitude of damage

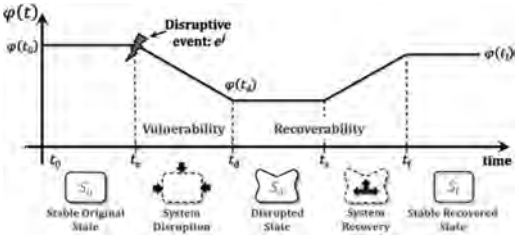

Figure 1. Network performance, φ(t), across state transitions before, during, and after the occurrence of a disruptive event.

in network performance due to a disruptive event (Jönsson et al., 2008), where the recoverability of a network describes the speed at which the network reaches to a desired performance level (Rose 2007). Resilience can be defined as the time dependent ratio of network recovery over its loss (i.e. $Я(t) = \text{Recovery}(t) / \text{Loss}(t)$where $Я_{\varphi}(t \mid e^{j}) = 1$ indicates that network is fully resilient [Henry and Ramirez-Marquez 2012]).

Recent research has explored the relationship between critical infrastructure networks are interrelated with the geographical vulnerabilities of the local regions where they are built and the social vulnerabilities of their surrounding communities (Cutter and Finch 2007). The specific and varying demographics of the communities that these critical infrastructures provide service to can be considered as the key factors to guide response and restoration operations.

In this initial study, we have considered a social vulnerability index as a community resilience measure which is a function of predetermined demographic factors of a community (Cutter et al. 2003). The weighted sum of these factors assigns relative vulnerability scores to disrupted components of the interdependent infrastructure networks according to the region in which they are located. In addition to the social vulnerability index, we have also considered the population density of the community whose interdependent infrastructure network service is disrupted.

2 SOCIAL VULNERABILITY INDEX

Different levels of socio-economic conditions and distinguishing properties of a community shape its resilience against disruptive events by either contributing to or counteracting its vulnerability. In their work on the Social Vulnerability Index (SoVI), Cutter et al. (2003) identify eleven key factors that contribute to measuring the vulnerability of a community including the age, gender, race, wealth, and occupation of members of the community.

A significant level for each of the factors has been identified and the percentage of population that is below these limits are considered as more vulnerable to disruptive events and, therefore, contributors to the overall social vulnerability. Due to their higher vulnerability, it is noted that through the recovery process, these subgroups would require more time and investment of resources to achieve a resilience level similar to the other communities (Cutter et al. 2003).

The SoVI-Lite technique (Cutter et al. 2011, Evans et al. 2014) is a reduced version of the SoVI that calculates a community's vulnerability score with the following steps:

1. Calculate the percentage of population that falls beyond the predetermined level of vulnerability for each factor,
2. Calculate the *z*-score of each factor by using mean and standard deviation of each factor, and
3. Sum the *z*-scores of all factors to find the total social vulnerability score of a specific community.

Furthermore, the SoVI-Lite score can be scaled between 0 and 1 using Eq. (1), where 0 represents the least socially vulnerable community and 1 is the most socially vulnerable community.

$$\frac{z - \min(x)}{\max(x) - \min(x)}, \forall\ z \in X \tag{1}$$

3 PROPOSED MODEL

In this study, we have proposed a multi-objective resilience-driven restoration optimization model using mixed-integer programming, where our main goal is to maximize the resilience of interdependent infrastructure networks while minimizing the total cost associated with the entire restoration phase (Almoghathawi et al. 2017). We have integrated social vulnerability index into the objectives to help guide interdependent infrastructure network restoration from a community resilience perspective.

Let K represent a set of infrastructure networks, $K = \{1, \quad, \kappa\}$, and T represent a set of available time periods, $T = \{1, \quad, \tau\}$. For each network $k \in K$, the sets of nodes and links are represented by N^k and L^k, respectively. The sets of source nodes and demand nodes are defined with $N_s^k \subseteq N^k$ and $N_d^k \subseteq N^k$, respectively. The sets of disrupted nodes and links are denoted by $N'k$ and $L'k$, respectively.

Let b_i^k be the maximum amount of supply at node $i \in N_s^k$ in network $k \in K$, considered to be the maximum flow from node $i \in N_s^k$ to all demand nodes in network $k \in K$. The amount of unmet demand at node $i \in N_d^k$ in network $k \in K$ in time $t \in T$ is denoted by s_{it}^k. Total unmet demand at all demand nodes in network $k \in K$ after recovery at time period $t \in T$ is $\sum_{i \in N_d^k} s_{it}^k$.

To introduce the social vulnerability index into the model, the SoVI-Lite score, $SoVI_i^k$, is calculated for node $i \in N'_d{}^k$ in network $k \in K$. To more effectively emphasize the social vulnerability index, Eq. (2) introduces an exponential effect to give more relative importance to nodes in socially vulnerable areas with V_i^k.

$$V_i^k = e^{b * SoVI_i^k}, \forall\ i \in N'_d{}^k, b \in Z \tag{2}$$

Additionally, population density was also included in the proposed model, where densities were assigned to demand nodes to more effectively place importance on them during the restoration process. P_i^k is the population density for demand node $i \in N_d^k$ in network $k \in K$, shown in Eq. (3).

$$P_i^k = \frac{\text{population of community where node } i \text{ is located}}{\text{total population of area being studied}}, \quad \forall i \in N_d'^k \tag{3}$$

The unmet demand in the network represents the system loss in the maximum flow which will be caused by disruptive event. In this manner, decreasing the total amount of unmet demand to a desirable level refers to the effectiveness of restoration process and a reasonable recoverability level of the network. Hence, the resilience of the system could be represented by Eq. (4) where it is the ratio of total unmet demand that is recovered over total amount of unmet demand after the disruption occurs. This equation represents cumulative recovery of the interdependent infrastructure networks over time $t \in T$ where Q_i^k is the unmet demand at demand node $i \in N_d^k$ in network $k \in K$ after a disruption and μ_i^k is the weight of demand node $i \in N_d^k$ in network $k \in K$ such that $\sum_{k \in K} \sum_{i \in N_d'^k} \mu_i^k = 1$.

$$\sum_{k \in K} \sum_{i \in N_d'^k} \frac{\mu_i^k}{\tau\left(Q_i^k V_i^k P_i^k\right)} \cdot \left[\sum_{t=1}^{T} \left[t\left(\left(Q_i^k V_i^k P_i^k\right) - \left(s_{it}^k V_i^k P_i^k\right)\right) - (t-1)\left(\left(Q_i^k V_i^k P_i^k\right) - \left(s_{i(t-1)}^k V_i^k P_i^k\right)\right)\right]\right] \tag{4}$$

The other objective of the restoration process minimizes the total cost associated with the restoration process. The fixed restoration cost for disrupted nodes and links are fn_i^k for $i \in N'^k$ and f_{lij}^k for $(i,j) \in L'^k$, respectively. The unitary flow cost through link $(i,j) \in L'^k$ is c_{ij}^k and p_i^k is the unitary unmet demand cost for node $i \in N'^k$. The binary decision variable z_i^k equals 1 if the node $i \in N'^k$ is restored and 0 otherwise, and y_{ij}^k is also a binary decision variable that equals 1 if link $(i,j) \in L'^k$ is restored and 0 otherwise. Finally, x_{ijt}^k is the non-negative decision variable that represents the total flow through link $(i,j) \in L'^k$ in network $k \in K$ at time $t \in T$. Therefore, the total cost of the restoration process can be represented as Eq. (5).

$$\sum_{k \in K}\left(\sum_{i \in N'^k} fn_i^k z_i^k + \sum_{(i,j) \in L'^k} fl_{ij}^k y_{ij}^k + \sum_{t \in T}\left[\sum_{(i,j) \in L^k} c_{ij}^k x_{ijt}^k + \sum_{i \in N_d^k} p_i^k s_{it}^k V_i^k P_i^k\right]\right) \tag{5}$$

In network $k \in K$, the restoration duration for node $i \in N'^k$ and link $(i,j) \in L'^k$ are dn_i^k and dl_{ij}^k, respectively. The link capacity is u_{ij}^k for link $(i,j) \in L'^k$. The binary decision variable β_{it}^k equals 1 if node $i \in N'^k$ is operational and 0 otherwise, where binary decision variable α_{ijt}^k is 1 if the link $(i,j) \in L'^k$ is operational and 0 otherwise in network $k \in K$ at time $t \in T$. For each network $k \in K$, R^k represents the available work crews or resources that are specific to network k (e.g., in terms of work crew expertise and restoration equipment). The scheduling variables are denoted by binary variables γ_{it}^{kr} and δ_{ijt}^{kr}, respectively, for node $i \in N'^k$ and link $(i,j) \in L'^k$, where they are equal to 1 if restoration of the related component is completed by work crew $r \in R^k$ at time $t \in T$ and 0 otherwise. Finally, the network interdependencies are denoted by $\left((i,k),\left(\bar{i},\bar{k}\right)\right) \in \Psi$ that node $\bar{i} \in N^{\bar{k}}$ in network $\bar{k} \in K$ depends the functionality of node $i \in N^k$ in network $k \in K$. The complete version of the proposed mathematical model is as follows.

$$\max \sum_{k \in K} \sum_{i \in N_d^k} \frac{\mu_i^k}{\tau\left(Q_i^k V_i^k P_i^k\right)}\left[\sum_{t=1}^{T}\left[t\left(\left(Q_i^k V_i^k P_i^k\right) - \left(s_{it}^k V_i^k P_i^k\right)\right) - (t-1)\left(\left(Q_i^k V_i^k P_i^k\right) - \left(s_{i(t-1)}^k V_i^k P_i^k\right)\right)\right]\right]$$

$$\min \sum_{k \in K}\left(\sum_{i \in N'^k} fn_i^k z_i^k + \sum_{(i,j) \in L'^k} fl_{ij}^k y_{ij}^k + \sum_{t \in T}\left[\sum_{(i,j) \in L^k} c_{ij}^k x_{ijt}^k + \sum_{i \in N_d'^k} p_i^k s_{it}^k V_i^k P_i^k\right]\right)$$

Subject to:

$$\sum_{(i,j) \in L^k} x_{ijt}^k \le b_i^k, \qquad \forall i \in N_s^k, k \in K, t \in T$$

$$\sum_{(i,j) \in L^k} x_{ijt}^k - \sum_{(j,i) \in L^k} x_{jit}^k = 0, \qquad \forall i \in N^k \setminus \left\{N_s^k, N_d^k\right\}, k \in K, t \in T$$

$$\sum_{(j,i) \in L^k} x_{jit}^k + s_{it}^k = b_i^k, \qquad \forall i \in N_d^k, k \in K, t \in T$$

$$x_{ijt}^k - u_{ij}^k \le 0, \qquad \forall (i,j) \in L^k, k \in K, t \in T$$

$$\gamma_{it}^{kr}\in\{0,1\}, \qquad \forall i\in N'^k, k\in K, t\in T, r\in R^k$$

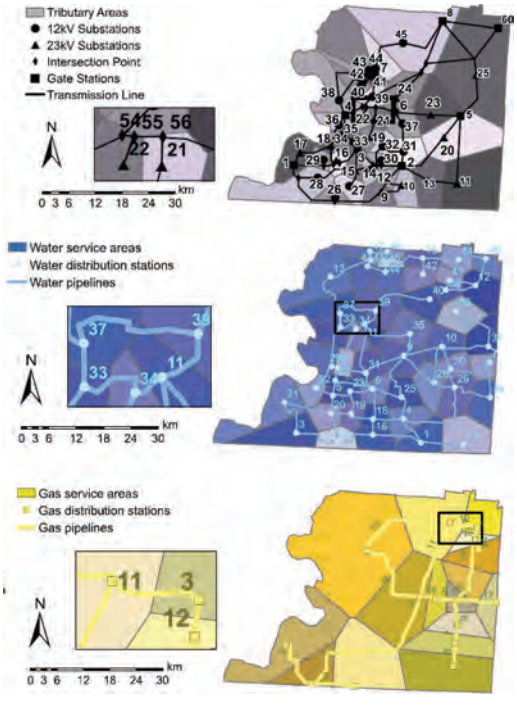

Figure 2. Critical gas, water, and power infrastructure networks of Shelby County, TN, respectively (González et al., 2016).

4 IUSTRATIVE EXAMPLE

In this study, the proposed model is illustrated with data collected for Shelby County, Tennessee in the United State, a location in the New Madrid Seismic Zone at risk of earthquake (González et al., 2016).

Three critical interdependent infrastructure networks, water, gas, and power distribution systems as shown in Figure 2, were examined. We consider a disruptive scenario consisting of a total of 43 disrupted components, 19 of which are demand nodes. We assigned two work crews for each network and time horizon of 23 periods in total.

Figure 3 represents five districts in Shelby County. To relate unmet demand in the three infrastructure networks to adverse community effects, SoVI-Lite was calculated for the five districts guide the restoration process with community resilience in mind. The demand nodes in each district were assigned the different V_i^k value that is specific to that district.

The SoVI-Lite algorithm (Cutter et al., 2011, Evans et al., 2014) was implemented using the available variables for Shelby County to cover the

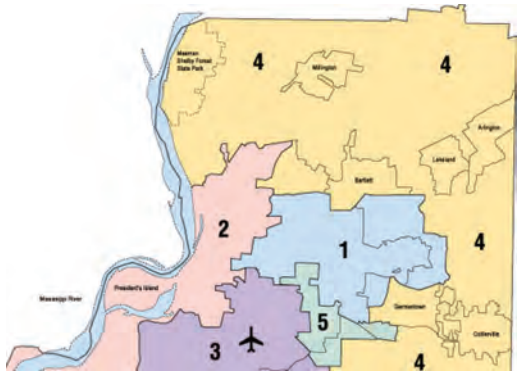

Figure 3. Representation of five districts in Shelby County, TN (www.smartcitymemphis.com).

eleven key factors, shown in Table 1. As shown in Figure 4, District 5 is assigned with the highest scaled SoVI, indicating that it may be given a higher priority in the restoration process. Figure 5 illustrates the exponential transform of the SoVI score, V_i^k, where District 5 stands out substantially from the other districts. Population density, P_i^k,

Table 1. SoVI-Lite algorithm variables for Shelby County, TN.

SoVI-Lite Variables
% of population that lives in poverty
% of population that is over 65
% of population that is under 5
% of population earning less than $75,000 per year
% of population lives in a single-mother household
% of population that is female
% of population that is Hispanic
% of population that is African-American
% of population that is Asian
% of population that isn't high school graduate
% of population that relies on food stamps
% of population that is unemployed
% of population works in low-skilled service jobs
% of population that speaks English as 2nd language

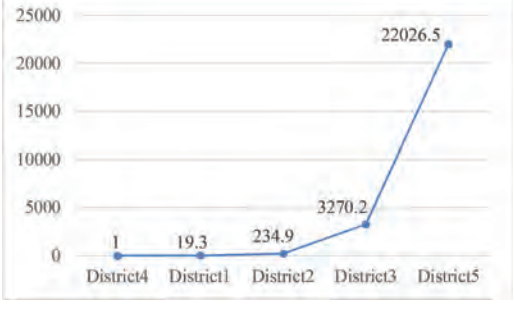

Figure 5. Exponentially increasing social-vulnerability scores for the districts of Shelby County, TN for b = 10.

was also calculated by and assigned to each district through the study.

The multi-objective problem was solved using the ε-constraint method where the resilient constraint was assigned values such that $\varepsilon \in [0,1]$ as in Eq. (6) (Almoghathawi et al., 2017).

$$\sum_{k\in K}\sum_{i\in N'^{k}_{d}}\frac{\mu_i^k}{\tau\left(Q_i^k V_i^k P_i^k\right)} \cdot\left[\sum_{t=1}^{T}\left[t\left(\left(Q_i^k V_i^k P_i^k\right)-\left(s_{it}^k V_i^k P_i^k\right)\right)-(t-1)\left(\left(Q_i^k V_i^k P_i^k\right)-\left(s_{i(t-1)}^k V_i^k P_i^k\right)\right)\right]\right] \geq \varepsilon \quad (6)$$

Tables 2, 3, and 4 are subset comparisons of the restoration optimization model results where second column represents the schedule without SoVI and population density factors and the third column represents the scheduling with consideration of those factors.

"Without SoVI and population density" refers to the removal of the V_i^k and P_i^k terms from the vulnerability objective function. Note how the ranking, that is, the order in which those particular components of the individual networks would be restored, differs when community resilience

Table 2. Water network restoration schedule comparison with and without considering social-vulnerability.

measures are taken into account. The trajectory of recovery, as measured by unmet demand over time, is depicted in Figures 6 and 7, comparison of total unmet demand with and without consideration of the community resilience perspective. Naturally, the figures display a different trajectory as a different priority is given to meeting demand at the demand nodes of the different networks.

5 CONCLUDING REMARKS

Critical infrastructure networks often rely on each other. However, such dependent and interdependent relationships potentially result in these networks being more vulnerable to disruption. However, not only physical infrastructure networks are adversely impacted, as the communities that rely on those networks can also be significantly disrupted. As such, restoration planning and resource allocation should account for disrupted communities in addition to disrupted physical infrastructure networks.

In this paper, we have studied the restoration process planning and scheduling with (i) social vulnerability and (ii) population density in mind. Social vulnerability was calculated using an established index, a variation on the Social Vulnerability Index (Cutter et al. 2003, 2011), that accounts for several age, income, race, and educational attainment dimensions.

This community resilience perspective was added to a multi-objective resilience-driven restoration model using mixed-integer programming. The objective of the model was maximizing the cumulative community resilience of the interdependent networks over time while also the total cost associated with the restoration process is minimized.

For the results of our study, we have found that accounting for community resilience measures impacts the restoration schedule of disrupted infrastructure networks. While more future work will follow up this initial study, at a minimum we have demonstrated that different restoration priorities are found when we account for the vulnerability and the density of the population associated with unsatisfied demand in the interdependent networks. The community resilience perspective should be emphasized in future research.

Resilience assessment of smart critical infrastructures based on indicators

K. Øien & L. Bodsberg
SINTEF Technology and Society, Trondheim, Norway

A. Jovanović

Steinbeis Advanced Risk Technologies GmbH, Stuttgart, Germany

ABSTRACT: The resilience of modern societies is to a large degree determined by the resilience of their Critical Infrastructures (CI). These infrastructures are critical because interruptions not only influence the infrastructures themselves, but loss of functionality has secondary effects on the society. The use of smart technologies makes these "Smart" CIs (i.e. SCIs) increasingly interdependent and vulnerable to various hazards, such as terror attacks, cyber-attacks and extreme weather. The EU H2020 research project SmartResilience has developed a baseline resilience assessment method, which measures the level of resilience indirectly through a selection of resilience indicators considered relevant by the user of the SCI in question. Other methods have also been developed in SmartResilience, but this paper focus on the development and application of the baseline resilience assessment method and the development and collection of resilience indicators used in the assessment method. The application is demonstrated using a production facility as a case.

1 INTRODUCTION

The power grid in Ukraine was cyber-attacked both in 2015 and 2017. The attack in 2015 was a complex and pervasive attack on three energy distribution companies, resulting in about 230 thousand people being left without electricity for a period from 1 to 6 hours (Wikipedia 2017). Energy supply systems, such as those attacked in Ukraine, are examples of critical infrastructures (CIs); *critical* because their functions are vital for the society.

Smart technologies are introduced in infrastructures to maximize the service they provide using intelligent systems. Thus, the term S*mart* Critical Infrastructure (SCI) is introduced. However, smart features may also make the SCIs more vulnerable, e.g. by providing a gateway for hackers and cyber-terrorists.

The need to defend these SCIs has been recognized for decades through e.g. Critical Infrastructure Protection (CIP) programs. However, in recent years, it has been realized that with increasingly complex and interdependent infrastructure systems, CIP is not enough (HSAC 2006). It is not enough to focus on protection of a CI from events like cyber-attacks, terror attacks and extreme weather, because the complexity and interdependencies makes it virtual impossible to foresee and prevent all scenarios, and when they occur—no matter how unlikely—it is vital for society that the loss of functionality is minimized, e.g. that the CIs are up and running as soon as possible after an event.

A shift of the focus from CIP towards CIR, i.e. Critical Infrastructure *Resilience* has been observed. "Overall, a resilience-based approach for CI is an approach that is gradually adopted by nations in order to face the challenges and costs of achieving maximum protection in an increasingly complex environment and to overcome limitations of the traditional scenario-based risk management approach, where the organization may lack capabilities to face risk from unknown or unforeseen threats and vulnerabilities" (Setola et al. 2016).

Resilience is not a straight-forward term. It has many different applications and a broad scope. A helpful review paper providing insights into the term and its history is Alexander (2013). Suffice to state here is that although the term was unfamiliar within risk of critical infrastructures in the US some ten years ago (HSAC 2006), it is now a well-recognized term. Resilience is also a familiar everyday term in English speaking countries, but it is not easily understood by lay people when translated to other languages. In addition, the CIR approach is relatively new in the EU compared to the US. This

gives some challenges for the implementation of CIR in EU and the single EU member states.

Recognizing the challenges with the term resilience, the questions are still: How can we make a system like the energy system in Ukraine, and other SCIs, resilient against cyber-attacks and other relevant threats? How can we know—and measure—the level of resilience of an SCI? These are the challenges that the EU H2020 project SmartResilience (2016) is set out to solve. It answers the DRS-14 call, which explicitly asks for an indicator-based approach.

Several methods and tools for assessing and monitoring resilience are developed in the SmartResilience project. In this paper, we present the baseline resilience assessment method measuring the Resilience Level (RIL) of SCIs through resilience indicators. We denote this as the "RIL method" in the following. It is based on review, adaptation and further development of relevant reference methods having their roots in high reliability theory (Wreathall 2006), resilience engineering (Woods 2006) and critical infrastructure resilience (Fisher et al. 2010).

The resilience indicators have been developed (identified and/or proposed) mainly by the case study partners in the SmartResilience project, covering a range of different critical infrastructures. They are stored in a database as "candidate" resilience indicators, i.e. the users select the most relevant indicators for their case from the candidates in the database, or add new indicators, when necessary.

Based on the selected set of resilience indicators, the RIL method provides a level of resilience on a scale from E (worst) to A (best) for one specific SCI, or several SCIs, within an area. In addition to an overall level of resilience, that can be trended periodically, the results point to areas where improvements are most needed. In this paper, the application of the RIL method is demonstrated for a production facility.

The description of the development of the RIL method and the resilience indicators are based on Øien et al. (2017a-c). Earlier versions of the Smart-Resilience methodology are also presented in Jovanović et al. (2017a; 2018).

1.1 *Concepts and definitions*

In the SmartResilience project, the *resilience* of an infrastructure is defined as: "The ability to anticipate possible adverse scenarios/events (including the new/emerging ones) representing threats and leading to possible disruptions in operation/functionality of the infrastructure, prepare for them, withstand/absorb their impacts, recover from disruptions caused by them and adapt to the changing conditions" (Jovanović et al. 2016).

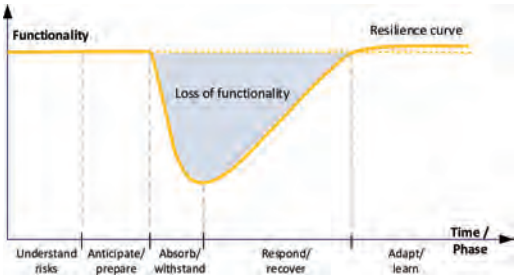

Figure 1. Resilience phases in the resilience curve/cycle.

Based on this definition, we derive at the following five *phases* of the resilience curve/cycle: understand risks, anticipate/prepare, absorb/withstand, respond/recover, and adapt/learn. The five phases, representing the main resilience attributes in SmartResilience, are illustrated in Figure 1.

Each of the phases are measured by indicators through the most important "issues" affecting each of the phases.

An *issue* is a very general term referring to anything (factors, conditions, functions, actions, capacities, capabilities, etc.) that is important in order to be resilient against severe threats such as terror attacks, cyber threats and extreme weather. It is *what* is important, and it is allocated to one of the five phases in the resilience cycle. E.g., it can be "training" performed in the anticipate/prepare phase.

An *indicator* is the description of *how* to measure an issue. Any type/form of indicators are considered appropriate in the RIL method, meaning that they can be yes/no questions, numbers, percentages, frequencies, or some other type. E.g., it can be "percentage of personnel in a certain response team taken a certain course".

2 METHOD DEVELOPMENT

The RIL method is an indicator based approach consisting of two main parts; the resilience assessment method itself and the indicators used to measure the resilience level. The development of the two parts are described in the following.

2.1 *Resilience assessment method*

The RIL method has its roots in high reliability organization theory (EPRI 2000, 2001) and resilience engineering (Øien 2010, 2012; Øien & Nielsen, 2012; Øien et al. 2012), but also more resent resilience developments within critical infrastructures, especially in the US (e.g. Petit et al. 2013, Linkov et al. 2014).

2.1.1 *The ANL method*

The Argonne National Laboratory (ANL) method for assessing a resilience index (RI) (Fisher et al., 2010), or a resilience measurement index (RMI), as it is termed in the most recent version (Petit et al. 2013), is structured in five (or six) levels, providing indicators on the lowest level. A similar hierarchy is used in the SmartResilience project for assessing resilience levels, entering the indicators on level 6. The structure is comparable in the two approaches, and many of the resilience attributes are the same; however, the level at which the various resilience attributes are found, differs between these two methods.

2.1.2 *The LIOH method*

The Leading Indicators of Organizational Health (LIOH) method focused on developing indicators for a set of seven themes important for the "health" of a nuclear power plant, some of which have their roots from the research on high reliability organizations (HRO) (Wreathall 2006). They also formed part of the basis for factors considered important in resilience engineering. In addition to *themes*, LIOH uses *issues* and *indicators* as the three levels in the structure of the method.

The LIOH method is a contributory-based method in which the users of the indicators take part in workshops and define their own issues (general and nuclear power plant—NPP—specific) for each theme, and for each issue they define indicators. There are no predefined examples of issues prior to the workshops, and no proposals or "candidate" indicators are in place prior to the workshops.

The case studies of the LIOH method show that there is often only one level of issues used, i.e. the issues are not divided into general and NPP issues (EPRI 2000, 2001). A second observation is that the results (the issues and indicators defined) from identical power plant units are very different. The reason for this difference is that there is no guidance with respect to issues and indicators (no a priori "candidates"), and that there have been different participants in the workshops in each of the case studies.

2.1.3 *The REWI method*

The idea of combining the issues into one common level was brought further to the Resilience-based Early Warning Indicator (REWI) method (Øien et al. 2010, 2012); using three levels to identify early warning indicators for resilience, i.e. starting with resilience attributes, followed by issues important for these resilience attributes, and finally developing indicators to measure the issues. In REWI, the level of resilience attributes is not termed themes as in LIOH, but rather *contributing success factors* (CSFs). Thus, the structure consists of *CSFs*, *issues* and *indicators*.

The CSFs are structured in two levels, of which the lowest level consists of eight factors, or resilience attributes. The CSFs at the first level are: risk awareness, response capacity, and support. The CSFs at the second level are: risk understanding, anticipation, attention, response, robustness (of response), resourcefulness/rapidity, decision support, redundancy (for support). The CSFs represent the REWI operationalization of the concept of resilience, similar as themes are used in LIOH and phases are used in the Smart-Resilience project. The CSFs are partly, but not entirely, sequential. For each CSF, there is a set of issues contributing to the fulfillment of the goals of the CSF. There is only one level of issues—denoted general issues—for which indicators are developed. The CSFs were developed based on a literature review and an empirical study on successful recovery of high-risk incidents; thus, the term *contributing success factors* (Størseth et al. 2009).

The REWI method consists of a predefined set of issues and a set of candidate indicators for each issue. This is a main difference compared to the LIOH method, and makes it less "open ended". However, it is still a contributory-based method and new issues may be added. The predefined set of issues and sets of candidate indicators "forces" the participants to assess the a priori set of general issues and candidate indicators. Thus, it counteracts the tendency to identify indicators during workshops just as random "indicators of the day".

The issues are just candidates, which may be considered appropriate or rejected, and additional issues may be included. After selecting the important issues, the next step is to consider how to measure them. How well are we doing with the selected issues? What would tell me that we are doing well (or have problems) with a specific issue? What information do we have about this? This is the role of the indicators.

The issues we try to measure, and the indicators we use to measure the issues, are two different things. The indicator will typically be described as a number, ratio, score on some scale, or similar. Without this type of specification or operationalization, we are left with just a theoretical issue. We cannot start with the indicators either, since we need to know what we want to measure (i.e. the issues) and why.

2.1.4 *The SmartResilience RIL method*

Like the LIOH method and the REWI method, the RIL method uses *issues* and *indicators* on the two lowest levels of the structure, whereas *phases* are used on the next higher level, compared to themes in LIOH and contributing success factors

in REWI. For each of the phases, issues that are important for them are identified, and indicators to measure the issues are developed.

In addition, the issues (and corresponding indicators) may be structured according to five *dimensions*, which are system/physical, information/data, organizational/business, societal/political, and cognitive/decision-making (Jovanović et al. 2016). The phases and dimensions forms what is denoted the Resilience Matrix, commonly used in several resilience assessment methods (e.g. Linkov et al. 2014). However, in the SmartResilience project, dimensions are only optionally used for structuring and triggering the identification of issues and indicators. Only phases are directly included in the quantification, i.e. it is the columns in the Resilience Matrix that are of interest, not the rows (or the single cells) in the matrix.

The SmartResilience RIL method has been developed through several iterations, including input from user requirements (Buhr et al. 2016), test case use, and feedback from case study partners in workshops and through a questionnaire (Jovanović et al. 2017b). A description of the resulting method is provided in Section 3.1.

2.2 *Resilience indicators*

The candidate issues and indicators collected in the SmartResilience project are to a large degree provided by the partners from existing standards, guidelines and reports within the areas of risk, safety, security, crisis management, business continuity and similar domains.

Resilience is considered an "umbrella" term (Setola et al. 2016), covering all the mentioned domains; thus, the term *resilience indicators* may include risk indicators, safety indicators, etc. The umbrella concept is illustrated in Figure 2.

In addition to standards, guidelines and reports, some indicators are based on what the case study providers already are using, and some indicators are developed as part of the project. Figure 2 also illustrates that the resilience concept in general and the resilience indicators, aim at capturing the unexpected, by using the metaphor "rain from a blue sky".

Candidate issues and indicators are stored in a database, and reported in Øien et al. (2017a), representing the status of the collected issues and indicators approximately half way through the project.

In addition, Øien et al. (2017c) present generic candidate issues (without indicators) covering more genuine resilience issues, i.e. capturing topics typically discussed in the resilience literature. The two main sources are the guideline for implementing the REWI method (Øien et al. 2012), and an emergency preparedness plan developed by SINTEF

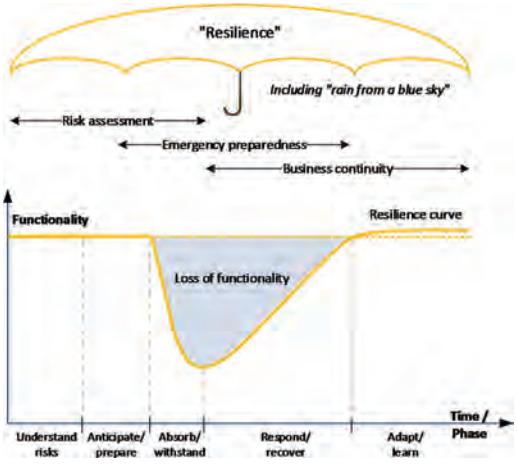

Figure 2. Resilience as an "umbrella" term.

(2014). Some issues are derived from IMPROVER (2016), a few from RESILENS (2016a, b), and the rest is based on input from SINTEF as part of the SmartResilience project. Some issues are taken directly from the original sources, whereas others are slightly adapted. Only for those generic candidate issues that are considered relevant for each user, indicators need to be developed.

A presentation of the collected candidate issues and indicators is provided in Section 3.2.

3 RESULTS

3.1 *The SmartResilience RIL Method*

3.1.1 *Model*

The three lower levels (level 4–6) of the hierarchical model are phases, issues and indicators, as described in Section 2.1. In addition, the overall structure consists of three more levels. The first level is the area level, e.g. a city. The second level consists of the smart critical infrastructures (SCIs), and the third level defines the threats. This is illustrated in Figure 3.

3.1.2 *Method steps*

At each level, the scores—alternatively combined with weights—corresponds to a certain resilience level (RIL) given by a character E-A, where E is worst, and A is best. A weighted score between 0–1 corresponds to resilience level E, a weighted score 1–2 corresponds to resilience level D, and so on.

The method steps are as follows:

Step 1: Select the area, e.g. a smart city
Step 2: Select the relevant SCIs for the area
Step 3: Select relevant threats for each SCI

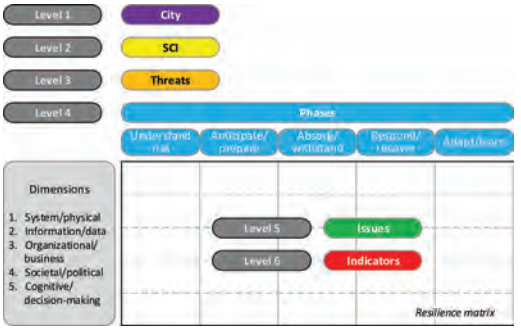

Figure 3. The six levels in the hierarchical model.

Step 4: Consider each phase for each threat
Step 5: Define the issues within each phase
Step 6: Search for the indicators for each issue
Step 7: Determine the range of values for each indicator (and optionally assign weights)
Step 8: Assign values to the indicators
Step 9: Perform the calculations (scores and RILs)
Step 10: Use the results and make decisions

The method steps have been described in Jovanović et al. (2017a) and we will only focus on the changes that have been made lately. This apply to Steps 7 and 9.

The indicators real values are collected and transformed to a *score* (or rating) on a scale from 0 (worst) to 5 (best). This requires the determination of best and the worst values for each indicator, i.e. Step 7. This part is simplified by using five categories, or value ranges (Øien et al. 2017b).

At every level, there is a possibility to give *weights*; however, we recommend being restrictive with the use of different weights. It is challenging to substantiate the assignment of weights (who and how), and the assignment itself can easily be criticized. Thus, equal weights are the default values at all levels. However, if different weights are considered necessary, we now propose using a simple type of pairwise comparison (Øien et al. 2017b). It can also be considered to include weights after gaining some experience, i.e. "tuning" the assessment.

In Step 8, the values are assigned to the indicators, i.e. the measurement itself is performed, and in Step 9 scores are calculated, first on the indicator level, and then aggregated upwards through all levels until the area level. On each level in the hierarchy, the scores can be transformed to resilience levels. This is new, and also the use of characters E-A is new; previously a scale 0–10 was used for RILs, and the transformation from scores to RILs only took place at the phase level (Øien et al. 2017b).

The use of the results, in Step 10, is described in Section 3.3.

3.1.3 *Special topics*

The way cascading effects, dependencies and interdependencies, interoperability, and smartness opportunities and vulnerabilities are treated in the RIL method is briefly described below. We strive for a good balance between the comprehensiveness of the analysis framework and the simplicity of understanding and using the framework. Thus, the specific topics have been addressed explicitly, but relatively simplistic.

Cascading effects where the SCI in question is affected from the outside should be *treated as a specific threat* e.g. toxic cloud, flooding, etc. If the effect is in the form of loss of service, then it is treated as dependencies as part of Step 5, i.e. explicitly as issues. Internal escalation of an event is also treated explicitly as issues (Step 5) reflecting the required safety systems or barriers needed to prevent escalation.

Critical infrastructures, or other infrastructures, services or systems that the SCI are dependent on, should be *addressed explicitly as issues* in the relevant phases for the relevant threats. This could e.g. be the need for redundant energy supply or communication networks. Interdependencies are treated in the same way. The difference is that the SCIs being dependent on "your" SCI, need to explicitly include this as issues in their resilience assessment.

If interoperability is an internal concern e.g. interoperable communication systems, then it should be *treated as an issue*. If it is related to external interoperability in the sense of external backup systems, e.g. "bus for train", then it should be included explicitly as an issue (e.g. cooperation agreements) if this is the responsibility of the SCI being assessed.

The relevance of smartness opportunities and smartness vulnerabilities related to smart features (sensors, gateways, processors, actuators, etc.) should be considered *explicitly as issues* in each phase.

3.2 *The collection of issues and indicators*

Øien et al. (2017c) describes candidate resilience issues and indicators to be used when assessing, predicting and monitoring resilience of Smart Critical Infrastructures (SCIs). A total of 233 candidate issues and 1264 indicators are provided for various threats, SCIs and the five phases of the resilience cycle.

Table 1 shows the number of issues and indicators in the five phases defined in the Smart-Resilience project. In addition, some issues and indicators are considered relevant for all phases.

Table 1. No. of issues and indicators in each phase.

Phase		Issues	Indicators
Phase I	Understand risks	46	226
Phase II	Anticipate/prepare	93	520
Phase III	Absorb/withstand	45	236
Phase IV	Respond/recover	39	180
Phase V	Adapt/learn	20	95
Relevant for all phases		10	182

Although a substantial number of issues and indicators have been collected, they will never be complete and they are just candidates. There will always be a need for additional and/or more relevant issues and indicators for each specific user; and in the end, it is always the user that is responsible for finding a relevant and complete set of issues and indicators for his/her own case study.

Issues are essential in order to focus on those aspects that are most important to measure. Therefore, issues are considered first, and then indicators to measure the selected issues are established. Focusing on indicators first may result in important aspects (issues) being missed and not measured.

The importance of issues is also reflected by the 143 generic candidate issues provided in Øien et al. (2016c).

3.3 *Results obtained by using the method*

From the overall result, i.e. the resilience level of an area or a specific SCI, we can "drill-down" through the levels 2–6 for detailed results, which can be used in Step 10, together with the overall result. We do *not* have "just one number" (the overall resilience level).

There are many possibilities for use of the results, including:

1. Following up own development over time (trending) and analyse status
2. Comparing with others (benchmarking)
3. Providing overview of strengths and weaknesses and point at improvement needs
4. Making any gaps visible (lack of relevant indicators)

3.4 *Example*

To explain the assessment and calculations performed, Table 2 shows an extract of an example RIL assessment of a production facility within the chemical industry. The threat considered is terrorist attack (threat 1), and only the first phase (phase I) is shown.

Issues and indicators (I & I) IDs are listed in the first column. The indicators for the first issue (I.1) are: Does a safety risk register exist? (I.1.1); Is this registry used in decision making? (I.1.2); Is a frequency for updating the registry defined? (I.1.3). The second issue (I.2) only have one indicator: Is a procedure for MOC established? (I.2.1). The third issue (I.3) has the following three indicators: Does an accident/incident register exist? (I.3.1); Frequency of communication about incidents (I.3.2); Percentage of employees informed about incidents (I.3.3).

Table 2. Calculations on indicator level (example).

Indicator scores, weights and RILs					
I & I	Real value	Score value	RIL	Weight	Weighted score
I.1 Safety risk registry					
I.1.1	Y	5	A	0,33	1,67
I.1.2	Y	5	A	0,33	1.67
I.1.3	N	0	E	0,33	0,00
I.2 Management of change—MOC					
I.2.1	N	0	E	1,00	0,00
I.3 Register of accidents/incidents					
I.3.1	Y	5	A	0,33	1,67
I.3.2	1/6 mth	1,5	D	0,33	0,50
I.3.3	80%	3,5	B	0,33	1,17

Each indicator is measured, i.e. providing the real values for the indicators, whether it is yes/no questions, frequencies, percentages, or some other type of indicator. Based on the real value and the predetermined range of values, from worst to best (not shown in Table 2), an indicator score value is calculated. This value can be transformed to an indicator resilience level, from E (worst) to A (best) according to a predefined scale. Weights are determined, and the default values are equal weights. By multiplying the indicator scores with the indicator weights, the indicator weighted score is obtained in the last column. The indicator weighted scores are brought to the next level in the calculations, i.e. the issue level (level 5), where similar calculations are performed obtaining issue weighted scores, and so on, all the way to the area level (level 1).

The calculations gave an overall score on area level of 3,06 corresponding to RIL = B (Øien et al. 2017b).

The overall result just represents one aggregated character or value, which provides limited information. We need to "drill down" in the levels beneath, to reveal more detailed information about the various contributions to the overall result. One example of results on level 2 (SCI level) is shown in Figure 4. Here it is revealed that the threats with the lowest scores are *Threat 1 – Terrorist attack* and *Threat 2 – Natural threats*, both with a score of 2,64, which would be natural to look further into to improve resilience.

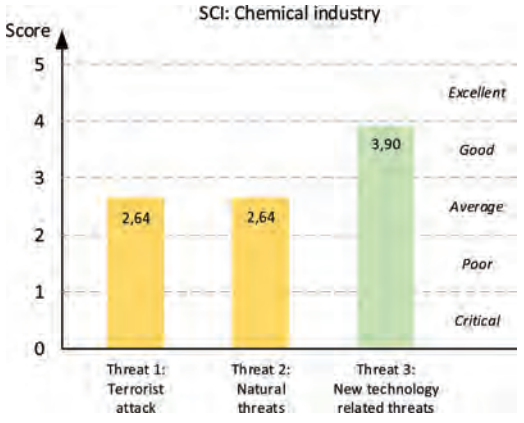

Figure 4. Resilience status at threat level (example).

4 DISCUSSIONS AND CONCLUSIONS

The SmartResilience RIL method helps to understand how resilient the SCIs are against specific types of threats and what measures could help improve their resilience. The results show the level of resilience (RIL) and where improvements are most needed ("drill-down"), emphasizing and fostering a continuous improvement mindset through regularly (typically yearly) updated assessments.

The resilience assessment uses a holistic ("umbrella") approach that goes beyond traditional risk of known events, emergency preparedness, crisis management, and business continuity. It covers e.g. preparing for the unforeseen, imagination, vigilance, flexibility, improvisation, recovery including business continuity aspects, and learning and adaptation.

4.1 *How to use the SmartResilience RIL method*

There are two main options for resilience assessment; internal self-assessment and external assessor audit. One main reason for using external assessments is the possibility for bench-marking between similar SCIs or even areas/cities with similar SCIs. To ensure comparability, it is important to use the same threats, issues and indicators, with the same range of indicator values, weights and similar requirements for collecting data for the indicators. This is possible to achieve (at least for a simple assessment/audit), but may not prove very useful for each individual user.

It is also possible to make user adaptation and customize the set of threats, issues and indicators, ranges of indicator values, weights and so on, e.g. by allowing to reject or add new indicators. However, the more the "dynamic checklists" (the tool used in the SmartResilience project) of threats, issues and indicators are adapted to take user requirements into account, the less comparable they will be.

Internal self-assessment can also be performed using similar checklists as an external assessor would use; however, if the focus is not on benchmarking and comparing with others, the assessment can be adapted to the specific requirements of each user. This will ensure a more relevant and accurate assessment useful for trending own development over time. A user customized self-assessment approach requires more engagement from the users. On one hand this is positive, since the users will take more ownership to the analysis framework and the results; however, on the other hand it will require more resources compared to an external assessment using a standardized framework.

4.2 *Usefulness of the SmartResilience RIL method*

The purpose of assessing resilience is to obtain a measure of how resilient a city or an individual SCI are against severe threats such as terror attacks, cyber-attacks and extreme weather. Assessing RIL provides a baseline assessment of resilience that gives insight on *status and improvement needs* to increase or maintain a high level of resilience.

A RIL assessment goes beyond traditional risk assessments by focusing on unknown and unforeseen events, and the capability to recover from events. This is achieved by capturing the time dimension through (five) distinct phases, incorporating e.g. emergency response and business continuity. A RIL assessment complements risk assessment; it is not a substitute for risk assessment. Risk assessments also provide valuable input to a RIL assessment, specially to phase I "Understanding risks".

An important purpose of a RIL assessment is to identify potential problems before they occur, so that risk reducing measures may be planned and implemented as needed, regardless of the likelihood of events. Most SCIs in the world have never, and will never, experience an extreme event. Still it is possible to assess the RIL, i.e. the level of risk understanding, anticipation and preparation, the capability to absorb and withstand, to respond and recover, and the abilities to learn and adapt. With a high RIL, it is less likely to experience adverse consequences due to an extreme event, and should it occur, then disruptions are likely to be less severe.

4.3 *Conclusions*

The SmartResilience project has developed a method for assessing resilience of SCIs with respect to specific type of threats on a scale from E

(worst) to A (best). An overall RIL is obtained by combining resilience levels for five main attributes/phases of resilience for each threat. For each phase, the user/analyst must identify the most important "issues" affecting SCI resilience and for each issue select relevant indicators, indicator range values, and perform calculations. The Smart-Resilience project has provided candidate issues and indicators for various SCIs that may be used as a starting point for identifying issues and indicators for resilience assessment of specific SCIs. This baseline resilience assessment can be used for trending as well as identifying improvement needs.

The resilience curve, describing the SCI functionality as a function of time, before, during and after an adverse event, is treated as a conceptual model, i.e. the method does not consider the exact shape, size or area of the curve directly. It is an indirect measurement. For direct assessment of SCI resilience, the SmartResilience project has developed a functionality assessment method with respect to specific threat scenarios. This alternative method provides a quantitative measure of loss of SCI functionality as a function of time addressing explicitly the resilience curve.

ACKNOWLEDGEMENTS

The contribution is based on the Grant Agreement No. 700621 supporting the work on the SmartResilience project provided by the Research Executive Agency (REA) ('the Agency'), under the power delegated by the European Commission ('the Commission'). This support is gladly acknowledged, together with the support from all the partners in the project.

Measuring infrastructure and community recovery rate using Bayesian methods: A case study of power systems resilience

H. Baroud & S. Murlidar
Vanderbilt University, Nashville, USA

ABSTRACT: With the increasing frequency and severity of disasters resulting especially from natural hazards and impacting both infrastructure systems and communities, thus challenging their timely recovery, there is a strong need to prepare for more effective response and recovery. Communities have especially struggled to understand the aspects of recovery patterns for different systems and prepare accordingly. Therefore, it is essential to develop models that are able to measure and estimate the recovery trajectory for a certain community or infrastructure network given system characteristics and event information. The objective of the study is to deploy the Poisson Bayesian kernel model developed and tested in earlier work in risk analysis to measure the recovery rate of a system. In this paper, the model is implemented and tested on a resilience modeling case study of power systems. The model is validated using a comparison to other count data models such as Poisson generalized linear model and the negative binomial generalized linear model.

1 INTRODUCTION

Recent disasters severely impacting both infrastructure systems and communities emphasize the need to prepare for more effective response and recovery. Communities have especially struggled in understanding the aspects of recovery patterns for different systems. Therefore, there is a strong need to develop models that are able to measure and estimate what are the recovery prospects for a certain community or infrastructure network given system characteristics and event information. In addition, the models need to account for uncertainty underlying the information that has been or being gathered before, during, and after the disruption.

Prior work on recovery rate modeling of infrastructure systems focuses on the time to recovery from power outages as a function of event attributes and impact of the disaster (Mackenzie & Barker 2013, Barker & Baroud 2014, Barabadi & Ayele 2018). In this research, the goal is to incorporate the uncertainty in estimating the resilience of systems after disruption. More specifically, the objective of the study is to analyze the recovery rate of a system or a community that has been impacted by a disaster. The response variable considered in this work is the average recovery rate computed based on the impact of the event and the total time to network recovery as well as other variables.

In order to integrate information from experts with data on the disruptive event and recovery process, this work proposes the use of a Poisson Bayesian kernel model which accommodates count data while accounting for prior information and uncertainty in the estimates. The model has been developed and tested using sample data in earlier work (Floyd et al. 2014) and has been applied to a risk analysis case study to predict the frequency of disruptive events in inland waterway (Baroud et al. 2013). However, the method has never been implemented in post-disaster scenarios, more specifically to model recovery rate. In this paper, the model is implemented and tested on a resilience modeling case study of power systems. More specifically, the recovery rate of a community from power outages is represented by a parameter following a Gamma distribution. This prior distribution is updated using historical data of disruptive events as well as a set of attributes that are represented by the kernel function, a measure of similarity between the new data point and the training set. The model performance is evaluated in comparison to other count data models such as the Poisson generalized linear model and the negative binomial generalized linear model.

Section 2 provides background literature on community resilience modeling and count data methods with an outline of the paper's contributions. Section 3 briefly describes the Poisson Bayesian kernel method and provides a structure to the model comparison and performance measures. Section 4 describes the case study with an overview of the data and a summary of the results of the models used in this work. Finally, concluding remarks are provided in section 5.

2 BACKGROUND AND CONTRIBUTION

2.1 *Community resilience modeling*

The ultimate goal of recovery measures after a disaster is to insure the society is able to bounce back from the losses incurred and reach normalcy as fast as possible, in recent studies this has been termed as "community resilience." One common definition for community resilience refers to the ability for a social system to respond and recover from a disaster. While vulnerability was previously used as an indicator, researchers and government policy have realized the advantages of utilizing resilience as an indicator to measure the ability of a community to not only recover during the post-disaster phase, but also advance beyond the pre-disaster state and adapt or transform to improve preparedness to future events. Furthermore, resilient communities are also less vulnerable to hazards than an equivalent less resilient community. Initially, community resilience modeling research focused on qualitative approaches founded in a set of metrics and indicators that describe the resilience of a community (Johansen et al. 2016). The concept of resilience can be useful when quantified and used as a decision-making tool, however, this can be challenging due to the uncertainty in many factors impacting resilience as well as the lack of data in recovery measures. As such, a number of research initiatives have focused on quantifying resilience ranging from stochastic modeling to simulation and data-driven approaches, among others.

Models of community resilience often include a variety of social factors. In one study, community resilience was modeled as categorical variables based on four primary sets of adaptive capacities-Economic Development, Social Capital, Information and Communication, and Community competence (Norris et al. 2008). It is proposed in this work that advancements within each category will aim to create a community that is more resilient to disasters as a whole. More specifically, one example of the hypothesis proposed in Norris et al. (2008) is the ability to measure infrastructure and economic resilience in terms of power restoration time which can therefore be used as a proxy to understand community resilience.

A more robust model for community resilience uses a composite index of social and geographical factors, the Baseline Resilience Indicators for Communities (BRIC) (Cutter et al. 2014). This relative value measure of resilience can point to counties and tracts within a specific geographic location that are particularly vulnerable to disasters and require more attention and more time to fully recover. This measure was found to have significant negative correlation with the previously established Social Vulnerability Index (SoVI).

Analysis has been performed to identify recovery rate specifically following a disaster. However, two relevant primary issues are dealing with missing data as well as homogeneity and heterogeneity across the data set and the fact that some models are so specific that they need to be adapted for different situations. In addition, most studies have aimed to provide restoration curves that give information on the number of customers with service over time. A lack of literature exists to model recovery rate specifically. One study focuses on the need to not only develop recovery rate plots but to be able to select the appropriate models based on the characteristics of a specific data set (Barabadi & Ayele 2018).

2.2 *Methods for modeling count data*

Modeling the recovery rate requires methods that can accommodate count data as the response variables in this case constitutes the number of recovered subjects per unit of time.

Generalized Linear Models (GLM) are widely used within regression models when count data is present. Within this class of models, the Poisson density function is often used with a log-link function, if the variance of the counts is higher than the mean of the counts, it is common to also use a negative binomial GLM. In certain special cases, extensions of these models can accommodate specific situations. For example, zero-truncated models and zero-inflated models can be used when there are excess zero counts (Shankar & Mannering, 1997), and both use an underlying Poisson distribution.

However, both Poisson and negative binomial lack the flexibility to handle data that is, for example, both underdispersed and overdispersed. As such, other models have been developed. One example is the Conway-Maxwell Poisson (COM) distribution GLM (Guikema & Goffelt, 2008). The model functions by having underdispersed data yield a Bernoulli distribution, overdispersed data yield a geometric distribution, and a Poisson distribution when the variance is equal to the mean.

Using a Bayesian framework to account for the uncertainty in the regression parameters, it is possible to improve on their accurate estimation by updating the parameter distributions with new data. Other approaches of analyzing count data using a Bayesian framework are conjugate priors. These methods are quite attractive as they offer the benefit of uncertainty modeling using Bayesian techniques without adding any computational cost. Given a specific prior distribution and a specific likelihood function, the posterior distribution will have the same form as the prior distribution but with updated posterior parameters. There are different forms of conjugate priors, one of which

is the Gamma conjugate prior used to model count data in the model presented in this paper. The method assumes that the rate of occurrence follows a Gamma prior and updates the distribution using information represented by a Poisson likelihood. The Gamma conjugate prior is the foundation of the Poisson Bayesian kernel model used in this paper and will be further discussed in the following section. This method allows the user to model and understand the uncertainty around each variable and estimate them by considering their probability distributions as opposed to point estimate.

2.3 *Contributions*

This paper presents new analysis for data-driven community resilience modeling. A Bayesian approach developed and tested in prior work is implemented and tested in a case study of community recovery from power outages. The work presented here constitutes a first step in advancing data-driven methods for applications in infrastructure and community resilience.

3 METHODOLOGY

3.1 *Poisson Bayesian kernel model*

Poisson Bayesian kernel methods estimate the rate of occurrence of the event rather than estimating a deterministic value for the number of times the event is estimated to occur. A common distribution to model count data within a Bayesian framework is the Gamma-Poisson conjugate prior. The development of the Poisson Bayesian kernel method discussed can be found in Baroud et al. (2013) and Floyd et al. (2014). The approach uses the Gamma conjugate prior as the basis of the model.

It is assumed that the parameter to be estimated is the rate of occurrence, $\lambda > 0$, which follows a Gamma prior distribution with parameters $\alpha > 0$ and $\beta > 0$, as shown in Eq. (1).

$$P(\lambda) = \frac{\beta^{\alpha}}{\Gamma(\alpha)} \lambda^{\alpha-1} e^{(-\beta\lambda)} \tag{1}$$

For the likelihood function, the product of the Poisson density function, shown in Eq. (2), is used, since this is a Gamma-Poisson conjugate prior approach.

$$\begin{aligned} L = \prod_{i=1}^{m} P(y_i) &= \prod_{i=1}^{m} \frac{\left(\lambda_i^{y_i} e^{-\lambda_i}\right)}{y_i!} \\ &= \frac{\lambda_i^{\sum_{i=1}^{m} y_i} e^{-m\lambda_i}}{\prod_{i=1}^{m} y_i!} \end{aligned} \tag{2}$$

Thus, the posterior distribution is the product of Eqs. (1) and (2). Rearranging the product of the likelihood function and the prior distribution function results in a Gamma posterior distribution where $\alpha^* = \sum_{i=1}^{m} x_i + \alpha$ and $\beta^* = m + \beta$.

$$\begin{aligned} &P(\lambda|x) \\ &= \left(\frac{\beta^{\alpha}}{\Gamma(\alpha)} \lambda^{\alpha-1} e^{-\beta\lambda}\right)\left(\lambda^{\sum_{i=1}^{m} y_i} e^{-m\lambda}\right) \\ &= \frac{\lambda^{\left(\sum_{i=1}^{m} y_i + \alpha - 1\right)} e^{-\lambda(m+\beta)} (n+\beta)^{\sum_{i=1}^{m} y_i + \alpha}}{\Gamma\left(\sum_{i=1}^{m} y_i + \alpha\right)} \\ &= \text{Gamma}(\alpha^*, \beta^*) \end{aligned} \tag{3}$$

This result is the basic Gamma conjugate prior approach used in Bayesian analysis. This approach assumes the notion of exchangeability meaning that for different sets of training and testing data, the resulting posterior parameters will be similar since they are a function of the prior parameter, the size of the dataset, and the summation of all the data points. The characteristics of each outcome are not taken into consideration in this case, but rather the overall property of the dataset (MacKenzie et al., 2014).

The Poisson Bayesian kernel approach extends the notion of the conjugate prior such that the posterior parameters computation not only depends on the prior parameters and the historical data but also on the attributes through the kernel matrix. The parameters for the Bayesian kernel model for counts are expressed in Eqs. (4) and (5). **K** is the $m \times m$ kernel matrix, **Y** is an $m \times 1$ vector containing the output data associated with the m observations of **X**, and **V** is an $m \times 1$ vector containing ones. Each entry in the kernel matrix represents the similarity measure between the attributes of the testing set and the training set, respectively. As such, the new data point is compared with the training set and according to the similarities of the attributes, new values for the parameter of the posterior distribution are computed. Note that in this case, the training and testing sets are assumed to have the same size, m. However, when the model is deployed, the sets can be of different sizes, and in some cases, the testing set could include only one data point such as in a leave-one-out analysis.

$$\alpha^* = \mathbf{KY} + \alpha \tag{4}$$

$$\beta^* = \mathbf{KV} + \beta \tag{5}$$

As with other statistical and mathematical models, there are a few assumptions underlying the deployment of such modeling approach. Even though the form of the prior distribution is

known from the conjugate prior, the model user would still need to identify the values of the prior parameters. While there are formal ways to determine the prior parameters (Kass & Wasserman, 1996), the selection of such parameters might not always be considered (Montesano & Lopes, 2009; Mason & Lopes, 2011). Oftentimes, the priors are either assumed to be known or are assigned such that the prior distribution is non informative. In other cases, these parameters are estimated using data and prior knowledge by matching the sample mean and variance to those of the prior distribution (MacKenzie et al. 2014; Carlin & Louis, 2008). Another assumption to consider is the choice of the kernel function which depends on the application and the model user. This research uses the most popular kernel function, the Radial Basis Function (RBF) in Eq. (6), where $k\left(\mathbf{x}_i,\mathbf{x}_j\right)$ is one entry in the matrix **K** representing the kernel function between the attributes of the i^{th} and j^{th} data points.

$$k\left(\mathbf{x}_i,\mathbf{x}_j\right)=\exp\left(-\frac{\left\|\mathbf{x}_i-\mathbf{x}_j\right\|^2}{2\sigma^2}\right) \tag{6}$$

In addition to being commonly used in kernel methods, RBF has nice properties. The function has only one parameter, σ, to be tuned to an optimal value. This reduces computation efforts significantly in comparison to other kernel functions with two or more parameters requiring a grid search to estimate them. Also, the structure of the function is based on the Euclidean distance, whereby similar data points are closer to each other in the feature space. Finally, the kernel matrix of the RBF has full rank and the entries fall between zero and one resulting in kernel functions of the data points acting as weights in the computation of the posterior parameters (Schölkopf & Smola, 2002). More discussion on the impact of the RBF parameter, σ, on the performance of the model will follow in the case study presented in section 4.

The estimated rate for the new data point follows then a Gamma distribution with parameters α^* and β^*. As a point estimate for this parameter, the expected value of the posterior distribution is considered, shown in Eq. (7) as the ratio of the Gamma distribution parameters α^* and β^*.

$$\hat{\lambda}=\frac{\alpha^*}{\beta^*} \tag{7}$$

Note that a different point estimate for the rate can be used such as the median, the mode, or the variance, depending on the type of problem and the model users.

3.2 *Predictive accuracy measures*

The ultimate objective of developing and identifying predictive models is their application in risk and resilience analysis problems, such as predicting the frequency of disruptions in a particular network system or the recovery rate of infrastructure and communities. While the goodness of fit is important to assess whether the model is capturing the pattern and variability in the data, is it equally important to analyze the prediction power of a statistical model if it is going to be used for forecasting purposes. Prediction accuracy is assessed by the out-of-sample error, which accounts for the discrepancy between the estimated parameter and the actual observation of data points that were not in the set used to train the model. In order to validate the prediction power of the models, several metrics are evaluated to assess the out-of-sample error, and they are summarized in Table 1.

While RMSE and MAE are the most commonly used measurements of error, the normalized RMSE is also considered to account for the variability across different samples of training sets generated by the multi-iteration validation process. NRMSE can either be normalized based on the standard deviation of the observed values, $sd\left(Y_i\right)$, or the range of values in the testing set, $Y_{maximum}-Y_{minimum}$, and both cases are considered in this paper.

3.3 *Comparative analysis*

In order to assess the performance of the models, the predictive accuracy measures are used to evaluate the models. More specifically, Poisson Bayesian kernel model is compared to a Poisson generalized linear model and a negative binomial generalized linear model (Cameron & Trivedi, 1986, 2013).

Table 1. Prediction accuracy metrics formulae.

Prediction accuracy metrics	Formula
Root Mean Square Error (RMSE)	$\frac{1}{n}\sqrt{\sum_{i=1}^{n}\left(Y_i-\hat{\lambda}_i\right)^2}$
Normalized Root Mean Square Error (NRMSEM & NRMSED)	$\frac{\frac{1}{n}\sqrt{\sum_{i=1}^{n}\left(Y_i-\hat{\lambda}_i\right)^2}}{sd\left(Y_i\right)}$ $\frac{\frac{1}{n}\sqrt{\sum_{i=1}^{n}\left(Y_i-\hat{\lambda}_i\right)^2}}{Y_{maximum}-Y_{minimum}}$
Mean Absolute Error (MAE)	$\frac{1}{n}\sum_{i=1}^{n}\left\|Y_i-\hat{\lambda}_i\right\|$

The Poisson GLM assumes that the rate to be estimated has an exponential relationship with a set of covariates representing coefficients for the different attributes, $\hat{\lambda}_{PGLM} = e^{\beta_i X}$, while the predicted rate for the PBK is equal to the expected value of the posterior probability distribution, $\hat{\lambda}_{PBK} = \frac{\mathbf{KY}+\alpha}{\mathbf{KV}+\beta}$.

4 CASE STUDY

A case study is presented in this paper to demonstrate the use of the Poisson Bayesian kernel model in assessing the resilience of communities. More specifically, the study is focused on major power outage events that happened in the US between 1999 and 2016. The goal is to compare the performance of the model against classical methods and assess its ability to predict, with a high level of accuracy, the recovery rate after these major events.

The ability to accurately measure and predict the recovery rate from power outages allows responders and recovery crews to improve their strategies and resource allocations before, during, and after a disruption.

4.1 *Data*

The data used in the case study is collected from the Energy Information Administration and includes information on the time, date and length of an outage occurred, the magnitude of the power outage (Megawatt Loss & Customers Affected) and the disturbance type (severe weather, equipment failure, among others). The dependent variable to be modeled is recovery rate which is the number of customers affected divided by the duration of outage. To model the rate using a Poisson linear model, an offset of duration was used. Recovery rate is modeled based on 10 regression coefficients that represent information on the cause of the outage, the severity, the location, the duration, and the time of the day and month.

Figure 1 is a scatterplot of all variables in the data set, each square represents a pairwise plot between the corresponding pair of variables on the x-axis and the y-axis, the red line represents a local regression line of the two variables. The numbers shown in the upper side of the scatterplot represent correlations of the pairs of variables which, in this data set, are not significant with the exception of a couple of variables. Examining Figure 1, it is

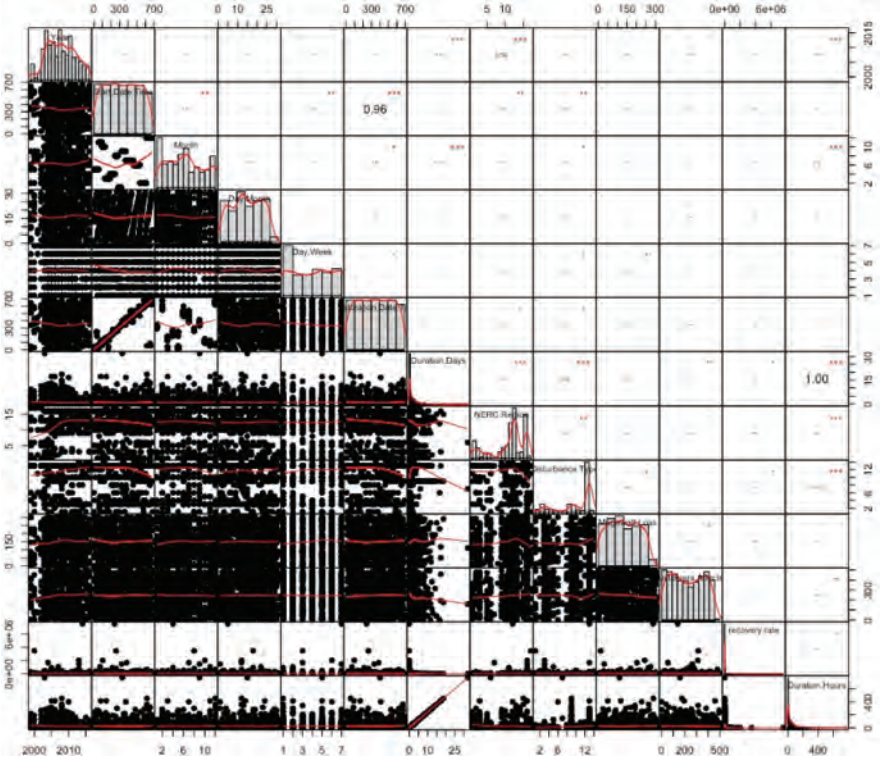

Figure 1. Pairwise scatter plots for all the variables in the data.

difficult to identify visually any particular relationships beyond the expected linear correlations due to multicollinearity such as start date and time with restoration time. The plot provides histograms for the different variables and it can be seen that there is a large variance for many predictors.

Further examination of the patterns in the data focus on the impact of seasonal variations and types of disturbance on the recovery process from power outages. Rates of recovery are generally slower in the winter than in the summer months (Figure 2).

While wide variations are observed in the recovery rate by the type of disturbance, outages due to load shed and fire/extreme heat experience the highest average recovery rate. Disasters such as flooding and hurricane, however, have much slower recovery rates (Figure 3). Also, Severe Weather events result in the largest number of outliers in the data.

4.2 *Results*

The Poisson Bayesian kernel model referred to as PBK, the Poisson GLM referred to as PGLM, and the negative binomial GLM referred to as NBGLM were used to model the data and predict the recovery rate as a function of the predictors related to the time, location, disruption, and other characteristics. The error measures discussed earlier and presented in Table 1 were calculated for each model and summarized in Table 2.

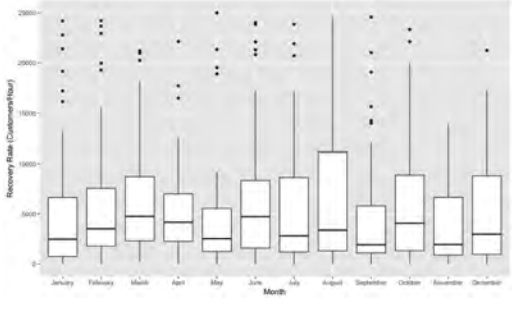

Figure 2. Recovery rate as a function of month.

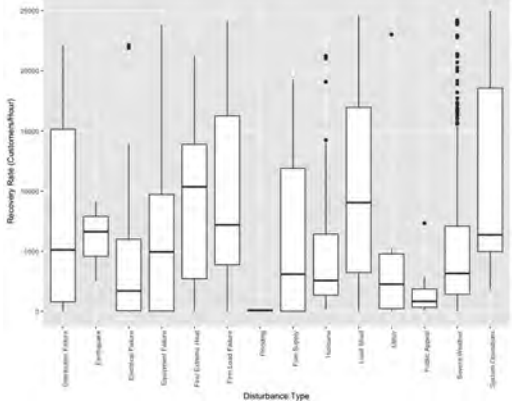

Figure 3. Recovery rate by disturbance type.

Across all predictive accuracy measures, PBK performs yields small errors overall. PGLM results in very large errors that could be driven by the extreme values under Severe Events for instance, whereas PBK is able to control for that and provide more stable estimates. For two of the predictive error measures, NRMSED and MAE, the PBK outperforms the NBGLM.

Overall the performance of PBK and NBGLM is comparable from a predictive accuracy standpoint. However, using PBK would provide an assessment of the uncertainty in the estimates through the prior and posterior distributions of the recovery rate, the outcome is a probability distribution of a comprehensive range of possible values for the recovery rate. As a result, it is possible for a decision maker to identify multiple point estimates based on their risk preference. For example, if the decision maker or infrastructure operator is risk averse, he/she will rely on a more extreme (lower) value than the expected value of the recovery rate posterior distribution since a more conservative mitigation and recovery strategy is preferred. However, if the decision maker is risk taking, the preference would be to save on cost of mitigation and recovery and the upper tail of the distribution will be considered as an optimistic measure of the recovery rate. The choice of the posterior point estimate is not the only way a decision maker is involved in this process. Stakeholders play an important role in identifying multiple initial parameters in the model.

As mentioned earlier, the definition of the prior is an important consideration for any Bayesian approach. In this case, a non-informative prior was assumed. However, another important consideration is the value of the parameter in the kernel function. The results in the table above were obtained based on an arbitrary value of sigma. In order to understand the effect of this parameter on the predictive accuracy, Figure 4 shows the value of the root mean squared error as a function of $1/\sigma$.

There is clearly an optimal value for this parameter valued at approximately 12. It would be ideal if the

Table 2. Prediction error values for all the models.

Model	RMSE	NRMSED	NRMSEM	MAE
PBK	2435	2.03	0.25	1258
PGLM	12961	10.88	1.34	5579
NBGLM	1706	2.06	0.17	2039

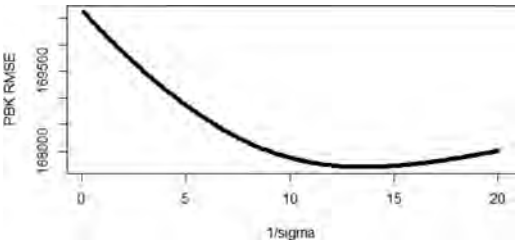

Figure 4. PBK RMSE as a function of different values for the tuning parameter of the kernel function.

parameter is tuned to minimize the error during the training process. The drawback of doing so is the additional computation time for tuning which would exponentially increase as more parameters are considered in other forms of the kernel function.

5 CONCLUSION

The work presented in this paper evaluates the use of Poisson Bayesian kernel models to measure and predict the rate of recovery. The ultimate goal of the research is to be able to quantify community resilience in order to inform resource allocation before, during, and after a disruption. The proposed approach to model the rate of recovery was compared to traditional count data models such as Poisson and negative binomial generalized linear models.

The advantage of using Bayesian techniques is their ability to provide probability distribution of the estimates, accounting for the uncertainty in resilience metrics. Another important benefit is the ability to update predictions as new information on the evolvement of the disaster and the corresponding response of the community becomes available.

An initial comparison to other methods shows that PBK provides a higher accuracy than traditional models with the added benefit of accounting for uncertainty and the decision maker's opinion and prior knowledge.

ABSTRACT: Critical technical infrastructures constitute the backbone of society by providing essential services to vital societal functions and the community at large, hence it is of essence that these are resilient. Critical infrastructures, e.g. power systems, telecommunication systems and railway systems, are designed and operated based on different philosophies of where to put the resilience emphasis, robustness, rapidity of recovery or a combination of the two. Here empirical failure data, such as duration and consequence of disruptions, from several critical infrastructures in Sweden are explored and analysed. To facilitate comparisons, a generic resilience assessment approach is also presented and applied. The results give insight to the resilience level of different infrastructures in Sweden and a basis for an exploration of its reasons, e.g. due to difference in regulatory schemes, design or risk cultures. It is concluded that there exist significant differences of infrastructures resilience levels and the factors shaping the resilience.

1 INTRODUCTION

The large scale societal consequences arising in past events involving critical infrastructures, such as the European blackout in 2006, the Eyjafjallajökull eruption in 2010 and Hurricane Sandy in 2012 (Johannsson et al., 2015), clearly indicates the need for approaches and measures aiming at increasing infrastructure robustness and rapidity of recovery, in essence addressing the resilience of critical infrastructures. These events have also revealed the complexities and uncertainties involved in assessing resilience of critical infrastructures.

During the last years there have been ample contributions of different, both academic and policy oriented, approaches for assessing critical infrastructure resilience. These include expert based methods, e.g. different types of index methods, modelling and simulation based methods and empirical data based methods. Limited attention has been drawn towards contrasting and comparing the resilience of different types of critical infrastructures through the use of empirical failure and interruption data that are normally gathered by regulatory authorities or internally by infrastructure owners.

Here we are presenting and applying a generic resilience assessment approach to this type of data, aiming at assessing and contrasting resilience levels as input to exploration of possible causes, e.g. underlying influential factors such as regulatory schemes, differing design philosophies or risk cultures.

In Chapter 2 a background is given for the generic resilience assessment approach as presented in Chapter 3 together with the data collection method. In Chapter 4 the data is presented for five critical infrastructures in Sweden, electric transmission, electric distribution, transport railway, transport road and water supply. In Chapter 5 the resilience levels of the infrastructures are contrasted and compared. The findings are then discussed in Chapter 6 and conclusions from the study are drawn in Chapter 7.

2 BACKGROUND

The most common approach in the scientific literature, related to critical infrastructures, is to assess resilience in terms of the system's functionality over a time period. Emphasis is normally on measuring a system's resilience towards a single specific event or scenario (e.g. Pursiainen et al., 2016, Hosseini et al., 2016, Panteli et al., 2017, Nan & Sansavini, 2017). The approaches also tend to follow the fundamental resilience conceptualisation proposed by Bruneau et al. (2003), sometimes

referred to as the "resilience triangle" and where the area of the triangle is defined as resilience loss. Several more detailed conceptualisations of this engineering oriented concept of resilience have lately emerged in the literature. For example, accounting for that the recovery behaviour is normally not linear but can e.g. be exponential (Cimellaro et al., 2010). There is also examples of where the resilience curve is divided into several different phases, e.g. original steady state, disruptive phase, system recovery state, and finally a stable end state (c.f. Henry & Ramirez-Marquez, 2012, Nan, C. & Sansavini, G., 2017). For these conceptualisations, the events in consideration seems to be for single large impact events, resulting in great stress on the measured system's functionality and high societal consequences. Further, the literature also presents a great variety of ways for defining or measuring the functionality of different infrastructures.

Methods for assessing the resilience of critical infrastructures can broadly be divided into three categories: expert based, modelling and simulation based, and empirically based methods. Expert based methods are generally an assessment based on system characteristics where the opinion from experts have been aggregated to produce some sort of index of infrastructure resilience (Hosseini et al., 2016, Hassel & Johansson, 2016). One example is Chang et al. (2014) that presents a resilience elicitation approach, where they estimate resilience levels based on expert opinions for a specific scenario in an interdependent critical infrastructure setting. Resulting in estimated service disruption levels, rated from no loss to severe disruption for different time lengths of disruption. Modelling and simulation based methods, in this context, are quantitative approaches aiming at observing modelled system behaviour during disruptive events (e.g. Hosseini et al., 2016, Ouyang, 2014). Some authors also include more general resilience metric conceptualisations, that could be applicable also for empirical studies, and utilize them in a modelling and simulation context (e.g. Nan & Sansavini, 2017, Panteli et al., 2017). Modelling and simulations efforts span e.g. from network theoretical, Monte Carlo, optimization to fuzzy logic approaches (e.g. Hosseini et al., 2016). Empirically based methods aim at deriving resilience levels of critical infrastructures during past events (see e.g. Johansson et al., 2015, Zorn & Shamseldin, 2015a). Normally it involves statistical analyses of the rapidity and robustness of one or several infrastructures during a specific disruptive event, sometimes also the quantification of interdependencies are addressed (Zorn & Shamseldin, 2015b). The empirical methods normally aim at measuring resilience during different phases of the disruptive event. These approaches are less applicable when addressing the overall resilience of an infrastructure towards the range from low impact to high impact events and specifically for assessing the resilience over time.

Here the aim is to provide such an approach that is based on assessing the resilience level of different types of critical infrastructures based on interruption data, which has not been covered in the scientific literature to our knowledge. It should be noted however that reliability oriented approaches for critical infrastructures (for power systems see e.g. Billinton & Allan, 1996) to a large extent deals with similar issues of assessing system functionality during disruptive events based on either modelling and simulation approaches or through empirical failure data, then however normally focusing on infrastructure specific indices and not towards a unified approach for the comparison of different types of infrastructures.

3 METHODS

3.1 *Data collection*

The data was collected through a three phase process: I) identifying technical critical infrastructures (CIs) within Sweden, II) identifying actors within these infrastructures, preferably at national level, that potentially collects interruption data for their respective CI, and III) contacting the actors and retrieving the data. This data then underwent an examination to gain further understanding of the quality and quantity of the data, e.g.: how the data is collected? (e.g. in the form of databases or in the form of incident reports?), what are the parameters given in the data?, and what is the delimitation and limitation of the data? In some instances, further contacts where made with the actors for clarifications or to gain additional data, resulting in an iterative data collection process. For each data set it was finally determined if it contained the desired parameters for the resilience assessment approach.

In the end data from the following five infrastructures and actors are included (out of 17 initially addressed infrastructure actors): a) Electricity transmission, Svenska Kraftnät (SVK), b) Electricity distribution, Energiföretagen, c) Transport Road, Trafikverket, d) Transport Railway, Trafikverket, and e) Water supply, Stockholm vatten och avfall (SVOA).

3.2 *Resilience assessment approach*

The aim of the Resilience Assessment Approach (RAA) is to present a generic method that is applicable for the resilience analysis of several different types of critical infrastructures, at a variety of hierarchical levels, based on empirical interruption data.

The approach is hence naturally bounded by the interruption parameters that are typically collected by infrastructure owners or regulatory authorities. The interruptions are typically reported as independent incidents, although there might be underlying correlations between the interruptions (e.g. during a storm). Furthermore, the collected interruption data of a single event generally lacks detailed information of the actual functionality during the recovery process for the recorded interruptions. Normally only start time, end time and maximum functionality loss is given. Hence the data does not reflect the widely spread "resilience curve" as normally depicted in the academic literature (e.g. Cimellaro et al., 2006, Hosseini et al., 2016, Panteli et al., 2017). If the interruption data would have had higher granularity, the approach presented here would however still be applicable.

The resilience assessment approach aims to measure the resilience of a critical infrastructure at a "national system level" to guide policy making and regulatory considerations at this level. As typically several sub-infrastructures together build up an overall critical infrastructure (e.g. in Sweden there are about 160 distribution system owners, 4 regional system owners and 1 national system owner of the electricity infrastructure) it is necessary to aggregate the data from several sub-infrastructures that covers different geographical areas to a national level. Each individual failure is considered to place a strain on the overall system with a negative effect on the functionality during a specific time period. In cases where two or more failures occur simultaneously or overlapping at any time period, these are summed up (stacked), resulting in a fictive national functionality loss of the system as a whole (F_L), see Figure 1. As the true behaviour of the system functionality during a single interruption is unknown, each individual reported interruption has been depicted with a box-shape profile.

The fundamental criteria for the approach is that each interruption is recorded with a start time, end time and one or several consequence parameters which can be transformed into a single functionality loss, F_L, by normalising with an appropriately chosen time-independent baseline.

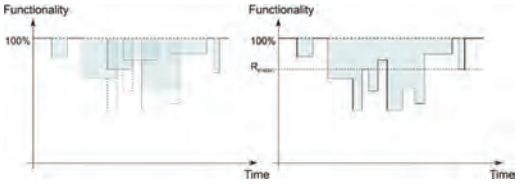

Figure 1. Illustration of how interruption data from several sub-infrastructures (left) is aggregated to a fictive "national system level" (right).

The total resilience, R_{Tot}, of a critical infrastructure over a specified time period is then derived as:

$$\mathbf{R_{Tot}} = \sum_{T_0}^{T_{end}} 1 - \mathbf{F_L(t)} \quad (1)$$

where:

F_L = Functionality loss during time period t,
T_0 = Start time of time period
T_{end} = End time of time period

In order to facilitate a comparison of different infrastructures and for varying time periods the mean resilience loss, R_{Mean} for a given time period is calculated as:

$$\mathbf{R_{Mean}} = \frac{\boldsymbol{R}_{Loss,Tot}}{N} \quad (2)$$

N = Total number of samples in time period

4 INFRASTRUCTURE DATA

Here the background and boundaries of the data for the infrastructures are presented. Many factors sets boundaries of the data, such as if its gathered due to regulatory obligations or for reasons of internal audits and improvements. If an interruption were lacking necessary information for the resilience calculations, these are labelled as "missing data".

4.1 *Electricity transmission*

Svenska Kraftnät (SvK) is the national operator and the Swedish authority responsible for the electric power transmission system. The transmission system transports high voltage power from generating sources, such as power plants and wind parks, to regional networks. The transmission system is also synchronously interconnected to other countries (Norway, Finland and Denmark), but the data is delimited only to the Swedish system. According to Swedish and EU regulations, all companies providing power supplies are bound by law to deliver reports of outages and disturbances since the year 2009 (ENTSOE, 2017, Regeringskansliet, 2009, SVK, 2017).

The data from SvK contained operational outages from the years 2006 to 2016. Each interruption has in total 14 different parameters. Of specific interest here is the start time, end time and the amount of Energy Not Supplied (ENS) due to the interruption. It should be noted that most interruptions in the transmission system leads to no loss of power supply (95%), due to high levels of redundancies and spare capacities.

The data set received from SvK is judged to be of very high quality and comes with only a few unusable data points each year, see Figure 2. Regarding data required for the resilience calculation, the data set is almost complete. In total 2468 interruptions are contained in the data, where only 113 (4.6%) were missing the relevant information.

The data used for the resilience calculations are the given start and end times, and the consequence is calculated by transforming the reported ENS to Power Not Supplied (PNS), averaged for the duration of the outage. The functionality loss is derived by dividing the PNS with the baseline of total Swedish power consumption for a specific year.

4.2 *Electricity distribution*

Energiföretagen is a relatively new Swedish trade association, formed in 2016 through the merging of existing trade organisations. Their main task is to ensure and maintain its members' commercial interests, but they also support the Swedish distribution actors to keep up to date with changing demands and environmental needs. Energiföretagen continuously gather and analyse failure data from their members, annually summarised and presented in the "DARWin-reports" (Energiföretagen, 2017). With almost 100 member companies, the data represents the distribution of electricity to nearly 90% of the end users in Sweden.

The data from Energiföretagen were anonymized (no reference to company) and contained outage data from the year 2005 to 2015, see Figure 3. Each interruption has in total 13 different parameters. As oppose to the data for the transmission system, disruptions at the distribution level to a much higher degree leads to consequences (only 0.75% of the interruptions had zero affected customers), due to the infrastructures limited redundancies and spare capacities.

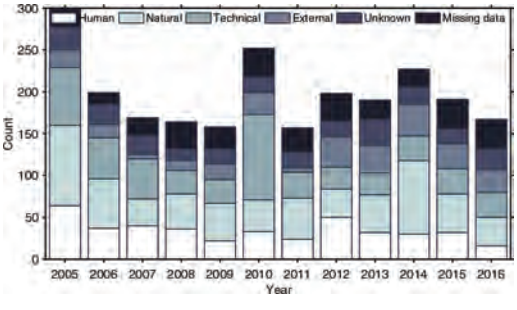

Figure 2. Interruption data for the electricity transmission infrastructure. Categorized into failure cause and missing data.

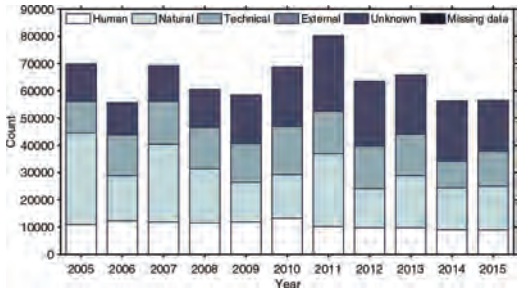

Figure 3. Interruption data for the electricity distribution infrastructure. Categorized into failure cause and missing data.

The data set contains about three hundred times more interruptions than the SvK data. The data is judged to be of high quality, where there is only one bad value, after correcting some obvious errors, of just over 700'000 interruptions in total.

The parameters used for the resilience calculations are the start and end times of the interruptions, and the consequence is calculated as the sum of affected low and medium voltage customers. The baseline for functionality is the total number of customers during a specific year for the reporting companies.

4.3 *Transport road*

Trafikverket is a public authority responsible for the long-term infrastructure planning of road-, railway-, shipping- and aviation-operations, and construction and maintenance of the road and railway in Sweden.

The data from Trafikverket regarding the road infrastructure comes from a project called "Total Traffic Stops" (TTS). This data started to be collected in 2016 and we have data until the first half of 2017. In TTS, unplanned and total stop of traffic for a given road section is reported. Hence e.g. planned interruptions or maintenance actions that give rise to considerable delays in the traffic is not included. On larger roads, with several lanes and the two directions completely separated, it is classified as a total stop only if all the lanes in one direction are closed. For roads where the two directions are not separated, all lanes in both directions must be in full stop to be classified and registered in the TTS.

In the data quite many parameters, 30 in total, are described for each interruption. Most of them for classification in accordance to TTS and considered less relevant here, e.g. coordinates of the accident and other location specific descriptions. The quality of the data is good. Of a total of 8295 recorded interruptions, no one where missing the

relevant data. 2730 interruptions had either zero duration or zero consequences.

As resilience metrics the given start and end times of the interruptions, and the consequence of each failure is given by the reported "Average daily traffic" in terms of vehicles affected. The baseline for calculating functionality is the average number of vehicles that is in the transport system on any given moment (about 600'000), derived from additional data provided by Trafikverket.

4.4 *Transport railway*

The data for the railway infrastructure is also from Trafikverket and covers the years 2012 to 2016. Failure data on railway system outages was scarce and according to Trafikverket there is no general data that sums up or connects railway outages or failures with a root cause. However, they do log train delays which can be used as proxy. If a train is more than 3 minutes delayed when passing a designated "measurement point" (usually a train station), it is registered. This is logged manually and if correctly logged, all train delays associated with the same root cause are given the same "delay ID". It is however quite uncertain how accurate and stringent these logs connect cause and effect. In total the data contains three million delays and about one million delay IDs. Less than 0.1% of the interruptions miss the relevant parameters. The quality of the data is judged to be fair.

Start and end time gives the duration, and the number of registered delays are averaged over the interruption duration with the unit of delays/hour. The baseline is derived from the total number of train departures in the system during the year 2012, in total 38 million. Hence, on average about 4 300 trains/hour are passing or departing from a measurement point on average. Due to lack of yearly data, this number is normalised and scaled with the total transported km in the system per year.

4.5 *Water supply*

For the water supply infrastructure, attempts to gather both national data and data from several different distribution system operators were made. However, only Stockholm Vatten och Avfall (SVOA), which is the main distributor of drinking water and operates the wastewater treatment for Stockholm city and the municipality of Huddinge, gathered interruption data in a format suitable for our purpose. In total, SVOA serves about 10% of the Swedish population and the data is used for internal audit, as no regulatory demands exist for the water sector with respect to disruption data. The data covers water outages caused by service and repairs of the infrastructure. The data set stretches from July 2009 to May 2017.

In total, each interruption has 9 different parameters, where those of specific interest here is start and end time, duration (given in "Hours without water") and consequence (given as "Number of users"). In total 2500 interruptions are recorded in the data, where quite many are missing the relevant information. About 1700 interruptions were in the end used. The baseline for calculating functionality

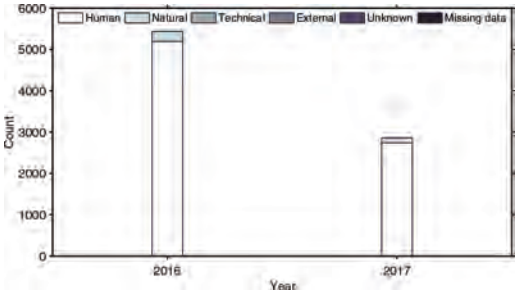

Figure 4. Interruption data for the transport road infrastructure. Categorized into failure cause and missing data.

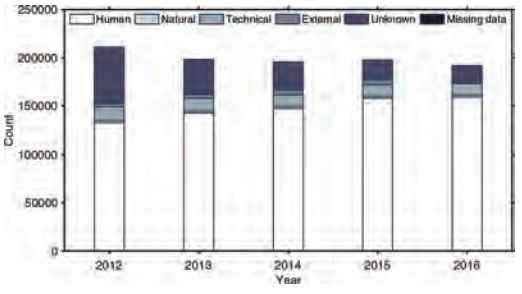

Figure 5. Interruption data for the transport railway infrastructure. Categorized into failure cause and missing data.

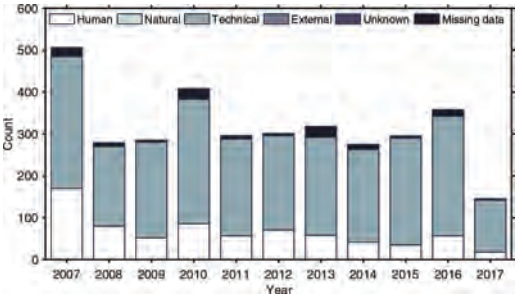

Figure 6. Interruption data for the water supply infrastructure. Categorized into failure cause and missing data.

is the approximate total number of customers that are served by SVOA (circa one million).

4.6 *Other infrastructures*

During the process of gathering interruption data attempts were also made to get data for telecommunication, electronic communication, maritime and aviation infrastructures. However, either due to reasons of sensitivity of data or incomplete/lacking data collection processes no usable data was possible to retrieve for these infrastructures.

5 RESULTS

5.1 *Comparison of resilience levels*

In Figure 7 the resilience level for the different infrastructures are presented. For each of the infrastructures, depending on the availability of data, the yearly mean resilience level for 2005–2017 is presented.

It is clear that there are rather large differences of the resilience levels when comparing the infrastructures. The worst performing infrastructure is the transport railway and the best is the electric transmission system. The resilience level for a given infrastructure also varies over the studied period. The electricity distribution system demonstrates quite fluctuation resilience levels over the years. The resilience levels of the transport railway system are declining over the years, with more or less similar resilience level during the last two years, 2015 and 2016.

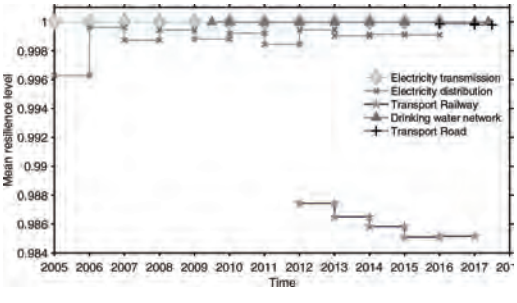

Figure 7. Annual resilience levels of the studied infrastructures.

Table 1. Resilience values for: ETr = Electricity Transmission, EDi = Electricity Distribution, TRo = Transport Road, TRa = Transport Railway, Wat = Water supply.

	Duration (h)			F_L			Resilience
Inf.	Mean	Var	Max	Mean (10^{-3})	Var (10^{-6})	Max (10^{-3})	Mean
ETr	2.23	76.5	67.3	0.51	8.00	44.5	1.0000
EDi	8.16	3420	8490	3.95	160	159	0.9989
TRo	5.87	3200	10500	0.24	0.229	7.48	0.9999
TRa	19.3	8170	42700	16.6	55.1	421	0.9899
Wat	4.76	130	350	0.17	0.155	7.55	1.0000

In Table 1 the overall mean resilience level are given, together with mean and variance of duration and functionality loss (respectively). The Electricity transmission scores the best result, closely followed by Transport road and Water supply. Then comes Electricity distribution followed by Transport railway that is by far the least resilient infrastructure.

5.2 *Comparison of duration and consequence*

In Figure 8 histograms of duration and functionality loss for each of the infrastructures are presented. All interruption data that meets the requirements for calculating the resilience metrics, in accordance with the data section, are included. Interruptions that either exceeds the duration threshold of 12 hours or the functionality loss threshold of 0.001 are binned. These binned data (i.e. the tails of the distributions) are also presented separately in insert figures.

Comparing the length of disruptions among the different infrastructures give that the water supply infrastructure seem to have slightly different shape with respect to the length of disruptions, where a typical interruption last for about 4–5 hours compared to 0–1 hours for the other infrastructures. Comparing functionality loss, the values are generally very small (maximum from 0.5% to 3%), except for the transport railway infrastructure that have experienced larger scale disruptions (up to 39%).

6 DISCUSSION

One of the complications of comparing critical infrastructure resilience levels based on empirical failure data is that the processes for gathering the data and the format of the data varies significantly between the studied infrastructures. To facilitate comparisons, the parameters that are of essence for assessing resilience levels of critical infrastructures at a national level needs to be defined, communicated and maybe even regulated. Some of the infrastructures are either legally obliged, or encouraged by official instances, to systematically gather interruption data, while for other infrastructures such incentives are lacking. If the latter, and if interruption data is gathered, these are generally more geared towards being suitable for specific internal usages, rather than for comparisons across different infrastructures.

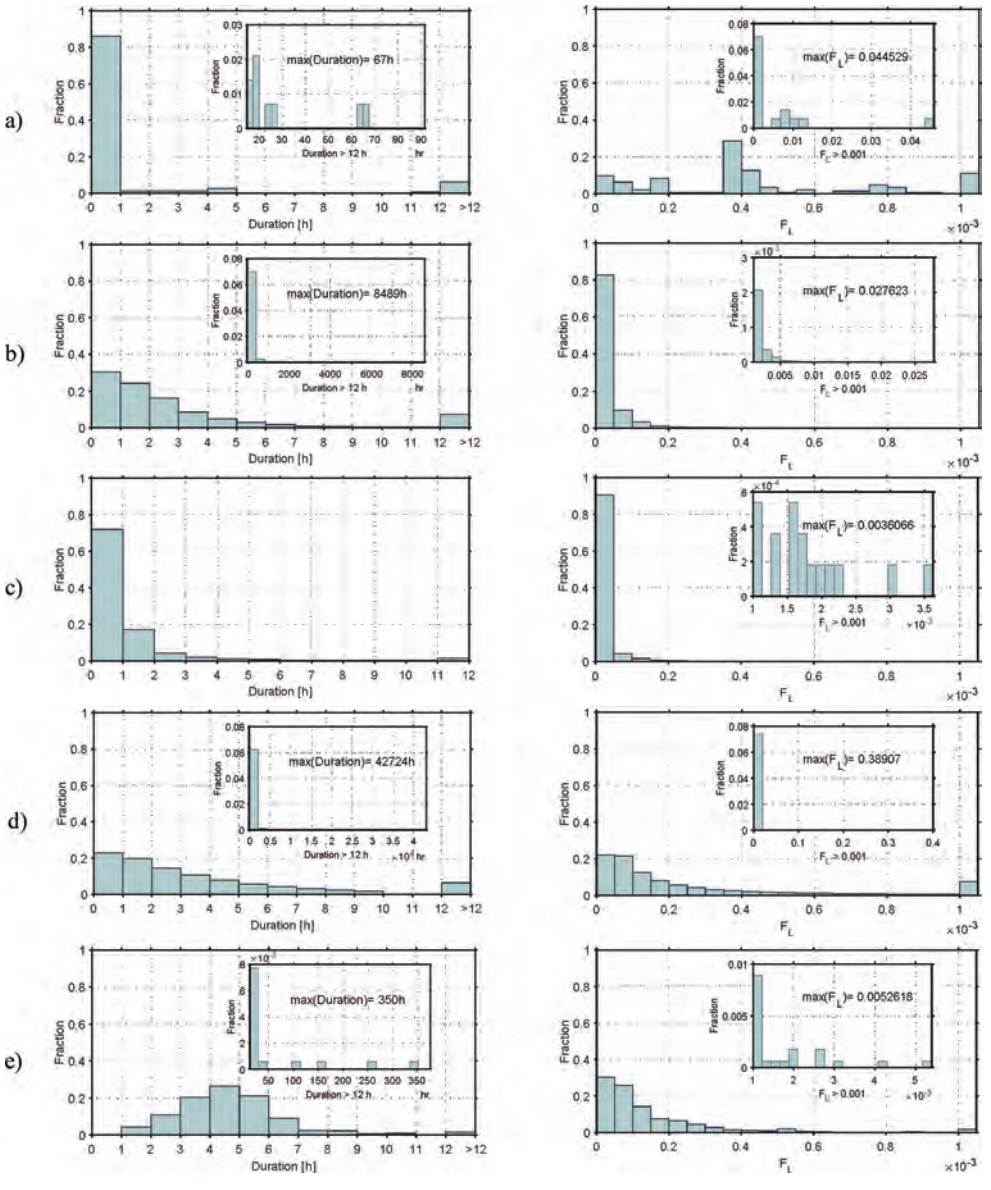

Figure 8. Histograms of duration (left) and functionality loss (right) for: a) Electricity transmission, b) Electricity distribution, c) Transport Road, d) Transport Railway, e) Water supply. In the plots the interruptions exceeding 12-hour duration or exceeding 0.001 functionality loss have been separately binned for reasons of clarity. In the inset figures these binned exceedance values are shown.

Striking a balance between these goals, national comparisons and internal usage, is hence of essence. For some infrastructures there seems to overall be a lack of structured data collection processes in place, e.g. water supply infrastructure and telecommunication/electronic communication infrastructures. For example, for the water infrastructure we found a document from the trade organisation Svenskt Vatten that is not encouraging collection of the kind of data that is necessary for empirical resilience estimations as carried out here. This document gives quite detailed suggestions of how to collect disruption data for the water distribution sector and what parameters to include, whereas only start time is proposed as being of importance and excluding end time. This is one of the causes why much of the data

we could receive from the water sector was not usable as it did not come with accounts of ending times for the interruptions.

There are many aspects that can potentially be explanatory of the found differences between the resilience levels of the infrastructures. For example, the infrastructure with the lowest resilience level, transport railway, is known to be a highly a congested system with few redundancies and a system that often operates close to the limits of maximum capacity, leaving no margins to absorb coincidental variations and stresses. In comparison, the transport road infrastructure has greater redundancies, where there are alternative routes available if a certain road is interrupted, lessening the overall consequences. Similarly, the infrastructure with the highest resilience level, the electricity transmission system, has a high degree of redundancy and more seldom are operating close to the limits of maximum capacity. The electricity transmission data was the only one with systematically collected zero consequence interruptions. These zero consequence interruptions are of high interest when trying to give an account of the level of flexibility and adaptability in the system for tolerating stresses, but unfortunately these type of interruptions are not systematically logged for the other infrastructures.

Since electricity transmission is one of the most critical infrastructures, for which many other infrastructures are dependent upon, (e.g. Johansson et al., 2015) there might be more incentives in place for this infrastructure that has led to the high level of resilience that we see in our data, which would be interesting to explore further.

There are also other structural properties and contextual factors that influence the resilience level as assessed from empirical failure data. For example, the electricity transmission system is a quite protected system, e.g. highly tree-secured and generally harder to access, compared to the electricity distribution system, where interruption due to falling trees and excavations are quite common and are, in general, more exposed systems. The water supply infrastructure was shown to be the second most resilient infrastructure, this is likely because even when failures occur, many times some degree of functionality can still be obtained (although loosing pressure in the system), where customers in many cases will not experience a complete loss of service.

The resilience assessment approach presented here is designed to utilise empirical failure data. We discovered that there are inherent limitations of the data in terms of resolution when it comes to assessing infrastructure resilience, such as that the behaviour during the disruptive- and recovery phase is unknown. As such the results are slightly pessimistic, as normally customers get incrementally reconnected during an interruption. Further, as with all empirical approaches it is a retrospective exercise, and hence have limited predictability of the resilience towards unknown or not yet experienced stresses. The approach however does allow for a robust resilience comparison of different critical infrastructures and how the resilience level changes over time. As such it provides relevant input for further explorations of causes and incentives for achieving resilience across infrastructures.

With further extensions of the presented work, it could also be possible to analyse the influence of infrastructure interdependencies on the resilience levels (c.f. Dueñas-Osorio & Kwasinski, 2012, Zorn & Shamseldin, 2015b). Given for example a power outage in the electricity transmission system it could be possible to quantify how that impacts other infrastructures, e.g. the electricity distribution system and the transport railway system. Further, if the interruption data is also combined with other data such as wind speed, rainfall and temperature, or average income or population densities given the outage area, further explorations into the causes and effects of infrastructure failures is possible.

The results presented here is valuable input for further studies of the underlying factors that are shaping and influencing the resilience levels of different infrastructures. In the end, giving guidance towards how underlying influential factors can shape the resilience of critical infrastructure, factors such as regulatory schemes, differing design philosophies or risk cultures. The approach can also be used for bench-mark type studies, e.g. how resilience strategies for one type of infrastructure might be possible, or impossible, to implement for another. It is also possible to explore different design philosophies in more depth and their impact on the resilience of critical infrastructures.

7 CONCLUSIONS

In the paper, a generic approach for the assessment of resilience levels of different types of critical infrastructures based on empirical interruption data is presented and applied to several Swedish critical infrastructures. It is concluded that the approach is applicable for a unified comparison of the resilience levels of different types of technical infrastructures at a national level. The most resilient infrastructures are Electricity transmission and Water supply, and the less resilient infrastructures are Transport railway and Electricity distribution. The results also reveal difference in how resilience seems to be achieved, where some infrastructure seems to focus on limiting the interruption times (such as Electricity transmission) and some focus on limiting the consequences that arise (Water supply). This type of information is valuable for

understanding the level of resilience and what is influencing and shaping the resilience of our critical infrastructures.

Working together towards Critical Infrastructure (CI) resilience

C. Lomba-Fernández, J.M. Sarriegi, P. Marana & L. Labaka
Tecnun, University of Navarra, Donostia-San Sebastián, Spain

ABSTRACT: Improving the resilience level of a critical infrastructure is vital to face crises and ensure its proper functioning. This paper describes the methodology followed to gather information for developing a methodology to assess the resilience level of Red Eléctrica de España (REE), which is the company responsible for the transmission and operation of the electricity system in Spain. The process was based on the three units of analysis of a crisis: peak of the crisis, lifecycle of the crisis, and learning process among crisis. In the peak of the crisis we identified the impact variables that allow to characterize a crisis, and the main key stakeholders. In the lifecycle of crisis, we analyzed how the preparation and prevention activities affect the response and recovery. Furthermore, a CIs' interdependencies analysis was carried out. Finally, the last step focused on understanding how the CI learns between one crisis and the next one.

1 INTRODUCTION

The welfare of society is highly dependent on the efficient performance of Critical Infrastructures (CIs). In general, CIs are those systems and companies that provide essential services that underpin, maintain and sustain vital societal functions in which relies societies' wellbeing (DHS 2017; EU 2017).

CIs are very complex systems with high degree of interconnections among them (Rinaldi 2001). These systems are designed to be reliable and robust but, at the same time, the inherent complexity increases their vulnerability since they become completely dependent of other CIs proper functioning. This vulnerability could be translated into impacts, direct and indirect, when one of those CIs fails.

Nowadays, as the potential threats affecting CIs are global, so are the effects of the crises they lead to. Trends like the technological advances of the last years, climate change or interdependencies among systems have modified how crises occur and evolve, making the events and their consequences more difficult to foresee and prevent. A crisis can be defined as a consequence of an unexpected triggering event that suddenly or by an accumulative process of near misses strikes the entire system (Coleman, 2004; Mitroff & Anagnos, 2000; Pearson & Claire, 1998).

Relevant crises in the las years, like Hurricanes Katrina in 2005, Sandy in 2012, the most recent Harvey in 2017, the earthquake in Japan that derived in the Fukushima nuclear accident in 2011 or the Ukraine Cyberattack in 2015 have something in common, all of them affected several CIs significantly causing important impacts in many sectors and making the recovery phase more difficult and longer (Comes & Van de Walle 2014; Chang et al. 2007). Sometimes, cross border effects and interdependencies make several nations being affected by crises, and require international cooperation. Dealing with crises requires a huge effort, and involves many stakeholders from different organizations of different nature and even from different countries.

It is clear that CIs must do all they can in order to anticipate and prevent crises but, at the same time, they should improve their capacity to act in a dynamic, flexible and creative way. Furthermore, CIs should develop skills and tools that lead them to a successful resolution of any type of crisis, predictable or not. Risk management is necessary but is not enough when facing unexpected crises. CIs must go beyond known risks and must be resilient (CSS 2011).

Resilience can be considered as a strategic property of the systems that enhances system's capacities to adapt to and face successfully any type of crisis, in a changing environment. Those capacities refer to: 1. – the ability to prevent, anticipate and then avoid a crisis; when the crisis occurs, 2. – the capacity of a system to resist the triggering event absorbing and mitigating the impacts; and 3. – the capacity to recover rapidly and efficiently, being able 4. – to learn, improve and prepare for future stressors (Ganin et al. 2016; Hosseini 2016; Francis & Bekera 2013; Hollnagel et al. 2007).

In the literature there can be found some approaches and proposals for measuring a CI resilience. The majority of them focus on their technical attributes such as the robustness of the physical assets or their redundancy level. Other methodologies

adopt a risk management approach, considering the system behavior against a specific risk. The organizational resilience perspective takes into account the sociotechnical attributes of the CIs but they don't pay special attention to the technical aspects. Furthermore, most of the methodologies lack to offer a more holistic view, and they don't provide tools to characterize both the event and the impacts (Cimellaro et al., 2010; Panteli et al. 2017; Brown et al. 2017; Labaka et al. 2016; Ouyang & Wang 2015; Aleksić et al. 2013; Petit et al. 2013; McManus et al. 2008).

To develop a methodology to evaluate the resilience level of a CI from a holistic approach, considering both the technical and the organizational aspects, it is necessary to get a deep knowledge about the crisis occurrence, analyzing how it happens and the effects it has in the CI. Furthermore, it is interesting to find the way to analyze the crisis evolution over time, to identify key cross-cutting capacities that, duly enhanced, will lead to a more resilient system.

Before defining the resilience assessment methodology, the challenge is to design an effective strategy to gather the most relevant information to create the method.

2 METHODOLOGY

Knowledge about CIs behaviour against crises is embebed into the practitioners' minds. Thus, to determine the CIs performance in a crisis, is essential to work together with all relevant stakeholders to agregate their knowledge and obtain a comprehensive vision of the whole crisis including all different points of view.

As the resilience building process needs the commitment and participation of all the stakeholders involved (Gimenez et al. in press), we can combine different methods to gather as much information as possible from all the sources available.

Individual interviews with key stakeholders are an interesting resource, as they provide precise data from their daily work that let get an idea about their personal perspectives, what kind of data they manage or how far they are familiarize with the topics under study.

If we want to collect information from a large group of people we could carry out a survey. A survey is a systematic method for gathering information from entities for the purpose of constructing quantitative descriptors of the attributes of the larger population of which the entities are members (Groves et al. 2011). The selection of a representative sampling, the adequacy of the questions and the processing of the data to reach the goals set will be crucial to get valid results from the survey.

Once the most significant issues related to resilience have been identified from a wide range of practitioners, we can work on the most relevant issues in workshops with reduced number of experts through collaborative methodologies.

Collaborative methodologies can be very useful, as people within the organization from different departments and with distinct levels of responsibility, share and discuss they knowledge and ideas to contribute to a common goal.

As a result, we will get a shared vision from the individual points of view and understanding.

Group model building (GMB) is an example of collaborative methodology that enables integrating fragmented knowledge, initially residing in the minds of different agents, into aggregated models (Scott et al. 2016; Andersen et al. 2007). GMB is based on workshops where modelers work on the problem jointly with multidisciplinary domain experts.

GMB has been employed successfully in many areas such as inter-organizational integration of information, health care system organization, organizational strategy changes, analysis of integrated operation strategy in a crude oil and gas company or CIP (Luna-Reyes et al. 2016; Hernantes et al. 2012; Ackermann et al., 2010; Rich et al., 2009).

The outcomes from the GMB process are essential to understand and identify the crisis behavior patterns, and then, to set the most representative variables to typify the resilience of the system.

This paper describes how the above explained methods have been used to identify the key elements in the CI under study for developing a methodology to assess its resilience level and improve it.

The process has been carried out within the context of a project with a CI from the energy sector in Spain called Red Eléctrica de España (REE).

3 INFORMATION GATHERING PROCESS

Crises can be analyzed from different perspectives. The analysis can only focus on the triggering event and subsequent direct impact, or it can have a broader perspective including the pre-crisis period, the peak of the crisis and the post-crisis. Furthermore, the analysis can focus on looking at how the system learns from one crisis to the next one, broadening even more the perspective.

In order to analyze the crises from different perspectives, this research uses the three units of analysis (see Figure 1) defined by Labaka et al. (2011): 1. Peak of the crisis. It focuses on the magnitude of the triggering event evaluating the immediate consequences due to the event and the impacts. This analysis provides relevant information about issues like what factors characterize the crisis, which are the most important impact variables, who are the

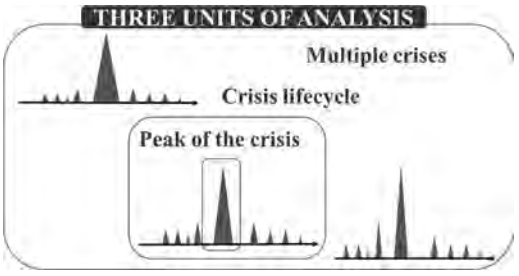

Figure 1. Three units of analysis (Labaka et al., 2011).

key stakeholders and which are the mechanisms of the CI to cope with the crisis. 2. Lifecycle of the crisis comprises the pre-crisis, the peak of the crisis and the post-crisis. The study of the complete cycle of one crisis allows to understand how the preparation and prevention activities carried out in the pre-crisis phase, affect the response and recovery activities. Finally, the last unit of analysis is 3. Multiple crises, where the period of time between one crisis and the next ones is analyzed. The objective in this case is to identify how the CI under study learns between one crisis and the next one.

This method has been successfully used in another project to analyze major power-cut crises in Europe. (Hernantes et al. 2013).

Based on the three perspectives defined, the process we followed was structured in the next three steps:

1. Analysis of the peak of the crisis.
2. Analysis of the lifecycle of the crisis.
   a. Analysis of the CI interdependencies.
3. Multiple crisis analysis.

Each of those three steps was performed for obtaining knowledge about specific objectives as it is explained bellow.

3.1 *Peak of the crisis*

The peak of the crisis covers the period of time between the moment when the crisis strikes, and the moment when the CI starts its recovery. It represents the most visible part of the crisis, in which most of the impacts appear. It is the moment where all the efforts we have made before to improve our capacity to face crises are tested.

The objectives for this first phase were: (1) To characterize the peak of a crisis in the CI under study, and (2) To determine the most important variables to characterize the impact of a crisis.

To reach the goals set we needed: to comprehend the CI under study, to understand what a crisis means for them and, finally, to know how they represent and measure their crisis.

With that aim, we asked the CI for information related to the organization itself and, in particular, everything related with crisis management, records and indicators.

The CI employees participating in the project were, firstly, interviewed individually. In particular, seven people were interviewed. The participants had technical profile and belonged to the transmision and operation divisions, more specifically to the following departments: renovation and facilities improvement, lines maintenance, substations maintenance, telecommunications, lines engineering, substations engineering and system operation.

All the interviews had the same structure. At the beginning general information was requested (company structure, departments, activities, business, …) and they were asked, in particular, about their function and responsibility in the organization. Secondly, they were asked about their knowledge regarding the crises related procedures in the organization (risk analysis, contingency plans, chains of command for crises management, reports of past crises and incidents, procedures and agreements with external stakeholders). After that, they were asked about the indicators and variables they managed to identify, report and register the crisis. We were interested, especially, in the indicators used to represent the crisis impacts.

In addition to the interviews with the participants in the project, we also interviewed the manager of the risk management department, to have the strategic view of the company about crises. The manager for the press office was also interviewed, to understand how crises are communicated externally, such as to the media, to other stakeholders and to the society.

The outcomes from this first step were:

1. A list of 21 indicators to quantify the impacts of an eventual crisis, independently of the triggering event and classified in four dimensions: structural impacts in the organization, social impacts derived from the CI failure, economic impacts, and environmental impacts.
2. A set of five representative indicators of the peak of the crisis, that will let us to represent the evolution of the crisis over time, taking into account both internal and external aspects for the CI. Those five indicators were chosen among the previously identified 21 indicators, and they are: percentage of their own infrastructures damaged (V1), percentage of users without electrical supply (V2), percentage of extra resources needed for the crisis resolution (V3), level of the company's knowledge about the situation (V4) and, finally, the public anxiety due to the crisis (V5).
3. The duration of a "standard" peak of the crisis in the CI was set in 48 hours.

4. A classification of the crises according to four extreme patterns defined based on two parameters: on one hand the resilience level of the CI and on the other hand, the magnitude of the event. Thus, we would be able to represent any kind of crises based on the resilience level of the system and the magnitude of the triggering event regardless of its origin (see Figure 2).

This first phase of interviews, highlighted some barriers that hindered the optimal data and knowledge collection. For that reason, we decided to apply, hereinafter, collaborative methodologies as GMB, to manage barriers like:

- Silo thinking: Each department is expert in a specific issue and they only focus in the aspects related to their specific field of knowledge.
- Confidentiality. Sensitive information is only available for a few people within the organization, usually "high" profiles and does not transcend to other operational levels.
- The existence of long chains of command (and levels of information) that derive in loss of perspective of the whole crisis and its impacts.
- Poorly established failure sharing culture.
- Reports about crises don't reflect a holistic view of the crisis as, in general, they focus on technical aspects and don't collect information about social or economic impacts.

3.2 *Lifecycle of the crisis*

In this unit of analysis, we extend the study taking into account the whole lifecycle of the crisis, that is: the pre-crisis, the peak of the crisis and the post-crisis.

Whilst in the peak of the crisis the focus was on the impacts, the lifecycle also considers the preparation and the recovery activities to manage the crisis. During the pre-crisis, CIs' activities are oriented towards anticipating and preventing the crisis occurrence identifying hazards, threats and vulnerabilities, and preparing plans to afford risks and reduce weaknesses. In the peak of the crisis all the efforts are concentrated on absorbing and minimizing the impacts, trying to reduce the human and material losses, avoiding the cascading effects and recovering the service, all in the shortest period of time. Finally, the post-crisis encompasses the recovery to the normal operation levels where all the equipment and physical systems damaged and affected must be repaired and restored. These activities can last several months or even years.

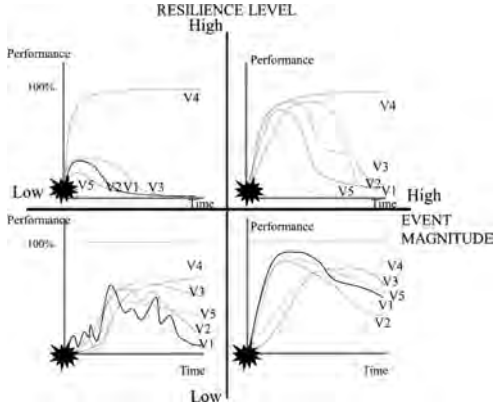

Figure 2. Four patterns for CI crises classification according to CI resilience level and the magnitude of the triggering event.

With the objective of obtaining information about the prevention, preparation, response and recovery activities in REE we carried out a table-top exercise with the participants. We put as an example a hypothetical catastrophe which damages considerably the physical systems, such as power lines and some important substations, as well as weaken the response capacity of REE leaving the system without the telecommunication service.

The session was structured in three parts.

In the first part the objective was to understand the mechanisms of CI for the response and recovery phases. With that aim, the hypothetical scenario of the catastrophe was introduced to the attendees and then, the participants were invited to describe, individually, the activities they would carried out to face the crisis to bounce back to their normal operational state. In addition, they should identify all the stakeholders involved in the crisis resolution. In particular, they were asked to match the stakeholders with the activities they should be involved in.

In the second part of the session the participants focused on the preparation phase. In this occasion they needed to think about the activities and measures that must be carried out to prevent a disaster and to be ready to solve it when it happens. We invited them not only to focus on technical issues but also to take into account management aspects. Moreover, they should identify strategic relationships with stakeholders within and outside the company for the satisfactory crisis resolution.

Finally, once the policies had been identified they recognized and analyzed the barriers and the difficulties to implement those policies.

The outcomes from this unit of analysis were:

1. The four dimensions of Resilience for REE, based on the literature (Labaka et al. 2016; McManus 2008; SMR 2016) and on the policies resulting from the table-top exercise. 1) Leadership: company management's commitment with resilience building process and its capability to promote and consolidate a cul-

ture, attitude and values based on it. 2) Preparedness: It refers to capabilities, knowledge, procedures and technical means of the company to afford crises. 3) Technical: it refers to system robustness and resistance capability in terms of impact reduction and loss of performance. 4) Cooperation: efficient management of human and material resources, internal and external, in major crises.

2. A set of policies to improve the resilience level of REE. Those policies refer to properties that the system should have and transversal activities that should be developed in order to enhance the resilience capacity of the CI.
3. A list of indicators for the preparation phase. For each of the policies identified at least one indicator is proposed, in order to be able to measure their evolution over time.
4. A list of indicators for the respond and recovery phase. As in the previous point, for each of the policies at least one indicator has been identified, to monitor and control the degree of implementation of each policy.
5. A tool to generate random scenarios of crisis (see Figure 3). Resilience is the capacity to withstand and deal with any kind of crises, predictable or not. With the idea of introducing a degree of uncertainty we proposed a tool that takes into account the potential risks but also trends, like Climate Change, demographic imbalances or interdependencies that can act as crisis enhancers. The core of the tool represents the resilience capacity of the CI.

3.2.1 *Analysis of the interdependencies*

CIs are tightly coupled than ever before constituting a very complex and strongly interconnected systems. The resilience approach takes into account the context of the CI under study and its interaction with other CIs, stakeholders, organizations, etc.

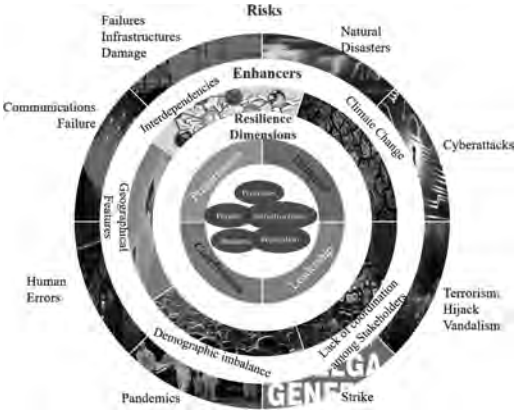

Figure 3. Random scenarios generator.

Interdependencies are the cause of many indirect impacts and cascading effects. Furthermore, they can be determinant for the recovery phase of one crisis. For that reason, when we want to evaluate the resilience level of a CI, an analisis of the interdependencies is needed.

As part of the crisis lifecycle analysis, we carried out the study of the CI interdependencies.

The objectives for this phase were:

1. Identify the CI's interdependencies:
   a. From which CIs they are more dependent.
   b. Which CIs are dependent from them.
2. Analyse in detail of the most critical interdependencies.

For the consecution of the objective 1, we decided to conduct an on-line survey within the company (CI) under study, based on the structure that Lauge et al. (2014) suggests, to analyze the CI interdependencies. We chose that method to obtain a broad view about interdependencies, and indirectly, about crisis management. In the survey 39 people participated, of whom 26 completed the entire questionnaire. They belonged to 15 different departments and most of them had technical profile.

The survey content focused on the dependencies that REE had with other CIs. We wanted to establish in which degree REE is dependent on other CIs' operation, in case of failure in any of them.

The survey proposes different scenarios of crisis due to a failure in one CI for different periods of time: less than 2 hours, from 2 to 8 hours, from 8 to 24 hours, from 24 hours to one week, more than one week.

With the obtained answers, the CIs from which REE is more dependant and the duration of the failure from which the situation becomes critical for REE were defined.

Furthermore, the analysis of the data from the survey also provided aditional information related to the perception of the employees about crisis and interdependencies. In general, there was not consensus on the issues asked. There was not a common view of the crisis and it was difficult for the employees to identify both the stakeholders and the dependencies.

To complete the interdependencies analysis (objective 2), a GMB workshop was carried out in order to share, discuss and then reach a consensus among the participants. In the first part of the workshop the results of the questionnaire were presented, explained and discussed. In the second part of the session, we focused on the analysis of the most critical scenarios according to the results of the survey.

We applied the tool dependency radar for the analysis (Laugé-Eizagirre 2014). The dependency radar provides a graphical representation of the level of dependency among CIs and helps to understand the CIs dependencies by identifying those dimensions that determine the dependency of a CI on others (see Figure 4). The tool sets out five dependency dimensions classified under two main areas. Failure area refers to how a CI can make another CI fail. Dependency for working, redundancy, and effect of external aggravating factors are the dimensions within this area. Recovery area refers to how the first CI can contribute or difficult the second CI's recovery. Recovery time and effects of resources sharing for recovery are the dimensions defined in this area.

Two scenarios of dependency were analysed with the dependency radar: the first one considered a power supply failure for 8 hours and the second one set out a 24 hours' communications failure.

They worked the cases in small groups of two and three people. Then, they were invited to explain and discuss the different radars to finally reach an agreement for each of the dependency scenarios.

The outcomes from this phase were:

1. The CIs from which the company is more dependent and the duration of the failure from which the situation becomes critical. This information is relevant as it lets REE to define actions to control and reduce, when possible, the dependency level with other CIs and, consequently, minimize the risks.
2. The period of time from which the situation becomes critical, when one of those previously identified CIs fails. This information is very important for characterizing the crises. Furthermore, it will help to design and choose appropriate prevention and mitigation actions.
3. A classification in four extreme patterns of dependencies, according to the CI dependencies to operate and to recover: FDRD (Failure Dependent Recovery Dependent), FDRI (Failure Dependent Recovery Independent), FIRD (Failure Independent Reovery Dependent, FIRI (Failure Independent Recovery Independent), (see Figure 5). This classification of the dependency relationships with other CIs by patterns allows to stablish similarities and differences among the scenarios analized.

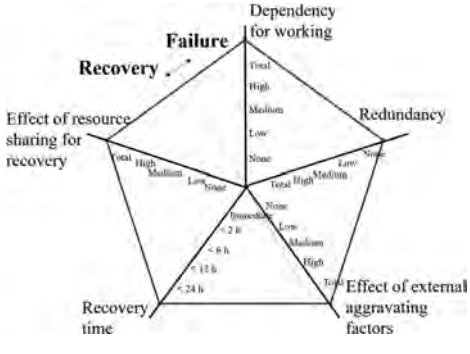

Figure 4. Dependency radar (Laugé-Eizagirre 2014).

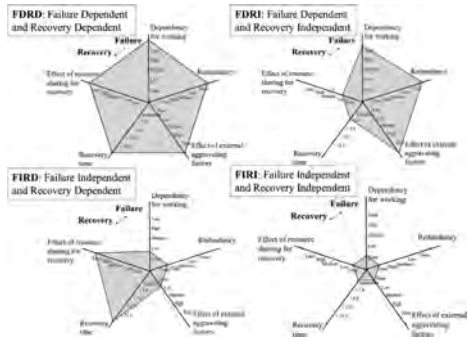

Figure 5. Dependency Patterns for dependency analysis.

3.3 *Multiple crisis analysis*

In the third unit of analysis we studied learning process from one crisis and the next one. When the learning process about the incidents or crisis is not systematize, organizations are condemned to repeat once and again the same mistakes.

Resilient systems learn from their own crises and also from others. One of the characteristics of the resilient systems is their situational awareness, an attribute that let them to maintain the warning level to detect small changes and signals that may prevent a crisis.

The objective of this third step was to understand how REE learns from its own crisis and from others'. With that aim we organized a workshop with the participants in the project. The session was structured in two parts.

In the first part we focused on the learning process and the knowledge they had about their own crisis. The exercise had four steps: 1. Identify relevant crisis of REE by heart, that is, without documentary support. The goal was to know the degree of knowledge, and awareness of the participants about their most relevant crisis. 2. To look up for information about those crises in the internal network. We wanted to get information about how they document their crises and incidents, which kind of information they report and the quality of the reports from a lessons' learned point of view. Moreover, how accessible was the information and how far they were familiarized with these searches. 3. Identify relevant changes in procedures and plans due to lessons learned from those crises. The aim was to see if the learnings turn into actions contribut-

ing to improve the resilience of the organization. 4. Identify indicators for the learning process in REE.

In the second part of the session, the objective was to analyze how REE learns from the crises that happen to others. With that aim, we asked them to repeat the four steps performed in the previous part of the session. Moreover, in this part, we asked them about their participation in national and international sectorial networks, related to crises management.

The outcomes resulting from this third unit of analysis were:

1. A list of indicators to monitor the learning process in REE. The indicators are classified in four dimensions of learning previously identified: documentation, analysis, dissemination and communities of practice. The documentation dimension assesses how far the organization reports the crises and incidents. In the analysis dimension we pay attention to the reports' quality and the reflection process and learnings derived from the incidents. Dissemination refers to how the organization spreads and shares the knowledge, lessons learned and good practices extracted from the crises analysis. And, finally, the communities of practice dimension studies how the organization promotes and participate in communities of practice about resilience topics within and outside the company, including international communities (see Table 1).
2. A set of good practices and lessons learned were identified extracted from the reports and from the workshop.
3. A list of barriers in learning identified by the particpants in the workshop and a proposal of actions for improvement.

Table 1. Dimensions and Indicators for the learning process.

Dimensions	Indicators
Documentation	Documented incidents in 1 year/total incidents in 1 year.
	Number of lessons learned from incidents in 1 year.
Analysis	Own incidents analized in 1 year/total incidents 1 year.
	Others' incidents analized in 1 year.
	Improvement actions from lessons learned in 1 year.
Dissemination	Number of incident analysis sessions in one year.
	Number of lessons learned sessions in one year.
	Man hours for incident analysis/total man hours per year.
	% of the staff whom receive direct communication of lessons learned.
	Level of knowledge of the staff about Company's incidents (0–10).
Communities of Practice	Quantity of communities of practice within the company, or conversations, related to crisis.
	Level of use of internal communities of practice (0–10).
	Company's level of presence in international communities of practice (0–10)

4 CONCLUSIONS, LIMITATIONS AND FUTURE RESEARCH

The process described in this paper has been successful for gathering the information needed to design a methodology to evaluate the resilience of REE.

Resilience building process requires of the participation and the commitment of all the stakeholders. In this way, it is very important to involve them from the early stages of the projects. While three units of analysis offers a wide view of the crisis cycle and establish an appropriate framework for the crisis analysis, the use of a combination of different methods to get the data and knowledge has created spaces for both the individual and the common reflection. Furthermore, the workshops themselves have provided an opportunity for encouraging the dialogue and the exchange of experiences around crisis management and resilience within the participants involved in the project.

However, the process has also highlighted some barriers. One of the most important is that information related to crises is treated as confidential, and only few people within the company have access to it. Related to this issue, in this case, it was not possible to interview or work with stakeholders outside the organization. Anyway the steps proposed consider also the participation of other external stakeholders.

Once the information has been gathered, the next step must be to analyze and manage all the gathered information, so it can be used to assess the resilience level of REE. Furthermore, the methodology should provide a guide to REE to improve its resilience level.

ACKNOWLEDGMENTS

This project has been promoted and supported for REE. The authors are thankful to REE for their implication in the project and their interest in disseminating the knowledge acquired.

ABSTRACT: Resilience of interdependent infrastructures increasingly depends on collaborative responses from actors with diverse backgrounds that may not be familiar with cascade effects into areas beyond their own sector. A simulation-game can enable societal actors to obtain a deeper understanding of the interdependencies between their infrastructures and their respective crisis responses. Following a design science approach, a simulation-game has been developed that combines role-playing simulation and computer simulation. The simulation-game challenges participants to address the interaction between payment disruptions, food and fuel supply, security problems (riots, robberies) and communication challenges (preventing hoarding). A number of crucial design choices were handled while developing the simulation-game. The main design challenges were: How to validate an unthinkable escalation scenario?; How to give the simulation a sufficient level of detail on all aspects and keep the complexity graspable so it can be played instantly?; and How much time should each playing round take?

1 INTRODUCTION

Resilience of critical infrastructures is a complex problem area. When societal actors with different backgrounds quickly need to orchestrate a collective crisis response, a deep understanding for the existing interdependencies between their respective infrastructures and crisis response strategies is required. Gaming-simulation can help to collaboratively develop a deeper understanding of such interdependencies and be a safe environment to explore the robustness of response strategies from a multi-sectorial perspective. In the context of tightly interrelated infrastructures a response strategy should not only be beneficial for individual organizations or sectors, but even mitigate consequences and limit escalations from a holistic multi-sectorial perspective.

Building a simulation game involves many design choices. Depending on which choices are made, consciously or unconsciously, very different simulations or simulation-games can be created for studying the same problem. It is important to build simulation-games of good quality and to understand how crucial design choices impact simulation-game design and simulation-game outcomes. Consequently, the contribution of this paper is a detailed description of our simulation-game design. Following a design science research approach, a simulation-game has been created that enables actors from a large variety of critical infrastructures to analyze and mitigate the cascading effects of payment disruptions on their respective infrastructures. Besides a presentation and motivation of the most important simulation-game design choices (Section 4), three major design challenges were identified: scenario validation, game complexity and length and number of playing rounds (Section 5).

2 THEORY BACKGROUND

Our research builds upon three research areas: critical infrastructures, resilience and gaming-simulation.

2.1 *Critical infrastructures and cascading effects*

Societies rely on well-functioning critical infrastructures such as Energy, Information and Communication Technology, Water Supply, Food and Agriculture, Healthcare, Financial Systems, Transportation Systems, Public Order and Safety, Chemical Industry, Nuclear Industry, Commerce, Critical Manufacturing, and so on (Alcaraz & Zeadally 2015). When one or more critical infrastructures break down or provide only limited service, large numbers of citizens, companies or government agencies can be severely affected (Boin & McConnell 2007, Van Eeten et al. 2011). Breakdowns can be caused by internal factors (human or technical failure), external factors (nature catastrophes, terror attacks) or by failures of other infrastructures as there are many dependencies between critical infrastructures (Van Eeten et al. 2011). Energy and Information Technology or Telecommunications are well-known event-originating infrastructures that generate cascading effects in many other infrastructures, as has been shown in different types of analyses (Van Eeten et al. 2011, Laugé et al. 2015). In times of increasing digitalisation and an ever increasing development towards a digitally interconnected society, security experts argue for more awareness for digital vulnerabilities, more attention for cyber security and a need to educate professionals and citizens on these matters (Hagen 2016).

Ansell et al. (2010) argue that resilience of interdependent infrastructures increasingly depends on collaborative responses from actors with diverse backgrounds that may not be familiar with cascade effects into areas beyond and outside their own organisation or sector. Boin & McConnell (2007) and Van Eeten et al. (2011) argue that there is limited empirical evidence of cascading effects across many infrastructures, which makes it hard to foresee which interactions may occur across sectors. Risk analysis, business continuity management and crisis management training are often performed within the context of a single organisation or sector and are seldom addressing the holistic analysis of multiple infrastructures (Van Eeten et al. 2011).

More research is needed to understand collective resilience in the context of critical infrastructure management. In this study, a contribution is made by focusing on one application area, i.e. how payment disruptions impact other critical infrastructures. Despite the long term efforts of public and private actors in the financial sector in Sweden to identify, analyse and understand risks and to develop routines for preventing and mitigating serious disruptions in the payment system in Sweden, there is still a lack of insight into how the proposed action plans exactly need to be executed and how numerous other actors in society (e.g. citizens, food stores, gas stations, voluntary organizations, governmental agencies and so on) will act in case of a temporary or complete breakdown of the payment system. For instance, several key actors in the payment system have in earlier studies expressed that they will take a larger responsibility than their formal responsibility (MSB-2009-3309 2010), but it is not clear what this implies and how these organizations actually will act when crisis hits.

2.2 *Resilience*

Lundberg & Johansson (2015) and Bergström et al. (2015) list that resilience amongst others can refer to: bouncing back to a previous state, or bouncing forward to a new state, or both; absorbing variety and preserve functioning, or recovering from damage, or both; and being proactive and anticipating, or being reactive (when recovering during and after events), or both. Given the variety of interpretations of resilience, resilience is hard to operationalize into measurable indicators (Lundberg & Johansson 2015).

Lundberg & Johansson (2015) made an effort to merge and compile different points of view in the field of disaster and crisis response resilience into one systemic model, the *Systemic Resilience Model* (SyRes). The model departs from the idea that the coping with an unwanted event can be seen as a downward spiral activating certain basic resilience functions (anticipation, monitoring, responding, recovery and learning) and their associated strategies (where the strategies are the actual manifestation of the functions, or their 'form', which may differ from system to system). Further, Lundberg & Johansson (2015) suggest that resilience is needed to protect *core values*, i.e. values central for the existence of the system in focus. In safety-critical systems, such core values usually take the form of maintaining safety, such as avoiding harm to humans or critical infrastructures. For a commercial business such as a grocery store, a petrol station or a bank, a core value is typical to create revenue, i.e. to assure a higher income than outcome. Without this profit, the business will seize to exist. This core value will manifest itself in a number of practical activities which usually take the form of different flows such as goods, money, services etc.

In line with the challenges to resilience suggested by Johansson & Lundberg (2010) comes the fact that most systems in society, such as the payment system, depend on several different actors to function properly. Therefore, resilience must be considered from a systems perspective. In the field of resilience, this is sometimes referred to as '*collective resilience*'. Weick & Sutcliffe (2007) argue that

loosely coupled systems relying on a '*sensemaking*' process generally are more resilient than tightly coupled systems based on the assumption that all system states can be predicted and safeguarded against possible threats. This resembles distinctions made in safety science between the paradigms labelled Safety I and Safety II (Hollnagel 2013) where Safety I is signified by the idea that safety can be designed into a system and Safety II is signified by the idea that human adaptability is the most important contributor to success despite inadequate design or insufficient predictive capacity of safety engineers. Weick & Sutcliffe (2007) argue that a dilemma exists in sensemaking: you can optimise for analysis or action, but not both. This dilemma seems contradictory to the requirements of resilience, because Weick & Sutcliffe argue for sensitivity to operations and reluctance to simplify (i.e. an interest in details and scrutinize the situation at hand) and simultaneous blunt and immediate action without thorough analysis. The solution suggested by Weick & Sutcliffe (2007) is that deep knowledge about the system should have been acquired earlier (long before the disruption) so that quick and blunt action based on deep understanding of the system's dynamics is possible in case of disruptions. As more actors may simultaneously initiate a quick and blunt response, a risk is that these responses counteract each other. Weick & Roberts (1993) discuss how attentiveness (heedful interrelating) is key in a resilient group response, i.e. while acting quick and blunt, various actors should pay close attention to how other actors respond and to what kind of system behaviour their collective response leads. Heedful interrelating has been demonstrated in small groups. Heedful interrelating becomes challenging when systems become larger, more interrelated and involve more and more decision makers that do not really know each other and do not understand the impact of their decisions on nearby systems, as in the case of large interdependent infrastructure systems (Ansell et al. 2010). Then these groups of stakeholders may lack swift trust (Weick & Roberts 1993) and may lack a shared understanding of the situation and a shared vision, which may lead to inferior performance (Berggren et al. 2014). Yet another risk might be organisations or companies who continue putting their own goals ahead of the common good, thus risking initiating counterproductive actions that may hamper the process of recovery from disruptions.

2.3 *Gaming-simulation*

Gaming-simulation is defined as a specific form of simulation. Simulation in general aims at designing a model of a system in a complex problem area in other to be able to experiment with the model. Deeper insight in the behavior of the system is created by evaluating various operating strategies against each other in one ore multiple scenarios. Gaming-simulation differs from other forms of simulation in that it incorporates roles to be played by participants and game administrators, implying that people and their (goal-directed) interactions become part of the simulation (Laere et al. 2006). In addition to role descriptions and interaction formats, simulation-games can also include a physical simulation model (a board game, a mock-up, a computer simulation, or any other representation of a physical reality) which the game participants need to interact with. It is important to understand that both the changes and impacts of changes to the physical simulation model in the simulation-game and the interaction between the participants (often negotiation processes about what to change and how to interpret changes in the physical simulation model) are part of the simulation-game and object of study (Mayer 2009). Gaming-simulation is especially relevant when the "*how and why*" of the interaction processes between the participants are of interest and when these interactions cannot easily be incorporated in computer simulation models. In addition, it creates a deeper learning opportunity, as simulation-game participants literally are active participants in the simulation, rather than passive observers of a computer simulation.

To design a high quality simulation-game, many design choices have to be taken into account, which often are not self-evident, but rather involve tricky cost-benefit analyses ending up with a dilemma (is the benefit worth the extra cost?). Examples of such design choices are for example (Laere 2003, Mayer 2009, Meijer 2009): defining a limited number of research or learning objectives, defining the number and content of roles, defining the scope of the modelled situation/problem, guaranteeing the validity of the simulation, defining rules and constraints, defining the load (difficulty), choosing the location/environment where the game will be played, selecting the type of participants to be invited, design of qualitative and quantitative data collection during the game, degree of realism of the scenario, degree of complexity of the game (often phrased as modelling internal complexity of the system to be modelled, but creating external simplicity, i.e. an easy to understand and easy to play game for the participants), degree of competition, degree of dynamics, macro cycle (preparation, playing, debriefing, follow-up), micro-cycle (number of playing rounds) and real-time or symbolic-time.

3 RESEARCH DESIGN

Our research design is based on an inductive research strategy and a qualitative research method.

A clear theory on how critical infrastructures exactly are related, and how the many actors involved collaboratively could manage disruptions that create cascading effects in many infrastructures, is lacking. As such, there is a need for theory building rather than theory testing, which leads us to an inductive research strategy (Eisenhardt & Graebner 2007). From an interpretative perspective, we are interested in exploring the many different interpretations of actors involved regarding what challenges disruptions can pose and how they could be handled collaboratively across the affected infrastructures. A simulation-game can be a safe environment where participating actors can experiment with different action alternatives, and through their participation and their choice of resilience strategies demonstrate the core values they hold.

For the design of the simulation-game a design science research strategy is adopted. The result of design science research is a purposeful artifact created to address an important organizational problem (Hevner et al. 2004). In our case, the problem is "*understanding critical infrastructure dependencies and exploring collective infrastructure resilience strategies*" and the artifact is "*a simulation-game that can serve as save analysis, learning and exploration environment*". As argued in Hevner et al. (2004) design science is an iterative search method aiming at identifying a creative solution for the problem at hand. Given our interpretative stance, our aim is not to design the best or an optimal simulation-game, but rather to design one appropriate simulation-game (amongst many alternatives), and developing a deep understanding what the benefits and drawbacks of our chosen design are. Design science addresses relevance by a strong interest the societal needs in the application environment studies, and aims simultaneously at rigor through reflecting on the design process and arguing how the produced solution informs the research front (where either the produced artifact and/or the insights regarding *how to design* such an artifact can be research contributions).

A first data collection phase consisted of document study of prior incidents (33 reports), 6 interviews with key representatives from each sector and two half-day workshops with respectively 26 national and 11 local actors in order to identify cascading effects, consequences, actors involved and potential mitigating actions which they could perform with regard to payment disruptions (Laere et al. 2017a). Mapping these characteristics of our problem environment contributed to identification of the elements to be simulated in our simulation-game. A second data collection phase aimed at analysing existing simulation-games for critical infrastructure resilience (Laere et al. 2017b). Here, six existing simulation-games where analysed in detail with the purpose of understanding how different design choices impact the capabilities of the learning environment and the learning experience of the participants.

Next, the collected data was analysed and transformed to elements of the envisioned simulation-game. During a series of six bi-monthly organised full day workshops with the project team of 10 researchers, different versions of the simulation-game were created, tested and refined. In between the workshops the involved researchers worked in smaller task forces on different elements of the simulation-game. During the last to full day workshops societal actors from the different sectors were involved to gather their feedback on the simulation-game design. The next two sessions summarize the main design choices and main design challenges that were identified and dealt with under this design process.

4 GAME DESIGN CHOICES

4.1 *Game overall structure*

When role playing simulation games and computer simulations are combined a powerful simulation environment is created. Actors, as game participants, can collaborate or compete with each other in different rounds, enter their decisions in the computer simulation and receive the output of the computer simulation as input in their next playing round. As such, participants can experience social interaction (role playing) and large scale system dynamics (impacts of their decisions over time, or on a large scale). The participating decision makers can compare intended consequences with unintended and unexpected consequences and create a deeper understanding of the system as a whole and the behavior of other game participants.

The main purpose of the simulation-game is to create a deeper understanding of the dynamics and interdependencies in the overall system. Alternatively or additionally, collaboration between the different actors involved could be a learning goal. When collaboration is a learning goal, actors may be placed in different rooms and different actors may have different information at hand. In such games sharing the right information with the right actor at the right time might be in focus. In our design became clear quite early that grasping the complexity of the overall societal system (i.e. all sectors that are impacted by payment disruptions) and their interactions is a challenge at such. It was decided that grasping this complexity created sufficient load and that additional collaboration challenges would adventure the main objective of understanding overall system dynamics. Therefore

it was decided that the players, who each can represent different societal roles (i.e. food sector, fuel sector, media etc.) would be placed in one team that in collaboration would try to manage payment disruptions.

Putting the participants in one team makes the use of simulation-game flexible. Teams could consist of either 3, 5, 7, 9 or 11 participants interacting as one team with the computer simulation. From a learning perspective it is preferable to have a larger group with a strong diversity in backgrounds, but from an execution perspective it is a benefit that a simulation-game session still can be performed even if two of the seven participants would not show up.

The team interacts with a fictive society represented in the computer simulation. The computer simulation is created with Anylogic simulation software. The main reason to choose this software package is that it enables to combine agent-based simulation, discrete event simulation and system dynamics simulation, which gives us a certain flexibility to implement different scenarios. The computer simulation covers a typical region with some cities and some countryside, where relevant societal infrastructures can be distinguished (see 4.2). The overall idea is that payment disruptions occur (see 4.3) in this fictive society and that the team can try out different combinations of actions strategies (see 4.4) to learn how they differ in impact on a number of performance criteria (see 4.5). An important characteristic of the simulation-game is that the participating teams can re-play the same scenario over and over again (see 4.6). By keeping the scenario conditions constant the participants can really compare their chosen action strategies and experience and learn how different combinations of actions give different impacts.

During the design process we have alternated between versions that could be played at a distance, or at one physical location. Playing at a distance allows for more elaboration time between playing rounds which might be beneficial for learning (i.e. making more thoughtful choices). While keeping the alternative of playing at a distance as a potential future development, our current impression is that the intense discussion and interaction between the participants in the team are of major importance (as the learning and creation of deeper insight occurs exactly there). Therefore physical presence at one location is to be preferred.

4.2 *Sectors represented in the computer simulation*

From the document studies and workshops with societal actors (Laere et al. 2017a) a number of societal actors, sectors and processes has been selected that are primarily vulnerable for payment disruptions and therefore form the core of computer simulation of the fictive society in the simulation-game.

The fictive society consists of a number of grocery stores of varying size, a number of fuel stations and a number of pharmacies (where medicine can be bought). For each store a customer flow is created. The number of customers, their demands, and the number of stores are balanced based on statistics for typical regions in Sweden. Stores offer one or several of the following payment options (card payment, cash payment, digital phone payments and delayed invoice payments). Individual customers have also one or more different payment options available. When customers collect goods in the store the store's payment options and their payment preferences need to match to create a transaction. Payment transactions are performed and accredited by the actors from the finance sectors (i.e. credit card companies and/or banks) and lead to account changes for stores and customers. When goods are sold new goods are order and delivered by transport companies. Customers and transport companies consume fuel, which in turn requires financial transactions when they buy new fuel. ATMs are available for those customers and transport companies who want to acquire cash and ATMs are refilled by certain transport companies. Security guards are present at the larger stores, and more could be hired when needed. Different media actors are represented who can spread news which in turn can influence consuming behavior.

In our current implementation there is a rather rough logic. The purpose in the development has been to quickly arrive at an implementation that can be played with actual representatives from different critical infrastructure managers. Given their feedback in early playing sessions the simulation-game will be further refined. Our aim is to perform 30 playing sessions in 2018 and 2019 and gradually improve the design science artifact under study.

4.3 *Payment disruption scenario*

Thus far one main scenario has been developed and implemented. During the course of our project (2016–2021) two additional scenarios will be created. Our current scenario is a 10-day card payment disruption at the store level. The other scenarios will be developed in such a way that they effect other parts of the payment system (i.e. disruptions in the transferring of money between accounts—or a long term scenario that covers multiple years rather than only a few days).

The current 10 day card-payment scenario is based on the fact that 90% of transactions in stores in Sweden is based on card payment, which makes

the Swedish society extremely dependent on that payment option as the other alternatives are not capable to instantly handle such large volumes of transactions. Although the scenario is much more detailed than presented here, the main elements of the scenario are as follows.

Day 1: Card payment disappears as payment option. The expectation of most actors is that it will take some hours. Stores close or offer digital phone payments or cash payments as alternatives. Chaotic scenes for those customers who are disappointed. Queues at stores and at ATMs.

Day 2–3: Banks and media announce that the disruption will take several days. Customers are confused where they can buy. Sales drop dramatically, use of cash and digital payments increase dramatically, some customers start hoarding, deliveries and logistics to stores are a mess as major fluctuations occur. A lot of cash in stores and in society at large increase robbery risks.

Day 4–5: Cash and digital payment options collapse as well as they cannot cope with the large volumes. Long queues, angry customers as they are running out of goods at home, customers become aggressive, a lot of stores close, those who are open experience massive hoarding. Perishable goods need to be thrown away as they cannot be sold. Logistics trouble increases.

Day 6–7: Government in collaboration with stores introduce a general "*buy based on your identity and pay later by invoice option*". Massive hoarding when stores open. Logistics collapse again as they have hard to adjust from total sales stop to massive hoarding.

Day 8–10: The general "*buy based on your identity and pay later by invoice option*" is too complicated and time consuming which creates enormous queues, frustration and aggression. Chaos and panic on more and more places. Police and army guard the few stores that still keep open.

The cascading effects that occur are not hard implementations, but do occur as cascading effects as a result of the initial card payment disruption. All other effects can be influenced when other actions are chosen by the players.

4.4 *Action alternatives to mitigate disruptions*

The team that plays the simulation-game in several rounds can select on ore more of the following actions. Besides these alternatives that are given (and prepared) we are open for creative ideas of the participants. When they come with a suggestion for an unforeseen action the game facilitators will try to simulate that action and its presumed impacts instantly in the simulation if possible.

Possible actions that the team can select are for example (note that each action can be implemented at any day in the scenario): offer more/less payment options at all or some stores; close or open stores; increase/decrease deliveries to stores; communicate information or instructions to customers; offer cash withdrawal in stores; limiting the amount of goods per purchase; increase/decrease the number of security guards for one or several stores; throw away perishable goods; give away perishable goods for free.

The design of the computer simulation involves an implementation of impacts of each and every action, based on interviews and discussions with key representatives from the different societal processes simulated. Even as we as designers know the approximate impact of individual action, the playing sessions need to reveal how the different actions in combination fall out. In addition, actions can be implemented on different moments in time (day one to ten in the scenario), which makes the number of alternative strategies near to infinite. Rather than experimenting with the computer simulation as such ourselves, the whole idea with involving real societal actors in role-playing is to let their expertise and value frames guide the selection and time-planning of combinations of actions. Moreover, not only the selection of actions as such is of interest, but also the motivation and reasoning behind. Therefore, the teams who play need to motivate the timing and selection of actions before they are implemented in various playing rounds and the collection of these motivations is seen as a crucial element of the simulation-game.

4.5 *Performance metrics*

Extensive discussions have been held at several of our design workshops and in intermediate work group meetings considering what indicators are most relevant and appropriate to visualize performance in the various sectors of society. Currently, three major performance areas have arisen: 1) payment options, 2) good flows, and 3) security

Available payment options are statistics on the actual use of each of the four different payment over time, or the amount of stores (in% of total stores) where they each option is available.

For good flows the main indicators is "disappointed customers" over time (the simulation counts the number of arriving customers that cannot fulfil their purchase for any reason). Additionally it is shown how many stores currently are closed (in%), which groups of goods currently are out of stock, how many perishable goods are destroyed over time, and how many planned deliveries that fail (due to fuel shortages).

Security related indicators are amount of cash in stores (implying increased robbery risk), number of shop lifting incidents, and the number of security guards per store.

A performance area which has been suggested but been hard to implement thus far is "trust". Although trust is a core value in society, it can be different kinds of trust (trust that you can obtain certain goods, trust in banks and stores, trust that you will be safe when being out in society). Our current interpretation is that trust depends on the other indicators and that is thus might be sufficient to only model them.

4.6 *Replay-ability*

After a short introduction into the learning goals, the computer simulation environment, the start scenario, and the way how the team can choose actions to influence the scenario, the team can play an optional number of rounds. When the start scenario is introduced the simulation is paused at day 1, day 3, day 6 and day 10 to show how the performance measures slowly deteriorate.

When the team later plays itself and chooses actions the simulation-games is initially paused at the same moments to be able to compare the new performance statistics with the earlier ones. Typically, it takes 10 to 20 minutes to discuss and decided on actions, so 1 to 1½ hour to play the full scenario once. Our expectation is that teams might succeed to play 3 rounds on a half-day (leaving time to sum up and debrief the whole playing sessions) and maybe 6–8 rounds one a full day (where the expectation is that playing speed slowly can be increased when the team plays more rounds as they get familiar with the simulation-game).

5 GAME DESIGN CHALLENGES

Most design choices have after some iterations and refinements evolved into more permanent choices where motivation why each respective choice was important gradually became more profound. Three design issues have been particularly challenging and are therefore interesting to highlight as potential areas for future research.

5.1 *Validation*

How to validate an unthinkable crisis escalation scenario? Many of the interactions that are simulated in the computer simulation are based on slightly related incidents and expectations of experts we have interviewed. It is however hard to translate observed effects of poorly related cases or judge the imaginary power of the experts. There might be certain interactions that are hard to imagine and which are not correctly represented in our current simulation. Normally, when building a simulation of an existing system, there is some kind of real data to validate against. As the purpose of crisis scenarios is to be far from the current equilibrium state, it is hard to foresee or imagine what relevant (new) elements and (new) interactions and dependencies are. An interesting future research area is therefore to develop methods and tools to improve the validation of crisis scenarios and simulations.

5.2 *Fidelity and playability*

A major concern in our current design is that players easily can get stuck in details. Multiplying 25 stores and several other actors with 3 decision points in time and roughly 15 different types of actions that each individual store can pick at each point in time results over 1000 potential actions which can be combined in infinite variations. Even though our simulation is a strong simplification of the actual complexity of our society, players might easily get lost here. It has particularly been clear that players easily can zoom in on individual decisions in individual stores and loose the "*overall society helicopter view*". This is a typical risk of introducing a detailed computer simulation in the role playing simulation.

In our current design discussions different options are explored to handle this issue. One is to develop facilitator strategies to keep the playing teams on track (while keeping the fine granularity of the computer simulation interface). Another is simplifying the computer simulation interface (i.e. limiting the amount or granularity of actions to be taken & decreasing the number of performance statistics). The latter has the danger that the simulation becomes to abstract and transferability between simulation-game learning and value of the lessons learned in real society is lost.

5.3 *Time per playing round and number of rounds*

A closely related concern is the number of playing rounds and the time per playing round for discussion in the team. More round is preferable, but they should not become so short that players quit discussing their motivations and just guess. On the other hand, teams might get stuck in endless discussions about which actions to choose without ever implementing them in the computer simulation.

Here, well-experienced facilitators are currently seen as the major viable option to fix this challenge. Alternative options could be to allow for playing the simulation independently at a distance after participating in the first facilitated team session.

6 DISCUSSION AND CONCLUSION

During the last two full day workshops where the latest version of the simulation-game was tested it was concluded (by designers and potential players, i.e. representatives from societal sectors) that the current design potentially can increase insight in collective critical infrastructure resilience. The main challenge is to make sure that the team who plays the game does not get stuck in details (due to complexity) and that the game facilitation is of such quality that a reasonable playing speed and number of playing rounds is achieved in a session, while at the same time team players experience to have sufficient time in each playing round to come to thoughtful and well-motivated action packages.

Researchers and practitioners can benefit from an increased insight into the challenges of designing simulation-games for critical infrastructure resilience analysis and training, as documented in this paper. Combining the insights from our design process with insights from alternative applications and approaches can increase the quality of our designs and thereby subsequently improve overall critical infrastructure resilience in society.

Resilient performance in response to the 2015 refugee influx in the Øresund region

H. Degerman, S. Bram & K. Eriksson
RISE Research Institutes of Sweden, Gothenburg, Sweden

ABSTRACT: September 2015 saw a sharp increase in the influx of refugees in the Øresund region. In this study, resilience defined as flexible adaptation was taken as a baseline to guide interviews with societal infrastructure actors and NGOs engaged in managing the situation. Different actors had different organisational preconditions that influenced their ability to adapt to the new situation. Among the strongest drivers behind resilient performance were the organisation's ways of relating to established rules, regulations, procedures and processes, the way relationships were formed between people and hierarchical layers within the organisations, and the perceived value of the human operator and the human contribution within the organisational whole. These values, in turn, determined how the organisations shaped many of the basic conditions that allowed resilient performance to develop. In the study it was found, for public actors in particular, that the criteria necessary to adapt to the situation were not met by organisational structures and processes.

1 INTRODUCTION

In the Øresund region, which consists of Denmark and the southernmost province of Sweden (Skåne), an increase in immigration was noticed during the spring and summer of 2015, but fluctuations were still within the normal range. However, in the beginning of September, the number of refugees reached unexpectedly high levels in just a few days, rising to the highest levels since the Second World War. In October the amount of asylum seekers doubled compared to the month before, and in November, with the argument that the large amount of refugees was threatening national safety and straining critical infrastructure functions to an unacceptable level (SOU 2017:12) the Swedish government decided to initiate border controls, which continued in steps during the rest of the year.

Refugees travelled to or through Denmark, Sweden, Norway and Finland, some reaching the Nordic countries by boat from Germany, but most travelling over the Øresund bridge, arriving in Malmö which is the third largest city in Sweden. Even though structures for the reception of refugees existed, the volume and rapid increase of refugees was a surprise for most of the organisations involved. The situation put a massive stress on infrastructure and vital societal functions, especially in the southern part of Sweden, and some organisations went into formal crisis management.

This article, which represents a limited part of a larger study, focuses on drivers and barriers for resilient performance within a group of organisations involved in immigration management in Malmö. The aim of this article is to identify areas of future organisational research and development that could contribute to better support for such performance.

2 STUDY OF CRITICAL INFRASTRUCTURE RESILIENCE IN THE ØRESUND REGION

This case study on critical infrastructure resilience was performed within the EU Horizon 2020 project IMPROVER. In the IMPROVER project, the concept "critical infrastructure" is defined in the following way:

Critical Infrastructure is an asset, system or part thereof located in Member States which is essential for the maintenance of vital societal functions, health, safety, security, economic or social well-being of people, and the disruption or destruction of which would have a significant impact in a Member State as a result of the failure to maintain those functions.

Resilience is a popular concept that is interpreted and applied in different ways (Bergström & Dekker, 2014; Woods, 2015). In this study, resilience defined as flexible adaptation was taken as a baseline. When studying resilience, researchers should strive to understand the factors that allow organisations to uphold their functionality despite changes in context, time constraints and workload, i.e. adaptability, how adaptability may manifest itself and evolve over time. This stance is exemplified by Woods (2015) saying that the search

for understanding rebound in past events should focus on understanding how the system changed for managing the new circumstances. This notion was used as the starting point for this case study. The rapidly increasing number of refugees within a short period of time meant that many organisations had to change their practices, particularly the public institutions on which society relies. In this study, the narratives provided by these actors were examined for signs of resilient performance.

2.1 *Research method*

A literature review of organisational aspects of resilience was conducted. In addition, several organisations were interviewed: DSB Trains (Danish national railway operator), the Danish police force, the Øresund bridge consortium (Danish and Swedish sides), the Swedish Migration Agency, Malmö Municipality, the Swedish Civil Contingencies Agency, the Swedish Armed Forces, Jernhusen (operator of Malmö central station), the Red Cross (Danish and Swedish) and Kontrapunkt (a Swedish autonomous NGO). In total, 28 semi-structured interviews were performed.

Since resilient aspects are not operationalised in most organisations today, informants could not be asked direct questions about resilience. Therefore a thematic analysis (Bowen, 2009) of the entire empirical and theoretical body was suitable, since such an analysis is directed towards the empirical data as a whole, not only towards already predetermined rules. Reflections over the empirical interview material were based on Alvesson's (2011) reflection approach and framework, where traditional notions of the interview have been complemented with eight metaphors with a social, psychological and linguistic nature.

An overarching goal of the IMPROVER project is to create an indicator hierarchy for resilience in critical infrastructure, but from a qualitative ethnographic perspective this could be problematic. Describing the performance of a complex system in terms of measurements may not provide the most useful information, because such system interactions typically require qualitative descriptions. The use of indicators is a logical non-contextual exercise, while real decision-making processes in everyday work or crisis is a complex analytical process (Salmon et al., 2014). Because of these difficulties, the abstraction hierarchy framework from Rasmussen (1985) was used as an inspiration when describing the identified themes from the thematic analysis in terms of indicators (or "things to look for in story-telling about past events in organisations"). The Rasmussen framework was originally intended for the design of technical decision support in complex systems, typically an automated system and a human operator combined. In this study we applied the framework to an organisational structure, where artefacts rather are procedural than technical.

2.1.1 *Result of thematic analysis*

The thematic analysis of the entire collection of empirical material resulted in four overarching themes. These themes represent areas where key examples of organisational resilient performance were identified.

1. Design of roles, tasks and processes
2. Artefact design: procedures and tools
3. Strengthening collaboration
4. Learning and re-design

Beyond these four areas, a fifth theme was identified which is referred to in the study as "Underlying values and interpretations", representing the way in which the other themes are interpreted. In the view of the authors, striving for resilience is not only about knowing what organisational abilities to enhance, but also about the way in which such abilities are sought—organisational values that may allow or deny developments that enable resilient performance. This article focuses on how design could support resilient performance.

2.2 *Focus of this article*

While the engineering community has spent many years looking for ways to measure and increase the reliability of isolated components in critical infrastructure, not nearly as much attention has been given to interactions within socio-technical systems. Paradoxically, this is precisely where the causes of many of the great disasters of our time can be found (Woods, Leveson, & Hollnagel, 2012). As time passed after the initiation of this study, official crisis evaluation reports were published (e.g. RiR 2017:4; SOU 2017:12) and measures were established. These measures have largely consisted of more administrative routines, plans and control processes, with little respect for the fact that similar structures caused problems when public organisations were faced with unexpected and rapidly evolving events. This article focuses on how design aspects within the five identified themes could equip these organisations with better adaptive capacities.

3 SIGNS OF RESILIENCE IN REFUGEE RECEPTION IN THE ØRESUND REGION

The results of this study reflect the notion in systems oriented safety research that because of system complexity, work is always to some extent

under-specified, and that humans in a socio-technical system should be seen as a unique asset instead of an unreliable and risky system component (Cook, 1998). Our study exposed several examples of resilient performance, i.e. adaptation to evolving circumstances and needs, both on a societal level and within each organisation.

3.1 *First response at Malmö central station*

The security guards of Jernhusen, the organisation that manages Malmö central station, made the first observations of the increasing amount of refugees at the station. Jernhusen informants said that they normally respond quickly to different circumstances, which explained their fast response in this situation. Jernhusen is a relatively flat organisation with few formal procedures and they have short paths of communication between hierarchical layers. Informants said decision-makers have a tradition of using the information provided by operative guards to build a picture of what happens at the station and to determine their response. Jernhusen functioned as a central hub during the entire autumn, organising space and functions within the station's walls and donating conference rooms where the involved organisations could meet twice a week. At an early stage, Jernhusen had to fight hard to get the attention of public agencies, and to get representatives of those agencies to visit the station and make their own assessment.

3.2 *Adaptations within public organisations*

The most affected public agencies were the Swedish Migration Agency and the Malmö municipality. In addition to the more obvious long-term responsibility of the asylum process, the Swedish Migration Agency was also responsible for the short-term housing of adults and families, while Malmö municipality was responsible for the housing of unaccompanied children. In the operative functions of these organisations, typically on or near the accommodation sites, the employees rapidly adjusted to the new circumstances.

As the workload quickly increased it was no longer possible to use the normal routines, which were deemed too time and resource consuming. Personnel at the accommodation sites understood that if they were to follow normal procedures, they would fail to meet the overall purpose of housing people in need. Instead they started to change the way they worked. Electronic registration forms were replaced with whiteboards, giving an overview of all the persons living there, their health status, their asylum process status and other important data. The formal way to procure materials and tools was too time consuming and had to be set aside. Instead managers themselves went to IKEA to pick up necessities like mattresses and kitchenware. These adaptations were crucial to fulfil the purpose of putting a roof over the head of every newly-arrived refugee. In all interviewed organisations, normal operations were abandoned in favour of new solutions, often based on the working experience and creativity of the personnel, or as Rasmussen (1985) states it, familiarity with the system's value structures. There is not only just one representation of how to operate, especially not when travelling towards the higher purpose in the abstraction hierarchy. The purpose could always be met in different ways.

3.3 *Focus on routines in public organisations*

Even though operative adaptations within Malmö Municipality and Swedish Migration Agency were necessary to handle the situation, these adaptations were not always facilitated by existing organisational structures or even condoned by management. Informants said that the abandonment of too rigid routines was to some extent contested by management and operative achievements were never fully acknowledged afterwards. Since the activities of operative personnel were not officially sanctioned, they were put in a sensitive situation in the case of negative outcomes.

Informants from the operative parts of public agencies said that during the whole event, no representatives of upper leadership came to the sites to form their own view of the situation. In the non-operative parts of these public organisations, there seems to have been a more wide-spread belief that the situation could be solved through ordinary processes, and this seems to have resulted in a lack of practical support for operations. It is known from safety research that when an outside observer attempts to describe the work of others, those descriptions tend to be more simplified and linear than actual work (Woods et al., 2012). In many organisations, decisions about procedures, plans and routines are made on a management level. If the gap between management and operations is too large, the assumptions guiding decisions about organisational structures may not reflect actual work needs, as seen in Malmö among the public actors.

3.4 *Internal organisational dynamics*

Judging from many examples described by informants, a key factor behind good internal collaboration and the ability to meet goals was a tight interface or likeness between those who detected and interpreted early signals of change and those who decided about actions. Signals of important changes are often sub-

tle and manifest in the course of operations, and if such information is not adhered to, the organisation's response may be delayed, which was the case for public agencies. Jernhusen on the other hand, where reactions were quick, generally depend on the input from their guards on the floor for decision-making. For Jernhusen surprises are normal for operations, which mean that reactions to these surprises have to be of the same flexible nature. In public organisations surprises are not desirable, which could be coupled to the demand on their processes for legal certainty. Paradoxically, in this case the focus on regular procedure combined with reluctance towards adaptations resulted in delays and problems in the process of fulfilling the basic needs of arriving refugees.

3.5 *Complementing NGO activities*

While public agencies were in some cases tied down by regulations, the results of this study showed that NGO's could sometimes fill the gaps created by slow official response. A large group of refugees arriving in Sweden were transit refugees, attempting to pass through Sweden on their way to Norway or Finland. In Swedish legislation, however, there is no such thing as a transit refugee. Any refugee arriving in Sweden has to seek asylum there, and the policies of the migration agency made it impossible for established NGO's to help these people. The Swedish Red Cross had a permanent barrack outside Malmö central station, on the square Posthusplatsen, which functioned as a welcome center and housed numerous different organisations. The organisations at Posthusplatsen had agreed to follow Swedish legislation, meaning that they would only help people who had the intention to seek asylum in Sweden. Instead, autonomous organisations stepped in to help the transit refugees. As one example, the cultural association Kontrapunkt arranged housing for 100–500 persons per night.

4 DISCUSSION

The analysis revealed a number of drivers for resilient performance within the studied organisations, such as different ways of relating to established rules, regulations, procedures and processes, the way relationships were formed between people and hierarchical layers within the organisations, and the perceived value of the human operator and of the human contribution to the organisational whole. These values, in turn, affect how the organisations shape many of the basic conditions that allow—or obstruct—resilient performance.

Different actors involved in the response to the 2015situation had different organisational formal and informal prerequisites that influenced their ability to adapt to the situation. This section deals with a number of such prerequisites such as tasks, roles, working environments, supporting tools and organisational structures.

4.1 *Heuristics for adaptation in organisational goals and values*

In the light of the present analysis, a likely challenge for public organisations will be to find ways of detecting when established rules and procedures are no longer appropriate and to find ways of adjusting them based on information from emerging events. In several of the organisations that were able to make successful adaptations, adjustments of normal procedures were made in relation to clearly defined and deeply rooted core goals. One way of approaching the issue of how to guide adaptations may be to look for such core goals or core functions which are central to the organisation and necessary for operations under any circumstances. Organisational goals may however have considerable room for interpretation. Because of that, it might be equally important to examine how organisations engage in dialogue around goals and values and who is allowed to participate when abstract goals are interpreted in terms of strategies and action.

4.2 *Adaptation supported by shared perceptions*

Examples of operative adaptations within the case could serve as an inspiration to more permanent and widespread design approaches within public organisations. Today, management typically has the final decision about artefacts such as plans, processes, procedures and work roles. For public actors a gap was observed between real work challenges and higher management's understanding of the circumstances and issues of operations. If organisations were to adapt supporting artefacts more consciously to operative needs, a first step may be to try to increase management knowledge about operative conditions, the real-life issues and difficulties faced by operators, so that solutions implemented by management do not run the risk of undermining operations. In terms of more profound changes to organisational practices, it could be rewarding to explore the implementation of design processes centred on system and user needs and to give employees a more active role in the constant evolution of artefacts. This could be an opportunity to bring the fields of safety science, organisational science and design science closer together.

4.3 *Lessons learned as re-design*

All of the interviewed organisations involved in the 2015 reception of refugees in the Øresund

region give examples of organisational lessons learned and adjustments that have been made with respect to these experiences. On the other hand, and for public organisations in particular, a large portion of learning and re-design seems to have been oriented towards formal organisational artefacts such as plans and procedures. For example, one of the main interventions has been to extend the practice of Risk and Vulnerability Analysis to the Swedish Migration Agency. These analyses are a national requirement for specific public agencies and are coordinated by the Swedish Civil Contingencies Agency (MSBFS 2016:7). As noted in the analysis, this could be interpreted as a reflection of the very focus on compliance and official doctrine that undermined adaptation during the crisis. From the perspective of systems oriented safety research, strict routines and procedures are in themselves no guarantees for safety and efficiency (Dekker, 2001). Yet another scenario is added to risk analyses, only to find that the next large disturbance has unexpected or unique qualities. The calibration of routines and procedures, or the addition of new documentation or similar symbolic barriers is a common response to negative events within organisations (Hollnagel, 2008). Here it must be acknowledged that procedures will never cover every possible scenario and may even limit the creative problem-solving abilities of professionals (Dekker, 2003). Every added barrier or new procedure will also increase system complexity, thus possibly increasing the demands on the people controlling the process, with potential negative effects on their performance (Praino & Sharit, 2016). On the other hand, procedures may provide stability and common ground, particularly in crisis response that involves a diverse set of actors. Just as with any organisational artefact, procedures can be consciously designed, informed by and adapted to their users. As noted above, it may also be possible to explore different ways for organisations to assess when normal procedures are not enough and adaptation is needed.

Another possible interpretation is that the problem does not lie so much in the procedures themselves, but rather in organisational perceptions and values around management and compliance. The process of gathering experiences and turning them into improvements should never focus only on administrative outputs. Firstly, future research within the public sector could explore the implementation of methods that allow for systems-oriented analyses of events and activities. This could give governmental organisations a more complete picture of past events and a better understanding of all the different pre-conditions that must exist to support operations. Secondly, event analysis could be tied more tightly to a general design process so that lessons learned are used to produce solutions that are suited to the needs of potential end users. This approach could counter the risk of adding to their administrative work burden.

4.4 *The role of employee experience and overarching organisational values*

Much of the above discussion centres on design issues, but the extent to which the studied organisations were able to perform resiliently also seems to depend on the way relationships were formed between people and hierarchical layers within the organisation, or on the perceived value of the human operator in the organisational whole. It is important to acknowledge that processes and tools do not in themselves guarantee good outcomes. Even though work-supporting artefacts from processes to decision-aids may have all the right attributes, an organisation can still prove too rigid and slow to adapt to the fast pace of real-world operations. For example, if an organisation is to reap the benefits of use-centred design, it also has to have a fundamental respect for the experience and practical knowledge of operative personnel. It is hard to imagine that the individual operator envisioned in resilience research -knowledgeable, creative and full of initiative—would be likely to exist within an organisation that does not have a fundamental appreciation of its employees, acknowledging the signals and interpretations emerging from operations. Furthermore, the existence of good adaptive designs that are achieved repeatedly presupposes a continuous dialogue around working conditions and developments within the organisation, so that designs can build on a good representation of reality. This concept calls into question the measure-centric, hierarchical paradigm of management and control found in many of today's organisations and raises the question of how future management could be steered towards more inclusive and systems-oriented principles. Purposeful designs cannot be reached without applying a systems perspective, making sure that solutions support not only individual actors within the system, but also activities that are distributed among people, mediated by technology, within an organisational context.

5 CONCLUSION

The 2015 increase of refugees arriving in Malmö meant a great challenge for the organisations involved in the response, and interviews within this study revealed a number of examples of resilient performance. One of the main findings of this study has been that resilience does not primarily

reside in simple organisational features, functions or resources, i.e. simple boxes to tick in an organisation's management system. Rather, some of the most important resilient behaviours in the observed case had to do with adaptations—trade-offs and judgments made by professionals under the sometimes harsh conditions of real-world operations.

In terms of resilient performance, although many examples of this emerged during the reception of refugees, it also became clear that disconnections between management and operative personnel may hamper adaptability and lead to designs of organisational structures that do not fully answer the needs of their users. For these reasons, it is suggested that future research investigates different ways of guiding adaptations e.g. from a basis of core organisational goals and values, and of creating joint perceptions between management and personnel.

Practices such as employee inclusion, increased local autonomy, user-centred design and systems-oriented organisational learning may require a new set of values within an organisation. These values include an understanding of the organisation as a socio-technical system and a fundamental respect for human experience, initiative, collaboration and problem-solving. While studies such as this one can provide positive examples of resilient performance, deeper changes may require a paradigm shift for both public and private organisations that in itself will require further research and interventions.

ACKNOWLEDGEMENTS

This study is part of the EU Horizon 2020 project IMPROVER (grant agreement no. 653390, www.improverproject.eu), where the Øresund region is included as a living lab.

ABSTRACT: Recent natural and man-made disasters highlight that a more resilient approach to preparing for and dealing with such events is needed. To address this challenge, the main objective of the research and innovation H2020 project DARWIN is the development of European resilience management guidelines for Critical Infrastructures (CI). Based on a systematic literature survey with a world-wide scope and prioritization of resilience concepts, the guidelines have been developed taking into account everyday operations, contingency plans, training, etc. This paper describes insights gained from the adaptation of these guidelines in the domains of Air Traffic Management (ATM) and Healthcare (HC). A collaborative and iterative process has been defined involving relevant experts and practitioners. To ensure transnational, cross-sector applicability and uptake, a Community of Crisis and Resilience Practitioners (DARWIN DCoP) has been involved. The preliminary results indicate that a big step has been taken in moving from the resilience theory to practice.

1 INTRODUCTION

ATM and HC have a great track record of safe operations in challenging conditions, even if disruptions or occasional crises may happen routinely. While it can certainly be improved, both domains have already implemented a number of practices and methods, especially related to being able to handle such disruptions or to learning from them. Still, recent examples from disasters are reminders of the urgent need to improve our ability to reveal, assess and manage resilience, both in everyday operations and during crises (Hollnagel et al., 2011, Adini et al, 2017).

The overall objective and main result of the Horizon 2020 EC project DARWIN is the development of European resilience management guidelines. These guidelines are called DARWIN Resilience Management Guidelines (DRMG).

The DRMG consist of suggested interventions and guiding principles to help or advise any organization in the creation, assessment or improvement of its own reference guidelines, procedures and practices.

What is really important is that DARWIN results are useful for our end users namely the Critical Infrastructures that include ATM and HC.

For this purpose, the DARWIN Resilience management guidelines are designed to address disruptions, changes and opportunities; facilitate anticipation, adaptation, flexibility; and provide a foundation for an effective crisis response (Adini et al., 2017).

An initial set of generic DRMG was produced (DARWIN D2.1, 2016) and then adapted to ATM and HC to make the guidelines more operational and usable in these domains.

This paper presents the approach and methodology carried out to adapt the DRMG to both domains and discusses relevant results.

1.1 *Nature of the DARWIN guidelines*

The methodology to obtain the list of DRMG has been thoroughly defined: based on a world-wide systematic literature review carried out for the DARWIN project (DARWIN D1.1), 56 concepts, approaches and practices have been identified and evaluated (DARWIN D1.2).

The results of an evaluation following a modified Delphi process with practitioners and experts resulted in essential and important resilience concepts to be included in the resilience management guidelines. These conceptual as well as user requirements are input for the development of the DRMG (DARWIN D1.3).

The guidelines are developed as individual topics that address the conceptual requirements identified. Those topics are referred to as Concept Cards (CC). CCs propose interventions that organizations can implement (the *how*) to reach the resilience management capabilities captured in the conceptual requirements (the *what*). Through those interventions, the guidelines aim to help CI organizations in developing a critical view of their own crisis management activities (management of resources, procedures, training, etc.). The CC are structured in content blocks that contain information such as: purpose; interventions proposed; actors in charge; illustration; associated practices, methods and tools; etc. In addition, while they address specific aspects of resilience management, CCs are not independent and links between them are captured through various means.

DARWIN CCs, and in particular adapted CCs, could be complementary to guidelines, procedures and practices already present in the organizations of the two domains, fostering their revision, improvement or even creation of new guidelines.

Also, each CC includes a Minimum Viable Product (MVP) which is the smallest way to start using the interventions proposed in the CC. The MVP is the set of minimum set of features required to test or experiment a solution. Its purpose is to get through the "build-measure-learn" feedback cycle as quickly and efficiently as possible (Ries, 2011). The DARWIN project proposed this solution based on interactions with experts (managers and front-line operations). This approach contrasts the traditional product development of designing, performing preliminary and critical reviews, producing and testing and perfecting the product.

1.2 *Content of the DARWIN guidelines*

The DARWIN CCs are organized under the following themes:

Supporting coordination and synchronization of distributed operations

1. Promoting common ground in cross-organizational collaboration
2. Establishing networks for promoting inter-organizational collaboration
3. Ensuring that actors involved in resilience management have a clear understanding of their responsibilities and the responsibilities of other involved actors

Managing adaptive capacity

4. Enhancing the capacity to adapt to both expected and unexpected situations
5. Establishing the capacity for adapting during crises and other events that challenge normal plans and procedures

Assessing resilience

6. Identifying sources of resilience
7. Noticing brittleness
8. Assessing community resilience to understand and develop its capacity to manage crises

Developing and revising procedures and checklists

9. Managing policies involving systematically—policy makers and operational personnel for dealing with emergencies and disruptions

Involving the public in resilience management

10. Interacting with the public not yet affected by or involved in a crisis

2 METHODOLOGY

The established methodology is a systematic step by step approach strictly intertwined with the other DARWN activities. These include in particular those relevant to the development of generic guidelines, to their evaluation and to interaction with the DCoP.

The adaptation process consists of two main steps:

- **Step 1: Selection of adaptable CCs**, i.e. the assessment for the adaptability of the generic CCs
- **Step 2: Adaptation of adaptable CCs**, that is the adaptation of the generic CCs to ATM and HC domains, and the release of the adapted guidelines.

2.1 *Selection of adaptable CCs*

This phase has been performed by applying a methodology based on a quantitative and qualitative SWOT (Strengths, Weaknesses, Opportunities and Threats) analysis that assessed if a CC was adaptable or not.

The SWOT analysis methodology is commonly used to develop a deep understanding of all kinds of situations in business, organizations, and for individuals, to support the decision-making process.

It is noteworthy that the SWOT analysis findings address relevant actions for Guidelines developers concerning the improvement of the generic guideline content also. In particular, during the development of DRMG, the CCs were simultaneously assessed with regard to a possible adaptation to the specific domains, possibly avoiding any gaps between development and later adaptation.

At the end of the adaptability assessment two lists are expected: the list of non-adaptable CCs including the rationale behind their non-adaptability or elements that can be improved, and the list of adaptable CCs including the rationale behind their adaptability.

The applied SWOT analysis has been defined combining the quantitative and qualitative approaches for a richer collection of data.

The quantitative SWOT analysis has been based on the definition of a set of Indicators (*I*) that were identified starting from the fields of the CC used for the process of adaptation.

Seventeen indicators (Table 2) have been established, each of them formulated as a specific statement and categorized according to the four areas of the SWOT:

- the Strength/Weakness (S/W) areas include indicators concerning internal aspects of the CC (i.e. specific contents of the CC fields).
- the Opportunity/Threat (O/T) areas include indicators whose assessment needs to take into account a more long-term perspective and the interdependency with external factors linked to the contexts of the CC application.

Table 1. Step 1 overview.

Input	Last available version of Generic CCs
Output	• List of Adaptable and non-Adaptable CCs • Information concerning content for CCs adaptation (from qualitative SWOT • Information concerning elements of the Generic CC improvement
Effort Required	• 1-day per each interview with each ATM/HC expert concerning each single CC SWOT • 3–4 days (per CC) to organize relevant information and perform additional research • 1 day to review the results with involved expert

Experts' opinions on the indicators have subsequently been collected through seventeen questions formulated as follows "*How much do you agree with the following statement (I_01, I_02, … I_17)?"*

The answers to each question were recorded using a 5-point Likert scale ranging from "Disagree" to "Very Strongly Agree", with "Somewhat agree" in the middle.

In order to obtain a quantitative figure for each indicator's assessment, a numeric value was assigned to each level of the scale, starting from 1 (="Disagree") to 5 (="Very Strongly Agree") and incrementing by one per level.

Thus, according to the *I* mean value, the assessment of each I has been classified according to the criteria described below.

The qualitative SWOT analysis of each generic CC was carried out by collecting comments and feedback from experts during the assessment of the quantitative SWOT analysis indicators.

After the quantitative assessment of each indicator, the expert was asked to explain the rationale of the scoring, indicator by indicator, while the interviewer was taking notes.

The interview started with the narration of the illustrative case or lesson learnt that, according to the expert, better supports the discussion on the contents of the specific CC applied to the domain.

The rationales provided during the interviews have been collected and grouped into four areas of the SWOT on the basis of the mean values calculated for each indicator (ref. Table 2).

It is noteworthy that also the rationales fully contrasting the average evaluation for the specific indicator have been kept and taken into account for the sake of richness of data.

In addition to the CCs adaptability assessment, the qualitative SWOT analysis results have been considered as one of the main sources of information used to adapt the CCs' content to the specific domain. Moreover, the collected information has been enriched using sources of information available online.

Some criteria were established to evaluate the adaptability of each CC to the specific domain. They were based on two mean scores of the SWOT analysis results:

- I-02 mean score—This indicator directly refers to the applicability of the CC to the local context in which the card will be used. The applicability is the condition *sine qua non* the CC can be used in real ATM/HC environment.
- Total mean score of all CC indicators—This value provides a synthetic measure of the "adequacy"

Table 2. List of SWOT indicators

Nr.	Statement
1	The CC overlaps with other CCs **SWOT category: S/W**
2	The CC is applicable to local ATM/HC contexts (where the card will be used) **SWOT category: O/T**
3	The CC can be complementary to local ATM/HC arte-facts (i.e. procedures, regulations) **SWOT category: O/T**
4	Actors, as described in the CC, are identifiable in the ATM/HC domain **SWOT category: S/W**
5	The roles and responsibilities of the actors, as described in the CC, are clear in the ATM/HC domain **SWOT category: S/W**
6	It is possible to identify actors, roles and responsibilities, as described in the CC, in case of sudden changes in the ATM/HC domain (i.e. regulatory bodies, etc.) **SWOT category: O/T**
7	It is possible to identify actors, roles and responsibilities, as described in the CC, in case of future changes in the ATM/HC domain (i.e. regulatory bodies, etc.) **SWOT category: O/T**
8	The implementation **before**, as developed in the CC, is rel-evant for the ATM/HC domain and adaptable **SWOT category: S/W**
9	The implementation **during**, as developed in the CC, is relevant for the ATM/HC domain and adaptable **SWOT category: S/W**
10	The implementation **after**, as developed in the CC, is rele-vant for the ATM/HC domain and adaptable **SWOT category: S/W**
11	Internal factors of the ATM/HC domain, facilitating or hindering the implementation of the contents of the CC, can be easily identified and explained **SWOT category: O/T**
12	External factors (cultural, social, economic environment), facilitating or hindering the implementation of the contents of the CC, can be easily identified and explained **SWOT category: O/T**
13	Expected results, that can be inferred from the CC, can be identified and explained within the ATM/HC domain **SWOT category: S/W**
14	Illustrative cases and/or lessons learnt, linked to the con-tents of the CC, are available in ATM/HC domain **SWOT category: S/W**
15	Practices, linked to the contents of the CC, are available in ATM/HC domain **SWOT category: S/W**
16	Methods, linked to the contents of the CC, are available in ATM/HC domain **SWOT category: S/W**
17	Tools, linked to the contents of the CC, are available in ATM/HC domain **SWOT category: S/W**

and maturity of the CC fields for the adaptation purposes.

The combination of these two mean scores—as explained in Figure 1 - defines the adaptability of each CC and specific issues to be addressed by CC developers.

Figure 1, Table 4 show the criteria applied to establish if a CC is adaptable or not, and the actions identified to handle the issue with guide-line developers.

2.2 *Adaptation of adaptable CCs*

Once a CC has been evaluated as adaptable, the second step of the adaptation process begins. The Adapted CCs have been developed by integrating several sources:

- The findings of the qualitative SWOT analysis performed in Step 1;
- The information collected during *ad-hoc* inter-views with domain specific experts;

Table 3. Criteria for the classification of SWOT results.

Indicator mean score	Classification of the Indicator I
$I > 3$	*I* classified as Strength or Opportunity The indicator is helpful to the CC adaptation to the ATM/HC domain
$I < 3$	*I* classified as Weakness or Threat The indicator is "harmful" to the CC adaptation to the ATM/HC domain
$I = 3$	Those Indicators whose mean value was =3 have been classified by taking into account the experts' comments collected by the qualitative SWOT analysis: • the Indicator has been classified as Strength or Opportunity if the majority of the comments mainly emphasized positive elements; • the Indicator has been classified as Weakness or Threat if the majority of comments highlighted lacks and missingpoints.

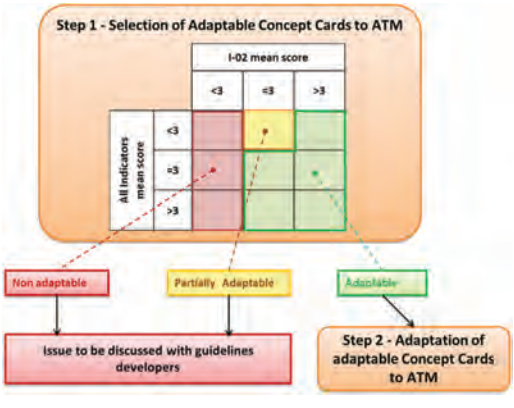

Figure 1. Adaptability Criteria.

– The information provided by the domain specific experts involved in the "initial evaluation of guidelines";
– The feedback provided by the DCoP during the workshop;
– The results collected during the implementation of Pilot exercises.

A strategic selection of participants from management as well as front line operators was performed. A template was prepared to follow a semi-structured interview with experts. The interview started with a narration of an illustrative case to better support the discussion of the context of the CC.

The topics covered concern actors involved, actions prior to, during and after the crisis. The template also includes context information, practices, methods and tools as well as other illustrative cases. The relevance of the content proposed by the CC, in particular concerning the interventions, was discussed.

Table 4. Rationale for CC classification (example).

CC Classific.	"Non-adaptable" or "Partially adaptable"
Rationale	• the concept is valid at a general level but difficult to adapt. It is not applicable in the local ATM/HC domain (i.e. due to type of organization and current policies of the local ATM/HC systems); or • the CC is not adequately developed to be adapted; or • so far, it has been particularly difficult to find specific ATM/HC content for the majority of the fields.
Action	Major amendments are needed and the issue has to be discussed with guideline developers
CC Classific.	**"Adaptable"**
Rationale	• the CC is applicable in the local ATM/HC domain; or • most of fields of the CC are adequately developed. However, in some cases some effort could be needed to make adjustments or to find specific ATM/HC content for some fields.
Action	The CC can be adapted and some issues to be discussed with guidelines developers

Table 5. Step 2 overview.

Input	• Last available version of Generic CCs • Output from Step 1: – List of Adaptable CCs – Information concerning content for adaptation of CCs (from qualitative SWOT)
Output	DRMG/Adapted CCs to ATM/HC
Effort Required	• 1 day (per CC) to interview one/two ATM/HC expert/s; • 5 days (per CC) to integrate Wiki with relevant information coming from SWOT, expert interviews, DCoP feedback, CC evaluations, feedback from pilots, additional research on internet.

3 RESULTS ON THE SELECTION OF ADAPTABLE CC

The adaptability assessment of the CCs has been gradually carried out during the development process of the generic CCs.

The SWOT analysis started as soon as the generic guidelines developers team considered the CC mature enough to be released and assessed for adaptation.

The information collected during the SWOT has been enriched using sources of information, suggested by the interviewee, available online and integrated in the DARWIN Wiki.

Overall review of expert feedback has provided guidance in terms of quality of the adaptable guidelines. It has been taken into consideration when updating the adaptable CC as well when elaborating new CCs.

Elements that have been mostly appreciated among experts are:

- The concepts developed by the CCs are relevant to the ATM and HC context,
- Actors in ATM and HC context are identifiable in a clear and concise manner; also roles and responsibilities are clear, being hierarchy well defined in ATM and HC,
- The list of actions/interventions give sufficient explanation of responsibilities making it easier to adapt to the ATM, and to HC, while taking into account the broader and different fields of HC,
- The triggering questions are useful and well grouped,
- The indications provided in the fields "implementation before/during/after" are sufficient to develop a CC adapted to the ATM and HC context,
- The level of provided information makes it easier to be integrated with local artefacts (procedures, plans),
- Useful examples, illustrative cases, practices and methods are available in the ATM and HC context.

Elements that need improvement:

- In some CCs, the information is very high level or too generic thus making it difficult to adapt,
- Some content concerning the "Triggering Questions" and "Actions" is redundant and needs to be simplified,
- No tools are provided in some of the current version of the CCs, thus, during the adaptation process, efforts should be spent, accordingly,
- Harmonization still needs to be reached among some CCs.

4 RESULTS FROM ADAPTATION OF CC

At first sight, ATM and HC seem to be very different contexts, but during meetings, the DARWIN team has discovered that they share many similarities and many common issues (i.e. criticalities of the infrastructures, impact on the public, etc.).

Notwithstanding that, the aviation domain in general is characterized by high level of standardization. The number of standards and regulations guarantee that ATM has a great track record of safe operations.

Regulatory bodies and concerned actors are well defined together with roles and responsibilities.

For example, the geographical limitation of an aerodrome makes this type of environment exposed to a relatively limited number of crisis types (e.g., aircraft accident during take-off or landing, disaster in the premises, loss of working resources, climatic event, etc.).

Although it is impossible to know when the crisis will occur, the characteristics and dynamics of crisis situations can be foreseen in advance to some degree. As a consequence, the concerned actors and the response procedures can be defined with sufficient accuracy before the crisis occurs.

On the other hand, other types of crises in ATM may be much more extended from a geographical point of view and less predictable in the way they evolve (as in the example of the Eyjafjallajökull volcano eruption in 2010).

As previously suggested, the HC domain exhibits common aspects with ATM that deals with criticalities and brittleness, and, in addition, they share the same scientific basis on which public health and HC tasks (i.e. care, surveillance, research, regulation and control) that are the same bases/criteria of Safety and Quality Assurance present in ATM.

What is, however, peculiar to HC is the individual/team resilience that HC workers (professional and operators) practice daily while performing their task and while coping with unexpected situations. In this case, the management of this resilient approach, i.e. systematically creating the conditions to bridge the gap between *work-as-imagined* and *work-as-done* (WAI vs. WAD), proves to be challenging.

Other relevant aspects include that this domain shows more complexity, and a variety of tasks, with many actors, ranging from surgeons to nurses, from regulatory bodies, providers, training organizations. These lead to an *variety* of systems, processes and outputs (protocols, documents, or records that could differ from hospital to hospital.

HC moves to innovation, however it should be recalled how professionals frequently support clinical decisions over standardization (a clinician sometimes stands on autonomous judgement provided for it is based on *knowledge and belief*).

One of the noteworthy outcomes of the adaptation process is that we discovered more uses than we expected at the beginning of the project. We found out that the guidelines are useful, they can

be adapted and adopted in many occasions such as training, workshops and meetings.

They help to start discussions and to deal with significant topics and they can be used to:

1. Check or update current procedures and guidelines, if already existing;
2. Define new procedures and guidelines if not existing;
3. Identify possible indicators and evaluation of trends (to do possible benchmarking);
4. Prepare plans;
5. Perform risk assessment and management.

During the interviews with ATM and HC experts concerning the CCs, some common aspects that play an important role in the resilient management of crisis emerged:

– **The CCs should concern all levels of organization**

Even if, at first sight, the DARWIN CCs may address only policy makers and management, being responsible for the modification of current procedures, it is noteworthy that all concepts address all levels of organization starting from senior management to front line operators.

– **The Roles and responsibilities of involved actors change according to the type of crisis and the related environment of operations**

In the ATM context, according to the type of crisis several actors are involved. According to 'ICAO Annex 14. Emergency and other services', An Airport Emergency Plan shall be established to coordinate the response and participation of all existing agencies which could assist in responding to an emergency.

Examples of possible agencies ON and OFF aerodrome are provided:

ON-aerodrome: air traffic control unit, rescue and firefighting services, aerodrome administration, medical and ambulance services, aircraft operators, security services, and police;

OFF-aerodrome: fire departments, police, health authorities (including medical, ambulance, hospital and public health services), military, and harbour patrol or coast guard.

– **The establishment of Just Culture and Safety Culture in all organizations**

With particular reference to the concept of "noticing brittleness", Just Culture and Safety Culture are the internal factors that could help in facilitating the identification of brittleness in each organization.

The concept of 'Just culture' is discussed in EUROCONTROL (2006) "*in recent years the concept of "Just culture" has become better understood and accepted by people employed in the aviation industry. However […] the need for a "just culture" is generally not understood by many legislators and therefore not accepted within their State judicial systems.*"

This issue causes "*increased fear of sanctions against the reporter, particularly if partly or fully responsible for the reported occurrence*."

"Furthermore, certain elements of the media may deal aggressively with apparent breaches of flight safety within certain airlines and ANSPs."

"These factors—punishing Air Traffic Controllers or pilots with fines or license suspension—may have the cumulative effect of reducing the level of incident reporting and the sharing of safety information. This hinders safety improvement and as a cascading effect resilience."

There could be concerns about possible misuse of information regarding brittleness in the organizations, since "*one of the major problems with collecting and analysing information is that such information can be a very powerful tool and, like any powerful tool, if used properly it will provide great benefit. However, it can also be used improperly and if that occurs considerable harm can be caused".*

In the last decade, many progresses have been made to encourage Just Culture in the European ATM context, mainly thanks to the efforts of EUROCONTROL: e.g. Air Navigation Service Providers are endorsing Just Culture policies and programmes, Task Forces have been created to promote, debate and discuss issues concerning safety and justice, meetings are organized to encourage interaction between safety and the judicial experts; special "just culture" courses for aviation experts and prosecutors have been organized, etc.

According to EUROCONTROL (2008), Safety Culture is "*the way safety is perceived, valued and prioritised in an organization. It reflects the real commitment to safety at all levels in the organization. […] It is not something you get or buy; it is something an organisation has. […] It can therefore be positive, negative or neutral.*"

Since 2006, there is an active involvement of EUROCONTROL, in collaboration with FAA and CANSO, in measuring and improving Safety Culture within ANSP organizations. Safety Culture surveys are continuously planned and performed, results and recommendations are taken into account and implemented to guarantee an effective SMS and a healthy Safety Culture.

– **The importance of planning, training and testing in advance**

The plan should include a clear definition of the agencies involved, the responsibility and role of each agency and the coordinates of offices/people to be contacted in case of emergency.

The **training** of the people allows to maintain the high level of preparedness for possible crisis events.

The **test** of the plan could be done in many different ways beginning with the organization of exercises, from a lower level to a higher level, with each one building on the concepts of the previous: discussion-based and operations-based exercises. The execution of the exercises allows to identify weaknesses in the plans and possibly improve them.

Discussion-based exercises are organized to discuss the plans for upcoming operations-based exercises, and to make everyone familiar with roles, procedures and responsibilities. They include: seminars, workshops, tabletop exercises, and games.

Operations-based exercises are used to validate and test plans and procedures that have been consolidated after the discussion-based exercises. They allow to better clarify roles and responsibilities of involved actors, identify gaps and limitations of the plan, and improve everyone's performance. They include drills, functional and full-scale exercises.

– **The importance of lesson learned dissemination**

The importance of the dissemination of the relevant information after the crisis events is fundamental in order to improve the resilience of the organization during crisis. In the ATM context and for this particular purpose, EUROCONTROL encourages the lesson learnt distribution and exchange of best practices though the website Skybrary. As well, the magazine Hindsight contains lot of useful case studies and provides the Air Traffic Controllers (ATCo) with a means to share their experiences concerning ATM-related safety occurrences. The objective is to "*broaden ATCOs understanding of the problems that may be encountered, learn more about possible solutions and be better prepared in the face of similar occurrences*."

Moreover, the presence of the "triggering questions" was particularly appreciated even if it may be difficult to use them during time-critical types of crisis as a checklist to be read step-by-step and to identify someone that checks their completion. On the other hand, it is important that all the actors involved in the management of the crisis are fully aware of the topics addressed.

For crises developing over a longer time (e.g. Icelandic volcano eruption or Ebola outbreak) it is possible to organize workshops and meetings to reflect with other colleagues on the possible sources of brittleness and use the triggering questions to support the reflection. The same approach can be used during a drill or a simulation by a facilitator to guide the simulation and stimulate participants to notice brittleness.

5 DISCUSSION AND CONCLUSIONS

The work performed so far confirms the intended readership as policy makers, front line operators, resilience engineering managers, crisis managers, critical infrastructures managers, methodologists, community of practice in ATM and HC. Stakeholders such as managers and policy makers can use this work as source of inspiration when adapting resilience guidelines to their domains.

In particular, applying the DARWIN resilience concepts, triggering questions, methods and tools, they will be able to:

- Apply the proposed interventions provided in the CCs to survey current practices, strategies, procedures and guidelines;
- Start to reflect on "what went well" and not only "what went wrong" when learning from events;
- Assess the effectiveness of roles and responsibilities during a crisis;
- Revise and/or define common action plans through periodical coordination activities and training;
- Identify brittleness in the system and the application of procedures and response to the crisis;
- Get to know practices, methods and tools applied by others;
- Test and improve their plan of communication with public during emergencies.

The collaborative method presented in this paper illustrates an iterative approach that brings theoretical concepts close to their practical implementation. We gathered information from other domains through workshops with members of the DCoP. The SWOT facilitated translation of resilience concepts into practical interventions. The methodologies proposed to adapt the concepts are defined in detail to ensure other concepts to be included in the future. The participation of experts is essential to ensure applicability, relate to the specific domain as well as enrich the cards with existing practices and methods.

At the beginning of the work, we planned separate guidelines for ATM and HC. The first results were cards that replicated the generic cards. This overlap in relevance and adaptation in CCs outcome in ATM and HC indicate the potential of the generic CCs to be applicable to other sectors. The current result combines generic fields with adaptations to HC and ATM as required. The results indicate the possibilities of similar adaptations to other domains.

A challenge is the achievement of consensus on the review process and iteration to achieve sufficient maturity. Another challenge as well as an opportunity is to merge different cultural perspectives across Europe when dealing with crises. We

found this as a window of opportunity to learn mapping recommended practices and methods within and across domains.

Further work includes evaluation of DRMG and associated CCs in relevant operational scenarios. We consider collecting feedback from ATM, HC as well as other domains from the DCoP.

ACKNOWLEDGEMENTS

The research leading to these results received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 653289. Opinions expressed in this publication reflect only the authors' views and that the Agency is not responsible for any use that may be made of the information it contains. The authors would like to thank the group of professionals—both researchers and practitioners from the DARWIN project as well to experts contributing to the work related to the adaptation and paper review including other members from CARR, ENAV, FOI, ISS, KMC and SINTEF.

PSA modeling method for a safety critical DI&C system

Sung Min Shin & Jaehyun Cho
Korea Atomic Energy Research Institute, Yuseong-gu, Daejeon, Republic of Korea

ABSTRACT: I&C systems in NPPs are being digitalized by adopting new features, such as software, fault-tolerant techniques, and network communication. Although the risk caused by these new features should be analyzed in an appropriate framework, at present there is no consensus on PSA methods for them. In this study, a general frame of a PSA model for the automatic safety signal generation function in a DI&C system is proposed, in consideration of the representative safety features of this system and the linkage between them. Through the related literature, we identified the requirements to construct the DI&C PSA model, constructed a general frame reflecting its possible parts, and specified the assumptions and approaches applied in this process. Although this study has focused on a qualitative approach because an appropriate database cannot be obtained yet, important failure modes that are understood in this current phase, and the research topics that need to be considered for the development of the enhanced DI&C PSA model, are summarized.

1 INTRODUCTION

Numerous analog Instrumentation and Control (I&C) systems in Nuclear Power Plant (NPP) are now being replaced by digital systems owing to the obsolescence of safety-critical analog components. This shift entails the adoption of new features that did not exist in analog systems, such as software, a Fault Tolerant Technique (FTT), and network communication. Although these features are expected to contribute to the enhancement of both efficiency and economy, from a safety point of view, the risk caused by the new features should be analyzed in an appropriate framework to ensure the dependability of the entire NPP (Kang, 2009, Authen, 2012). In recent years, regulatory bodies in each country have been actually demanding that the reliability of DI&C systems be incorporated in the PSA model. In this regard, some studies have been conducted in relation to software reliability, which are the representative feature of DI&C system; however, a more comprehensive approach seems necessary, such as how to integrate it with other digital features and apply it to the actual NPP PSA model.

Therefore, in this study, an approach of the DI&C PSA model is suggested in consideration of the representative safety features of the DI&C system and the linkage between them. In this preliminary phase for the DI&C PSA, it is based on a qualitative approach, without considering the available database, and we focused on the reliability model related to the automatic signal generation part, excluding the part related to human behavior among the functions of the DI&C system.

2 AUTOMATIC SAFETY SIGNAL GENERATION IN DI&C SYSTEM

Although a more appropriate modeling method for the DI&C system can be developed during the research progress, in this phase, a conventional fault tree (FT) format is considered for the DI&C system reliability model in terms of the convenience of integration with the plant model.

From the risk perspective, the modeling factors caused by the introduction of the DI&C system can be roughly expressed through Figure 1.

- DI&C induced initial event (spurious operation of DI&C system)
- Hardware and software failure (failure mechanism)
- Fault tolerant failure (fail-safe mechanism)
- Human error in digital environment

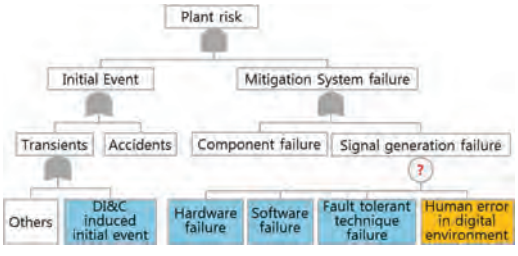

Figure 1. DI&C modeling factors from risk perspective.

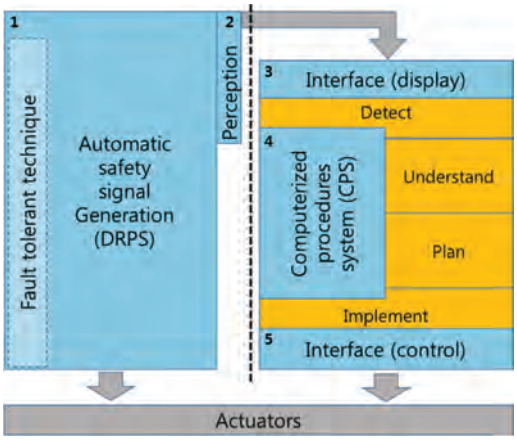

Figure 2. Functions implemented for safety signal generation.

Among the four categories, the initial DI&C induced event is not considered in this first phase, as this factor can have different effects on the system and is possible to be considered separately.

The remaining factors, in combination, implement certain functions for safety signal generation, as expressed in Figure 2. The functions in orange indicate human behavior. As can be seen from this figure, there are two methods for safety signal generation. One is a fully automated one in which the fault tolerant technique is applied. In another one, the safety signal is generated by a human operator using the information transmitted. This method also utilizes digitalized features, such as a display, CPS, and control, helping the decision making of the human operator. To develop a reliability model of this, information of the hardware and software failure in the functions corresponding to 2 through 5 (numbers in Figure 2), and the Human Error Probability (HEP) in this digitalized environment, should be analyzed.

Because the reliability model of the two methods can be treated separately, and the HEP has to be additionally obtained, research into the reliability model of human intervention is being conducted separately, with a plan to merge them later.

Therefore, this study focuses on only the automatic safety signal generation (1 in Figure 2) in consideration of the failure mechanism and the effect of the fault tolerant technique.

3 TYPICAL CONFIGURATION OF DRPS

The DRPS of NPP has some differences in a detailed configuration according to the type and reactor model. To develop a general frame, it is first necessary to confirm the typical configuration of the DRPS covering various types through the examination of many systems. For this purpose, the DRPS applied to the IDiPS-RPS (Integrated Digital Protection System-Reactor Protection system) developed through the KNICS (Korean Nuclear Instrumentation and control) project, the OPR-1000 (Optimized Power Reactor), and the APR-1400 (Advanced Power Reactor) are investigated, and a typical configuration, as shown in Figure 3, is confirmed. For reference, only the parts related to automatic safety signal generation are shown in this configuration except for the indication parts. The notations of each configuration are as follows.

- AIM: Analog Input Module
- DIM: Digital Input Module
- PM: Processor Module
- CM: Communication Module
- F: Fiber Optic Module (FOM)
- DOM: Digital Output Module
- AT: Automatic Test Module
- CPC: Core Protection Calculator

The more detailed functions are as follows.

- It consists of four physically isolated multiple channels (A, B, C, and D) and performs the same function independently in each channel.
- There are two sub-racks in each channel, sharing the inputs and performing the same function.
- Each sub-rack in each channel is composed of bistable logic (B) that generates Trip and Engineering Safety Feature (ESF) signals through comparison with internal set points, and coincidence logic (C) that receives signals generated from each PM in bistable logic in each channel and applies a voting.
- Bistable logic receives inputs from sensors using two AIMs and CPC values through one DIM, and the actual comparison with internal set points is proceeded using AS (Application Software) in PM.
- There are three PMs in each coincidence logic, two of which perform trip-related functions, one PM applies ESF-related functions.
- The two DOMs in the coincidence logic receive the trip signal from connected PM and transmit it to the function of selective 2/4 logic.
- The safety signal generated by the PM in the bistable is transmitted to the coincidence logics in the other channels. In this process, FOM is used to ensure one-way signal transmission and independence between channels.
- Each PM in the coincidence logic receives two values generated by PMs in the different rack in the different channel. Before performing 2/4 voting logic in the associated PM in the coincidence logic, 1/2 logic is performed first for the two values at each PM.

– Regarding the fault tolerant techniques, each input module and PM has a self-diagnostic function that is performed in real time at the operating system level, and the AT module, which exists in each channel, detects some portion of faults in each module within a channel periodically through the network and the CMs. The fault detection coverage of each technique for each module is different but partially overlapped.

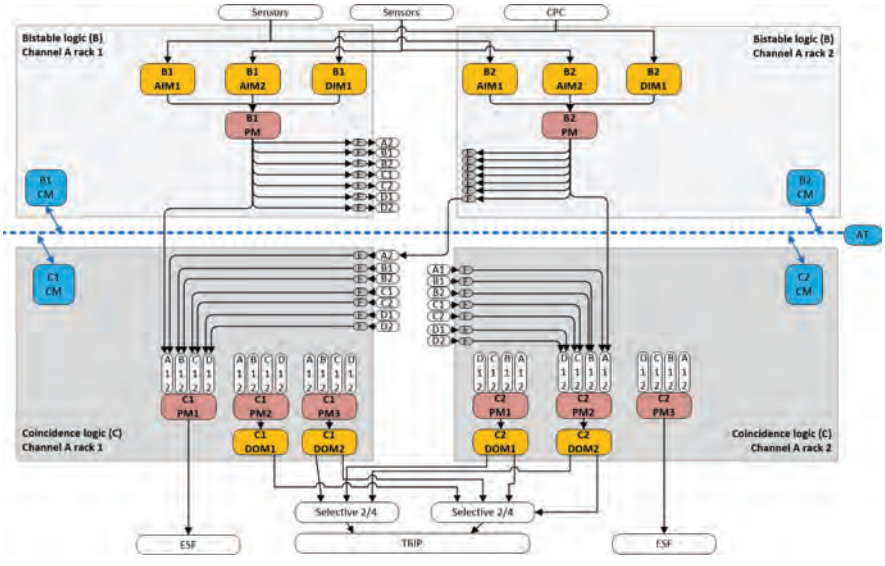

Figure 3. Typical configuration of DRPS for safety signal generation correspond to one channel (channel A).

4 REQUIREMENTS FOR DI&C PSA

The US is also carrying out research on a reliability evaluation of a digitalized I&C system in relation to the second-lifetime extension issue. However, because the recent guidance (10 CFR part 52) does not provide sufficient details regarding the DI&C system, a separate ISG (Interim Staff Guidance), which is consistent with the existing guidance, is issued to provide the reviewers with much more detailed requirements to be identified in the DI&C PSA (U.S.NRC, 2008). To consider the requirements to the general frame of the DI&C reliability model, the 12 review guidelines (R-x) and the 10 additional steps (A-x) in this reference are checked and marked according to the applicability to this study. In Table 1, the marks in the note column mean the follows: "A" means the requirements selected for consideration in this study, "B" indicates what is required in the actual review process, and "C" shows the requirements that are difficult to consider or apply in this phase of the study.

5 GENERAL FRAME OF RELIABILITY MODEL FOR SAFETY SIGNAL GENERATION

To implement the requirements selected in chapter 4 to the general frame, the DI&C system is basically divided into standard units, and within each unit, the characteristics of the HW/SW failure and the effects of fault tolerant techniques are considered. Some assumptions are made in this standard unit based approach and a general frame is developed on it.

5.1 *Assumptions and approaches*

The top event of the DI&C reliability model is defined as the failure of automatic safety signal generation for each mitigation system in each accident scenario.

To effectively analyze the DI&C system, this study took the module level, such as the input, output, and processor module, as the standard unit, as the different sets of modules are utilized for different safety signal generation.

Within a single module, the categories of failure are largely divided into an HW (hardware) failure, OS (operating system) failure, and AS (application software) failure. Although one failure among them can affect another, it is assumed that the original cause is independent of each other. As for the AS and OS, because the development process, developer, and functions of each is different, the two need to be considered separately. Furthermore, a different AS can be applied to the same base (HW and OS), and thus the AS and OS should be distinguished in order to consider the CCF in a more realistic way.

The effect of a fault tolerant technique can be reflected in such a way that the technique detects some portion of each HW, OS, and AS failures in each module and treats them in a fail-safe way so as to not lead to a module failure, and the reliability of the technique can be considered in this approach together.

5.2 *General frame of reliability model for a module failure*

Figure 4 shows the general frame of the reliability model for a module failure. This frame is applicable to all modules as a basic structure, but only some of them can be modeled according to modules. For example, the processor module has a specific AS for comparing the set points and input value, but the input/output modules are composed of only an HW and an OS, and do not have an AS.

The safety signal is generated by a sequential process in which a value generated in one module is passed to another module and a value generated in that module is passed to the other module. Therefore, the linkage between the modules can be modeled such that the failure of the previous module is input as the 'signal transmission failure' and the failure of that module is connected to the 'signal transmission failure' to the next module reliability model.

Failures of the HW, OS, and AS in each module leads to a module failure when they are not detected by the FTT or are detected but cannot be handled properly by the FTT. Based on the HW failures illustrated in Figure 4, if an HW failure is not detected by the FTT, it simply leads to a failure of the module. On the other hand, when an HW failure is detected by the FTT, it can be treated in a fail-safe way when the FTT works properly. Therefore, the reliability of

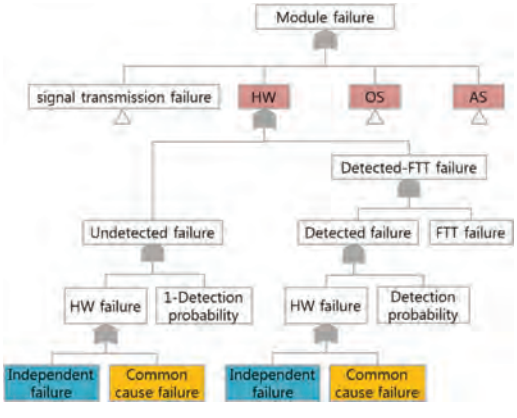

Figure 4. General frame of reliability model for a module failure.

the relevant FTT needs to be considered together in this case. The reliability of the FTT itself proportionally affects the reliability of the entire DI&C, and the degree of the influence depends on the magnitude of the fault detection coverage that the FTT has for each fault.

In certain cases, various FTTs are applied to a specific module simultaneously, in which case, regarding the detection probability and FTT failure, it is necessary to integrate the effects of the various FTTs or to model the effect of each in detail. In either approach, it can be extended based on this structure.

5.3 *Example application: Steam generator low water level trip*

In order to verify the feasibility of the proposed frame, as an example, a fault tree was developed for the configuration of the DRPS shown in Figure 3. As a result of analyzing which trip signal is required first for 18 initiating events of the OPR 1000 nuclear reactor model, the steam generator (SG) low water level trip signal was most likely to occur first [Cho et al., 2016]. The following assumptions were made during the development of the reliability model for the failure of this trip signal generation. The sensor for the SG water level is connected to each AIM1 in each rack, FOM integrity of both the transmitting and receiving sides should be guaranteed for the signal transmission from the bistable logic to the coincidence logic, and the failure of hardwired connection is ignored.

Figure 5 shows a part of the reliability model for the typical configuration of the DRPS shown in Figure 3, and Figure 6 shows an example of the

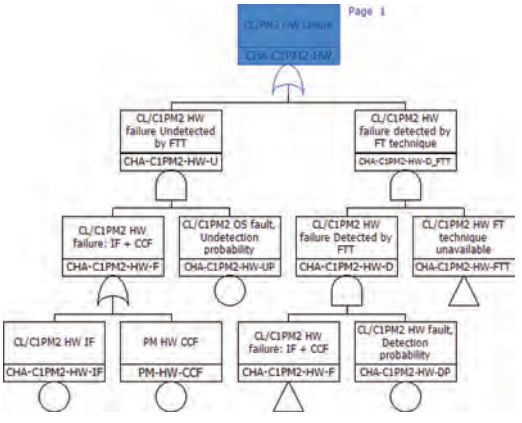

Figure 6. Example of application of the module reliability model (Processor module failure in figure 5).

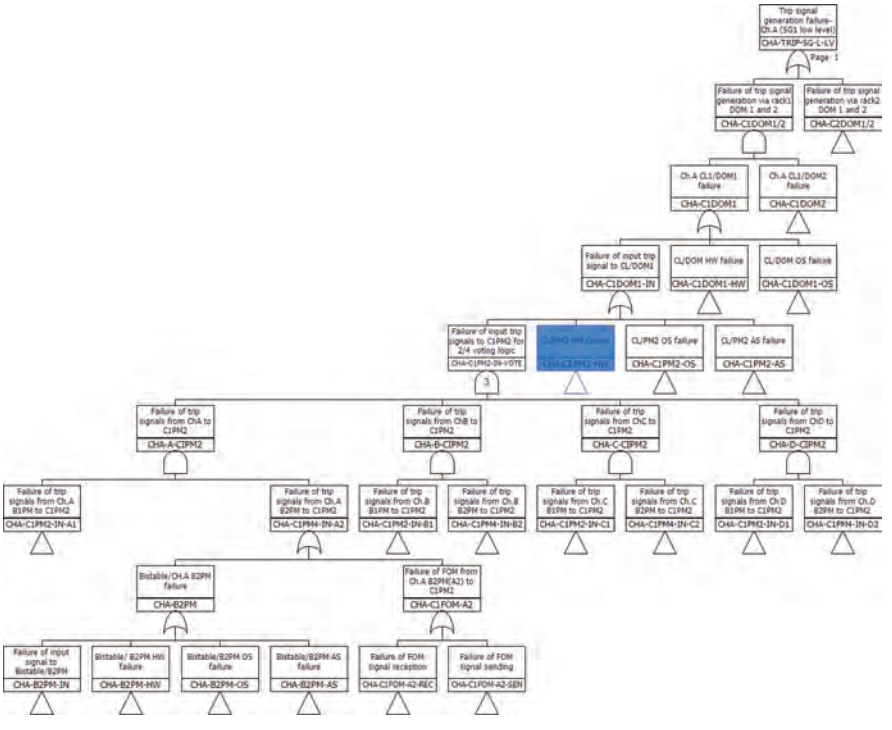

Figure 5. Example of reliability model of the general configuration of DRPS.

application of the general frame (Figure 4) for a module failure regarding the processor module HW failure shown in Figure 5.

6 DISCUSSION OF PROPOSED APPROACH

Although the failure information needs to be obtained to develop the actual reliability model, in the first phase of this study, we focused on the development of the general reliability frame for the DI&C system. On the other hand, the frame of the DI&C PSA developed through this study may suggest the required characteristics of the reliability data to be collected or the direction for securing them.

The important failure types identified based on the example application are basically the form of CCF, which can disable the independence and redundancy in the following cases, resulting in the failure of the entire system.

- Bistable logic input module HW/OS CCF
- Bistable logic PM HW/OS/AS CCF
- FOM HW CCF and OS CCF
- Coincidence logic PM HW/OS/AS CCF
- Coincidence logic DOM HW/OS CCF

Because it is difficult to compare the objective significance of the above cases through this qualitative analysis, it is necessary to reconfirm its importance by comparing the impacts on the overall system by developing/applying appropriate reliability data. Although the reliability data that can be applied at present have not been obtained yet, we can consider the importance of priority under the following conditions expected.

- Regarding the CCF Group, OS and HW are expected to be grouped into the same size according to each module, and the size of the AS CCF group is expected to be relatively small (CCF group size: HW = OS> AS).
- For the CCF parameter, the Alpha factor can be applied for the HW CCF, but the beta factor is more likely to be valid for the OS and AS CCF (value of CCF parameter: OS = AS>>HW).
- The reliability data value is expected to be large in the order of HW, AS, and OS (value of reliability data: HW>>AS > OS).

Finally, in addition to the above topics (CCF group, CCF parameter, and reliability data), for the development of the more advanced DI&C PSA, the following points should be further investigated or confirmed.

- The self-reliability of various FTTs and the combined fault detection coverage for each module
- Interdependency between SW and HW

7 CONCLUDING REMARKS

In this study, a method for DI&C PSA modeling for the automatic safety signal generation based on a general reliability model frame of a module. Although there are some assumptions and things to check to confirm the validity of this methodology, authors think that the complex relationship between elements composing the DI&C system can be objectively modeled by using frames suggested.

Air traffic safety in relation to visualization systems reliability

J. Skorupski
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

P. Ferduła
Polish Air Navigation Services Agency, Warsaw, Poland

ABSTRACT: Complex technical systems assist air traffic controllers in management of air traffic in the airspace. Their very important task is to provide the controller with visualization of the traffic situation, thereby enabling situational awareness and making right decisions. In practice, errors sometimes occur, despite the efforts to improve the reliability of visualization systems. The purpose of this paper is to present a method to determine the impact of error types on the air traffic safety. The assessment of the threat level is influenced by subjective factors and cannot be expressed in a precise way. Therefore, the fuzzy reasoning theory has been used in the paper. The developed fuzzy model has been used to obtain a tool enabling the experimental simulation of the impact of various factors on traffic safety assessment. As the results of experiments indicate, the most important determinants of safety are: the time when air traffic controller remains unaware of the breakdown and the total time he/she does not have full knowledge of the traffic situation. It can be therefore stated that the key role for the proper operation of the air traffic visualization system and thus the restoration of full situational awareness is played by self-diagnostic systems that can restore the visualization system's correct functioning without even the controller being aware of the error occurrence. Their role in assuring safety might be even greater than redundancy which is commonly used.

1 INTRODUCTION

The airspace is divided into smaller volumes called sectors in every of which a radar controller is responsible for the safety of aircraft. One of the most important determinants of ability to issue appropriate clearances is precise information about the traffic situation. The controllers are supported by Air Traffic Control (ATC) systems. Their subsystem of key importance is the Traffic Situation Visualization System (TSVS) that is responsible for representation of the aircraft's positions. ATC systems are constructed with the awareness of their role in air traffic safety. Nonetheless, software bugs and hardware failures still occur sometimes. One of the most severe effects are visualization systems operation errors.

An error in the visualization system causes a partial loss of controller's situational awareness (Endsley & Smolensky 1998). Depending on the complexity of the situation and the error type, various risks of air traffic safety may be caused. In this paper different types of visualization systems' errors are analyzed, their impact on the air traffic safety is assessed quantitatively, and finally, some case studies are conducted, vulnerability is examined and opportunities to reduce the risk are sought.

There are many studies examining the various types of factors affecting air traffic safety, as well as evaluating it. Many authors suggest a quantitative approach to the analysis and assessment of safety and security (Lee 2006, Ali et al. 2015, Vismari & Camargo 2011, Skorupski 2015, Skorupski 2016; Patriarca et al., 2017; Stroeve et al., 2015).

In typical ATC systems, information about three-dimensional (3D) scenery is displayed with a two-dimensional representation. Bagassi et al. (2010) presented an innovative concept based on a four-dimensional (4D = 3D space + time) visualization. A new working environment containing special information was proposed by Rohacs et al. (2016).

Many papers have been devoted to analyzing controllers' information perception (Moehlenbrink & Papenfuss 2011, Inoue et al. 2012). Ahlstrom (2005) analyzed the results of improper construction of visualization systems, on the probability of causing a threat to air traffic safety. Kesseler & Knapen (2000) highlighted the need to consider the interactions between the controllers, ATC systems and functions offered by individual systems.

Many papers suggest using the fuzzy logic methods and tools in the area of air traffic management (Hadjimichael 2009, Teodorović & Lučić 1998, Lower et al. 2016). The research by Xianfeng &

Shengguo (2012) and Skorupski & Uchroński (2015, 2016) includes the attempt of airport security assessment where the human factor was taken into consideration. The other examples of fuzzy methods utilization in air traffic management can be found in Babić & Krstić (2000) and Netjasov (2004).

The literature review indicates the need to analyze the visualization systems' errors that occur in air traffic controllers' practice. This analysis will be the basis for assessing the risk caused by different types of errors. This assessment has a significant degree of subjectivity and is impossible to be quantified unequivocally. In such situations, methods which deal well with uncertain and imprecise information are applied. In our paper, fuzzy logic, more precisely fuzzy reasoning systems are used to develop an expert advisory system that will categorize different error types to hazard classes.

It is also important to look for the kinds of errors that have the greatest impact on safety. Several distinct factors are considered, such as the ability to identify the error quickly or the availability of backup resources. The rest of the paper is organized as follows. Section 2 outlines the essence of visualization systems' errors. Section 3 provides a brief introduction to the theory of fuzzy reasoning systems. Section 4 describes a fuzzy model for assessing the hazard caused by TSVS errors. Section 5 shows the results of several simulation experiments using a computer tool created in the SciLab environment. Section 6 provides a summary and final conclusion.

2 AIR TRAFFIC CONTROL SYSTEMS

The main task of ATC systems is to assist air traffic controllers in ensuring a safe and effective flow of air traffic, but their range of applications is much wider. That is why they are often called Air Traffic Management (ATM) systems.

2.1 *General structure of ATC systems*

The main part of an ATM system is usually a server processing data from multiple sources. Following main data processing modules can be listed:

- surveillance data processing module,
- tracker—its task is to follow objects based on surveillance data,
- flight data processing module,
- decision supporting modules.

2.2 *Air traffic controllers work technology*

Actions performed by radar controllers depend on many factors, like type and distribution of traffic streams, traffic volume or airspace availability. To ensure safety and efficiency of air traffic, the controller needs information. The most important source of traffic information is the visualization system. It allows determining the position of the aircraft related to different objects.

Anticipating future positions of the aircraft is an essential element of the controller's work. A function of displaying routes according to current flight plans and so-called vectors (predicted trajectories of the aircraft) is used for this purpose.

Another action of the controller interacting with the TSVS is to read the predicted time necessary for the aircraft to arrive at a specific point. A major part of the radar controller's work is also monitoring the aircraft maneuvers to ensure that they are consistent with the expectations and do not jeopardize safety.

A cardinal part of the work is verifying of the data displayed by the system, such as the flight level, its speed, the heading, the altitude selected by the crew in FMS (Flight Management System). These data are essential for making the right decisions.

2.3 *The role of the visualization system*

The actions performed by the controller, which are presented in Section 2.2, show that the visualization system is a fundamental component of the air traffic control system. Functionally, the most important role of the TSVS is to assist the controller in creating an image of the current and future traffic situation. As this is the basis for decision making, the visualization system is the controller's essential tool. Its role is further enhanced by integrating the TSVS with some executive features, for example transfer of control to an adjacent sector.

2.4 *Errors in ATC systems*

Experience in using TSVS shows that some errors may occur. This section contains their classification. All the described errors have been observed during operational work at the air traffic control position at approach (APP) and area control (ACC) units (one of this paper's co-authors is an active air traffic controller).

2.4.1 *Incorrect indication of aircraft position*

This error lies in showing the aircraft position symbol at a distance from its actual position. The most likely cause is a malfunction of the tracker algorithm due to an internal error or erroneous input. The significance of this error is determined by the number of incorrectly positioned symbols and the type of misrepresentation. The most dangerous situation occurs when the symbols on display are spaced apart while, in fact, aircraft are close together. In case of significant divergences, the

error is relatively easy to spot, but it generates stress and high workload to clarify the situation. Furthermore, this situation is dangerous also because of distraction from observing other traffic.

2.4.2 *Flight plan—track linking error*
This type of error may appear as a total or partial lack of flight plan data, that should be available when aircraft's position symbol is indicated. Another variant of this error is the inability to update the current flight plan. This function is integrated with the visualization system as standard. The threat to safety is dependent on the number of aircraft affected by the error, the period that the issue exists and the number of flight plan parameters which are incorrect.

2.4.3 *Disappearance of aircraft position symbol*
Threat level caused by this error depends on the time when the symbol is not displayed. During a straight and level flight, a temporary disappearance of the symbol of a single aircraft makes a relatively small trouble. However, when more complicated maneuvers are performed or when the disappearance prolongs, the threat created by such a failure is much higher. Also, aircraft symbols' disappearance prevents the controller from monitoring the aircraft's maneuvers which in some cases can substantially increase the safety risk.

2.4.4 *Delayed aircraft position update*
It takes some time from the moment of measuring the aircraft's position to the moment of displaying it in the TSVS. It consists of the data transmission time, processing time, hardware delay. As long as the delay is approximately constant, the error may be compensated. The problem occurs when this value is variable. In such a situation, an aircraft movement may be displayed unrealistically. The error of this kind is easy to spot and is not a serious problem as long as the image is constantly visible and the deviations are not large. The problem, however, arises when the crew performs an incorrect maneuver or crosses the final approach track.

2.4.5 *Conflict warning systems malfunctions*
ATC systems are equipped with the functions of short- and medium-term conflict detection (STCA and MTCD). All of the above-mentioned positioning algorithms' shortcomings and errors such as information delay and incorrect input data may indirectly lead to conflict warning systems malfunctions. The most serious is the lack of necessary STCA or MTCD action or its too late activation. However, this type of error is extremely rare. The so-called false alarms are much more widespread. False alarms may also be caused by errors in STCA and MTCD algorithms. Whatever the cause, false alarms can pose a threat.

2.4.6 *Total loss of image*
An error of this type may be caused by a restart of the workstation resulting from an internal system error, a major technical failure or even a terrorist activity. This error can be divided into two kinds: the image disappears entirely or just stops refreshing. The latter situation is obviously better from a safety point of view, as it allows the controller to use historical data to build a picture of the traffic situation for some time. Depending on the number and type of the protection systems (additional power sources, additional data lines) the period for which the image is lost may differ. Lack of image on several workstations is even more critical as there is no opportunity to use the picture at the workstation nearby.

3 FUZZY REASONING SYSTEMS

The problem discussed in this paper is distinct by two major characteristics. On the one hand, we consider a socio-technical system where the role of the human factor is crucial. The result is an intense subjectivism of opinions. That is since the controllers are not equally vulnerable to make mistakes arising from a faulty indication in the TSVS.

On the other hand, high ambiguity and lack of precision characterize the problem. Errors in the visualization system are concerned, that are unpredictable. Not only we cannot predict the time of their appearance, but also we are unable to define their type precisely. That is caused by the fact that errors can result from numerous causes.

In such situations, literature recommends using the tools and methods suitable for problems of epistemic uncertainty, i.e. ones in which full knowledge of the phenomenon is unavailable. In such cases, it is required to use expert opinions. It is a known fact that very often they are formulated in a descriptive and an imprecise way.

Among the possible approaches, we have chosen to use the fuzzy logic, in particular, fuzzy reasoning systems. Zadeh (1965) created the basis for modern applications of fuzzy logic.

A fuzzy set A will denote a set of

$$A = \left\{ \left(x, \mu_A(x) \right) : x \in X, \mu_A(x) \in [0,1] \right\}$$

where μ_A is the membership function of this set and X is a set of considerations.

A linguistic variable is a variable whose values are words or sentences in a natural or artificial language. These words or sentences will be called the linguistic values of a linguistic variable.

Within the scope of the reasoning process, we will use the input value fuzzification block, reasoning block using some fuzzy rules and the defuzzification block. The rule sets will be created using experts' opinions, in particular, air traffic

controllers. We will use the so-called compositional method of reasoning introduced by Zadeh (1973) which uses a generalized "modus ponens" fuzzy reasoning rule.

4 FUZZY REASONING SYSTEM FOR THREAT LEVEL ASSESSMENT CAUSED BY ERRORS IN VISUALIZATION SYSTEMS

In this section, the fuzzy reasoning system, which allows for an assessment of the threat caused by errors in the visualization system. Factors influencing threat assessment are introduced as well as their representation by linguistic variables that are inputs to the fuzzy inference system. The knowledge base plays a critical role in this system. We have gained it from experts—air traffic controllers. A computer application created in SciLab environment allows for assessment of specific breakdown situations.

4.1 *Factors influencing the threat level assessment*

4.1.1 *Degree of situational awareness loss*

The concept of 'situational awareness loss' generally describes all situations when a controller or pilot is not entirely aware of what the current traffic situation is. Visualization errors cause safety risks only if they cause a loss of situational awareness for the air traffic controller. Obviously, the level of threat depends on the degree of loss of situational awareness, that is how the image of the traffic situation created in the controller's mind differs from reality.

4.1.2 *Awareness of errors in the situation image*

The problem of the loss of situational awareness is linked with the issue of the controller's belief that the picture of the traffic situation he/she has created in mind is correct. In some cases, he/she may be convinced that the image is proper, while reality is different. That is the most dangerous case because the controller will continue to work based on the wrong image without taking any verification action.

Knowledge of the existence of a malfunction may appear after some time, which depends on the obviousness of this error. The period from the moment the error occurs until the controller learns about it will be used as an evaluation criterion for this factor.

4.1.3 *Time of situational awareness loss*

Another factor affecting the degree of threat is the time interval in which the controller, because of a system error, does not have full situational awareness. It may range from a few seconds to dozens of minutes. The longer the time, the greater the safety threat. For this factor, we will use a judgment based on the anticipated time of situational awareness loss.

4.1.4 *Backup resources availability*

When a controller is aware of the error, especially if the error persists for an extended period, he/she will try to use other available resources to keep him/her aware of the situation. A straightforward and efficient manner is to use:

- an image in another workstation,
- a backup system,
- another data source of aircraft positions.

An important remedy is the use of traditional flight progress strips, which can be employed when no traffic picture is available.

Backup resources availability should be considered in two ways. Firstly, it is necessary to determine whether backup resources are available at all and, secondly, to assess their quality.

4.1.5 *Human factor*

Maybe the most important, factor influencing the assessment of the safety threat in case of visualization system failure is the human factor. One of the key components is the level of training. Certain standards and requirements must be met by all controllers, but the differences between individuals may affect their ability to deal with an emergency.

Besides, the experience of the controller, which can be expressed both by the number of years of work or by the number of hours worked at the position, affects the level of threat.

On the other hand, the perception abilities of the human being fall with age, so that the older person is less able to perceive and remember, and this can have an adverse impact on actions in a particular situation. Another, equally important component of the human factor that affects the level of threat is the psychophysical condition of the controller.

4.2 *General structure of the Threat level fuzzy inference system*

The scheme of the fuzzy model for assessing the level of threat caused by the error in the visualization system is shown in Figure 1. The output variable *Threat level* (z_t) depends on five input variables. These are: *Loss of situational awareness* (x_{sa}), *Time without knowledge of error* (x_{wk}), *Time of situational awareness loss* (x_{lsa}), *Quality of remedies* (x_q) and

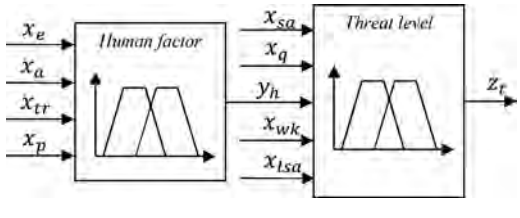

Figure 1. General scheme of the *Threat level* fuzzy model.

Human factor (y_h). The last of these input variables is the output of the local fuzzy reasoning system, with four input variables: *Experience* (x_e), *Age* (x_a), *Training* (x_{tr}), *Psychophysical condition* (x_p).

The form of membership functions of linguistic variables values, the basis for their determination and the knowledge bases of both fuzzy reasoning models will be presented in subsequent sections.

4.3 *Input linguistic variables of fuzzy reasoning system*

4.3.1 *Loss of situational awareness*

The degree of divergence of the traffic situation picture in the controller's mind relative to reality can be assessed based on the difference between the actual position of the aircraft and the position indicated (incorrectly) by the visualization system. We refer this value to the separation minimum that is obligatory in a given airspace. Based on expert knowledge, it has been assumed that the linguistic variable *Loss of situational awareness* will take one of the six values: *slight*, *small*, *significant*, *serious*, *large*, *total*. We propose the use of an integrated indicator with the following form to determine the value of a linguistic variable:

$$d = max\left(n \cdot e^{\frac{\delta_r}{S_r}}, n \cdot e^{\frac{\delta_v}{S_v}} \right)$$

where:

d – integrated indicator determining the degree of situational awareness loss,

n – number of aircraft, which visualized positions do not correspond to their actual locations,

δ_r, δ_v – the amount of deviation of the imaged position from the actual position of the aircraft in the horizontal and vertical plane respectively,

S_r, S_v – separation minimum obligatory in the considered airspace in the horizontal and vertical plane respectively.

Membership functions of values of linguistic variable *Loss of situational awareness* are shown in the logarithmic scale in Figure 2.

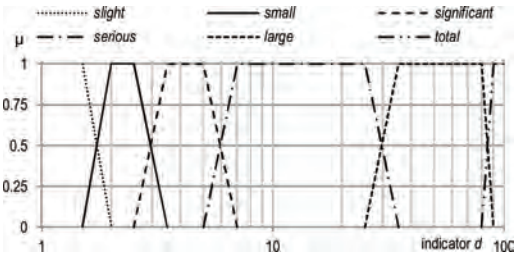

Figure 2. Membership functions of values of *Loss of situational awareness* linguistic variable.

4.3.2 *Time without knowledge of error*

The level of safety threat depends on whether the controller is aware of the occurrence of an error or, more specifically, how long he/she is not. Accordingly, we have used the linguistic variable *Time without knowledge of error*, which can take five values: *very short, short, average, long, very long*. The membership functions of the values of this linguistic variable were adopted based on expert knowledge, and their logarithmic form is shown in Figure 3.

4.3.3 *Time of situational awareness loss*

Depending on the type of error, the period in which the situational awareness of the controller is disturbed differs. In case of a short-term disappearance of the track of individual aircraft, controller's situational awareness is usually maintained all the time. In case of major system malfunction, the time of situational awareness loss may be long and is not necessarily the same as the time when the system works incorrectly.

The linguistic variable *Time of situational awareness loss* may take five values: *very short, short, average, long, very long* (Figure 4).

4.3.4 *Quality of remedies*

A controller who is aware of the dysfunctional operation of the TSVS will seek to use other available means to ensure air traffic safety. As already

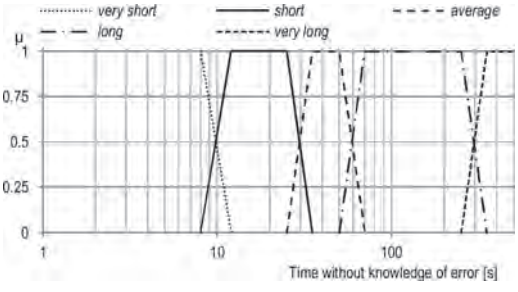

Figure 3. Membership functions of values of *Time without knowledge of error* linguistic variable.

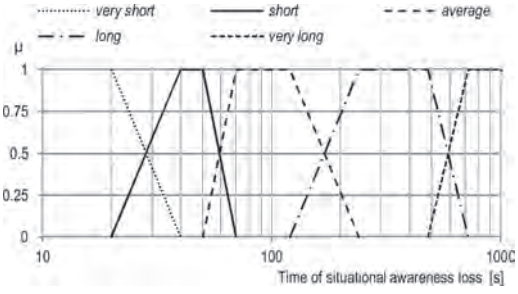

Figure 4. Membership functions of *Time of situational awareness loss* linguistic variable values.

Table 1. Fuzzy inference rules for the local model *Threat level*.

Rule number	Loss of situational awareness (x_{sa})	Time without knowledge of error (x_{wk})	Time of situational awareness loss (x_{lsa})	Quality of remedies (x_q)	Human factor (y_h)	Threat level (z_t)
1	*total*	any	≠ *very short*	*none*	any	*very high*
9	*large*	any	*short*	*none*	any	*high*
27	*significant*	*very short*	*average*	*none*	*very high*	*average*
30	*significant*	*average*	*average*	*average*	*average*	*high*
40	*small*	any	*average*	any	*very high*	*low*
45	*slight*	any	*very short*	any	any	*very low*

mentioned, the possibility of using them in each situation will be considered within two categories—availability and quality of available remedies. Linguistic variable *Quality of remedies* will take four values: *none*, *low*, *average*, *high*.

4.3.5 *Human factor*

For an assessment of the influence of the human factor on the degree of safety threat in the event of a TSVS failure, we will use combined information about the professional experience, age, the level of training and psychophysical condition of the controller. The linguistic variable *Human factor*, which describes the ability to cope with a failure of a visualization system in general, will take five values: *very low*, *low*, *average*, *high*, *very high*. It will be determined by the result of the local fuzzy reasoning system with four inputs – *Experience*, *Age*, *Training*, *Psychophysical condition*.

The linguistic variable *Experience* will take three values: *low*, *average* and *high*, and will be determined by the number of years of operation at the radar control position. The linguistic variable *Age* will take three values: *young*, *middle* and *old*. The linguistic variable *Training* will take one of three values: *poor*, *average* and *good*, and will be determined by the controller's level of training in procedural control. The linguistic variable *Psychophysical condition* will take one of three values: *poor*, *average*, *good*.

4.4 *Output variables of the fuzzy reasoning systems*

Both local models *Human factor* and *Threat level* are Takagi-Sugeno-Kang models with singleton output values. The *Human Factor* variable, discussed in Section 4.3, is also the input variable for the *Threat level* model. In turn, this variable will take five values: *very low*, *low*, *average*, *high* and *very high* (Figure 5). At the output of the fuzzy reasoning system, we evaluate the level of safety threat caused by the visualization system error as a real number from the interval [1,5].

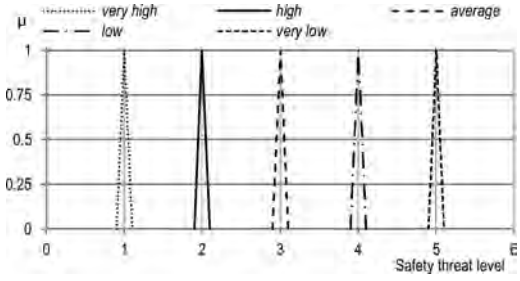

Figure 5. Membership functions of values of *Threat level* linguistic variable.

4.5 *Knowledge base of the fuzzy reasoning system*

The knowledge in inference systems describing complex socio-technical systems is subjective to some degree and as such impossible to quantify precisely. Therefore, fuzzy inference rules based on expert knowledge have been applied. One of the authors of the paper is an active air traffic controller, but for more credibility of the knowledge base, the rules have been verified with other field experts.

In the *Human factor* fuzzy reasoning system, 81 fuzzy inference rules are defined. In the *Threat level* fuzzy reasoning system, 49 rules have been defined, some of which are shown in Table 1.

The fuzzy model for evaluation of the safety threat to air traffic caused by visualization system errors has been implemented in the SciLab 5.4 environment with Fuzzy Logic Toolbox package.

5 SIMULATION EXPERIMENTS

The developed model together with its computer implementation allows us to assess the influence of errors in TSVS on traffic safety. Simulation experiments have been carried out to check the usability of this software tool for threat assessment and also for the selection of the most critical system components that influence the safety

of air traffic control. Some of these experiments are described in this section. For all experiments, it was assumed that the controller who encountered an error has been characterized by the average values of parameters related to their individual characteristics (age, experience, training, psychophysical condition).

5.1 *Scenario S1 – minor failure*

The analyzed scenario (S1) can be described as follows. Due to an anomaly in the tracker subsystem, one of the tracks representing an aircraft stops and does not change its position. Because of heavy traffic, the air traffic controller does not notice an error, and after one minute the system automatically switches to a backup tracker. The maximum deviation of the radar position shown in relation to the actual aircraft location was 7 NM. The aircraft involved was performing a level flight. Remedies were not available.

The input parameters of the fuzzy inference system and the results of the experiment for the scenario S1 are given in Table 2.

For the scenario being analyzed, the result obtained from the fuzzy inference system places the emergency in a *low* threat area with a slight shift towards the *average* rating (Figure 5).

5.2 *Scenario S2 – major failure*

The scenario S2 can be described as follows. Because of power failure, the controller completely loses indications from TSVS and the monitor goes blank. At the time, there are 10 aircraft in the control sector. The backup display located nearby is available, so after one minute the air traffic controller starts to work with its use. That finishes the emergency. The controller's characteristics are the same as in the scenario S1.

The input parameters of the fuzzy reasoning system and the results of the experiment for the S2 scenario are given in Table 3.

For the scenario being analyzed, the result obtained from the fuzzy reasoning system places the situation in a *high* threat area with a slight shift towards the *average* rating.

Table 2. Results of the experiment for the scenario S1.

Parameter	Value	Threat level
Human factor	3.0	
Loss of situational awareness [indicator *d*]	2.7	
Time without knowledge of error [s]	60	3.8
Time of situational awareness loss [s]	60	
Quality of remedies	*none*	

Table 3. Results of the experiment for the scenario S2.

Parameter	Value	Threat level
Human factor	3.0	
Loss of situational awareness [indicator *d*]	27.2	
Time without knowledge of error [s]	0	2.3
Time of situational awareness loss [s]	60	
Quality of remedies	*none*	

Table 4. Results of the experiment in scenario S1a.

Parameter	Value	Threat level
Human factor	3.0	
Loss of situational awareness	8.5	
Time without knowledge of error [s]	90	2.0
Time of loss of situational awareness [s]	120	
Quality of remedies	*none*	

5.3 *Sensitivity analysis in scenario S1*

The scenario S1 is characterized by a relatively small deterioration of safety because TSVS quickly switches to a backup tracker. At this point, we will assume that the switch to the backup tracker does not take place, and the track does not move for a few minutes. We will mark it as scenario S1a. After about 90 seconds the controller notices the error and, using the available previous generation ATC system, continues the work after about two minutes. The difference between the displayed and the actual position of an aircraft is 15 NM.

The input parameters of the fuzzy inference system and the results of the experiment for scenario S1a are set out in Table 4.

As we can see extending the duration of the failure causes the threat level to fall into the *high* rating area. That clearly shows how dangerous these errors can be, and how important it is to implement effective self-diagnostic means in TSVS, that are responsible for detecting, for example, a tracker error and switching to a backup.

6 SUMMARY AND FINAL CONCLUSIONS

Traffic situation visualization modules are essential elements of air traffic control systems. They constitute a basis for building situational awareness for air traffic controllers. At the same time, they focus all the hardware failures and software errors which, despite the use of technology with a very high level of reliability, can happen in practice.

Regardless of the origin of malfunctions of the system, they can result in several typical situations

that have been categorized in Section 2.4. The essence of this paper has been to analyze the level of threat to air traffic resulting from errors of each category, taking into account factors such as the controller's experience or the volume of traffic at which the error occurred.

Experiments have shown that one of the most important factors influencing threat assessment is the amount of time a controller does not have full knowledge of the traffic situation. The time depends on the awareness that we are handling an abnormal image of the TSVS. That, in turn depends on the type of error. The results of experiments carried out using the created computer tool confirm these observations. In addition, they allow for quantitative assessment. It is worth noting that the results indicate a crucial role of diagnostic modules built into ATC systems. Waiting for the controller to notice an error in TSVS and take any corrective action can significantly increase the time spent without complete knowledge of the traffic situation. It is therefore possible to provide a general recommendation to extend and further develop such systems. They can be even more important than redundancy that is usually used for increasing reliability of the system. In the case of redundancy, duplication of the same error can occur on all backup devices. In contrast, self-diagnostic systems can restore system performance even without the controller being aware of the malfunction.

Automated driving on steel and rubber

H. Schäbe
TÜV Rheinland InterTraffic GmbH, Köln, Germany

ABSTRACT: In this paper, we provide a comparison between principles and experience of autonomous or automatic systems on rails and on the street. An automatic metro operates in a controlled and well-defined environment that makes automatic driving possible. Passengers are separated from moving systems, e.g. by using platform screen doors that allow access only directly into the train, which is at standstill. In addition, passengers and third persons are separated from driving trains by fences, tunnels, etc. For road vehicles, currently a large number of assistance system is available that are able to handle specific situations. This leads to the impression that these vehicles can move autonomously. However, these assistance systems are developed in such a manner that the driver must always be able to interfere. There are only some exclusions with genuine autonomously moving vehicles. In general, the environment, in which a road vehicle operates, is much more complex than that of a train, mainly caused by unforeseen situations. We describe differences regarding approval for automated metros, road vehicles and so called Automated Guided Vehicles (AGV). Legal requirements for homologation of road vehicles according to the convention on road traffic are discussed and the implication for the system and the behavior of the driver. We sketch the current technical possibilities for automated driving and the existing technical solutions.

1 INTRODUCTION

Autonomous driving on the street has become more and more popular and the first demonstrator systems are operational. On the other hand, automatic metros and people movers are already successfully working for many years.

In this paper, we provide a comparison between principles and experience of autonomous or automatic systems on rails and on the street.

We compare the different levels of automation as defined by UITP and SAE and their meaning for the system. In addition, manual fallback modes are considered.

An automatic metro is located in a controlled and well-defined environment that makes automatic driving possible. Passengers are separated from moving systems, e.g. by using platform screen doors that allow access only directly into the train.

For road vehicles, currently a large number of assistance system is available that are able to handle specific situations. This leads to the impression that these vehicles move autonomously.

In general, the situation for a road vehicle is much more complex than that of a train.

We describe differences regarding approval for automated metros, road vehicles and so called Automated Guided Vehicles (AGV). Legal requirements for homologation of road vehicles according to the convention on road traffic are discussed and the implication for the system and the behavior of the driver.

We sketch the current technical possibilities for automated driving and the existing technical solutions. Especially, we discuss the possibilities and restrictions of artificial intelligence. We briefly describe a roadmap of possible next steps.

2 THE STATUS WITH METROS AND PEOPLE MOVERS

In many cities in the meanwhile automated metros and automated people movers are working

Examples are

- On the New York City Subway, the BMT Canarsie Line.
- On the London Underground, the Central, Northern, Jubilee, and Victoria lines run with ATO.
- On the Nuremberg U-Bahn, existing U2 and new U3 lines converted to ATO.
- On the Barcelona Metro, the L9 (as the Europe's longest driverless line), L10 and L11 runs with ATO.
- The Rio Tinto Group has the iron ore railway driverless go-ahead.
- The Tren Urbano, has an Siemens ATC system that allows for fully automatic operation.
- The Vancouver SkyTrain.

- Frankfurt Airport Skyline.
- Copenhagen Metro.
- On the Milan Metro, the M1 Red Line runs with ATO.

On the Mass Rapid Transit (Singapore), all lines operating currently run with ATO since 1987

For metros and people movers, a principle of separation has been applied: The automated trains are separated from all other traffic, running in the tunnels, open track is separated by fences, platform screen doors are used to separate the trains from passengers. This simplified the exploitation conditions significantly.

The Automated Train Protection system (ATP) is used to prevent collision and derailment. This allows also manually operated trains to use the same network.

The normal safety requirement for the ATP is a safety integrity level SIL 4. Nevertheless, manually operated fallback modes exist. Partially stewards are present to assist the passengers, especially in case in case of evacuation.

For metros and people movers, the UITP (2017) has established 5 levels of automation. That means, the picture is not black and white, knowing either manual or automated driving. Automation is a stepwise process. The following five levels are established, UITP (2017).

GoA 0 is on-sight train operation, similar to a tram running in street traffic. (No automation at all)

GoA 1 is manual train operation where a train driver controls starting and stopping, operation of doors and handling of emergencies or sudden diversions.

GoA 2 is Semi-automatic Train Operation (STO) where starting and stopping is automated, but a driver operates the doors, drives the train if needed and handles emergencies. Many ATO systems are GoA 2.

GoA 3 is Driverless Train Operation (DTO) where starting and stopping are automated but a train attendant operates the doors and drives the train in case of emergencies.

GoA 4 is Unattended Train Operation (UTO) where starting and stopping, operation of doors and handling of emergencies are fully automated without any on-train staff.

As a conclusion, automatic metros and automatic people movers can be seen as established systems. However, one needs to note that they operate in a controlled and simplified environment.

Road vehicles: The general impression on how autonomous driving works is mainly dominated by vehicles as the Google vehicle or the Tesla and other systems that have shown up in the meanwhile. Simpler systems are those for automated parking, which is carried out using the mobile phone, the driver being outside. Studies for autonomous driving have been carried out with a driver on board for testing purposes or for demonstration. Automated Guided Vehicle on closed areas or transport systems in workshops are also applied. The latter systems are strictly speaking not road vehicles but moving machines.

As an example, just consider the Google vehicle. This is a Smart-like vehicle with two seats and one can read that it drives autonomously, with no driver action being necessary.

Alas, an accident has been reported and Google said it bears "some responsibility" after the car struck the municipal bus in Mountain View, Google (2016). That means that the Google vehicle caused a crash. In that case, the car would be responsible, i.e. finally its manufacturer. However, also the driver and his responsibility need to be discussed.

Another example is a Tesla vehicle that crashed into a trailer. The driver did not react since he relied on automated driving and died as a consequence of the crash. In fact, the technical driving system of the Tesla was not able to detect the trailer. Then the question arises on the responsibility for the accident. Surely, the automatic systems needed permanent supervision by the driver and the question arises whether the driver was sufficiently instructed. Also, it needs to be discussed whether the driver had the possibility to stop the vehicle or take over the steer. This includes reaction time as well as features of the technical systems.

Some statistics might be done for the Tesla S at the time of the accident to illustrate the problems. One fatality has occurred after 210 Million km that have bene accumulated by the Tesla S model, see Focus (2016). This yields a rate of approximately $5\ 10^{-9}$ fatalities/km = $1/(2.1\ 10^{8}$ km). We need to admit that this "rate" has been computed from just one fatality and a serious statistical investigation would indicate that this figure contains a lot of spread.

What does this rate practically mean? We demonstrate this with some data on traffic accidents in Germany.

In 2013, in Germany private cars travelled 494 080 million kilometers, see Statista (2016). Let us now estimate the number of additional fatalities to be expected. We get $5\ 10^{-9}$ fatalities/km $*5\ 10^{11}$ km = 2500 additional fatalities per year, provided everyone would use the Tesla S model.

Note that a driver would have noticed the trailer and have reacted.

Moreover, in the statistics only possible additional accidents have been computed under the provision that the Tesla S model will be rolled out as it is now and that all drivers would behave as the one who died in the accident. On the other hand, accidents that would have been prevented by the Tesla S are taken into account.

This short computation shows the complexity and the problems connected to autonomous driving. Mainly this is caused by the very complex situation on the streets.

By the SAE (2016) and the UN (2017) the following levels have been defined.

- 0 No automation
- 1 Driver assistance
- 2 Partial automation
- 3 Conditional automation
- 4 High automation
- 5 Full automation

Detailed information on the levels is shown on the following Figure 1.

The currently present systems are mainly systems for assisted driving. The assistant helps in simple situations, however, the driver has always full responsibility. Examples are

- Distance assistant,
- Platooning,
- Lane assistant,
- Highway pilot for trucks.

A short glance on the approval systems shows the differences:

- Automated metros are approved according to EN 50126, EN 50128, EN 50129 and local laws on metros, that differ per country,
- Road vehicles are approved by a European approval based on ECE rules. In Germany this institution for approval is the KBA, in Netherlands this is the RDW,
- AGVs are not road vehicle and not a train, they are considered as automated machines and approval is according to Machine directive (2006) and IEC 61508 (2011).

A new law for homologation of road vehicles in Germany allows automated driving in specific cases—note that this is not assisted driving—but driver must be able to overrule the technical system.

This is in line with Convention (1973) on Road Traffic, which says:

- article 8,1: "Every moving vehicle or combination of vehicles shall have a driver",
- article 8, 3: "Every driver shall possess the necessary physical and mental ability and be in a fit physical and mental condition to drive.",
- article 8, 5. "Every driver shall at all times be able to control his vehicle or to guide his animals."

Currently, these principles are implemented in the law of the countries.

What does this mean for automated driving? The requirement "… driver must always be able to overrule the system" leads to the following requirements:

SAE level	Name	Narrative Definition	Execution of Steering and Acceleration/ Deceleration	*Monitoring* of Driving Environment	Fallback Performance of *Dynamic Driving Task*	System Capability *(Driving Modes)*
***Human driver* monitors the driving environment**						
0	No Automation	the full-time performance by the *human driver* of all aspects of the *dynamic driving task*, even when enhanced by warning or intervention systems	Human driver	Human driver	Human driver	n/a
1	Driver Assistance	the *driving mode*-specific execution by a driver assistance system of either steering or acceleration/deceleration using information about the driving environment and with the expectation that the *human driver* perform all remaining aspects of the *dynamic driving task*	Human driver and system	Human driver	Human driver	Some driving modes
2	Partial Automation	the *driving mode*-specific execution by one or more driver assistance systems of both steering and acceleration/ deceleration using information about the driving environment and with the expectation that the *human driver* perform all remaining aspects of the *dynamic driving task*	**System**	Human driver	Human driver	Some driving modes
***Automated driving system* ("system") monitors the driving environment**						
3	Conditional Automation	the *driving mode*-specific performance by an *automated driving system* of all aspects of the dynamic driving task with the expectation that the *human driver* will respond appropriately to a *request to intervene*	System	**System**	Human driver	Some driving modes
4	High Automation	the *driving mode*-specific performance by an automated driving system of all aspects of the *dynamic driving task*, even if a *human driver* does not respond appropriately to a *request to intervene*	System	System	**System**	Some driving modes
5	Full Automation	the full-time performance by an *automated driving system* of all aspects of the *dynamic driving task* under all roadway and environmental conditions that can be managed by a *human driver*	System	System	System	**All driving modes**

Figure 1. Overview of automation levels.

1. Technical possibility: brake, accelerator pedal, steering wheel must have a priority over automatic systems. Must be implied in safe controllers (ASIL C or ASIL D)
2. Driver must be present and vigilant, i.e. no sleeping, no messaging on the smartphone, no games including Pokémon GO etc.
3. Driver must have the necessary time to react. If there is a failure of the system or an unwanted reaction.

In fact, the last point leads to the following requirements for automatic driving.

- Braking: braking by automatic systems must be with a smaller acceleration than the driver could apply, the difference in accelerations (vehicle, driver) must still allow for a reaction time of the driver (braking curves),
- Steering: the distance from dangerous objects (other vehicles, border of the lane etc.) must be large enough to allow for drivers reaction, together with a limit of the steering angle. This might lead to speed restrictions.
- Perhaps the driver needs special training.

Figure 2 shows an example of a brake curve. Speed (m/s) versus distance is shown. There are two curves, one for automatic braking (deceleration 3 m/s**2) versus braking by driver (5 m/s*2), where a reaction time of 1.3 s has been taken into account for the driver. The initial speed is 20 m/s.

In this example, the driver is still able to come to a standstill in time, if he detects that the automatic system fails to brake. Of course, the driver must react and be able to react with 1.3 s.

For steering, similar requirements must be taken into account: Driver must have necessary reaction time. This reaction time depends on the distance to shoulder or adjacent lane, the speed and the reaction of the system. The latter includes maximal angular velocities and accelerations with which the system might show a faulty reaction.

The current technical solutions are supported by the following existing equipment:

- Different controllers or safe computers are available that are qualified according to up to ASIL D/SIL 4,
- Sometimes even “intelligent sensors” with a SIL available.
  - Different, diverse sensors (no SIL), which are cross-validated by the safe computer. Examples of such sensors are cameras, lasers, radar, infrared, ultrasonic etc.
- Multiple, diverse actors; safety relays as electric actors, the use of proven mechanical systems is also possible.

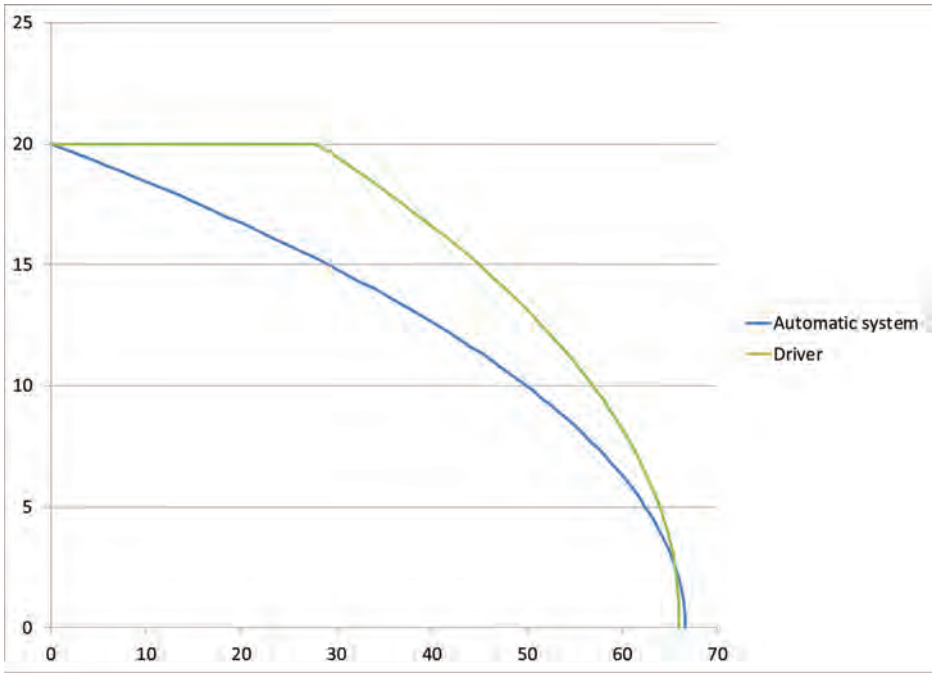

Figure 2. Example for a brake curve.

3 POSSIBLE NEXT STEPS

Based on the current status one can imagine the following future steps for road vehicle.

- Safe guidance (lane keeping) could be implemented, e.g. using differential GPS together with good update service of precise maps. All work on the road and all temporarily blocked roads need to be present on these maps.
- Stopping before traffic lights enforced by a wireless transmission of information between traffic lights and vehicles. Nevertheless, the driver needs to watch out for violators, e.g. cyclists even if he has a green lights.
- Speed limit enforcement, e.g. the speed limit is transmitted in a wireless manner form a sign broadcasting the speed limit or the sign is read by a camera, alternatively a map is used as source.
- Handling of simple traffic situations as e.g. on motorways following the lane, without overtaking maneuvers.
- Vehicles on separated areas and on separated road networks.

Further development leads to a following scenario, which include:

- The road or lane might be separated by two fences forming a controlled environment and on this environment a vehicle can run automatically, with steering, braking, driving implemented according to ASIL D.
- Vehicles drive with very short distances using platooning.
- At certain places entry and exit to this network of roads is allowed. There, the driver takes over the automatic vehicle and drives it manually to the destination.
- The necessary information as maps, position, speed limits, communication with other automated vehicles would be implemented on the vehicle, rather than on the road.
- The infrastructure would be rather cheap, consisting of the road and fences. Comparing this with a railway, the infrastructure is more flexible, no signals, no switches, no ballast and sleepers are necessary.

In all these cases, the relevant technical systems would need to be safe life systems with a safety level up to ASIL D/SIL 4.

A safe life system is a system, in contrast to a fail-safe system, does not switch itself off in case of a failure, but where the safety function is ensured even in case of one (or sometimes several) failures.

The safety integrity levels (SIL/ASIL) are defined in standards for functional safety. IEC 61508 and EN 50129 define SIL 1 to SIL 4. ISO 26262 defines the automotive SIL (ASIL) A to D.

The SIL/ASIL consists of two essential requirements:

- Maximum tolerable rate of dangerous failure which cannot be exceeded
- Measures against systematic failures (verification, traceability of requirement, specific techniques)

Regarding future development, also possible problems need to be considered, that an automatic or autonomous vehicle driving on the road need to face to become comparable with a human driver. First of all, such a system needs to distinguish objects as persons or animals from unmoving objects. Another example would be to distinguish vehicles on high wheel from bridges etc. Another problem is that sometimes intentions of a person or animal need to be guessed: does the person or the animal intend to cross the road and step on the road? A typical example would be a child with a ball standing on the sidewalk, having dropped the ball and this has moved on the street. There are a lot of such tasks would require intelligence and one would tend to use artificial intelligence for such a task.

Assume now that artificial intelligence should be implemented for autonomous driving. Then requirements for SIL 4/ASIL D would need to be implemented in full rigor in the software and the hardware. On the other hand, the algorithms for artificial intelligence are voluminous and complex. If then e.g. traceability needs to be shown from a requirement as e.g. "The algorithm must distinguish human beings from other objects" one might imagine the complexity of such a task. This would only be one requirement. The entire complex of requirements to the software would have to take into account a lot of driving situations, in the environment etc. If the algorithm is a self learning algorithm, one needs to ensure that it has learned in a certain time enough and this must be proven in the light of the standards /IEC 61508/and/or/ ISO 26262/. Another possibility would be to use a proven in use argument and accumulated 3 10^9 hours in service, see /IEC 61508/part 7 annex D. With 600 hours of driving that would mean to have 5 000 000 vehicles driving an entire year under controlled circumstances, i.e. with trained drivers that can override the system and that would also register all events—or the vehicle has to do this. One can decrease the number of vehicles by increasing the number of driving hours per year, e.g. up to 6,000, which would mean driving in shifts. Nevertheless, still 500,000 vehicles would be necessary. In addition, each change of the software would require to repeat this approval process

The conclusions is that solutions for the safety relevant software must be simpler, without

guessing intentions etc. in order to overcome these problems. Artificial intelligence would be good for assistance systems.

4 CONCLUSIONS

In this paper we have provided some considerations on automatic (or autonomous) driving for rail and road vehicles. It turns out that for road vehicles, the environment is much more complex than for rail vehicles. Therefore, the experience from e.g. automatic metros cannot be directly used.

Most of the existing systems are either pure assistance systems or they are dedicated to simplified traffic situations

It has to be expected that the first safe solutions for autonomous driving would come for situations with a simplified environment, especially where the environment is controlled or even adapted to the task of autonomous driving. Here, a special solutions are AGV (automatic guided vehicles) that are just moving in an environment fully adapted to them, but not on an open road.

Probabilistic analysis of faults affecting multiple trains of the electrical power supply system of nuclear power plants

B. Brück, G. Gänßmantel, A. Kreuser, C. Müller, E. Piljugin & J.C. Stiller
Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) gGmbH, Germany

ABSTRACT: Faults simultaneously impairing multiple redundant trains of the electrical power supply system of NPPs recently received growing attention by the nuclear community. This was triggered by events at several different NPPs including Byron in the U.S. or Forsmark in Sweden. Such events have generally not been included in PSAs of NPPs yet. Therefore, GRS has initiated a research project aiming at a comprehensive and in-depth analysis of events characterized by fault states of multiple trains of the electrical power supply system (including but not limited to open phase conditions) and at the development of modelling and quantification methods to include them in PSAs. The project consists of different interacting efforts. Firstly, the possible causes of faults affecting multiple trains of the electrical power supply system and their consequences are assessed from an operating and modelling perspective. The second step comprises the development of a detailed dynamic model of the electrical power supply system of a German PWR and the investigation of the cause and the propagation of such faults. Then, a current PSA model of a German PWR is extended to allow for the modelling of the phenomena identified in the previous steps. This includes adding relevant equipment not modelled before and new failure modes of equipment already modelled. The additional reliability parameters and frequencies of initiating events required to quantify the extended PSA model are estimated. Finally, the additional failure mechanisms considered in the extended PSA model are evaluated quantitatively.

1 INTRODUCTION

Faults simultaneously impairing multiple trains of the electrical power supply system of Nuclear Power Plants (NPPs) have recently received growing attention by the nuclear community (Brück 2016). This was triggered by events that involved so-called asymmetrical faults at several different NPPs where such faults occurred. An asymmetrical fault results from the degradation (e.g. an interruption) of one or two of the three phases in a three-phase alternating current system. For example, at the Byron NPP in the U.S., asymmetries in the power supply system arose from a single failure of an insulator in the switchyard of the plant. The asymmetry failed to cause the Reactor Protection System (RPS) to initiate the isolation of the emergency bus bars and the operation of the emergency diesel generators. As another example, at the Forsmark NPP in Sweden, the failure of one pole of a breaker to open led to an open phase condition that was also not detected by the RPS. In both cases the electrical consumers remained connected with the fault and were exposed to an asymmetric voltage supply, leading to unavailabilities and even destruction of electrical equipment.

Such events have generally not been included in Probabilistic Safety Analyses (PSAs) of NPPs yet. Therefore, GRS has initiated a research project aiming at a comprehensive and in-depth analysis of events characterized by fault states of multiple trains of the electrical power supply system, including—but not limited to—open phase conditions, and at the development of modeling and quantification methods to include them in PSAs.

The electrical power supply system is particularly susceptible to faults affecting multiple trains since during normal power operation there is no separation between the redundant trains. As shown in Fig. 1, failures that occur on or above the generator bus bars will affect all underlying bus bars simultaneously.

2 PROJECT

This project consists of different interacting efforts:

Initially, the possible causes of faults affecting multiple trains of the electrical power supply system and their consequences are assessed from an operating and modeling perspective. To achieve the project goals, first a detailed analysis of international

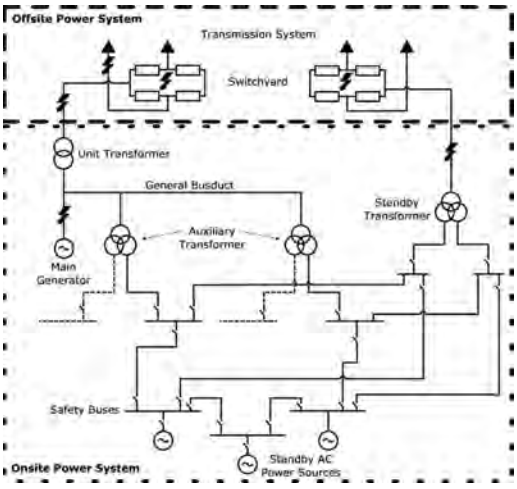

Figure 1. Typical electrical systems of a NPP (inspired by IAEA 2016).

operating experience is carried out with respect to actual and potential faults affecting multiple trains of the electrical power supply system of NPPs, complementing the German operating experience that had also previously been analyzed by GRS with respect to this topic in the course of the general monitoring and analysis of German operating experience (Mildenberger 2016).

The second step comprises the development of a detailed dynamic model of the electrical power supply system of a generic modern German Pressurized Water Reactor (PWR) and the investigation of the cause and the propagation of such faults.

Then a current PSA model of a German PWR is extended to allow for the modeling of the phenomena identified in the previous steps. This includes adding relevant equipment not modeled before and new failure modes of equipment already modeled.

The additional reliability parameters and frequencies of initiating events required to quantify the extended PSA model are estimated. New approaches and procedures to achieve this are developed as needed.

Finally, the additional failure mechanisms considered in the extended PSA model are evaluated quantitatively.

3 OPERATING EXPERIENCE ANALYSIS

The events at the Byron and Forsmark NPPs highlighted the importance of the grid connections and the associated equipment for the reliability of the plants' safety system. These events also revealed the importance of a systematic evaluation and analysis of their operating experience; while the physical and electro-technical effects that led to the failures were all well-known and well understood in theory, this theoretical knowledge was not used in the design of the safety system of NPPs worldwide until operating experience made these problems obvious.

Therefore, an evaluation of operating experience with a special focus on effects that might impair multiple trains of the electrical power supply system is performed. By doing so, two targets are pursued:

- Identification of failure mechanisms that might lead to multi-train impairments and that are not yet covered by the design assumption of the plant. Also, events where so far no (multiple) failures have been observed but where the effective failure mechanism may cause such failures in case of other circumstances are relevant.
- Development of failure scenarios that describe how such failure mechanisms would affect modern German KWU type NPPs. With the development of the scenarios it is intended not only to "copy" the event to the KWU type plant, but also to develop variations of the actual event.

3.1 *Events with asymmetrical faults*

As a first step, the systematic evaluation of international operating experience with a focus on asymmetrical faults, which was conducted by GRS after the events in Byron and Forsmark, was taken as basis to develop failure scenarios. This evaluation (NRC 2007) revealed that such faults can be observed regularly in NPP operating experience. Ten events were revealed where the active grid connection of the plant was affected by an asymmetrical fault. In four events such faults were discovered in the standby grid connection. The identified events where active grid connections were affected are presented in Table 1.

The systematic analysis of asymmetric faults showed that a single failure mechanism might lead to various different failure scenarios.

In case of an asymmetrical failure event, the following set of features that had a significant influence on the extent of the degradation of the onsite power system could be identified:

- Type of failure: Failures of one and of two breaker poles have been observed in operating experience and need to be analyzed.
- Location of the failure: Asymmetrical failures may occur in the main grid connection, the auxiliary grid connection and the generator bus duct, each with different consequences. In case of grid side asymmetries, the different distances between the location of the failure and the plant

Table 1. Events with asymmetrical faults.

Date	Plant	Failure cause
1994-05-13	Kalinin	Collapse of a transformer duct, OPC in one phase
1997-02-25	Balakovo	Unintended closure of a single breaker pole
2001-03-31	South Texas	One breaker pole in the switchyard failed to close
2005-11-11	Koeberg	One breaker pole in the switchyard failed to close
2006-07-26	Vandellos	Mechanical failure of a disconnector
2007-05-14	Dungeness-B	One pole of a HV-transformer breaker failed to close
2012-01-30	Byron	Collapsed insulator caused a line interruption
2012-12-01	Bruce	Mechanical line failure during severe weather (storm)
2013-05-30	Forsmark	Failure to open on command of a single breaker pole
2014-04-27	Dungeness-B	Open breaker pole in the switchyard

have to be considered as well as parallel grid connections that are not impaired.
- Neutral point treatment: Operating experience has shown that the treatment of the neutral point of the main or auxiliary transformers has a crucial effect on the propagation of a grid side asymmetry into the plant.
- Load of the onsite power system: Both the load and its characteristics (inductive or ohmic) have an influence on the asymmetry and need to be evaluated carefully.

In total, more than 500 combinations of features can be derived from the list above. Currently, methods are being developed how this number can be reduced to a practicable amount of failure scenarios. Once this reduction is achieved, the identified scenarios will be analyzed with the simulation model described in Section 4.

3.2 *Extended scope*

Beside the asymmetrical faults, several other phenomena that might affect multiple redundant trains of the electrical power supply system are already known from operating experience, both from the International Reporting System for Operating Experience (IRS) and from German operating experience. Among these phenomena are the Forsmark event of 2006-07-25 (NRC 2007), where combined voltage and frequency fluctuations in the 400 kV grid caused multiple impairments of Uninterruptible Power Supply (UPS) units necessary for the startup of the emergency diesel generators (EDGs), and an event in a German NPP (RSK 2015) where four inverters (each in a separate redundant train) failed because of a single failure in a 660 V breaker of a residual heat removal pump.

In the light of these insights it was concluded to extend the scope of the analysis from asymmetrical faults to all failures that are capable of affecting more than one of the redundant trains of the electrical power supply system. This includes non-redundant components or systems like the grid connections, the generator or the generator bus duct, but also redundant components inside and outside of the safety systems that have caused impairments in more than one train during a failure event.

Since German operating experience with NPPs is limited to about 800 reactor years, it was decided to extend the scope of the analysis. Based upon an evaluation of the technical comparability of the plants, the accessibility of the necessary information and the amount of available data, it was decided to use the operating experience of the U.S. NPP as it is provided through the Licensee Event Reports (LER) as additional information source. Although all these events have already been analyzed in depth by the U.S. NRC, it was concluded that additional insights from the events could be gained by an analysis focused on possible effects on modern KWU type plants, which have a safety system that relies primarily on redundancy rather than diversity.

3.3 *Methodology*

Effects with the potential to affect multiple redundant trains simultaneously are rare since extensive precautionary measures are taken to avoid such events. Therefore, a substantial amount of operating experience has to be analyzed to identify some of these types of failures. To achieve this, all 3466 LERs with events in PWRs and BWRs from the beginning of the year 2000 to the end of 2009 were included into the scope of the analysis. To cope with this high number of events in a reasonable amount of time, a four stage process was developed to identify the relevant fault scenarios:

1. Initial screening of the events; based upon an event summary, all available events are screened to filter out all those events that are obviously not relevant for a further analysis.
2. Thorough analyses of the remaining events to further reduce the number of events; at this stage all information included in the LER is used for the assessment.
3. The remaining events are analyzed and described in depth by taking into account all available information.

4. Based upon the results achieved in step 3, failure scenarios (see Section 3.1) are developed.

The first step of the process resulted in 250 potential events, which were reduced to 29 events in step two.

They cover a wide range of effects like external impacts (severe weather or grid fluctuations), component failures inside the plant or in the associated switchyard, or events due to human error. Therefore, it may be expected that a comprehensive set of relevant failure scenarios will result from this effort. Up to now, three scenarios have been developed.

4 DETAILED DYNAMIC MODEL

A generic model of the auxiliary power system of modern German KWU type NPPs has been developed using the software NEPLAN (NEPLAN), see Fig. 2 and Fig. 3. Using this model, different calculations and analyses can be performed, such as load flow calculations, short circuit calculations, harmonic analysis, and dynamic simulations.

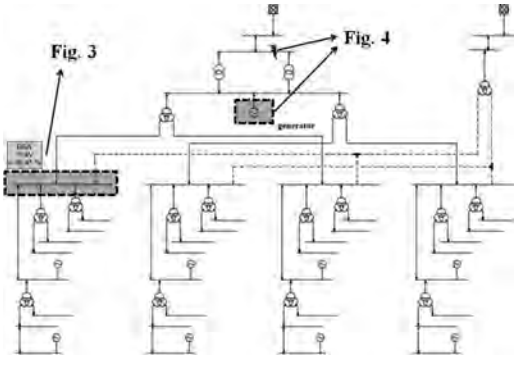

Figure 2. Generic model of the auxiliary power system of a German NPP. On each bus bar, several individual electrical consumers are modelled (see Fig. 3).

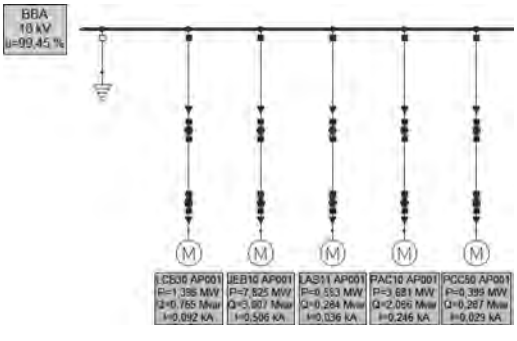

Figure 3. One of the four main 10 kV bus bars with electrical consumers.

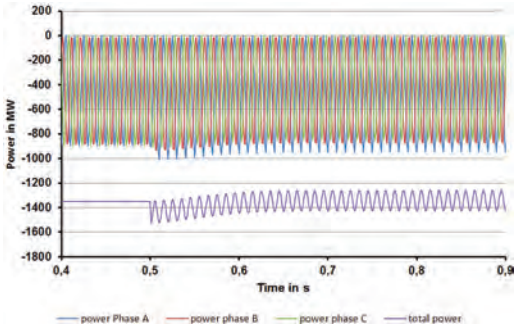

Figure 4. Total power and power of the three phases at the generator terminal after a single-phase interruption occurring at t = 0.5 of the connection to the grid (see Fig. 2).

The model currently consists of 733 elements (including 114 asynchronous machines as consumers) so far and is currently being further developed. It is already suitable for estimating the impact of different scenarios on the NPP's safety system.

As an example, Fig. 4 shows the voltage and current of the generator for all three phases as a function of time for a three phase disturbance as marked in Fig. 2. The next step will be the detailed investigation of the scenarios to examine the failure modes and effects.

5 PROBABILISTIC MODEL

First analyses have shown that the appropriate modelling of realistic single phase failure scenarios and other scenarios simultaneously impairing multiple trains of the electrical power supply system in a PSA requires extensive augmentation and modification of present PSA models. This comprises modeling the complex impacts of such phenomena on the electrical equipment, including parts of the electrical power supply system not important to safety, in the PSA model and adding additional failure modes of electrical components already modeled. To efficiently and systematically integrate such modifications into existing PSA models, GRS has developed and continuously improves the software tool "pyRiskRobot" for modifying complex fault tree topologies in an automated and traceable manner (Berner 2017). This tool will facilitate modifying and enhancing the PSA model.

6 QUANTIFICATION

To quantify the model, the frequencies of the new initiating events and additional reliability parameters need to be estimated including e.g. failure

probabilities and failure rates for electrical equipment that is or has been exposed to single phase failure conditions. While the extension of the PSA model is expected to be more or less straightforward, quantification will pose a major challenge since reliability parameters for the equipment under the respective conditions or analyses of relevant operating experience that would be suitable to base estimations of these parameters on are not readily available.

To achieve this nonetheless, information from existing databases, from operating experience and expert knowledge will be utilized. Models, methods and procedures to extract and combine the available information will be developed and evaluated as needed. This may include modeling of the emergence of relevant initiating events by fault trees in order to estimate their rate, modeling of the failures of components under appropriate boundary conditions as a result of failures of their piece parts by fault trees, quantitative analysis of operating experience using Bayesian statistical methods, and quantitative assessments by experts.

As first step, the rates of the initiating events single-phase and dual-phase failures in the active grid connection have been assessed utilizing the operating experience analysis described in section 3. The rate of single-phase failures in the active grid connection is comparable to the rate of small Loss of Coolant Accidents (LOCAs) while the rate of dual-phase failures is approximately one order of magnitude smaller.

7 CONCLUSIONS

Faults affecting multiple redundant trains of the electrical power supply system of NPPs—including but not limited to open phase conditions—may pose a significant threat to the safety of NPPs. Such failures have generally not been appropriately considered in PSAs despite the fact that the rate of such events is comparable to small LOCAs. An on-going project of GRS to research this subject comprises the systematic analysis of national and international operating experience, the development of a detailed dynamic model of the electrical power supply system and the extension and modifications of an existing PSA model and the quantification of the enhanced model. The advancements made so far suggest that substantial new insights will be gained in the frame of this project. However, the estimation of the reliability parameters and rates of initiating events needed to quantify the enhanced PSA model will still pose a challenge.

A scenario-based risk analysis oriented to manage safety critical situations in autonomous driving

A. De Galizia & A. Bracquemond
VEDECOM Institute, Versailles, France

E. Arbaretier
APSYS—Airbus Group, Elancourt, France

ABSTRACT: Risk analysis is very useful for identifying hazardous events affecting the functional limits of complex systems as autonomous vehicles. To ensure the robustness of an autonomous vehicle architecture, new approaches should be investigated providing the dimensioning parameters related to functional scenarios. Research is currently ongoing at the VEDECOM Institute to identify and analyze safety critical situations including accidents. For this reason, a set of functional scenarios has been defined as an abstraction of real life driving situations. The aim is to explore how autonomous vehicles evolve and behave under various environmental and traffic conditions. Thus, this paper presents a qualitative risk analysis approach taking into account the evolution of a scenario by means of the concept of transition between successive scenes. Then, combinations of hazards are identified potentially leading to safety critical situations. Finally, the feasibility of our proposal is shown on an application case examining a level 4 autonomous vehicle behavior in high traffic driving.

1 INTRODUCTION

During the last decade, focus of research in the automotive industry has shifted to the development of highly if not even fully automated (autonomous) driving (Bengler et al. 2014). Recent progress in this field showed that nowadays is possible to provide the driver with useful assistance systems, *e.g.* lane departure warning (Dickmanns 2002), lane change assistant (Ruder, M. et al. 2002), Adaptive Cruise Control (ACC), or even autonomous driving over long distances on highways (Dagli et al. 2004).

Nevertheless, in order to achieve highly robust autonomous driving systems, there are still challenging use cases that must be mastered (Schmidt et al. 2015, Geyer et al. 2014). In fact, mastering these cases is not only substantial for the Society of Automotive Engineers (SAE) level 4 and 5 automated vehicles (Donges 1999), which are capable of sensing its environment and navigating without human inputs, but relatedly on the rate of triggering driver take-over requests in case of level 3, conditional automation. Outside of these areas or circumstances, the vehicle must be able to safely abort the trip, i.e. park the car, if the driver does not retake control. Increasing the automation level requires remarkable improvements on the existing perception, prediction and planning algorithms but also on the system architectures (Weiss et al. 2004). Although the former have been an active field of research, focus on the system (functional) architecture has been limited so far. In our point of view, system architecture, and in particular its behavioral planner layer, is a key element for future autonomous vehicles (Bertolazzi et al. 2004, Bonic et al. 2017).

In order to set up a robust decision module in an autonomous systems, a number of functions have to be realized in an integrated architecture. As processing tasks for perception, situation assessment, behavioral module and actual control of the vehicle have tight constraints, it is necessary to focus on the environment around (Chan et al. 2004, Dickmanns 2003, Bertozzi et al. 2000).

Developing a safe functional architecture is one of the main objectives of the 'Robustness of architectures and systems' program at VEDECOM (Bonic et al. 2017).

Today, risk and safety analysis has not sufficiently addressed the problem of explore the behavioral and decision module of an autonomous system architecture taking into account the surroundings (Donges 1999, Figlewski & Levich 2002).

In this sense, risk analysis should provide for relevant design insights concerning the overall robustness of an autonomous vehicle, *i.e.* its faculty to adapt and operate properly under a large

diversity of operating conditions (e.g. infrastructure, weather, illumination, traffic etc.). However, most of existing risk analysis approaches are rather specialized in assessing system reliability and usually they focus on system and components failure modes (Kontio & Basili 1997). Moreover, in these approaches information is more or less used directly on a quantitate level, with an uncertainty that have to be considered.

In this paper, we present a risk analysis approach which aims to qualitatively identify hazardous patterns and by this way the underlying critical situations. In that way, we want to focus on the limits of behavioral performance of a SAE level 4 autonomous vehicle. The aim is to address the robustness of the autonomous system architecture by focusing on the evolution of a driving scenario.

Then, the risk is manly seen as discussed in (Polychronopoulos et al. 2004) as the approaching critical situations resulting from the combination of several hazardous events which might endanger the autonomous vehicle and its passengers or other traffic participants. Concretely, the paper addresses risk analysis qualitatively and thus allows for describing the abstract critical situations in a comprehensible way. Based on an approach oriented to the dynamic modelling, it allow for integrating risk analysis insights on an experimental evaluation (simulation) platform for a scenario-based design of autonomous system architecture (Go & Carroll, 2004).

The rest of the paper is structured as follows: Section 2 gives an overview of the global framework on which our risk analysis methodology relies on. Section 3 introduces the conceptual formalization of scenes and scenarios along with some notions relating with dynamic modeling of autonomous driving. In Section 4 an application case is proposed. The paper close with some conclusions and an outlook for further developments to adapt the proposed technique to specifics for autonomous systems design.

2 FROM REAL WORLD DRIVING TO SAFETY CRITICAL SCENARIOS

The risk analysis approach that we propose is based on a global framework allowing to assess risks in critical driving situations generated by the occurrence of *hazardous events* combined with critical operational modes. We make the choice to use the adjective *hazardous* since it makes the tradeoff between the semantic usage specific to dependability studies and the standardized expressions used in a research area such as that related to autonomous driving.

As illustrated in Figure 1, this risk analysis methodology has been proposed to the need of analyzing nominal functional scenarios designed starting

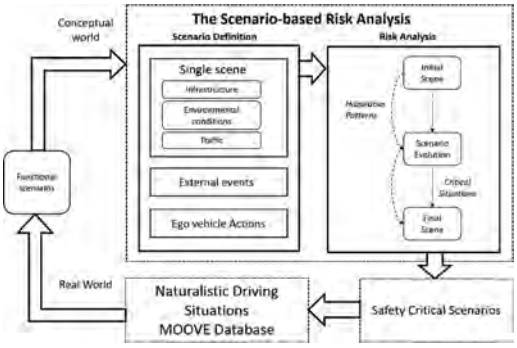

Figure 1. Scheme of the global approach.

from real world driving data collected in the context of the MOOVE project (Bonic et al. 2017).

The parameterization of the functional scenarios makes it possible to do queries in the MOOVE database and search "virtual" aggravating situations in driving records.

In our risk analysis approach, we focus on the hazardous events leading to major risks situations linked to safety issues affecting the autonomous vehicle performance (behavioral and decision).

After this introduction to the main concepts and the framework of development in which this method fits, in Section 2 we present in detail the different parts that compose it and the underlying approach aiming to make the link with dynamic modelling.

3 A SCENARIO-BASED RISK ANALYSIS FOR AUTONOMOUS DRIVING

3.1 *Defining the main terms*

In the literature several definitions exist which are used in different application fields. We have considered those that fit better with the choices made in the context of the MOOVE project. Thus, the following terms have been defined as they constitute the basic components of our approach.

First of all, we need to define the term scene as below:

> *A scene describes a snapshot of the ego vehicle and the surrounding including the infrastructure, the environmental conditions as well as all the interacting traffic participants, and their relationships with the ego vehicle.*

The objects in the scene can be characterized in different ways:

– Dynamic or static (*i.e.* "potentially" mobile or "always" static objects);

– Environmental elements;
– Etc.

Overall, the *scene* describes the current state of the system according to the *traffic conditions* (position, speed, etc. of the ego and the other vehicles), the *environment* (weather, road surface, visibility, etc.) and *infrastructure* (type of road, number of lanes, slope, presence of working zones and mobiles objects, etc.).

The second term which has to be defined is *scenario*:

> *A scenario describes the evolution of the system by a succession of scenes. The (temporal) succession starts with an initial scene and ends with a final scene.*

The mechanisms for moving from one scene to another are mainly of two types:

– *Actions, i.e.* the ego vehicle state changes;
– *External events, i.e.* other vehicles or the environment state changes.

After having formalized the current situation (initial scene), how it evolve and the final state of the ego vehicle, the nominal development of the scenario can be modified or degraded by adding sequential hazardous event (Bengler et al. 2014). These can be maneuvers of traffic participants interacting with the ego vehicle can be considered along with an unsafe behavior of the ego itself. This allow for identifying *critical patterns*, and by consequent, risks of a missed control about deviations of a specific scenario.

So, we have to define two last concepts, *hazardous event*:

> *A hazardous event is an event that may increase the risk likelihood or severity. It is any condition that can degrade the development of the ongoing scene towards a negative evolution of the scenario, with more or less serious consequences on the achievement of objectives directly related to safety.*

and *critical pattern*:

> *A critical pattern is a set of hazardous events which combined with actions or external events leads to a critical situation.*

Based on the nominal scenario, we have to deal with a large combinatorial explosion concerning the scenario branching as in sequential critical patterns (Lattner & Herzog, 2004). This combinatorial explosion essentially depends on:

– The *actions* and/or *external events* that may take different values and occur at different times;
– The number of *hazardous events* and their combination to produce *critical patterns*.

This representation of a driving scenario is naturally oriented to the dynamic modelling of an autonomous system functional architecture. Next section provides for a further formalization supporting the dynamic modelling.

3.2 *Formalization of transitions for dynamic modelling*

Following the definition of the concepts that we have proposed in previous section about this risk analysis approach, *i.e.*:

– *Scene*, which in turn is based on the 'infrastructure', 'environmental conditions' and 'traffic' descriptors,
– *Scenario*, which start with an initial scene, evolves and ends with a final scene,
– *Critical patterns,* which are introduced in a scenario by considering a combination of hazardous events, then we give some elements to formalize the evolution of a driving scenario for dynamic risk assessment. This formalization is intended to provide a way to deal with the dynamic modelling of autonomous driving functions.

To do that, we have referred to the concept of *transition* which is well known in graph models for risk assessment, as Petri Nets (Reschka et al. 2015; Ulbrich et al., 2014). So, in this risk analysis methodology a transition is defined as follows:

> *A transition is any action of the ego vehicle or external events occurring during the evolution of the scenario and leading to the successive scene.*

Otherwise said, scenes are connected and triggered by transitions. Graphically, a driving scenario can be then represented as a discrete event dynamic system. As Petri nets, it is a directed bipartite graph, in which the nodes represent transitions (i.e. events that may occur, represented by bars) and places (*i.e.* conditions, represented by circles) (see Figure 2).

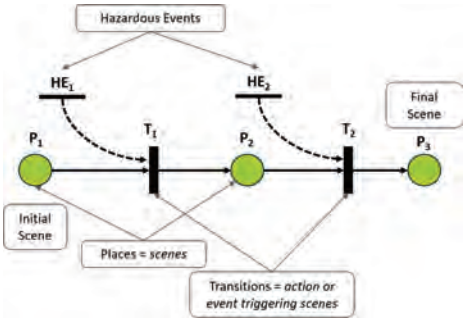

Figure 2. Illustration of the evolving driving scenario as a state-transition system.

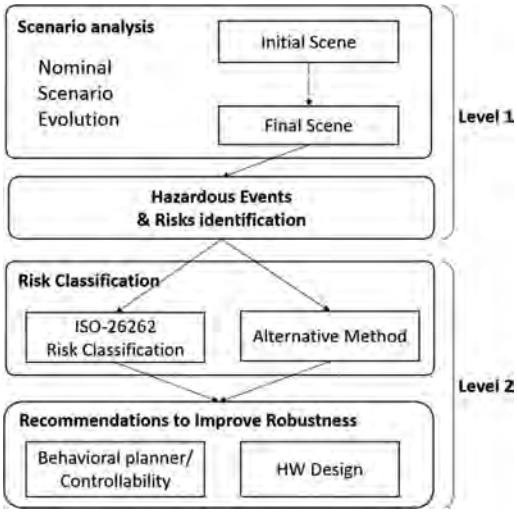

Figure 3. Illustration of the proposed risk analysis methodology: level 1 focuses on the scenario evolution and how harzards can lead to critical situations; level 2 allows for identifiyng risks bsed on the critical situations and classify them.

To resume, the risk analysis methodology proposed in this paper can be depicted as a top-down approach (Matthaei & Maurer, 2015) (Figure 3).

In Section 4, an illustrative case is presented as application of the level 1. In particular, the analysis of a relevant scenario is discussed for the decision and behavioral module of an autonomous vehicle.

4 ILLUSTRATIVE CASE

As application cases, we tested the approach on a set of scenarios of interest in the context of the MOOVE project. Among these, a very interesting and illustrative one is the "Inconsistent yellow and white lane marking" scenario. It allows for showing the behavioral layer of the ego vehicle architecture in the presence of a working zone (WZ). In particular, it is a WZ characterized by two types of lane markings simultaneously: white marking for lanes before the WZ, and yellow marking for lanes after the WZ. The superposition of both white and yellow markings on the road makes lane detection problematic for the perception system. Consequently, the ego vehicle trajectory planner depends on tracking (*i.e.* following the target vehicle ahead). The absence, or in any case the loss of the target vehicle, significantly compromises the possibility for the ego vehicle to go beyond the WZ.

So, we proceed to identification of all the critical patterns potentially leading to critical situations. As illustrated in Fig. 4, level 1 proceeds by analyzing the scenario evolution as described above, *i.e.*:

- Initial scene;
- Evolution (*i.e.* transitions);
- Final scene.

This first part is followed by the identification of hazardous patterns and the critical situations.

Let's consider the nominal scenario evolution analysis. The scenario that we are considering starts with an initial scene, illustrated in Figure 4. The ego vehicle drives on the right lane and follows the green car ahead (the target vehicle). Let's name this latter T1.

The initial scene is described in our methodology as shown in Table 1.

An event occurring after the initial scene marks the evolution of the scenario. This event is the beginning of a working zone (WZ), as illustrated in Figure 5.

T1 detects the WZ and changes lanes.

Figure 4. Snapshot of the initial scene.

Table 1. Initial scene as analyzed in the methodology.

Level 1 – Initial scene	
	Description
Infrastructure	– Road with separate carriageways; – Two or more lanes for the same direction; – Dashed lines in the middle;
Environmental Conditions	Nothing to report (NR)
Traffic	– The ego vehicle (**E**) drives on the rightest lane at a constant average speed; – The vehicle (**T1**) in front of E advances at the same speed; – Other vehicles drive on the left lane.

Figure 5. Evolution of the scenario: An event occurs consisting on the presence of the WZ.

Based on this event, ego vehicle performs actions basically consisting in T1 tracking in order to go over the WZ (see Figure 6 below).

The scenario closes with the final scene (Figure 7).

Table 3 shows how the final scene is described in the risk analysis it before to proceed to

Figure 6. Evolution of the scenario: Ego vehicle do some actions in response to the events occurred in the scenario.

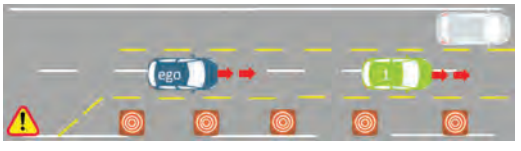

Figure 7. Final scene of the scenario: Action.

Table 2. Scenario evolution.

Level 1 – Evolution	
	Description
Infrastructure	– In the right-hand lane there is a working area indicated by warning signs; – New traffic lanes are marked in yellow on the ground, and white markings of initial lanes are still present.
Environmental conditions	Nothing to report (NR)
Traffic	– **T1** turns on the left indicators and follows the lines of the new yellow marking to go beyond the working zone; – **E** detects that **T1** changes lanes to the left, detects the new marking lines, turns on the left indicators and follows **T1**.

Table 3. Final scene.

Level 1 – Final scene	
	Description
Infrastructure	– Two tighter lanes are available
Environmental conditions	Nothing to report (NR)
Traffic	– **E** continues to drive behind C1 in the new lane on the right (yellow marking) and goes beyond the working zone.

Table 4. Hazardous patterns & critical situations.

Level 1 – Hazardous patterns & critical situations	
Hazardous patterns	Critical situations
1. **T1** suddenly changes lanes without turn signals AND E brakes too late;	2. Collision in the working zone;
3. **T1** stops abruptly;	4. Accident between **E** and **T1**/Exit of lane or road;
5. **E** does not detect or detects too late the work area (panels placed too close to the work) AND does not brake sufficiently before;	6. Accident in the work area with injured workers;
7. **E** brutally shifts to the right (bad weather conditions: e.g. rain, side wind, loss of grip: e.g. slippery ground).	8. Accident with one or more injured pedestrians.

identification of the critical patterns and the resulting critical situations (Table 4).

5 CONCLUSIONS

In this paper we presented a risk analysis approach adapted to the specifications of the autonomous vehicle. For a SAE level 4 autonomous vehicle the driver only provides a destination or navigation instructions.

Then, a robust behavioral planner should manage safely a large number of critical situations. Then, critical situations need to be well identified and mastered to deal with the design of the functional architecture of an autonomous vehicle. The aim is to evaluate the performance limits of a level 4 autonomous vehicles.

To identify these limits, in this paper we proposed a risk analysis methodology which focuses on a specific scenario and identify possible hazardous events. In that way, we tried to contribute to two main research axes relevant for autonomous driving:

1. Exploring the ego vehicle behavior qualitatively in functional scenarios and identifying the safety critical situations dimensioning the ego vehicle architecture without taking into account failure modes;
2. Mastering critical situations by proceeding with a contextual semantic adapted to autonomous vehicles operational behavior.

In order to validate these contributions, this methodology has been applied to one of the

functional scenarios defined in the MOOVE project basing on our real life driving database. Scenarios have been designed to explore the ego vehicle behavioral limits (safe functional) and identify critical situations which could face in real life. These critical situations arise by combining hazardous events. As hazardous events, we do not considered those related to failure modes but we focus on hazards arising from extreme or critical operational modes that no longer allow the ego vehicle to safely behave.

Based on the application case, some perspectives have been identified to extend this approach to fully deal with autonomous driving safety:

- On the one hand, in the first part of the analysis, the integration into the scenario analysis of failure modes concerning perception and control;
- On the other hand, in the second part, the authors would like to simulate a deeper discussion on the risk classification new exigencies for autonomous vehicles compared to the classical ISO-26262 standard (International Organization for Standardization, 2011).

A whole system approach to managing defective on-train equipment

A.J. Gilchrist
RSSB, London, UK

ABSTRACT: This paper describes recent risk analysis work undertaken to determine the safest operational responses to on-train equipment failures on the mainline railway in Great Britain. The current rules and guidance for managing these failures have focused on minimising the risk to passengers onboard the train with defective equipment. In more recent years, the rail network has become significantly more congested and it has become increasingly necessary to also consider the safety impact any control measures applied to an individual train will have on the rest of the network. For different operational responses two types of safety risk were calculated: the immediate risk from a train not being able to use the defective on-train equipment; and the knock-on risk resulting from any impact on train performance. To illustrate the methodology, results are presented for an Automatic Warning System (AWS) failure on a passenger train.

1 INTRODUCTION

Each train operator on the mainline railway in Great Britain (GB) is required to produce a contingency plan outlining how they will manage situations where certain items of on-train equipment fail. The pieces of equipment for which contingency plans should be made includes a wide range of safety-critical equipment, such as train protection systems and cab radio failures.

The safety impact from an on-train equipment failure will depend on the equipment which has failed and the role of that equipment onboard the train. The loss of on-train equipment will generally result in an increased risk from train accidents such as train collisions, derailments and buffer stop collisions. This is called the 'immediate risk' and may be reduced by imposing restrictions on the train, such as reducing the maximum permissible speed or detraining passengers.

Over the last decade, passenger usage on the GB mainline railway has increased significantly. The annual number of passenger journeys in 2006 was 1.2 million whilst this has increased to 1.7 million in 2016 (Office of Rail and Road 2017). This increased passenger usage has resulted in increased congestion on the rail network, with both trains and stations becoming busier. Any control measures which impact train performance will further increase this congestion and has a resulting safety impact. This is called the 'knock-on risk' and includes personal accident risk resulting from extra boarding, alighting, and crowding at stations, as well as train accident risk caused by miscommunication and additional red signal approaches.

In order to effectively manage on-train equipment failures both the immediate and knock-on risks must be taken into account so that the immediate risk to the train with defective equipment is reduced whilst minimizing the knock-on risk to the rest of the rail network. The management of defective on-train equipment is currently covered by a rail industry standard (RSSB 2016) and associated guidance note (RSSB 2015) as well as Rule Book module TW5 (RSSB 2017). These documents outline the basis by which a train operator should produce their contingency plans, including speed restrictions and maximum distances travelled with the defective equipment. The current rules and guidance were determined to reduce the immediate risk as low as possible but did not fully consider the knock-on risk associated with these operational responses.

Quantitative risk models have been developed to calculate both the immediate and knock-on risk for a range of different operational responses to defective on-train equipment. Using these risk models, the operational response resulting in the lowest total risk (both immediate and knock-on) has been determined. This paper will describe the risk modelling undertaken to determine the most effective way of managing an Automatic Warning System (AWS) failure on a passenger train.

2 AUTOMATIC WARNING SYSTEM (AWS)

2.1 *Introduction*

The primary safety role of the AWS is to provide warnings to the driver of potentially hazardous

situations that are approaching. This might be signals where the train is required to slow down and be prepared to stop, or of approaching severe speed reductions.

When the driver is approaching a potentially hazardous situation:

- The driver will receive a warning horn.
- The driver must acknowledge the warning within a set time period.
- The AWS will then change visually to indicate that the driver has acknowledged the warning.

An emergency brake application will be applied on the train if the driver does not respond correctly to an AWS warning.

Fitment of AWS at signals became standard for British Rail in 1956. Figure 1 shows the historical number of accidents caused by Signals Passed At Danger (SPADs) for the years 1950–1980 (Evans 2003). It can be seen that in the years immediately after AWS fitment became standard, the number of accidents caused by SPADs was significantly reduced (approximately 3 to 10 times). Whilst other factors such as the change from steam to diesel and electric trains and the introduction of colour light signals will have contributed to this decrease, the introduction of AWS is thought to have been a major factor contributing to this decrease.

In the years after 1956, AWS has been introduced at locations other than signals, primarily as a response to major accidents. Following the Morpeth derailment in 1969, a recommendation was made to provide AWS for Permanent Speed Restrictions (PSRs) requiring a third reduction (or more) in speed. Following a derailment at Nuneaton in 1975, temporary AWS magnets were provided on the approach to Temporary Speed Restrictions (TSRs) and, since 1987, they are also provided on the approach to Emergency Speed Restrictions (ESRs). AWS started to be provided on the approach to certain locally monitored level crossings in 1981.

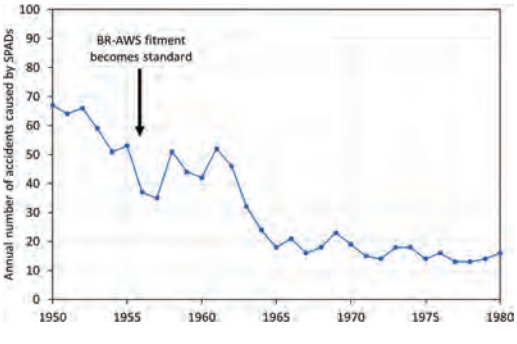

Figure 1. Historical number of accidents caused by SPADs for the years 1950–1980.

3 CALCULATING THE IMMEDIATE RISK

3.1 *Risk model structure*

The immediate risk from a train travelling without AWS is principally from the train either travelling too fast or too far at locations where AWS is fitted. The hazards which have been explicitly quantified in the risk model are therefore:

- Train collisions (caused by SPADs).
- Derailments (caused by overspeeding at speed restrictions and from SPADs).
- Collisions at level crossings.

All frequencies and consequences have been quantified based on established risk models. The main risk model used to determine the immediate risk in this work was RSSB's Safety Risk Model (SRM).

The SRM consists of a series of fault tree and event tree models representing 131 hazardous events, which collectively define the overall level of risk on the GB mainline railway. It provides a structured representation of the causes and consequences of potential accidents arising from railway operations and maintenance on railway infrastructure as well as other areas where the industry has a commitment to record and report accidents. These risk estimates are for the current level of residual risk on the railway, which is the level of risk remaining with the current risk control measures in place and with their current degree of effectiveness. The SRM is calculated assuming that all events are independent and can be attributed to a single cause, reflecting how safety event data has been historically recorded in GB. More information on the SRM and how it calculates risk may be found in the Risk Profile Bulletin (Dacre 2014).

The SRM has been designed to take account of both high-frequency, low-consequence events (occurring routinely, and for which there is a significant quantity of recorded data) and low-frequency, high-consequence events (occurring rarely, and for which there is little recorded data). For each of the low-frequency, high-consequence train accidents considered in this work the SRM has a specific fault and event tree structure. For example, for train collisions, the national frequency of SPADs manually coded by type of signal and cause is used as a precursor. Fault trees are then used to estimate a predicted frequency of train collisions for each type of SPAD, based on the probability the train will reach a potential conflict point and whether there is another train at this location. Event trees are subsequently used to determine the average consequence from a train collision, considering escalation factors such as the probability of train fires and secondary collisions. Where there is sufficient data, all

probabilities and frequencies in the SRM fault and event trees are derived from historical event data by determining average rates and trending analysis. Since all available event data is used to determine these probabilities, the SRM provides national average risk estimates. Because of the network-wide nature of the SRM, it is necessary to make average assumptions that represent the general characteristics of the network when calculating the risk values.

To determine the effect of operational responses on the immediate risk, risk estimates were required for trains travelling at different speeds and passenger loadings. This required significant modification of the fault and event trees contained within the SRM, including estimating the change in effectiveness of the Train Protection and Warning System (TPWS) in stopping a train from reaching a potential conflict point following a SPAD. TPWS is a system which is fitted in certain high-risk locations and automatically applies the brakes on a train if it passes a signal at danger, or if the train's speed is excessive when approaching a signal at danger, permanent speed restriction or buffer stop. Note that not all signals are fitted with TPWS and of those that are, only some are additionally fitted with overspeed protection on approach. By analysing the historical data from trains which have been stopped following a TPWS intervention, the effectiveness of TPWS fitment at signals and speed restrictions can be estimated (Harrison 2007). This methodology was incorporated into the SRM fault and event trees to determine the effect of a speed restriction on the train's immediate risk. The TPWS effectiveness calculations have assumed Network Rail's standard Overspeed Sensor (OSS) and Train Stop Sensor (TSS) loop positions and set speeds, including the addition of an additional TPWS+ loop for line speeds of 75 mph and over.

3.2 *Risk without AWS*

The risk values in the SRM are based on recent historical data and therefore only estimates the risk for trains with AWS fitted and working. In order to calculate the increase in risk during an AWS failure the increase in driver error probabilities when AWS is no longer available as a reminder was estimated using Railway Action Reliability Assessment (RARA) (Gibson 2012). RARA provides a consistent approach to human error quantification for the rail industry and may be used to determine high-level estimates of the increase in driver error rates without AWS for different causes of train accidents.

To estimate the increase in train collision and derailment risk at signals, the causes of SPADs most likely to be affected by AWS were determined. These were found to be:

- The driver failing to check the signal aspect.
- The driver failing to react correctly to a cautionary aspect.
- The driver misreading a signal (either misreading the correct signal or reading the incorrect signal).
- Miscommunication between the driver and signaller.

Of these causes, failing to check the signal aspect and not reacting correctly to a cautionary aspect were determined to be those where AWS would have the greatest influence since these are the situations where AWS can directly prevent the error. For these causes of SPADs, RARA analysis gives two estimates of the increase in SPAD frequency without AWS:

- 20 times increase—drivers who have driven the route many times before and have a good knowledge of where signals are so that, even without AWS, approaching signals is still a simple, routine task.
- 150 times increase—drivers who are less familiar with the route or are particularly reliant on AWS to let them know where they are and react correctly to signals. This may only be a very initial increase for a short distance whilst the driver becomes used to driving without AWS.

In reality, this increase will not be constant and will vary with different signal approaches and drivers. Some signal approaches will be simple and correspond to the lower increase whilst the more complex approaches may correspond to the higher increase. Therefore, an average increase of 85 times has been used as a best estimate for this increase.

For the other causes of SPAD identified as being influenced by AWS, the initial error will not be prevented by AWS but the AWS sunflower will act as a visual reminder to the driver, providing an opportunity to rectify the initial error before it results in a SPAD. For these causes the effect of AWS being unavailable will be less and RARA analysis suggests that there should be a 6.25 times increase in these causes of SPADs without AWS.

As well as accidents caused by SPADs, the calculated error rate increases were also used to estimate the increase in drivers overspeeding at speed restrictions. Since AWS is not generally fitted at buffer stops, no increase in the frequency of buffer stop collisions is predicted without AWS.

The total calculated immediate risk for different line speeds is illustrated in Figure 2. The figure shows the estimated immediate risk without AWS, including the upper and lower bounds as calculated from the RARA analysis. For reference, the baseline level of risk calculated by the risk model for when AWS is working is also shown. The drop in risk at

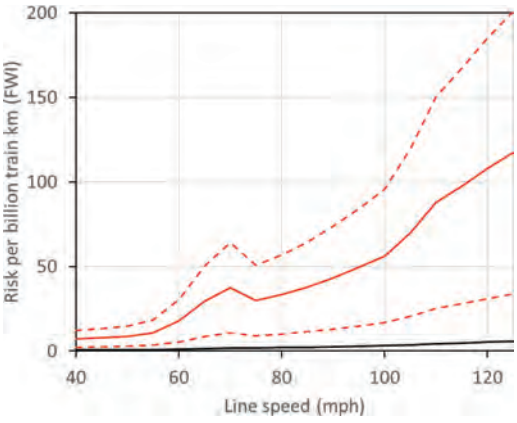

Figure 2. Immediate risk per billion train km in FWI as a function of line speed. The black and red lines show the average calculated risk with and without AWS respectively. The dashed lines show the upper and lower bounds of the calculated risk values without AWS using the two different estimates for the increase in driver error from the RARA analysis.

75 mph is due to the addition of a second TPWS+ loop, providing extra protection at signals. The risk results are given in units of Fatalities and Weighted Injuries (FWI) per billion train km. This is an aggregate measurement of safety risk, using weightings for fatalities, major injuries, minor injuries and shock/trauma events which have been agreed for use by the GB rail industry (Jones-Lee & Loomes 2008).

Analysis of the historical data in Figure 1 can also give an estimate of the risk without AWS. This will, however, not take into account any reliance on AWS that a driver may have developed by driving regularly with AWS. The level of risk calculated from historical data can be therefore be thought of as the level of risk in areas where AWS has never been introduced or if AWS has been unavailable for a long period of time. The values calculated from historical data analysis are almost identical to the lower bound of the RARA estimate. This may be expected since in areas where AWS has never been provided drivers will not have developed any reliance on AWS to warn them of signals and approaching signals without it will be a routine task.

4 KNOCK-ON RISK

Analysis of data shows that there is a strong correlation between certain types of hazardous events and train performance. Any operational response which affects train performance will therefore result in an increase in the risk from these hazardous events. This risk increase is called knock-on risk.

4.1 *Relationship between train performance and risk*

In order to calculate the knock-on risk, the amount of risk associated with train performance needs to be determined. This is achieved by estimating the percentage of annual risk, as calculated by the SRM, which is attributable to train delay minutes and cancellations. These percentages may be derived by investigating the correlation between event frequency and train performance data. Four main areas of risk were considered:

- SPADs
- Staff assaults (both physical and verbal)
- Boarding and alighting incidents
- Passenger slips, trips & falls at stations.

The daily frequency with which each of these events occur may be plotted against Public Performance Measure (PPM) data (Office of Rail and Road 2017) to determine the percentage of these events which are attributable to performance. PPM is a measure of the percentage of passenger trains which were delayed or cancelled on a particular day. An example plot for SPADs is shown in Figure 3. In this example, it can be shown that each delayed train approximately results in an additional 1 in 10,000 chance of a SPAD and that 34% of current SPADs are related to train delays. The knock-on risk from SPADs is subsequently determined by adding together all of the risk in the SRM associated with SPADs, calculating the fraction of the annual delay minutes accumulated during the failure and multiplying this by the portion of the risk identified as resulting from delays. This process was then repeated for each of the four main risk areas.

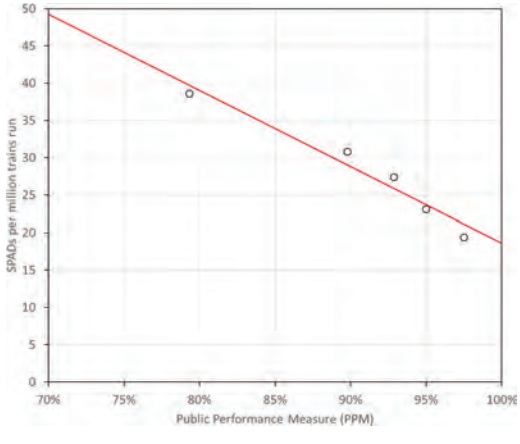

Figure 3. Number of SPADs per million trains run as a function of Public Performance Measure (PPM). The red line is a linear best-fit to the data.

In addition to the risk areas where the percentage associated with delays and cancellations have been determined through the analysis of current data, other risks have also been included in the knock-on risk calculations. These were identified in a previous risk assessment for the Interim Voice Radio System (IVRS) through expert judgment in workshops (Harris 2006).

4.2 *Calculating the knock-on risk*

Delay minutes and the number of cancelled trains are calculated for each possible operational response to an on-train equipment failure. The factors considered when calculating these delay minutes are:

- Any delays (both reactionary and primary) from running at reduced speed.
- Delays accrued from part or full cancellation of trains.

In addition to delay minutes, any extra boarding or alighting resulting from cancelling a train mid-journey is also calculated. These delay minutes and extra boarding and alighting are then used with the relationships described previously to determine a knock-on risk for each operational response.

5 OPERATIONAL RESPONSES

For AWS failures, once a failure has been detected the train should travel to the next available location where the train can be dealt with. At this location it is assumed one of the following will occur:

1. The train is taken out of service and is replaced by one with working AWS for the rest of the day.
2. The affected cab is "boxed in" so that it is not required to be used for the rest of the day.
3. If the rear cab has working AWS, then the train enters service driven from the working rear cab, and at the end of this subsequent journey, either 1 or 2 above occur.

Whilst travelling to the next available location, the train should proceed at a maximum speed of either 40 mph or 60 mph. If passengers are onboard the train, they may either be detrained at the next suitable station or remain onboard whilst the train travels to the next available location in order to complete their journey. Therefore, the total risk during four possible operational responses has been explicitly calculated:

1. The train proceeds with a maximum permitted speed of 40 mph. Passengers may remain onboard the train for the duration of the distance to the next available location whilst they finish their journey.
2. The train proceeds with a maximum permitted speed of 40 mph. Passengers are detrained at the next suitable station and the train then proceeds without passengers to the next available location.
3. The train proceeds with a maximum permitted speed of 60 mph. Passengers may remain onboard the train for the duration of the distance to the next available location whilst they finish their journey.
4. The train proceeds with a maximum permitted speed of 60 mph. Passengers are detrained at the next suitable station and the train then proceeds without passengers to the next available location.

6 RESULTS

The calculated risk values, in units of Fatalities and Weighted Injuries per million trains (FWI/mt), for each of the possible operational responses are given in Figure 4. The risk is calculated for each train from the point of failure (assumed to be halfway through the day), to the end of the day (when the failure is assumed to be fixed). The baseline is the risk from a train running from the middle of the day till the end of the day with no failure. The risk values have been calculated by assuming the train is operating under approximately network average conditions and using the average risk increase from

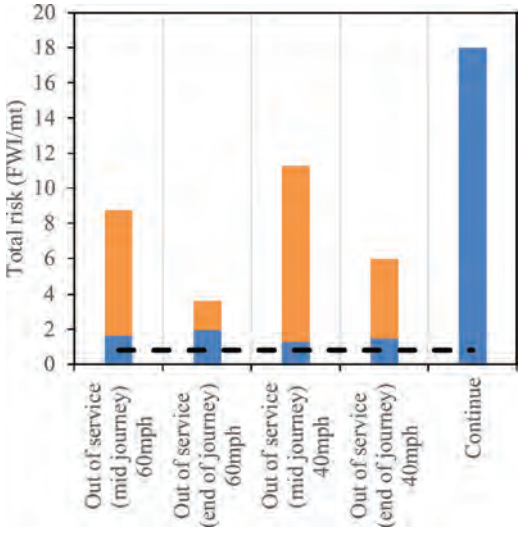

Figure 4. Risk in FWI/mt for different operational responses to an AWS failure. The blue and orange bars represent the immediate and knock-on risks respectively. The black dotted line is the baseline level of risk for a train with AWS working.

the RARA analysis. For comparison, the level of risk if a train continues until the end of the day without AWS is also shown.

As can be seen in Figure 4, for a train operating under network average conditions the operational response which results in the lowest total risk is when:

- The train proceeds to the next available location with a maximum permitted speed of 60 mph.
- Passengers remain onboard the train for the duration of the distance to the next available location whilst they finish their journey.

6.1 *Effect of speed restrictions*

There is only a very small safety benefit in the immediate risk from reducing a train's speed further from 60 mph to 40 mph. The main reason for this is due to the effectiveness of TPWS at stopping a collision. TPWS is designed at signals to automatically apply the brakes if trains are overspeeding on the approach to a signal as well as if they go past the signal at danger. The majority of overspeed sensors for TPWS systems are set so that they only intervene if trains are travelling over speeds in the range 42–46 mph on the approach to a signal at danger. Reducing the train's speed to 40 mph therefore removes most of the protection provided by the overspeed sensor. Whilst the effectiveness of applying the brakes once the train has passed the signal will increase as speed is reduced, the overall effect is that the effectiveness of the TPWS system is very similar at 40 mph and 60 mph. The overall predicted effectiveness of the TPWS system is illustrated in Figure 5 for a train travelling with different speed restrictions on a track with a maximum permitted line speed of 70 mph. Whilst this only applies to signals where TPWS is fitted, since these junction signals represent a large percentage of the overall train collision risk they have a large influence on the overall results.

Reducing a train's speed does, however, cause a large number of extra delay minutes and consequently an increase in the knock-on risk. Reducing the train's speed from 60 mph to 40 mph results in an increase in the knock-on risk from 1.6 FWI/mt to 4.5 FWI/mt for an initial line speed of 70 mph. Since any safety benefit in the immediate risk from reducing the speed is very small, it is outweighed by the approximately three times increase in knock-on risk as delay minutes increase. It is found that for any initial line speed, applying a speed restriction of 60 mph always provides a lower total risk than 40 mph.

6.2 *De-training passengers*

The knock-on risk from de-training passengers immediately and not letting them remain onboard to complete their journey has been calculated to be 5.5 FWI/mt. This risk is mainly due to the risk from extra boarding and alighting at unscheduled stations, where the platform may not be as suitable as a terminal station to accommodate a train full of passengers.

The immediate risk for a train operating without passengers is still significant since an empty train could have a collision with another passenger train. Whilst the knock-on risk from de-training passengers will only depend on the loading of the

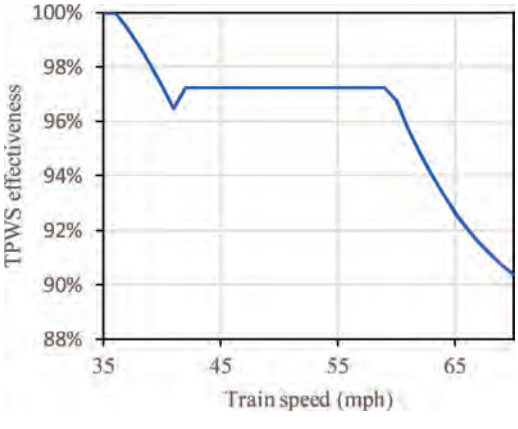

Figure 5. Predicted effectiveness of TPWS at stopping a train collision at a signal for different trains travelling with different maximum speeds on a track with a maximum permitted line speed of 70 mph.

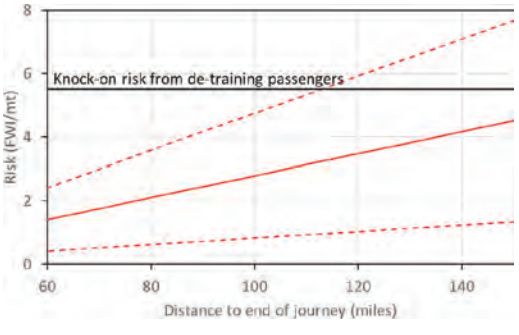

Figure 6. Immediate risk associated with allowing passengers to remain onboard a train to complete their journey or knock-on risk from de-training them, given by the red and black lines respectively. Results are for a train travelling with a speed restriction of 60 mph on a section of track with a line speed of 125 mph. The dotted lines represent the upper and lower bounds of the immediate risk estimate using the two different estimates for the increase in driver error from the RARA analysis.

train when it is cancelled, the immediate risk will depend on the distance passengers would need to remain on the train in order to finish their journey. Figure 6 illustrates how the difference in immediate risk (with and without passengers) increases with journey distance for a train travelling with a speed restriction of 60 mph on a section of track with a line speed of 125 mph.

From Figure 6 it can be seen that, even for a track with a line speed of 125 mph, the additional immediate risk of passengers remaining onboard in order to complete their journey is less than the knock-on risk of de-training them immediately for distances of up to approximately 100 miles. For distances of over 100 miles, the upper bound of the risk estimate starts to outweigh the knock-on risk. Therefore, if the remaining journey distance is longer than 100 miles, passengers should be de-trained before this distance is reached.

7 CONCLUSIONS

Following the risk analysis work, the operational response which was found to provide the lowest total risk during an AWS failure was determined to be:

- The train to proceed to the next available location at 60 mph once the failure has been identified.
- If passengers are onboard, they should be allowed to remain onboard in order to finish their journey whilst the train proceeds to the next available location.
- If the distance to the next available location is greater than 100 miles, the distance passengers remain onboard should be limited to 100 miles. The train should proceed for the remainder of the distance to the next available location without passengers.

Another possible mitigation for AWS failures is to provide a competent person in the driver's cab to monitor the driver and ensure they react correctly to speed restrictions and signal aspects. The risk from operating with a competent person was reviewed separately and all results presented in this paper have assumed no competent person has been provided.

These operational responses represent a change from the current rules whereby the train proceeds at 40 mph and passengers are de-trained at the next suitable station. These rules were previously determined by only considering the immediate risk to the train without AWS and before the national fitment of TPWS was completed. The proposed increase in speed restriction therefore seems reasonable and is consistent with more recently updated rules for other items of defective on-train equipment. The sensitivity of the chosen operational responses to the various assumptions and input parameters in the model has been assessed and the results are found to be robust.

The changes proposed in this work should provide a more effective way of dealing with an AWS failure, considering both the immediate risk to the train operating without AWS and the knock-on risk an operational response has on the rest of the rail network. These changes should therefore provide a benefit both in terms of safety and performance for the GB mainline railway.

Multi-risk and L.U.P.: A methodology to evaluate neglected risks and risk interactions. An Italian case study

E. Pilone & M. Demichela
Politecnico di Torino, Torino, Italy

G. Camuncoli
ARIA s.r.l., Torino, Italy

ABSTRACT: The paper presents a semi-quantitative methodology developed to help Italian local authorities in facing multi-risk aspects in their Land Use Planning practices. The methodology acts as a pre-screening of the risks present on the territory, highlighting the areas more exposed to risk and risk interactions, also taking into account aspects neglected by the sectorial plans. A quick overview of the methodology is provided, together with a significant Italian case study: a small town in Piedmont, for which neither the land use planning related to major risk plants, nor the supra-regional plans for flood preventions were sufficient to obtain a detailed representation of the overall risk. The proposed methodology analyzed the context and evaluated the possible interactions, identifying possible environmental consequences, and then addressed further studies and interventions to the critical situations. A dedicated questionnaire was developed for the plants, to examine in depth the assets more exposed to NaTech risks.

1 INTRODUCTION

Land Use Planning (LUP) procedures improve and program the use of territories, therefore they have to deal with several types of risks, starting with the natural ones deriving by the territory itself (flood, earthquake) and arriving to the risks generated by men (Technological risks, climate change, etc.). Risks are faced through dedicated sectorial plans, that have a hierarchical development and application: i.e. in Italy, they are usually drafted by regional or supra-regional authorities and then applied by the Municipalities. However, the multiplication of tools dealing with risks (City plans, Emergency plans, supra-local plans) can sometimes bring to lose some important information; also, climate change is varying the reliability of the calculations of return times for events influenced by climate. Most of all, currently an integrated plan containing all the risks does not exist, therefore also the possible risk interactions are neglected.

Several projects related to Multi-risks have been developed in recent years, proposing different types of methodologies to deal with the problem of interactions. Besides qualitative approaches, that are mainly adopted at a wider general scale, many projects proposed quantitative analyses aimed at taking into account and harmonize the different probabilities of occurrence of the risks. However, these methodologies can be affected by the lack of data, and are very long, costly and difficult for the final users and stakeholders, that means LUP decision-makers (Menoni et al, 2006; Nadim & Liu, 2013). This is particularly evident for Italy: Municipalities, as final LUP planners, have not the right expertise and financial resources to apply any multi-risk approach, most of all if it is not made mandatory by law. The lack of integration between risk plans and the non-consideration of risk interactions, summed up to the increasing effects of climate changes, already brought to several disasters (i.e., the repeated floods in Geneva, caused by a creek whose dangerousness was well known but not adequately represented in the Municipal emergency plan and City plan, or the Rigopiano hotel tragedy, where an avalanche caused by a earth shake invested an hotel built in an area where constructions should not have been permitted. The dangerousness of this area was correctly identified by an old map produced by Abruzzo region, that

however was not reported in the updating of the local City plan).

In order to help the Municipalities in taking into account their territorial risks in an integrated way, the authors proposed a semi-quantitative methodology for the local scale, acting as a pre-screening instrument to rapidly identify the areas more exposed to risks and their possible interactions. Further studies, resources and planning actions shall be primarily addressed to these areas. A semiquantitative methodology, based on indexes, and intended for a direct use by the Municipality technicians, was developed by the authors; it is briefly summarized in the following Paragraph 2; an in-depth explanation can be found in (Pilone et al, 2017). This paper mainly focuses on the application for an Italian case study, a Municipality in the Piedmont region, where possible interactions between flood and industrial risks were identified.

2 METHODOLOGY FOR RISK INTERACTION

The steps of the proposed methodology were partially inspired by the ERIR, a Plan for the safe LUP around Seveso plants, that in Italy is mandatory for the Municipalities with a Seveso plant inside their territory. While ERIR only considers Industrial risk, the objective of the proposed methodology was the identification of the impact of several territorial risks and of their possible interactions, on the basis of a semi-quantitative rating scale, going from 0 to 3 onwards:

$0 < I \leq 0.99$: Negligible
$1 < I \leq 1.99$: from Low to Moderate
$2 < I \leq 2.99$: from Moderate to High
$I \geq 3$ onwards: from High to very high.

The methodology was explicitly designed for a direct use by the Municipality technicians.

2.1 *Risk characterization*

The most relevant territorial risks have to be described and investigated according to three Macro-categories, that express peculiar aspects of the risk analyzed and determine its impact: 1) *HE Historical and recent events*: recurrence of the risk events analyzed; 2) *PM Protection measures*: protection and preventive measures that could reduce the impact of the risk analyzed; 3) *SE Strengthening effects*: Local characteristics increasing the risk effects. The latter was explicitly introduced to consider risks not only on the basis of their probability of occurrence, but also in relation to all the intrinsic factors, sometimes neglected in the sectorial plans, that could enhance the final risk impact: i.e., for earthquakes, the quality of the soil; for floods, the section reductions and flow obstructions, for Seveso industries, the quantity and type of substances detained and type of items etc.

The macro-categories are rated in accordance to the local variations of the risk, in compliance with the scale above-mentioned. A dedicated guideline was developed to help the Municipality technicians in this procedure; at the moment, the guide is related to the most diffused risks in Italy and in Europe: industrial, flood and seismic risks (Table 1 reports the first two).

2.2 *Risk interaction*

The macro-categories constitute the basis to evaluate possible risk interactions, because they accurately describe each risk and its possible impact. Therefore, when risks overlay, the effects of one risk on another one (binary interaction) can be assessed through an average sum of the ratings assumed by the two risks in the analyzed point of the territory, following Equation 1 below:

$$Interaction = \left[\left(HE_{R1} + HE_{R2} \right) * 2 + \left(SE_{R1} + SE_{R2} \right) * 1 + \left(PM_{R1} + PM_{R2} \right) * 0.5 \right] / 6 \quad (1)$$

Equation 1 also shows the different weights assigned to the Risk macro-categories for the interaction assessment; in fact, they have different reliability in terms of available data and capacity to influence the final interaction value. The weights assigned following these criteria were validated through expert judgement.

2.3 *Risk compatibility and planning phase*

The values obtained for binary interactions and risks have to be superimposed to the territorial and environmental vulnerabilities, whose identification follows the Italian legislation for ERIR (Ministerial Decree 09/05/2001). If the values of the interactions or of the macro-categories overcome the threshold of 2.5 (medium-high impact) in areas where relevant or extreme vulnerable elements are present, a potential incompatibility is identified. The Municipality shall conduct further studies and investigations to verify the situation and adopt opportune planning measures.

An optional step was introduced in this phase of the methodology to help the Municipalities in the assessment of the interactions involving industrial risks: thanks to two modelling software (ALOHA® and HSSM®), the possible spatial extension of the damage areas can be hypothesized and taken into account for the planning phase.

Table 1. Rating guideline—industrial and flood risks.

Category	Rating		
	1 < I ≤ 1.99	2 < I ≤ 2.99	I ≥ 3 onwards
INDUSTRY			
SE	Few items with Na-tech risk; scenarios related to flammable substances, with a reduced area of impact.	Items with NaTech risk; scenarios related to flammable and environmental substances	Huge quantities of hazardous substances. Items with NaTech risk. Toxic scenarios and/or with a great extension.
HE	No relevant or NaTech accidents occurred.	Low impact events (NaTech/ with external repercussions)	High impact events (NaTech/ with external repercussions)
PM	No dedicated measures for NaTech; lack of protective measures towards the environment	Good safety level, partially effective also towards NaTech accidents	Preventive measures adequate for avoiding NaTech risk and domino effects
FLOOD			
SE	Interaction with other rivers/ creeks with low or reduced criticalities; hydraulic devices in good state; no or few critical points	Interaction with and hydraulic control devices with moderate criticalities; critical points; the river/creek/etc. analysed contains key element for the safeguarding of the general safety of the system	Problematic interaction, recognized high critical areas, reported in Flood plans. Hydraulic devices in bad conditions, with recognized criticalities
HE	Rare main flood events, return time of Flood management plans is confirmed (zones classified as C, or Em, Cn—if recent events do not evidence different distributions/timing of the floods)	Floods of moderate impact, and/or in areas not included in Plans, with a short return time (≥50 years) (zones classified as B, or Eb, Cp—if recent events do not evidence different distributions/timing of the floods)	Events with return time > than that of the Flood management plan worst zone. (zones classified as A, or Ee, Ca—if recent events do not evidence different distributions/timing of the floods)
PM	No water regulation artefacts/ systems or insufficient number/way. Criticalities and inadequate safety level	Water network/river/creek is properly controlled, the artefacts do not show relevant criticalities	The management of the water network/river/creek is well coordinated, evidencing no criticalities

3 CASE STUDY

The application of the proposed methodology is showed through an Italian case study: a little Municipality near Turin with 16000 citizens, interested by flood and industrial risks provoked by "minor sources", which are not adequately considered in the sectorial planning.

The town raises on a flat land crossed by several artificial channels, derived from Stura river and used in the past for irrigation purposes. Urbanization and industrialization completely altered the functioning of the water network: many channels were deviated, interrupted or undergrounded, and their maintenance completely ceased, while the waterproof surface dramatically increased. Besides this minor water network, the northern portion of the municipal territory is crossed by a creek, connoted by several reduced sections of the water flow and banks with low height.

Banna-Bendola and the water network produced extensive floods in 1994, 2000 and 2008; the water height reached 80–100 cm. The flooded areas were mapped in detail by (Regione Piemonte, 1998) and (Provincia di Torino, 2009), but the new PGRA Piano Gestione del Rischio Alluvioni—Plan for Flood management (AD.B.Po, 2016), only reported the potential flooding areas of the creek. The dangerousness of the secondary water network and its combined effects with the creek in case of intense rainy events were not analyzed and neither mapped. At the same time, the return times assigned to the creek buffer-zones were not so in line with the recurrence of the recent events, as demonstrated also by (Politecnico di Torino, 2009).

The industrial risk of the Municipality analyzed is ascribed to a single Seveso plant, a former plating factory named 'X' for this paper, that was closed in 2010 for breach of obligations related to the

AIA—Integrated Environmental Authorization. Since it was never ascertained if the underground platin basins had been emptied in a safe way, the Municipality had to prepare ERIR plan. ERIR plan was drafted in compliance with (Regione Piemonte, 2010) and (Provincia di Torino, 2010) that require to include in the analysis the so-called Seveso Sub-threshold plants (detaining the 20% of the hazardous substances necessaries to be classified as Under-tier Seveso plant) and all the potential hazardous activities. Thanks to this request, not applied in other Italian regions, two potential Seveso plants (named 'Y' and 'Z'), not signalled by the Authorities in charge, were identified. Probably, since ERIR was drafted immediately after the approval of Legislative Decree 105/2015 (Italian implementation of Seveso III Directive), these plants had not adequately checked the new classification of hazardous substances imposed by the decree. The hazardous plants identified are majorly located close to the water network; they were repeatedly interested by flooding, even if there are no testimonies on the consequences of these events (see Figure 1 in the following page).

Since the current sectorial plans neglect some sources of risk (i.e. the secondary water network) and do not allow to consider the danger deriving from the interaction Flood/Industry in an integrated way, the methodology was applied to assess possible unforeseen consequences of the compresence of the risks on the Municipal territory.

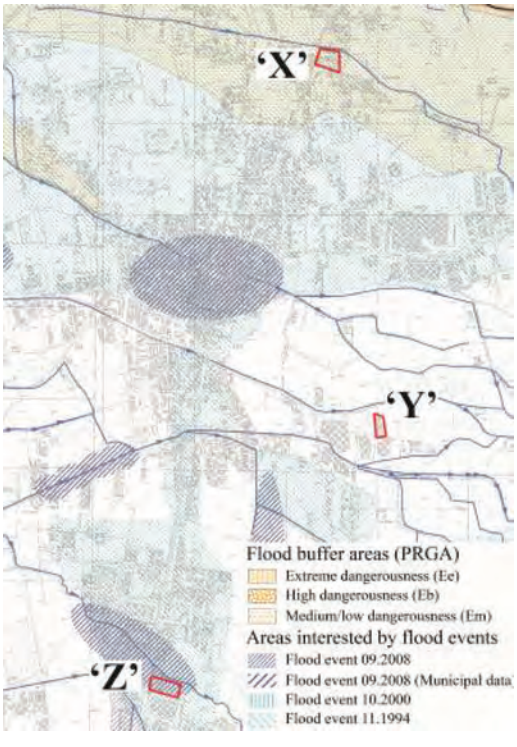

Figure 1. Plants and areas interested by flood risk (Provincia di Torino, 2009).

3.1 *Risk characterization*

FLOOD: In order to proceed with the rating assignment for flood risk macro-categories, rivers and creeks have to be divided in portions connoted by homogenous characteristics and behavior. For the creek, a unique portion was identified in the Municipal territory, because according to (Politecnico di Torino, 2009), this is a unique sub-basin, uniformly connoted by very small slopes of both riversides and river course. The secondary water network was also considered as a unique element, given the complexity of the interactions and interdependencies between the canals, and also because all the main canals equally produced overflowing during the past events.

Table 2 shows the rating attributed to the macro-categories of these two hydraulic elements, responsible of the municipal flood risk. As showed in Table 1, as far as it concerns *HE* ratings, the areas with higher probability of flood obtain a higher rating. However, the return times of the flood events that interested the municipal area in the last 20 years were higher than those defined by PGRA, in particular for areas interested by medium-low flood hazard. The necessity to re-assess the buffer zones for the creek because of this mismatch was recognized also by (A.D.B.Po, 2016). As a consequence, *HE* rating of the areas with medium-low flood hazard (Em) was raised to 2, instead of 1 (see Table 2, fourth column of 'Creek').

For the secondary network, no flood return times were available, but since the network participated in all the major flood events of the last 20 years, being responsible in 2008 of a proper breakdown (Politecnico di Torino, 2009), a *HE* value equal to 2 was assigned.

SE ratings considered all the possible criticalities encountered both for the creek and the water network, while unfortunately *PM* ratings reflect the total absence of protection measures, in spite of the interventions proposed by (Provincia di Torino, 2009).

INDUSTRY: The ratings for the plants 'X,' 'Y' and 'Z' were assigned on the basis of the following information: for the first plant, officially recognized as Seveso → Emergency plan (Prefettura di Torino, 2007), Environmental Authorization—AIA (Provincia di Torino, 2007) and Notification of the plant, that were the last documents drafted before the closure; for the other plants → questionnaires compiled by the owners during ERIR draft.

Table 2. Flood risk—rating assignation.

SE		PM	HE
Interaction with other elements	Criticalities of the artefacts, sections	Hydraulic artefacts, levees etc.	Recurrence
Creek			
Possibilities of inverted flow from the creek to the tributaries or upstream	5 critical sections producing hydric insufficiencies were identified in correspondence of bridges	2 areas for flood expansion and a stone riverbank were planned; only the last was realized, after the flood in 2000.	2 zones: Extreme flood hazard Ee (20–50 yrs), Medium-low flood hazard Em (300–500 yrs). Floods in Em more frequent than the assigned Return time, water height 1 m.
3		**0**	**Ee 3 Em2**
Secondary water network			
Water intakes from Stura cannot be regulated; The creek can feed the channels network during flood events	Reduced slope of soil and canals, scarce maintenance, obstructions, riverbeds not defined, inadequate crossing artefacts; covered portions, diversions. Raised roads block the natural flow	5 floodway channels were planned to return the exceeding flows to Stura, but no interventions were executed.	No flood buffer zones and return times assigned, except for a little portion in an agricultural area (Em). Recurrent overflowing in 1994, 2000 e 2008, water heights between 30–80 cm in the city centre, other areas.
3		**0**	**2**

However, essential information related to case history, storage conditions and preventive and protection measures were missing for all the plants.

Table 3 shows the rating assignation to the macro-categories of each industrial plant: for the macro-categories *SE* and *PM*, Google maps and Google street view allowed to partially integrate the missing data on items exposed to NaTech risk, waterproof aprons, etc., but no alternative sources of information were available for *HE*. Therefore, a common indicative value of 1.5, corresponding to a low-medium impact, was assigned if the plant had been involved by past flood events. A negligible *HE* value, equal to 0.5, was given to the plants not hit by flood events located in proximity of canals, to take into account the possibility overflowing water. The ratings assigned to the macro-category *PM* were maintained generally low because of cautionary reasons.

3.2 *Risk interaction*

The industrial and flood characterizations made clear that the analyzed Municipality is not interested by extremely high risks, due to huge plants or important rivers; the risks are generated by little lower-tier Seveso plants and low energy flood events. However, the interaction of plants, mostly detaining toxic and environmental hazardous substances, with the recurrent overflowing events, could produce unexpected and severe conditions for people and environment, because of the lack of adequate protection and prevention measures. In order to verify possible consequences, Equation 1 was applied to each area where flood areas and plants overlay, through dedicate Binary Interactions tables (Tables 4, 5 and 6). They report the ratings attributed to the risks in a specific point of the territory (in this case, in the areas of plants 'X', 'Y' and 'Z') and allow to repeatedly apply Equation 1.

The possible interaction was verified also for plant 'Y', even if it was never interested by flood, because of a cautionary reason: in fact, it is adjacent to canals whose slope, maintenance and riverbed conditions are not different from those of the other canals. Indicative low values were attributed to Flood risk in this area: SE = 1, HE = 0, PM = 0.

3.3 *Compatibility assessment*

The vulnerable elements were investigated according to the requests of national and regional legislation. For the territorial vulnerability, related to urban density and people density, the majority of the residential areas was included in the classes C and D of Ministerial Decree 09/05/2001 (building ratio index $\leq 1.5\ m^3/m^2$). Some punctual

buildings were categorized as A (mostly schools) and B (discotheque, bowling center), because of their high frequentation. In relation to Environmental vulnerability, no elements with Extreme vulnerability were encountered, but Relevant vulnerable elements typical of flat land areas were present: 1) depth of the aquifer between 0 and 3 meters; 2) Land use capacity of soil between 1 and 2. These features made the Municipal territory very vulnerable towards possible pollution events.

The compatibility assessment was verified in the areas of risk interactions (flood → industry), corresponding to the zones of plants 'X', 'Y' and 'Z': a buffer zone of 500 m. was drafted around each

plant, projecting here the values of the Industrial macro-categories and of F/I interaction.

The condition of compatibility can be considered satisfied if no A and B vulnerable elements are included in buffer zones where H.E., S.E. or Interaction values are higher than 2.5, a threshold corresponding to a medium-high impact.

Figure 2 shows an example of Territorial compatibility analysis for the plant 'X': inside the buffer zone, residential areas classified as C and D, and E areas (building ratio index I ≤ 0.5 m^3/m^2) are identified.

Figure 2. Plant 'X' buffer zone with territorial vulnerable elements.

The threshold of 2.5 is adopted for the environmental vulnerability too, but the specific relation between the threats and the environmental vulnerable element has to be investigated (not all the elements are equally sensitive to risks). The environmental vulnerable elements identified for the case study were sensitive both to Industrial risk and its combined effects with flood.

The assessment of the territorial and environmental compatibility for each plant is reported in Tables 7, 8, 9.

3.4 *Results and planning steps*

The application of the methodology to the case study demonstrated that the simultaneous presence of Industrial and Flood risk can produce unexpected interactions, connoted by low-medium impacts (plant 'X' area = 2.17, plant 'Z' area = 1.98), which are reasonably in line with the verified low energy of the flood events in the areas (water height between 30–80 cm).

The Interaction values do not overcome the alert threshold of 2.5, however the plants analyzed are subjected to potential incompatibility related to their Industrial macro-category SE, whose values are high because of particular conditions (abandon of plant 'X', not compliance with Seveso regulation of plants 'Y' and 'Z'). HE received low ratings only as a consequence of the unavailability of data.

The overcoming of the 2.5 threshold signals to the Municipality that further investigations are needed, in order to: 1) confirm or not the

Table 7. Compatibility—Plant 'X'.

Territorial vulnerabilities inside 500 m.	*Environmental vulnerabilities inside 500 m.*
1) C and D Residential areas. 3 productive areas (E) destined to future commercial function. Two are interested by Flood HE = 3; *2)* Few C punctual elements are included; *3)* No linear elements and strategic areas/building/ infrastructures	Land use soil capacity 1st and 2nd classes; Water table depth <3 m; historical urban areas. Canal for irrigation adjacent to the northern border of the plant, probably used in the past to drain the rainy water. Presence of a well inside the plant.
Territorial compatibility	*Environmental compatibility*
HE and SE ratings for Flood and Industrial risks ≥ 2.5 threshold; no manifest incompatibility because of low people density. However, the state of abandon of the plant represents a potential threat for the territorial elements, particularly in case of flood events (medium value of interaction). Further analysis should be carried out, in particular to verify the state and filling of the containment basins. Areas addressed to future transformations: considering the High Flood risk level, avoiding high density of people and adopting specific constructive parameters.	A potential incompatibility is detected: Industrial SE and HE ratings ≥ 2.5 threshold, in an area where the environmental elements are particularly sensitive to pollution. The interaction value is medium: flood events, even with their low energy, could cause unexpected consequences of spreading and diffusion of pollutants towards the underground water and superficial water. No prevention and protective measures for the environment have never been adopted. An onsite visit is recommended to verify the actual conditions of the plant, and to organize a recovery procedure.

Table 8. Compatibility—Plant 'Y'.

Territorial vulnerabilities inside 500 m.	*Environmental vulnerabilities inside 500 m.*
1) E productive areas; *2)* No A and B punctual elements; *3)* No linear elements and strategic areas/buildings/ infrastructures	Water table depth <3 m; land use soil capacity 1st and 2nd classes (agricultural areas around the plant); two canals for irrigation are close to the plant
Territorial compatibility	*Environmental compatibility*
No incompatibilities were encountered with respect to the territorial vulnerabilities.	Potential incompatibility (SE ≥ threshold) in a highly sensitive area. The plant declared adequate Protection measures, however, since it is not in line with the Seveso regulation, at least an in-depth analysis on the storage methods, and protection and preventive measures should be carry out.

Table 9. Compatibility—Plant 'Z'.

Territorial vulnerabilities inside 500 m.	*Environmental vulnerabilities inside 500 m.*
1) C residential areas + 2 E productive areas for future commercial function; *2)* 2 punctual elements in B (commercial centre, bowling; church); *3)* Energetic lines	Water table depth <3 m; presence of a canal for irrigation adjacent to the northern of the plant
Territorial compatibility	*Environmental compatibility*
Potential incompatibility: threshold for SE > 2.5 with two punctual elements classified as B. An in-depth analysis is recommended for: 1) specific activities of the 2 vulnerable elements; 2) the storage methods and protection and preventive measures of the substances classified as toxic (H2)	Potential incompatibility: SE = 2.8 overcomes the compatibility threshold; the interaction with flood events, even if connoted by a low-medium value (1.98), could enhance the threat. Further analysis on the possible pollution scenarios and prevention and protective measures against flood should be carried out.

incompatibility; 2) plan possible LUP actions, taking into account the actual conditions of the plants and their possible interactions. However, collecting further information on the plants could be a difficult task: Sub-threshold plants and abandoned plants indeed represent a potential threat for population and environment, but they have no legal obligation to provide information about substances detained, or possible external risks deriving from their activities. This lack of obligation and monitoring could in some cases enhance the level of risk in comparison to a Seveso plant.

In order to verify the actual hazardousness of the plants, and establish their compatibility, it is essential to know at least the type of storage, the prevention and protection measures adopted and the case history. For this reason, a detailed questionnaire, reported in Table 10, was proposed by the authors; the portion related to the environmental

Table 10. Questionnaire for in-depth investigation of plants.

A. STORAGE CONDITIONS & NA-TECH ITEMS
1) With reference to the hazardous substances detained, please indicate in detail the storage conditions of each hazardous substance, describing type, capacity, quantity and containment measures adopted:
Hazardous substance:
Stored in (container type):
Number of containers and/or total capacity:
Single Container Capacity:
Position (Inside, outside, outside under coverage, underground, etc.):
Containment measure adopted for the container (basin, waterproof ground etc.):
2) Please report if the following items are present:
Underground pipelines, pipelines passing on not-waterproofed soil *Description (length, width, substance transported, protection measure):*
Long and slim structures (torches, chimneys, cooling and distillation towers etc.) *Description of the structure and its function*:
Open-air water treatment basin/liquid waste storage. *Description of the installation and related preventive measures*
B. CASE HISTORY
3) Please report a list of the accidents occurred in the last 20 years that have provoked release of hazardous materials
Date Item interested Accident description
4) Please signal eventual damages provoked by: flood events, extreme climate events, earthquake.
Date Item interested Accident description
C. ENVIRONMENTAL ANALYSIS[1]
5) For the environmental protection, the owner shall demonstrate to have adopted the protective and preventive measures recommended by Turin Province Guidelines;
OR
5) Proceed with a vulnerability analysis of the conditions of water and soil around their plants:
➢ Depth and the direction of the phreatic aquifer nearby the plant, in a sector with 30° degrees of amplitude and 3 kilometres of extension, measured from the possible point of release in the direction of the aquifer flow;
➢ Presence of wells inside the same sector, within an extension of 500 metres
➢ Presence of drains in superficial creeks or canals.

analysis is extracted from Provincia di Torino Seveso guidelines (Provincia di Torino, 2010).

1. Turin Province guidelines; If the three conditions reported are all verified, the owner shall adopt all the measures of points 1, 2, 3 (although the Municipality could in some cases relieve the owner of the application of point 3).

4 CONCLUSIONS

The application of the proposed methodology to the case study quickly identified the areas more exposed to risk, returning feasible results in terms of possible risk interaction impact, in line with the initial risk values. The risk pre-screening allows to take into account in an integrate way the risks information contained in the various sectorial plans, and at the same time, the Municipality technicians can employ their direct and enriched knowledge of the Municipal territory. Therefore, the methodology can create an increased awareness about risks and a correct risk and LUP management.

Many possible developments and further steps could be carried out: the proposed framework, till now elaborated for 3 risks (Industrial, Flood and seismic), can be extended to more territorial threats and the methodology could be exported to other countries simply adapting the criteria for rating assignation. The authors are currently working on the development of participative practices to facilitate the approach of the technicians to the methodology, and some contacts are in course with Municipalities to directly experiment the proposed approach.

Emergency assessment in case of hazardous substance leakage at Czech Republic freight rail transport in 2008–2016

Š. Hošková-Mayerová
Department of Mathematics and Physics, Faculty of Military Technology, University of Defence, Czech Republic

ABSTRACT: Emergency occurrence during the freight rail transport does not necessarily have to be and frequently is not affected by the type of the material transported; however, in case that such an emergency occurs, the category of the substance transported may indicate an increased risk; in particular, the risk of explosions, fire, and significant threat to property and people. Leakage of any substance, in particular a hazardous substance, represents a significant part of all emergency cases at rail transport. Despite the seemingly decreasing number of these risky threats, every single incident has to be investigated and analysed. After examining every case in question, it was found out that the leaked substance was not classified hazardous because it was either plain water or frequently leaking operating fluids. Nevertheless, every leakage has to be thoroughly investigated because it is not clear beforehand what category the substance belongs to. Our aim was to identify crucial factors resulting in emergency cases occurrence on the railway in the Czech Republic through a detailed examination of past incidents. Most of these factors are the same for railway transport in general; however, there may be particular local specificities and organizational faults in individual transport units. Another goal of research consisted in revealing these specifics.

1 INTRODUCTION

Emergency occurrence during the freight rail transport does not necessarily have to be and frequently is not affected by the type of the material transported; however, in case that such an emergency occurs, the category of the substance transported may indicate an increased risk; in particular, the risk of explosions, fire, and significant threat to property and people.

Leakage of any substance, in particular a hazardous substance, represents a significant part of all emergency cases at rail transport. Despite the seemingly decreasing number of these risky threats, every single incident has to be investigated and analysed. After examining every case in question, it was found out that the leaked substance was not classified hazardous because it was either plain water or frequently leaking operating fluids. Nevertheless, every leakage has to be thoroughly investigated because it is not clear beforehand what category the substance belongs to. Správa železniční dopravní cesty (Management of Railway Network Company) provided us the access to its database, which was thoroughly studied, and data from the 9-year period (2008–2016) could be selected and processed. Unfortunately, a longer data period was not available for further use and processing due to the different data archiving method. In 2008–2016, 597 leakages were recorded in the Czech Republic. In accordance with the Regulations for international rail transport RID, dangerous substances are classified into categories depending on their hazard class. The most hazardous substance leakage according to this categorization was in the hazard class 3 – flammable liquids, class 8 – corrosive substances, and class 2 – gasses.

Our aim was to identify crucial factors resulting in emergency cases occurrence on the railway in the Czech Republic through a detailed examination of past incidents. Most of these factors are the same for railway transport in general; however, there may be particular local specificities and organizational faults in individual transport units. Another goal of research consisted in revealing these specifics.

Using the statistical processing of available data, a model of accidents distribution based on the leakage location has been developed (Hasilova, et al. 2017b). The research also identified the operating units with the highest number of emergency cases, the risk of emergency occurrence and the development trend. The unambiguous research objective was to contribute to increasing the safety of hazardous substances transport by rail. All the data obtained were passed to the transportation company for further assessment and incorporation into internal safety regulations.

Presence of hazardous substances in rail transport poses a higher risk effect on the individuals, critical infrastructure an environment.

The most frequent factors affecting the emergency cases occurrence on the railway are as follows:

1. *Technical condition:* state of the track, state of safety devices, state of a notification device, state of the crossing security equipment, state of railway rolling stock, conditions for equipment used for the railway infrastructure maintenance. Technical state is frequently affected by vandalism: equipment and various devices are often damaged, destroyed or stolen. Therefore, frequent monitoring of all equipment connected to the transmission system is necessary.
2. *Human factor:* Poor competence, fatigue, negligence, failed thinking, inattention, scattered attention, non-observance of working/technological procedures.
3. *Climate conditions*: snow, rain, fog, floods, calamities.

In recent years, many incidents and accidents have occurred on the railways. The impact of these accidents could have been much worse if hazardous substances were involved. Therefore, the issue covering transport of hazardous substances on the railways is still urgent and critical. Our effort is aimed at reducing and eliminating consequences of possible accidents to minimum. In order to prevent emergency cases and reduce negative effects, it is necessary to examine thoroughly both causes and consequences of all accidents which had occurred; in addition, knowledge of current situation in terms of hazardous substances transport has to be available as well. The scope of consequences of a possible accident is related both to the type of material transported and the extent of residential zones which are close the site of the accident. Selecting an appropriate route as well as the right time is one of crucial safety factors. Quality analysis of the current state and the identification of the busiest corridors and stations, determination of the level of safety at work in particular operating units and understanding the overall transport context will be of great help in the subsequent proposing measures in terms of ensuring the maximum transport safety.

The developed analysis specifies in the first phase the most loaded corridor sections (operating units); in the second phase, there are specified their risky segments, potential sources of threat at typical activities, and predicted the occurrence frequency of emergency cases.

The Czech Republic belongs to the countries with the densest railroad network used for both domestic and international transport. The chemical industry in the Czech Republic is the third largest industrial sector with basic chemistry, petroleum processing (petro-chemistry), pharmaceutical industry (drug production), rubber industry, industry producing plastics and paper producing industry. Production of basic chemicals (64% of total sales) and drug production (17%) are dominating. Other five sectors are represented in lower quantities: production of specific chemical products and fibres (9%), cleaning and cosmetic agents (5%), production of coating material and paints (4%), production of pesticides and agrochemicals (1%) (Jenerálová, 2011).

The company ČD Cargo, a.s. is dominating in freight transport by rail and a substantial part of transport is made up of transport of hazardous substances.

Table 1 shows the most important producers of chemicals in the Czech Republic that use the company ČD Cargo, a.s. for transporting commodities. There is also listed the number of carriages with hazardous substances, which had been transported by the company ČD Cargo, a.s. within the Czech Republic territory.

The presented data are analyzed for a 3-year period (2014–2016) according to data provided by the ČD Cargo, a.s. database. There are considered data covering only the transport within the Czech Republic territory. The assessment of transported hazardous substances comprises the total of 141,229 railway carriages for a monitored period. The authors also prepared an overview of all companies using the service of the company ČD Cargo, a.s. considering both individual hazard classes and number of railway carriages transported. However, the table is too extensive and cannot be presented here. Therefore, a map had been created to visualize a current situation: there are shown 4 transit corridors that are used by the

company ČD Cargo, a.s., which transports hazardous substances produced by the most significant companies. The map also shows the sites where hazardous substances are loaded depending on the operating units (main stations).

In 2009–2016, the system of data storage changed: some transport units were excluded (Nymburk, Olomouc and Plzeň), and the available data do not show where they were subsequently included. Therefore, the analysis has to be divided into two time periods.

In the first period, the highest number of emergency cases at transport of hazardous substances belongs to Ústí nad Labem and Praha. In the second period, it is Praha again, Ostrava takes the second position. The main reason of high number of emergency cases consists in the highest density of shipment in these regions; in terms of transport, the operating unit Praha is the busiest. The operating unit Praha also comprises the former operating unit Nymburk and operating unit Plzeň. In 3 years (2014–2016), this operating unit dispatched 142,079 railway carriages with hazardous substances, i.e., approx. 130 carriages a day. At this station, hazardous substances of hazard class 3 prevail, i.e. flammable liquids. The analysis was complicated by the fact that the company ČD Cargo, a.s. does not file all defects; therefore, it was necessary to get additional data (incompatible with the original ones) from the Management of Railway Network Company (hereinafter referred to as SŽDC-MRNC). Having carried out a detailed analysis of these data as well as manual comparison of the individual RID for 2006–2016 periods (inland shipment of hazardous substances), the following data were obtained. Due to the amount of information presented in the Table 2, the table is processed using years and figures. Explanation of particular figures is provided below the table (Table 2).

Table 2. Number of defects at shipment of hazardous substances reported by the company ČD Cargo, a.s.

Type of defect	2006	2007	2008	2009	2010	2011

Explanatory notes in terms of recorded defects:

1. A column not marked with a cross,
2. Incorrect or missing entry necessary for RID transport,
3. Incorrect entry "EMPTY TANK", "LAST LADING" or alternatively "EMPTY, UNCLEANED", or "RESIDUES, LAST CONTENT",
4. Leakage of the transported agent—tanks are not sealed properly, leakage through some device/valve/fittings,
5. Faults without hazardous substance leakage—improperly set boards with labels, missing blind flanges, screws,
6. Relevant specification for transport and inscription of the stored goods are inconsistent (gasses of class 2 are in tanks),
7. Overfilling of the transport unit

2 EMERGENCY CASES DUE TO HAZARDOUS SUBSTANCE LEAKAGE

Leakages of hazardous substance at transport by rail represent a significant share of all emergency cases. The following tables illustrate the leakages of hazardous substances that occurred at the operation of the company ČD Cargo, a.s. in the Czech Republic. SŽDC-MRNC made us possible

to access the database; after detailed examination, the data were processed to get the following results. (Bekesiene, et al., 2016).

In a 9-year period 2008–2016, 597 leakages of hazardous substances occurred at transport by rail in the Czech Republic. There are recorded all emergency cases where various amounts of hazardous substances leaked. In compliance with the Regulations for international rail transport RID, the highest number of hazardous substances leakage occurred in hazard class 2 i.e., flammable liquids. Considerable number of leakages also occurred in class 8, i.e. corrosive substances, and in class 2, i.e. gases. Table 3 presents the number of leakages of hazardous substances according to hazard class that occurred within the Czech Republic territory. (Becherová & Hošková-Mayerová, 2017).

From the presented table becomes evident that the highest number of leakages in the Czech Republic occurred at the operation of the company ČD Cargo, a.s.; they belong to class 3 in compliance with RID, i.e., flammable liquids. The aim of the analysis consisted in the emergency cases distribution, particularly leakages, within the Czech Republic territory.

The following Table 4 is focused on the number of accidents at transport of hazardous substances in compliance with a specific UN code. Data presented cover a 9-year period 2008–2016. Presented data come from the database provided by SŽDC-MRNC.

From Table 4 and supplement N becomes evident that the most frequently leaked hazardous substances in a 9-year 2008–2016 periods are the following agents:

- class 2 – carbon dioxide (UN 1013) and propane butane (UN 1965);

Table 3. Number of leakages at transport of hazardous substances in 2008–2016 periods.

Year	Number of leakages in compliance with relevant hazard class								Total
	2	3	4.1	4.2	5.1	6.1	8	9

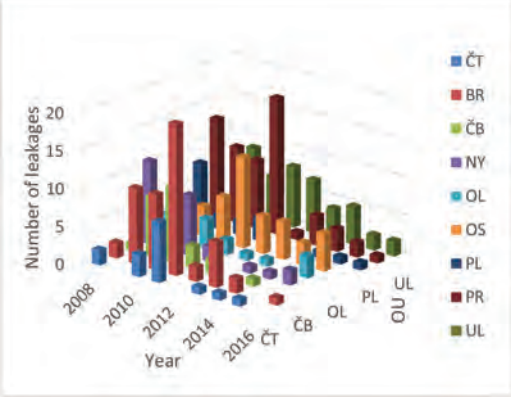

Figure 2. Accident distribution—leakage of hazardous substances according to operating units. Source: processed by the author.

- class 3 – diesel (UN 1202); class 8 – sodium hydroxide (UN 1824) and hydrochloric acid (UN 1789);
- class 9 – liquid tar (UN 3257).

From the Table 5 and graph illustration becomes evident that the accident distribution depends on the site of the leakage. This graph results totally from the operating units, i.e., the number of emergency cases occurred both in Praha, Ústí nad Labem and Ostrava.

3 DISCUSSION AND CONCLUSION

The analytical part examines in detail main factors affecting the railway traffic fluency and the emergency cases occurrence at shipment of hazardous substances. Having applied detailed identification and risky segment exploration involved in shipment, potential sources of threat for typical activities were identified; therefore, the most loaded operating units could have been selected (Hošková-Mayerová et al., 2017, Kass, 1980).

Having solved the specified area of interest, a crucial factor consisted in exploring the cargo company ČD Cargo, a.s. in terms how the company operates, which companies it cooperates with, what goods and in what volumes are cargoes transported, etc. The developed analyses showed what hazardous substances are transported within the Czech Republic territory most frequently, which operating units are the busiest, how many railway carriages and how many tons of particular substances were transported, what the accident rate is during the transport itself (Hošková-Mayerová, 2016, Vališ et al., 2017).

In 2009–2016 periods, 2,384 emergency cases occurred on the Czech Republic railways at the operation of the company ČD Cargo, a.s. In a 3-year period (2014–2016), 3,809,266.262 tons of hazardous substances were shipped; most of them belonged to hazard class 3, i.e., flammable liquids. In the monitored periods 2014–2016, 12,114 loadings of hazardous substances were carried out. The analysis showed that the highest number of loadings was in the operating unit Ústí nad Labem. In terms of number of railway carriages, 142,079 carriages were loaded with hazardous substances in that period: most of them were from the operating unit Praha. Number of reported defects and failures at hazardous substances shipment within the company ČD Cargo, a.s. was monitored as well. In a 11-year period (2006–2016), 2,514 defects and failures were reported; most of them belonged to the category: 'Incorrect or missing record required by RID transport'. In terms of hazardous substance leakages, 696 more or less significant leakages occurred in 2008–2016 periods. The analysis showed that the highest number of leakages occurred in class 3 (in compliance with RID), i.e., flammable liquids at the company ČD Cargo, a.s. operation within the Czech Republic territory (Procházková, 2016, Procházková & Procházka, 2016).

4 SUGGESTED SYSTEMIC MEASURES TO IMPROVE THE PREDICTING EMERGENCY CASES, THEREBY INCREASING RAILWAY SAFETY

Due to the employee fluctuation, the database with data record is not unambiguous. The categorization of emergency cases changed every year; therefore, the data processing was very complicated. In particular, it is essential to

- have data available in uniform and specified form,
- obtain the data in the same way,
- categorize them using the same method which is not modified.

These systemic measures lead to accurate and practical data handling, therefore to more accurate analysis of a possible emergency causes and thereby increasing the safety of persons and property (Hasilová, 2017a, b).

In case that both data categorization and record face the inevitable change, the employees have to be retrained in a particular type of categorization (Woch, 2015, 2017).

The practical benefits are a thorough review of emergency cases in which hazardous substances were present. The paper provides the assessment of hazardous substances transported within the Czech Republic territory in 2008–2016 periods. The phenomenon of exact time information identifying where a particular hazardous substance is present, might contribute to increase the population safety resident close the operating unit area. Close proximity of particular hazardous substance found close residential zones might result in serious consequences; therefore, the introduction of accurate records of particular substances transported by rail would encourage preventing such situations and eliminating possible consequences of emergency cases. (Málek, et al., 2017, Otřísal, et al., 2017, Rosicka, 2006).

The interlink between the information system of the company ČD Cargo, a.s. and SŽDC-MRNC, and between the company ČD Cargo, a.s. and the Integrated rescue system would result in fast notification of employees and further to immediate warning of the population.

ACKNOWLEDGEMENT

The work presented in this paper was supported within the projects "Development of basic and applied research developed in the long term by

the departments of theoretical and applied bases FMT" (Project code DZRO 217) and "Development of the methods for increasing mobility of military vehicles" (Project code: MOBAUT) by the Ministry of Defence the Czech Republic.

The work presented in this paper was also supported by MŠMT ČR, research project no. *SV17-FVL_K106-BEN*: Identification and security of places with high population movement.

A study on the influence of uncertainties in physical security risk analysis

D. Lichte & K.-D. Wolf
Institute for Security Systems, University of Wuppertal, Velbert, Germany

ABSTRACT: In security risk analysis and assessment, uncertainties regarding occurring threats, consequences and the capabilities of security systems to mitigate vulnerability are enormous. Although some quantitative approaches exist in security risk analysis that allow the consideration of these uncertainties, most practical assessments are based on expert knowledge in semi-quantitative or qualitative models. This paper presents a study on the influence of uncertainties in physical security risk analysis using the example of a semi-quantitative risk assessment of a notional production infrastructure. Therefore, a procedure is suggested as a systematic approach to transfer differing expert ratings into a pdf-based description for a quantitative approach. The influences of uncertainties on the exemplary assessment are calculated and discussed regarding the validity of the results. To visualize these results and to support the decision-making process, a three-dimensional risk matrix is proposed.

1 INTRODUCTION

In security risk analysis and assessment, uncertainties regarding occurring threats, consequences and the capabilities of security systems to mitigate vulnerability are high. Although some quantitative approaches exist in security risk analysis that allow the consideration of these uncertainties, most practical assessments are based on expert knowledge in semi-quantitative or qualitative models.

As uncertainties are hardly or not completely considered, these models do not allow an estimation of their influence on the validity of a conducted assessment. Additionally, the influence of occurring events with a very low probability of occurrence and disastrous consequences, e.g. black swan events, are possibly not considered in these models, as they are very uncertain.

This paper investigates the influence of uncertainties on physical security risk analysis for the example of a semi-quantitative risk assessment of a notional production infrastructure.

To demonstrate the described lack of consideration of uncertainties, the state of the art regarding security risk assessment and vulnerability assessment is outlined. Existing approaches are briefly introduced and the occurring difficulties regarding the use of expert knowledge are described.

For analysis purposes a simple semi-quantitative model for security risk assessment is set up and a transition to a quantitative approach based on (Lichte & Wolf 2017) is introduced. This approach uses probability density functions (pdfs) to describe the abilities of security measures as well as the probability of occurrence of a threat and also the level of possible consequences. The variance of the security measure-related pdfs can be interpreted as the uncertainty concerning the capabilities of the considered measures that are part of the security system. At the same time, differing ratings by experts reflect a rising level of uncertainty that consequently lead to a higher level of variance of the generated pdfs.

Besides the intended purpose of the analysis, the transition is developed to suggest a systematic approach to transfer differing expert ratings to the pdf-based description for the quantitative appSroach. Subsequently, the influences of the resulting uncertainties on the exemplary assessment are calculated and discussed regarding the validity of the results. To visualize these results and to support the decision-making process, a three dimensional risk matrix is proposed. Finally, the study is summarized and discussed in the general context of security risk assessment and the consideration of uncertainties.

2 STATE OF THE ART

2.1 *Security risk analysis*

Security risk analysis is conducted by experts from different fields of expertise, as security is a holistic term (Harnser Group 2010). The protection of infrastructures against intentional physical attacks is covered by the subdomain of physical security

(Beyerer et al. 2010). In detail, the protection of infrastructures is implemented by security measures intended to prevent attackers from reaching their targets or assumed infrastructure assets. The measures include different means of protection, detection and intervention and additionally resilient structures to mitigate the consequences of successful attacks (Garcia 2008).

A possible definition of security risk is formulated as a function of the triplet threat, vulnerability and consequence (Contini et al. 2012, McGill et al. 2007):

$$\text{Risk} = \text{Threat} \times \text{Vulnerability} \times \text{Consequence}$$

This definition is the common basis for mostly all semi-quantitative methods for risk assessment that are used in the field. Recently, this classic definition was discussed e.g. in (Amundrud et al. 2017), regarding its lack to consider uncertainties inherent to its parameters. If the above introduced formulation for security risk is considered as a multiplication of quantitative values, it is apparently only valid for stochastically independent discrete probabilities. Usually, these preconditions are not given, as at least threat and vulnerability are fraught with uncertainty. It may even be discussed whether the description of these parameters as probabilities in the sense of classical frequentist probability theory is justified. However, probability theory is an established concept to handle uncertain quantities. Additionally it can be extended in accordance to the axioms of Kolgomorov in a suitable manner to use it according to the above outlined constraints in security risk assessment. For example, the interpretation of the risk definition based on Bayesian probability theory enables the modeling of the parameter triplet by the formulation as degree-of-belief-densities, thus enabling the consideration of inherent uncertainties formally compliant with probability theory (Beyerer & Geisler 2016).

Thus, the definition combines in a quantitative manner consequences of attacks and probabilities of threat scenarios with the risk of success of individual attacks defined as vulnerability. The above quantitative definition of risk may help to deduce acceptable risks and necessary measures to reduce risks (Broder & Tucker 2012). Inherent uncertainties regarding the three risk factors should be cautiously considered (Campbell & Stamp 2004).

Various approaches to security risk assessment have been developed, which may be divided into qualitative, quantitative and hybrid methods (Meritt 2008). Qualitative methods are mostly based on expert knowledge, while existing quantitative methods use discrete probabilities. Additionally, some quantitative methods aiming at cost-benefit analysis have been developed. Typically, cost-benefit analyses of security measures compute potential financial losses as a result of an attack, the probability of occurrence of various attack scenarios and the vulnerability of the security system (Flammini et al. 2009). This analysis yields accurate results but raises the complexity compared to qualitative methods (Landoll 2011).

2.2 *Vulnerability assessment*

Quantitative vulnerability analysis as part of the quantitative risk analysis is mostly based on methods adapted from reliability and general risk analysis. Here, the considered model is dependent on given attack scenarios (French & Gootzit 2011). This dependency is detrimental to a comprehensive analysis as knowledge about the behavior of a potential attacker may be insufficient (Cox Jr. 2009). The different modeling approaches can be further split up into mainly analytical but also formal methods. An overview of approaches is given by Nicol et al. (Nicol et al. 2004). Analytical methods are often based on attack trees, which can be seen as a derivative of the fault trees known from reliability analysis. Attack trees were first used by Schneier (Schneier 1999) for IT-security analysis and since then have been further developed by different authors, summarized e.g. by Vintr et al. (Vintr et al. 2012).

Contini et al. have introduced incoherent attack trees to characterize the dynamic behavior of the considered system (Contini et al. 2008). Additionally, they integrated simple probability distributions for protection into attack trees to investigate the chronologic sequence of attacks. Hence, it is possible to analyze the security system's ability for an attack intervention by comparing the probabilities of residual protection and system's response (Contini et al. 2012).

Garcia describes this relation (Garcia, 2008), where feasible attack paths as part of different attack scenarios and corresponding barriers are used. The model is time-based and introduces the critical detection point, which is the latest possible point of detection that ensures a successful intervention against the potential attacker.

A quantitative model that further develops the approaches of Contini et al. (Contini et al. 2012) and Garcia (Garcia, 2008) was introduced in (Lichte et al. 2016) and applied to an infrastructure in (Lichte & Wolf 2017). The suggested vulnerability model uses pdfs to describe the characteristics of security measures and uses a path-based barrier model. Additionally it uses the principle of the weakest path. The developed approach in this paper uses this vulnerability model as a basis.

Summarizing, the different existing approaches to analytical modeling and analysis of vulnerability as well as security risk analysis are lacking the consideration of uncertainties in the system parameters and overall behavior. Additionally a great

number of these approaches relies on expert knowledge, causing various problems that are described in the next paragraph.

2.3 *Expert knowledge and uncertainty in security risk assessment*

The elicitation and use of expert knowledge is an often used approach in risk assessment, e.g. to determine point estimates for unknown parameters (Kaplan 1992). Especially, this approach is used to develop and parametrize models for risk assessment in case the available database is very small or there is a lack of objective data (Bolger & Wright 2017).

Therefore, methods for the elicitation of expert knowledge are developed to minimize subjectivity and uncertainty in parameter estimation. Though, the use of expert knowledge itself generally raises the problem of uncertainties in probabilistic risk assessment that should cautiously be analyzed (Rausand 2013) (Aven & Zio 2013). Latest developments in general risk assessment are focusing on uncertainty as a key concept of risk assessment (Aven 2016). Especially in the analysis of rare events that may lead to catastrophic consequences with large uncertainties, different approaches to deal with uncertainty have been suggested and analyzed, e.g. in (Flage et al. 2014).

Especially security risk assessment is often accompanied by great uncertainties, as there is a lack of evidence of threats, consequences and the abilities of security measures. Thus, qualitative or semi-quantitative models that strongly rely on expert knowledge are often used, although these models can lead to misleading or even wrong results (Landoll 2011). Consequently, an analysis of the described resulting uncertainties should be conducted for security risk assessment. This paper discusses an approach of a transition from a semi-quantitative to a quantitative model, which enables further analysis in this direction.

3 APPROACH

To analyze the influence of uncertainties especially emerging from the dependence on expert knowledge in semi quantitative risk assessment methods, an approach is introduced that allows the transition to a risk model that uses triangular pdfs. Both methods are gradually applied to an exemplary infrastructure depicted in Figure 1. The results of both risk models are analyzed for deviations and possible causes. Therefore, a simplified semi-quantitative approach to security risk assessment is presented first. It is based on existing methods, e.g. (Harnser Group 2010). The part of vulnerability assessment reflects four basic assumptions presented in (Lichte & Wolf 2017):

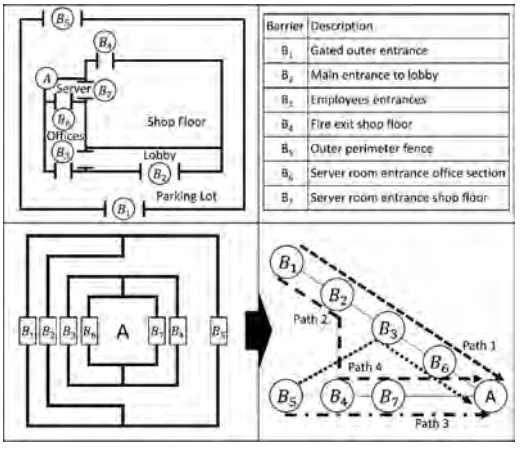

Figure 1. Outline of infrastructure and security system.

1. The weakest path of the security system determines the system's vulnerability as the chosen path of the attacker is uncertain.
2. The combination of protection and observation at barriers is necessary as an attacker is always able to break through a barrier given infinite time without being detected.
3. The detection of an attack is possible only if the protection is sufficient to prevent a breakthrough under observation until detection.
4. After detection, an attack can be stopped only if the residual protection along the remaining attack path lasts long enough to prevent the attacker from reaching the asset until intervention is completed.

In a second step, the developed approach is extended to be able to consider various contributions from expert knowledge. Subsequently, a transition is presented that uses triangular pdfs to represent the various semi-quantitative ratings of the experts. Thus, the differences of the experts' assessments are treated as uncertainties. In the last step, possible results for the semi-quantitative model are compared to the transformed model.

3.1 *Exemplary production infrastructure*

A basic drawing of the considered production infrastructure is outlined on the upper left of Figure 1. The model only considers security measures located along paths that lead to the server room, which is assumed as the asset of a possible attack. The upper right of Figure 1 denotes the security measures marked in the drawing.

The model depicted on the lower left of Figure 1 (onion layer model) represents the structure and feasible attack paths by means of barriers. Four individual attack paths lead to the asset A via barriers B_1-B_7.

All feasible attack paths of the exemplary infrastructure are extracted into a path-based model. The result of the extraction of the attack paths is shown on the lower right of Figure 1. It includes all four attack paths directed towards the asset.

3.2 *Semi-quantitative risk assessment*

The presented semi-quantitative method for security assessment is divided into three submodels. In analogy to the risk definition there are submodels for threat, vulnerability and consequence assessment. The security risk is then indicated in a two dimensional risk matrix, in which the ordinate shows the probability of occurrence of a threat incorporating the vulnerability of the infrastructure against the threat. The axis of abscissas maps estimated consequences.

Threat and consequence assessment are simplified to the estimation of threat probability and level of consequences in ranking scales with five steps, which are described in Table 1.

The presented semi-quantitative model for vulnerability assessment is based on a barrier-oriented view of the infrastructure. Therefore, the commonly used parameters protection, observation and intervention have to be estimated at every security barrier of the infrastructure (Lichte et al. 2016). To realize this, the model uses a five step ranking scale to estimate the time based capabilities of the considered security measures. The ranking scale that is chosen depending on the considered infrastructure as well as the corresponding estimations is shown in Table 2 and 3.

First, the probability of a detection of the attacker needs to be modeled—Based on the four basic assumptions a high level of protection and observation enables a high probability of a triggered alarm A_i at a barrier, so that:

Table 1. Ranking scale threat & consequence.

1	2	3	4	5	Expert score
Scale threat [probability]					
0.0–0.2	0.2–0.4	0.4–0.6	0.6–0.8	0.8–1.0	2
Scale consequence [100k $]					
0–1	1–2	2–3	3–4	4–5	4

Table 2. Score descriptions P,O,I.

1	2	3	4	5
Scale P,O [s]				
0–90	90–180	180–270	270–360	360–450
Scale I [s]				
0–180	180–360	360–540	540–720	720–900

Table 3. Ranking scale threat & consequence.

	Expert score		
Barrier i	P	O	I
1	1	5	3
2	4	1	1
3	2	2	4
4	2	5	5
5	1	5	4
6	5	3	2
7	5	2	2

$$A_i = \frac{P_i + \left(O_{max} - O_i\right)}{P_{max} + O_{max}} \tag{1}$$

Herein P_{max} and O_{max} represent the highest possible score in the ranking scale. For the first barrier B_1 of path 1 of the example infrastructure we get:

$$A_1 = \frac{1 + \left(5 - 5\right)}{10} = 0.1 \tag{2}$$

In a second step, the level of security of a barrier is described by the possibility of an intervention taking place before the attacker reaches the asset. This is described by merging the residual protection of a barrier with the estimated duration of an intervention. The residual protection R_i can be interpreted as the sum of all remaining *n* protection times along the considered attack path. Using a floor function to obtain an integer as a result we obtain:

$$R_i = \left\lfloor \frac{\sum_{i=1}^{n} P_i}{n} \right\rfloor \tag{3}$$

$$R_1 = \left\lfloor \frac{1 + 4 + 2 + 5}{4} \right\rfloor = 3 \tag{4}$$

The residual protection is then merged with the duration of intervention I_i of the barrier to obtain the possibility of a timely intervention T_i.

$$T_i = \left(\frac{R_i - I_i}{R_{max} + I_{max}} \right) + 0.5, \; T \in \left(0.1, \ldots, 0.9\right) \tag{5}$$

$$T_1 = \left(\frac{3 - 3}{10} \right) + 0.5 = 0.5 \tag{6}$$

Using the results for the possibility of a triggered alarm and a timely intervention the vulnerability of the feasible attack paths depicted in Figure 2 is calculated by:

$$V_{Path} = \prod_{i=1}^{n} 1 - \left(A_i \cap T_i\right) \tag{7}$$

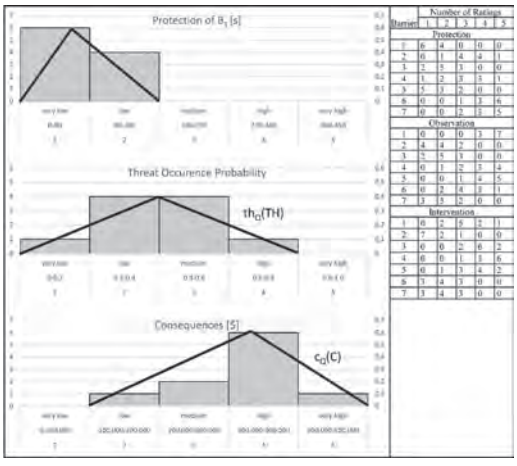

Figure 2. Exemplary histograms and rankings according to aggregated expert knowledge.

For path 1 this yields:

$$V_{Path,1} = (1-0.3)(1-0.35)(1-0.25)\cdot(1-0.35) = 0.147 \quad (8)$$

3.3 *Consideration of multiple expert knowledge*

In order to analyze the influence of uncertainties in threat, vulnerability and consequence assessments, judgements of multiple experts are now introduced. Hypothetical assessments of k = 10 experts are introduced and aggregated in a histogram that shows the frequency of the scores given by the experts. As an example, the histogram of the absolute and relative frequencies for protection measures at B_1 as well as for threat and consequence are shown in Figure 2.

On the right-hand side of Figure 2 the ranking of all experts for all barriers of the security system of the example infrastructure is included.

3.4 *Transition to the usage of probability density functions*

In this step, the semi-quantitative models are transformed into quantitative models. Both types of models use similar operations based on conditional probabilities to describe the security risk of an infrastructure.

Therefore we develop triangular pdfs on the base of the above found histograms that result from the differing ratings of multiple experts. Triangular distributions are widely used in different fields of risk analysis to estimate probability distributions under uncertainty (Haimes 2015). The characteristic parameters of the function are lower limit *a*, upper limit *b* and mode *c*. The determination of the parameters for all input parameters of the risk model are based on the respective histograms of the relative frequency (see Fig. 2).

Table 4. Distribution parameters for th_Q & c_Q.

	a	b	c
th_Q	0	0.8	0.4
c_Q	1	5	3.33

The lower limit *a* and the upper limit *b* for the pdfs of threat and consequence are determined by the minimum and maximum value given in the ranking score for probability of occurrence and costs of a successful attack, respectively. The median interval of the respective histogram is assumed as mode *c*. The resulting fitted triangular pdfs are outlined in Figure 2.

The obtained values for the pdf parameters for threat $th_Q(TH)$ and consequence $c_Q(C)$ are listed in Table 4.

In contrast to the simplified threat and consequence submodels, the transition of the vulnerability submodel is more complex due to the relations between the input parameters. To manage transition, the five ranking scores are transformed to time-based intervals depending on the chosen time-based ranking scales (see Tab. 2) to describe the characteristics of the security measures according to [Lichte & Wolf 2017]:

- Protection is characterized by an estimated time needed for a break-through.
- Observation is the time span needed for a detection.
- Intervention is the period of time until an intervention is completed.

The resulting intervals mark reasonable time steps to describe the time based characteristics and at the same time reflect the assessment of the experts.

In order to ensure comparability within the model, the J = 5 time intervals for all protection and observation measures Δt_{ij} at the i barriers of the infrastructure lie in the time span $[0,t_{max})$. The reasonable choice for the value of t_{max} depends on the considered infrastructure. The intervals Δt_{ij} are all of the same size. For the example infrastructure $t_{max} = 450$ [s]

Due to the modeled relations, the time span of the intervention measures can possibly reach higher values. Therefore the upper considered time span for intervention measures is set to $t_{max,I} = 900$ [s]. As the number of intervals does not change, the intervals $\Delta t_{I,ij}$ grow proportionally.

Now, a triangular pdf can be fitted into the histograms for protection, observation and intervention measures of the security system. The intended fitting of the function is outlined in Figure 2.

Therefore, the lower limit *a* and the upper limit *b* are defined for protection and observation as the minimum and maximum value for t within the intervals comprised in the scoring of the experts. The lower interval l of the j = 5 overall intervals containing expert scores can be found via the following conditions:

$$\sum_{j=1}^{l} k_j > 0 \quad \text{and} \quad \sum_{j=1}^{l-1} k_j = 0 \tag{9}$$

The conditions for the upper interval u are:

$$\sum_{j=1}^{u} k_j > 0 \quad \text{and} \quad \sum_{j=u}^{j} k_j = 0 \tag{10}$$

Following, the lower limit a and the upper limit b are determined by:

$$a = t_{\min} = \min(\Delta t_{il}) \tag{11}$$

$$b = t_{\max} = \max(\Delta t_{iu}) \tag{12}$$

The definition of intervention is equal using $\Delta t_{I,ij}$. The mode *c* for all security measures is determined by means of calculating the median of grouped data. First the median interval of the grouped data can be defined as the interval *m*, which contains the median of the dataset:

$$\sum_{j=1}^{m-1} k_j < \frac{k}{2} \quad \text{and} \quad \sum_{j=1}^{m} k_j \geq \frac{k}{2} \tag{13}$$

Following, the median within the found interval *m* is estimated by linear interpolation assuming an equal distribution as no further information about the distribution within the interval is available. With the lower boundary of the median interval l_m and the upper boundary u_m we obtain:

$$c = t_m = l_m + \frac{\frac{k}{2} - \sum_{j=1}^{m-1} k_j}{k_m} \cdot (u_m - l_m) \tag{14}$$

For the derivation of the parameters of the triangular function of the protection measure at barrier B_1 of the example system we obtain:

$$\sum_{j=1}^{l} k_j > 0 \quad \text{and} \quad \sum_{j=1}^{l-1} k_j = 0 \rightarrow l = 1 \tag{15}$$

$$\sum_{j=1}^{u} k_j > 0 \quad \text{and} \quad \sum_{j=u}^{J} k_j = 0 \rightarrow u = 2 \tag{16}$$

$$a = t_{\min} = \min(\Delta t_{11}) = 0 \tag{17}$$

$$b = t_{\max} = \max(\Delta t_{12}) = 180 \tag{18}$$

$$\sum_{j=1}^{m-1} k_j < \frac{k}{2} \quad \text{and} \quad \sum_{j=1}^{m} k_j \geq \frac{k}{2} \rightarrow m = 1 \tag{19}$$

$$c = t_m = 0 + \frac{\frac{10}{2} - \sum_{j=1}^{1-1} k_j}{6} \cdot (90 - 0) = 75 \tag{20}$$

As all parameters for the triangular pdfs for the vulnerability submodel p(t), o(t) and I(t) are now defined, the calculation of the path vulnerability $V_{Q,Path1}$. by applying the quantitative model is possible. The characteristic parameters and their relation to each other in the quantitative vulnerability submodel are taken from (Lichte& Wolf 2017).

Inserting the obtained pdfs for the barriers of path 1 of the example system into the quantitative model we obtain for the path vulnerability $V_{Q,Path1}$

$$V_{Q,Path1} = 0.028 \tag{21}$$

3.5 *Results and analysis*

As the vulnerability of both models is based on the principle of the weakest path, the other three feasible attack paths also have to be calculated. The results for the semi-quantitative and the quantitative model are summarized in Table 5:

The resulting risk is entered into a security risk matrix for both models. The risk matrix for the semi-quantitative model considering the vulnerability of the weakest path 4 is shown in Figure 3.

The security risk R_S estimated by the semi-quantitative model is calculated to:

Table 5. Vulnerability V_S & V_Q for all attack paths.

Path	V_S	V_Q
1	0.147	0.028
2	0.141	0.014
3	0.328	0.209
4	0.341	0.430

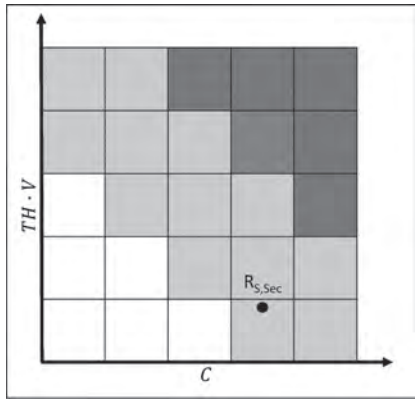

Figure 3. Security risk matrix for the semi-quantitative model.

$$R_{S,Sec} = \left(TH_S \cdot V_{S,Path4}\right) \cdot C_S = 59{,}752\ \$ \tag{22}$$

As the quantitative model uses pdfs the risk matrix is extended to a three dimensional risk matrix. Basically, the matrix maps the bivariate pdf of the risk $R_{Q,Sec}$. It incorporates the probability of occurrence of a threat considering the vulnerability of the infrastructure and the consequences. The distribution-based quantitative risk matrix of the example infrastructure is depicted in Figure 4.

The security risk estimated by the use of the quantitative model is received by the cumulated bivariate pdf. For the example infrastructure we obtain:

$$R_{Q,Sec}\left(c_Q, th_{V,Q}\right) = \int_0^{c_Q} \int_0^{th_{V,Q}} f_{C_Q,TH_{V,Q}}\left(C_Q, TH_{V,Q}\right) \times dC_Q\, dTH_{V,Q}, \boldsymbol{TH}_{V,Q} = TH_Q \cdot V_{Q,Path4} \tag{23}$$

Thus it is possible to calculate the overall security risk.

$$R_{Q,Sec} = 133{,}344\ \$ \tag{24}$$

Other results for interesting boundaries of the distribution variables can also be obtained For example we chose two especially important risk cases to be considered:

- Very high estimated consequences C > 400,000 $
- Black swan events with a very low probability of occurrence of the threat TH < 0.05 and very high consequences C > 400,000 $

When calculating according to (23) we are able to obtain a probability P for the special case, given the overall scenario as well as the resulting risk in terms of consequence:

$$R_{Q,1} = 29{,}920\$,\ P_{Q,1} = 0{,}07 \tag{25}$$

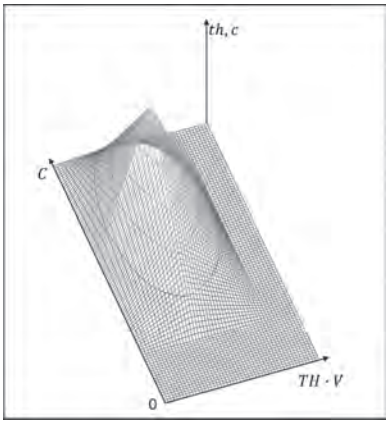

Figure 4. 3D security risk matrix.

$$R_{Q,2} = 1029\$,\ P_{Q,2} = 0.0024 \tag{26}$$

The analysis shows that the semi-quantitative model covers a smaller window of possibly occurring security risks and estimates a significantly lower overall risk. As a result, the model only provides a risk point estimate. Therefore, information about certain cases, e.g. rare events, is neither visible nor can be considered in the risk assessment.

This is especially shown by the two risk cases applied to the considered scenario and the example infrastructure. In contrast to the quantitative model, the information about a probability of occurrence of such events is not comprised in the results of the semi-quantitative model. This information is visualized in the three dimensional risk matrix of the quantitative model (see Fig. 4). It shows the probability of occurring risk cases at the boundaries of the considered scenario besides an average risk, e.g. black swan scenarios like in $R_{Q,2}$.

Furthermore, this is reflected in the differing results of the vulnerability analysis. Although the trend for the vulnerability of the single attack paths of the considered infrastructure is similar, the absolute results differ. The reason for this difference is again a result of the consideration of uncertainties within the vulnerability assessment resulting from the elicitated expert knowledge.

Both findings underline the importance to consider uncertainties to be aware of possible boundary cases, e.g. of rare events with great consequences in a complete risk analysis and decision-making process.

4 CONCLUSION AND OUTLOOK

The paper shows the influence of uncertainties on physical security risk assessment and the resulting need for a consideration of uncertainties. Therefore the paper outlines the state of the art in the field of security risk assessments and expert knowledge especially regarding resulting uncertainties. It is shown that semi-quantitative modeling using expert knowledge is a common used practice though these models lack a consideration of uncertainties so far. To tackle this problem, an approach is introduced that enables a transition towards quantitative modeling using expert knowledge as a basis.

Following, the approach is further detailed and step by step applied to a notional production infrastructure. Therefore a simplified semi-quantitative security risk assessment method is introduced and the transition using triangular pdfs is shown. In a last step a three dimensional risk matrix based on a bivariate pdf resulting on threat, vulnerability and consequences is set up. Subsequently, a comparison of the results of the example infrastructure for

both modeling approaches is conducted. Hereby, differing results for the risk analysis and the possible influence of uncertainties are revealed.

The presented approach shows the influence of uncertainties to physical risk analysis and proposes a three dimensional risk matrix that visualizes possible rare events at the boundaries of estimated threats. Additionally it presents a method for elicitation and use of expert knowledge in the context of physical security risk assessment. Continuously this approach can be further developed to support profound decision-making based on a comprehensive security risk assessment.

Nevertheless, the approach needs further enhancement especially in detailing the input parameters for threats and consequences. The further analysis of the vulnerability is needed also. Here, the influence of uncertainties on the vulnerability assessment should be analyzed, e.g. by Monte-Carlo simulation and sensitivity analysis. The applicability of other modeling approaches like info-gap models should be investigated.

Use case-based consideration of safety and security in cyber physical production systems applied to a collaborative robot system

D. Lichte & K.-D. Wolf
Institute for Security Systems, University of Wuppertal, Velbert, Germany

ABSTRACT: An increasing number of Cyber Physical Systems is used in different areas of application like smart grid, smart factory or smart home. This paper outlines a first approach for an integrated consideration of safety and security for Cyber Physical Production Systems in the so-called Industry 4.0 context which can be interpreted as Systems of Systems. The approach is based on a use case-based model for application in the context of Industry 4.0. To realize a safe and secure operation of Cyber Physical Production Systems in System of Systems a high number of elements, relations and functions have to be taken into account. A Systems Engineering-based approach will be introduced in this paper to deal with this complexity. The approach consists of a SysML-based model which is associated with a procedure that ensures the safe and secure design of Cyber Physical Systems. Specified safety use cases will be used in the following security analysis and assessment. By harmonizing security assessment and safety use cases the integrated consideration is accomplished. The results can be used for technically solution-neutral designs in early development phases.

1 INTRODUCTION

Cyber Physical Systems (CPS) have become increasingly important. As mechatronic systems they consist of sensors, actuators, an embedded intelligence and the ability to communicate with other CPS (Anderl et al. 2013). Applications of CPS are diverse, e.g. advanced automotive systems, environmental control or smart structures (Lee 2008), like e-health, smart home, smart factories, micro grids etc. (Geisberger & Broy 2012).

This paper focuses on applications in industrial environments, where CPS are an important part of so-called Industry 4.0 (Jazdi 2014), where intelligent manufacturing systems (IMS) are communicating and collaborating within production networks (PN) which are connected via internet of things (IoT). These systems are defined as cyber physical production systems (CPPS). Basically, CPPS are systems of systems (SoS), as they consist of autonomous and cooperative elements and sub-systems that are interacting with each other depending on predefined (production) goals (Monostori 2014).

Besides autonomous machine to machine communication (M2M), the collaboration of humans and machines, so-called human machine interaction (HMI), is essential in Industry 4.0 scenarios. Collaborative robots (Cobots), on which a strong emphasis is put on in this paper, are a representative example for these interactions. Cobots collaborate with humans without special safety barriers and use sensors and intelligence to avoid collisions with co-workers. They are connected to other machines in a CPPS for e.g. collecting data and updating production procedures or steering software.

A primary challenge is to maintain safe and secure operation of these CPPS for industrial applications (Lee et al. 2008), since safety and security requirements are key factors to reduce operational risks. The design of a safe and secure system may be a difficult task because of inherent tradeoffs (Lichte et al.) like for example a safe shutdown of a cobot in case of an imminent collision with the collaborating human and the protection against an interruption of production by an intentionally precipitated malfunction of the safety system. If several CPPS are considered simultaneously, this task is getting even more difficult, the result is a high number of CPS combinations and associated use cases.

Frequently, CPS research focuses on interfaces or technical standardization approaches for communication. Yet these approaches are not harmonized so far to provide safe and secure interoperability between the great variety of connected collaborating devices (Kim et al. 2014, Knight 2007, Sarijari et al. 2014). The detailed level and discipline specific focus of these approaches do not allow to adopt the design of the SoS sufficiently.

In this context, this paper demonstrates a first approach for an integrated consideration of safety

and security for CPS in a CPPS by a use case-based model. To realize a safe and secure operation of a large number of elements, relations and functions have to be taken into account (Banerjee et al. 2012, Axelrod 2013).

A systems engineering-based approach will be introduced in this paper in order to deal with this complexity. The approach consists of a SysML-based model which is combined with a procedure to ensure the safe and secure design of Cyber Physical Systems. The procedure is then applied to the cobot system and a first simplified model focusing on the CPS in the CPPS based on use cases is developed. Overlapping use cases (by time and location) are investigated throughout the analysis and supported by the model for a safe and secure design. Finally, results are summarized and discussed.

2 STATE OF THE ART

In a scientific context, safety and security are often defined as a deliberate threat (security) and an unwanted hazard (safety) (Beyerer et al. 2010). Safety functions are designed to protect users from hazards, e.g. an accident. Security functions protect the system and its contents against attacks like intentional misuse. The variety of components and their IT-based networking lead to a growing number of safety and security requirements, which have to be fulfilled by functions.

Regarding CPS in SoS, the variety and diversity of requirements, components and functions is growing as industrial applications are increasingly integrated into the Industry 4.0 context. As the general development in the field of CPPS is similar, CPPS mainly face the same challenges.

The diverse functions are often subject to a fundamental goal conflict. For reasons of safety, redundancies are designed to ensure safety in dangerous situations. Simultaneously these redundancies should not be implemented for reasons of security, because they result in additional attack vectors. Consequently, safety and security functions influence each other.

Additionally, the system's complexity, which is defined by the number and diversity of elements, relations as well as dynamics (Meyer 2007), is increasing, e.g. due to networked systems. Results are for example the requirement of additional security functions to avoid an intrusion into the SoS. Besides the mentioned diversity of elements, complexity is also described, by the high number of participating systems. In turn systems, which carry out tasks independently of each other, as well as together for a limited period of time, can be considered as a SoS (Holt & Perry 2014). According to this characteristics CPPS, which are considered to be SoS of CPS, can also be defined as virtual SoS:

- No central management and no overarching agreed-upon purpose.
- No consistent configuration or maintenance of the SoS as a whole system.
- The individual constituent system will be configured and managed.

These constituent systems consist of a variety of components. For instance, a Cobot includes components for movement, steering, control and positioning, which implement various safety—and security-related functions. As there is no central management or consistent configuration of such a virtual SoS—which is composed of such systems—an integrated safety and security considering model is needed.

Use cases of CPS allow an extensive description of their safety-related behavior. These use cases do not describe the behavior of a SoS consisting of different collaborating CPS. To focus on a comprehensive description of safety and security aspects and resulting goal conflicts, intersection points between the CPS in a SoS have to be investigated. These intersection points have to be defined by CPS specific use cases, which can be postulated (Cockburn 2015). Nevertheless, these use cases do not contain the required information on consequent safety and security goal conflicts.

In order to reach a defined level of safety and security, different methods and concepts may be used, e.g. TSM or GlobalPlatform for security architectures or risk analysis to estimate a safety level. Although specific methods for safety or security exist, an integrated, simultaneous consideration of both aspects is not possible yet (Lichte et al. 2016) or only for software related aspects (Axelrod 2013).

Safety and security aspects need an interdisciplinary understanding for CPS as well as CPS in SoS. Many existing approaches lack a common understanding.

While focusing on complexity, Systems Engineering (SE) can handle these challenges (Mamrot et al. 2014) as it is about creating effective solutions to problems and managing the technical complexity of the resulting developments. SE includes a system model for handling complexity with an interdisciplinary procedure. However many different SE-based approaches were developed. In (Marchlewitz et al. 2015) a first common model for SoS was developed and combined with a procedure. This new Generic Systems Engineering (GSE)-based procedure consists of a standardized procedure using the modules "analysis" (problem identification and system analysis), "target definition" (problem localization) and "design" (recommendations) (Winzer 2015).

The order and structure of these modules is depending on the specific problem under consideration.

Different GSE-based approaches are used, e.g. for requirements engineering (Nicklas 2015) or for the design support of autonomous robots (Mamrot et al. 2014, Marchlewitz et al. 2015). However, the existing system model which was introduced in (Mamrot et al. 2014) does not support the specific combination of CPS in CPPS which is needed for an integrated safety and security consideration as well as a standardized notation. Therefore, a SysML-based approach will be used. Based on its diagrams and standardized notations, an integration in the existing common GSE model of thinking can be realized.

In summary, the following challenges were identified:

- No standardized model for SoS or CPPS (of CPS) for safety and security aspects already exists.
- Missing description of the virtual SoS and its behavior by the CPS specific use cases.
- Difficulties in handling diverging high level use cases caused by inherent complexity.

To deal with these challenges, the approach for an integrated consideration of safety and security aspects for smart home applications will be developed and introduced in the following section.

3 APPROACH

In order to analyze the described complex systems and enable a further development, a Systems Engineering-based approach is introduced [24]. This new GSE-based approach is shown in Figure 1. The proposed procedure is combined with a safety and security integrated system model for applications in the context of CPPS as SoS of CPS. In step 1 the CPPS and its scope are analyzed by using the GSE-module "analysis". This analysis is initially realized by the CPS use cases. Hazardous behavior of the CPPS is then identified by combining relevant use cases, e.g. by time and location intersection points. Step 2 represents the safety use case definition based on SysML notation and diagrams. This is then combined with the GSE target definition module. In the following step 3, resulting safety use cases are investigated to identify related attack scenarios. The security analysis based on the derived safety use cases is necessary as safety use cases possibly create new attack vectors. This ensures the extensive analysis of goal conflicts between safety and security. Finally, the harmonization of safety and security is carried out in step 4. As a result, design recommendations can be derived based on the GSE-module "design".

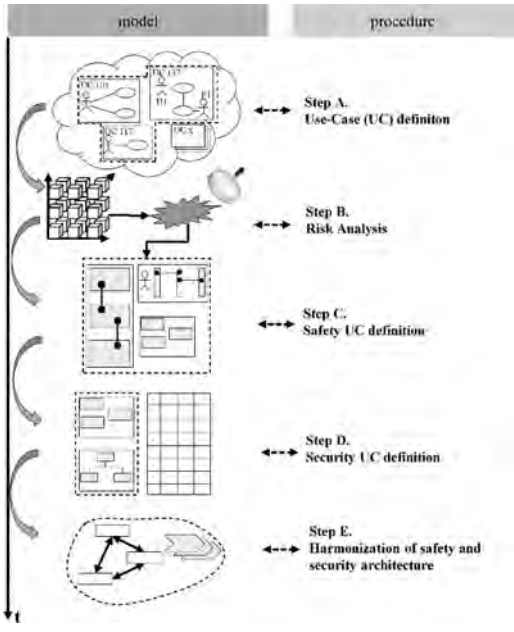

Figure 1. Approach.

Following, the four-level approach will be explained in detail.

3.1 *CPPS definition*

In a first step being based on systems thinking the scope of system has to be limited in order to handle the complexity of SoS [25]. Therefore the proposed CPPS is divided into its subsystems and users. With this limitation, the focus is placed on systems and interacting users. In this article an example based on four different systems will be used:

- Cobot (CB),
- Smart wristband (SWB),
- Intelligent emergency reaction unit (IER),
- Communication hub (CH).

The smart wristband worn by the co-worker is used for position tracking while working with the cobot to avoid hazardous collisions and to monitor the health status in case of potential work accidents. In addition, the communication hub is understood as a part of the CPPS and not as a central management. It only enables the communication between the systems. With the help of these systems the identified challenges and use cases have to be derived. A typical use case description includes preconditions, postconditions, primary flow and an alternative or exception flow (Friedenthal et al. 2015). Therefore, a predefined template is suitable. Different suitable use cases are shown in Figure 2 which have to be

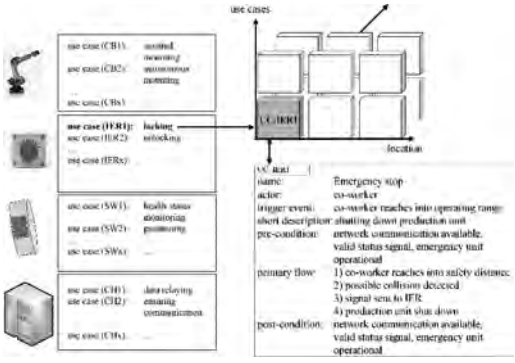

Figure 2. Use cases and combination.

Safety UC: AC	
name:	avoid collision
actor:	co-worker
trigger event:	co-worker falling below safety distance
short description:	avoid collision between co-worker and „CB“
pre-condition:	co-worker wearing „SW“, „CB“ operational, network-communication available
primary flow:	1) recognize direction of co-worker movement 2) adapt dmovement of „CB“ to regain safety distance
Alternative flow:	1) recognize direction of co-worker 2) adapt movement 3) collision
post-condition:	co-worker wearing „SW“, „CB“ operational, network-communication available

Figure 3. Safety use case “AC”.

analyzed regarding safety risks. The challenge is to identify every hazard resulting from an interaction of two or more CPS. This interaction is depicted by the intersection points with regard to time and location. For example, the use case analysis determines that the use cases “CB1-assisted mounting” and “CB2-autonomous mounting” (see Fig. 2) cannot overlap.

In the following exemplary application these four use cases will be used:

- Use case “CB1-assisted mounting”
- Use case “SW1-health status monitoring”
- Use case “SW2-position tracking”
- Use case “CH2-ensuring communication”

By combining the use cases the virtual CPPS is formed out of the cobot, the smart wristband and the communication hub.

For the identified intersecting use cases respectively the new CPS in CPPS a risk analysis has to be performed. This risk analysis is state of the art and therefore not further focused on in this paper. Here, the risk is defined in a quantitative or qualitative way as a function of the severity, the exposure, the occurrence and the controllability (ISO 2011).

By this procedure the risk is assessed for the corresponding use case (Step 2). As a result potential risks are identified for the following steps (step 2–4) to achieve a sufficient safe and secure CPPS.

3.2 *Safety use case definition*

With the result of step 2 safety use cases are defined. The goal of the safety use cases is derived from the risk analysis in step 2. In the example of the combined use cases “CB1” and “SW2” the collision between the user and the AVC should be avoided. Therefore, a new use case “AC” (avoid collision) is defined. The following Figure 3 shows the storyline of this use case.

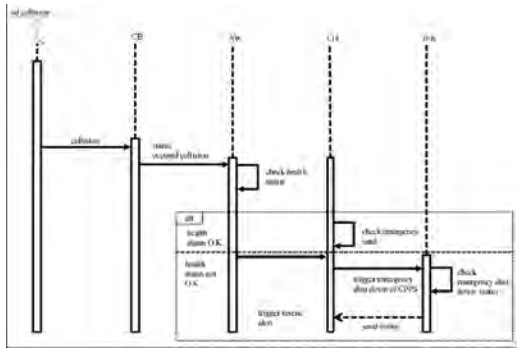

Figure 4. Sequence diagram for “collision” from safety UC: AC and safety UC: emergency.

Unlike “IER1” (see Fig. 2) the use case “AC” has an alternative flow to include a possible collision. Therefore it is necessary to consider a safety use case that reflects the resulting hazard of the collision of the alternative flow. In consequence the safety use case “emergency” is equally defined and documented.

Consequently, a sequence diagram is used to describe the interaction of the safety use cases. Sequence diagrams are based on the predefined use cases (Cockburn 2000). The use cases will be depicted and considered in the safety sequence diagram, which shows the required exchange of messages to describe the functionality of the safety scenario (SysML 2015).

In the example the alternative flow from safety use case “AC” is represented by the first two sequence steps of the diagram. The other part illustrates the steps of the subsequent safety use case “emergency”. An emergency alert will be triggered and “IER” will shut down the whole CPPS if the monitored health status of the user is not okay after the incident (see Figure 4).

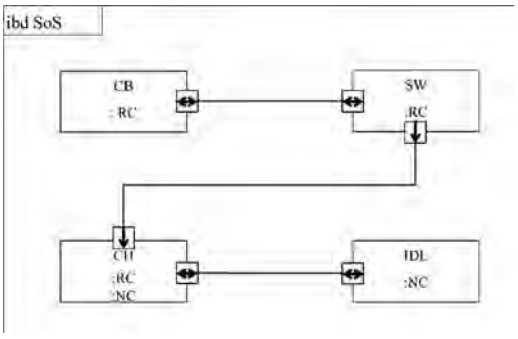

Figure 5. Internal block diagram.

The technical safety relevant information flow of the involved CPS "CB", "SW", "CH" and "IER" is determined by an internal block diagram (see Fig. 5). In addition to the logical task-orientated sequence the internal block diagram allows the description of information flow. Hereby, design support and further security analysis of the involved CPS are prepared. Figure 5 shows the information flow through the radio ("RC") and network ("NC") communication ports and its direction. Likewise, communication redundancies can be defined.

Based on the internal block diagram a security analysis and assessment is prepared in step 3.

3.3 *Security analysis and assessment*

In step 3 the needed security measures are defined to prevent the intended occurrence of threats as results of the safety use case by an outside attacker. The goal is to describe barriers between the components that show necessary limitations of information flow and encryption of communication between the components of the CPPS. Both items of information can be used to extend the solution structure of the safety use case by adding security barriers and hierarchic structures.

Therefore, the CPPS is analyzed by means of a security assessment based on attack scenarios. The most important results of these scenarios are goals and methods of the attack. The safety use case derived in step 2 is used to define the goal of the attack. The attack goal that results from the exemplary safety use case is achieving access to the home. Feasible attack paths and methods are deduced by the diagrams of the CPPS defined in step 2, which show involved CPS and information flows between them. The description of use cases and attack paths may require the integration of further CPPS components. The resulting simplified attack scenarios are summarized in attack trees, which were introduced by (Schneier 1999).

Figure 6 shows five resulting scenarios defined by the CPPS information flow of the use cases. Following, a qualitative assessment is conducted on the CPPS considering the developed security scenarios. The assessment includes a ranking regarding the probability of occurrence (PO) and goal achievement (PG) based on the attack trees shown in Figure 6. The scenarios S5 and S6 are excluded from further analysis as they are very unlikely to occur in terms of PO and PG.

As a result of the security analysis the attack vectors of the probable scenarios (S1-S4) have to be investigated. This shows where barriers are needed to secure the considered CPPS for the specific use case. The simplified block diagram in Figure 7 depicts this.

The above shown barriers describe the limitation of flowing information or needed encryption. Additionally, a simplified hierarchic model is established by analyzing the proposed limitation of

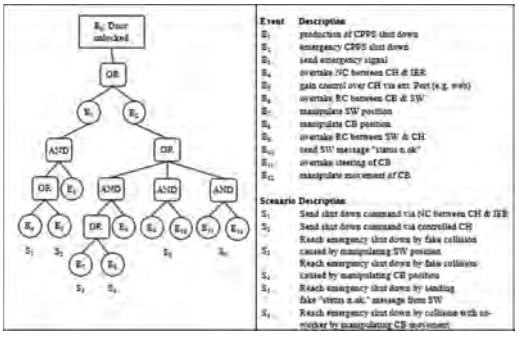

Figure 6. Attack tree.

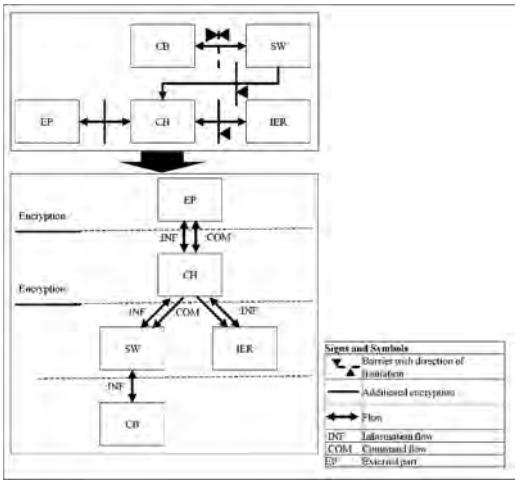

Figure 7. Security ibd and communication flow.

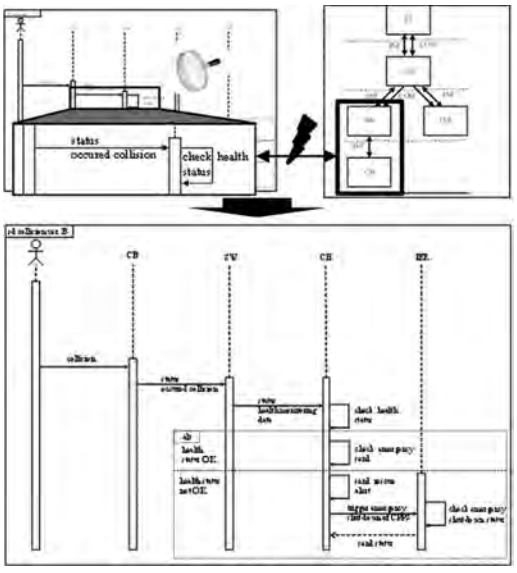

Figure 8. Sequence diagram for "collision" from safety UC: AC and safety UC: emergency.

direction of command and information flow signals between the components of the CPPS.

3.4 *Harmonization of safety use cases and security scenarios*

In the last step, the results of step 2 and 3 will be matched to expose and solve the safety-security goal conflicts related to the analyzed safety use case. As a result, Figure 8 shows a harmonized sequence diagram to achieve an adequate safety and security level. The analysis of information and command flow leads to changed connections in the sequence diagram. In the explained example, the connection of "SW" and "CB" is identified as critical for security. Therefore, the tasks "check health status" and "check emergency send" have to be executed by the "CH". The activity "send rescue alert" is additionally realized by the "CH". As a result, the sequence diagram "sd collision ver. B" is recursively adjusted.

As a result an integrated safety and security consideration for the CPPS based on the use cases is derived. On the one hand possible goal conflicts between safety and security functions are revealed. On the other hand the method enables a designing process that solves these conflicts. Due to the high degree of abstraction, early and technically solution neutral design can be planned.

4 CONCLUSION AND OUTLOOK

In this article a first use case-based approach is developed, which integrates safety use cases and resulting security scenarios for a widespread overview. First the problem of goal conflicts between safety and security was outlined and the state of the art regarding Cyber Physical Production Systems (CPPS) that can be considered as SoS and especially cobots as CPS was summarized. It was shown that existing models and approaches regarding SoS do not focus on an integrated safety and security perspective. Simultaneously the security of CPPS in the context of Industry 4.0 has to be considered in a more detailed way with regard to users and experts. Hence this article proposes an approach based on Systems Engineering to analyze and harmonize safety and security at the same time. The four individual steps of the approach include use case definition, safety use case definition, security scenario analysis and harmonization. Additionally, an example illustrates how the concurrent single steps may contribute to a safe and secure model of the CPPS, which is enhanced in every step of the procedure. In the first step, use cases are defined that may overlap in time and space and combined by time and location for the identified systems of the CPPS. These combinations are analyzed. Step 2 comprises the definition of the resulting safety use cases to avoid risks. They are described by storyline, internal block diagram and sequence diagram in SysML-based diagram types (Alt 2012). The security analysis in step 3 identifies attack goals as a result of the safety use cases and establishes attack scenarios based on attack trees. The probabilities of occurrence and goal achievement of the attack scenarios are qualitatively assessed and security structures containing the limitation of communication and encryption are derived. The resulting security structure is compared to the safety use case in step 4. Occurring goal conflicts are solved by adapting the sequence diagram of the safety use cases.

ABSTRACT: The aim of this paper is to present a mathematical framework for estimation the expected heat loss due to the implementation of de-icing measures for vessels operating in the Arctic offshore. Sea-spray icing on vessels operating in Arctic waters imposes financial and safety risks, such as loss of vessel stability, safety risks for vessel crew, as well as delays in maintenance and operations of offshore units. In Arctic offshore logistics, efficient planning of platform supply vessel operations should be performed while accounting for the risk of spray icing associated with selected voyages. Although Arctic vessels are equipped with a range of anti-icing and de-icing options, an optimum design and estimation of energy consumption for winterisation purposes remains a challenging task especially due to the uncertainties associated with the temporal-spatial variation of meteorological and oceanographic parameters contributing to ice accretion. However, long-term forecasts of such parameters are hardly available during logistics planning phase. Thus, this study uses 3-hourly reanalysis hindcast data (Norwegian Reanalysis 10 km data: NORA10) for estimation of icing rate and develops a probabilistic framework for estimation of expected heat loss, due to implementation of winterisation measures, over sea voyages for long-term logistics plans. Expected icing rate and winterisation-related heat loss can be used as safety and financial risk indicators in Arctic offshore logistics operations and their involved long-term decision-making processes. The framework is illustrated by a case study in the Arctic-Norwegian waters.

1 INTRODUCTION

Sea-spray icing is considered the most severe icing type due to its potentially high accretion rate (Ryerson, 2008; Ryerson, 2011) and a major safety concern for vessels operating in the Arctic offshore as the weight of the ice negatively affects vessel's stability and manoeuvrability. Spray icing can threaten the safety of crew on-board and structural reliability of platforms and vessels. It can interrupt routine on-board maintenance and operations activities due to safety concerns. Heavy icing events and its following de-icing operations can delay the delivery of goods, spare parts, and services (Jones and Andreas, 2009; Naseri and Barabady, 2016; Samuelsen et al., 2015). Figure 1 shows a severe spray icing on KV Nordkapp vessel on 26.02.1987 in the Barents Sea.

There are numerous works on planning offshore logistics operations such designing and optimising offshore fleet size and scheduling a number of platform supply vessels to support the needs of a cluster of offshore platforms; for example, see

Figure 1. 110 tons of ice accumulating during a 17 hours period on KV Nordkapp on 26.02.1987, while sailing from Tromsø to waters between Bjørnøya and Hopen in the Barents Sea (Samuelsen et al., 2015).

(Fernández Cuesta et al., 2017; Halvorsen-Weare et al., 2012; Maisiuk and Gribkovskaia, 2014; Stålhane et al., 2016). Some other works tackle the issue of reducing CO2 emission and vessel voyage cost by lowering fuel and energy consumption (Norlund and Gribkovskaia, 2013; Norlund et al., 2015). However, application of these research findings and developed frameworks and techniques for Arctic offshore logistics may be faced with a great deal of uncertainties due to the contribution of icing risks, its related safety concerns, and induced operational delays.

In order to tackle the issue of icing, vessels and platforms operating in the Arctic offshore are equipped with a range of anti-icing and de-icing techniques such as using heat tracers, insulations, shelters, semi-enclosures, or chemical ice protection options (DNV, 2013; Farzaneh M., 2015; Rashid et al., 2016; Ryerson, 2008; Ryerson, 2011). Implementation of such techniques, on the other hand, increases capital and operations costs, energy usage, greenhouse gas emissions, and fuel consumption. In addition, one should make sure of the reliability of winterisation techniques, whether or not they manage to perform their required functions as expected, and if malfunctioned, they can be maintained and repaired within an acceptable timeframe.

In this regard, efficient planning and execution of platform supply vessel operations is crucially important in terms of timely supply of goods and services to Arctic offshore units while taking the risk of spray icing associated with selected voyages into consideration. To this aim, long-term and real-time estimation of spray icing rate over the voyages is vital, especially due to the temporal-spatial variation of meteorological and oceanographic parameters contributing to ice accretion.

However, modelling sea-spray icing rate, is in general very challenging. This is mainly due to the uncertainties related to accurately estimating the spray amount during wave-ship interaction, the turbulent heat transfer between the atmosphere and wetted surfaces on the ship, and the freezing temperature of the brine water. The brine water on the wetted surfaces of a ship is namely lower than the temperature of the incoming sea water due to salt expulsion during the freezing process (Samuelsen, 2017a). In spite of such challenges and issues, some researchers have proposed highly sophisticated models to estimate spray-icing rate (e.g., (Horjen, 2013; Kulyakhtin and Tsarau, 2014)). However, these models have been little verified, and their complexity are therefore not justified by observations. A major drawback is for instance the fact that they assume that the wave height may be estimated directly from the wind speed, which is rarely the case in observed icing events (Samuelsen et al., 2017). In this study, MINCOG model developed by Samuelsen et al. (2017) is adopted for estimating spray icing rates. A brief description on the MINCOG model, is given in Section 2.

Long-term prediction of icing rates or the parameters contributing to spray-ice formation are hardly available during logistics planning phase. Therefore, by employing MINCOG model, and using 3-hourly reanalysis hindcast data (Norwegian Reanalysis 10 km data: NORA10), icing rates are estimated for a sufficiently long period in the past. By the use of such estimates and applying a non-sequential Monte Carlo simulation technique (Zio, 2013), a probabilistic representation of icing rate for a specific sea voyage and time period is developed to simulate the icing events and their rates in future for that voyage. This is further used as a fundamental input for estimation of expected icing rates and expected amount of energy required for winterisation purposes associated with selected sea voyages during certain time intervals.

This framework and its provided information on expected icing risk and winterisation-related energy consumption can be used as a safety and financial risk indicator for long-term decision-making processes in Arctic offshore logistics operations. In addition, by applying short-term weather prediction data, the presented framework can help vessel crew for making short-term decisions with respect to icing risks along the selected sea voyage. The rest of this paper is organised as follows. In Section 2, after reviewing spray-icing process, the MINCOG model is briefly discussed. Section 3 describes the proposed mathematical framework for estimating expected icing rate and its related energy consumption for a given voyage. The case study and conclusions are presented in Sections 4 and 5, respectively.

2 SEA-SPRAY ICING RATE MODELLING

In this study, a newly developed physics-based ship-icing model, known as Marine Icing model for the Norwegian COast Guard (MINCOG), is adopted from (Samuelsen et al., 2017) to predict the sea-spray icing rate. This model uses the Norwegian coast guard ship class named "KV Nordkapp" as a reference ship type for ship-icing calculations. Samuelsen (2017b) shows how this model provides higher verification scores than previously-applied ship-icing models and nomograms, like the commonly-applied Overland (1990) model, when the models are verified against ship-icing data from Arctic-Norwegian waters, outside Alaska, and at the east coast of Canada.

Sea-spray generated from the interaction between ships and waves are considered the most

dominating water source in ship-icing events (e.g. (Samuelsen, 2017a) and references therein). The MINCOG model is, therefore, based on the modelling of wave-ship interaction icing. Firstly, the sea-spray flux is calculated based on spray data derived from (Borisenkov et al., 1975). Icing rate r, can be calculated from the average sea-spray flux by taking into account the different heat fluxes involved in the icing process on a fixed position in the front of the ship. The heat balance is given by (Samuelsen et al., 2017),

$$q = q_c + q_e + q_d + q_r \quad (1)$$

where q is the energy that is released by freezing process, during which, salt is expelled making freezing temperature lower than that of incoming sea water. In Equation (1), q_c is the convective cooling from the air to the freezing brine, q_e is the evaporative cooling of the brine, q_d is heating (or cooling) from the sea water to the brine, and q_r is the incoming or outgoing longwave and shortwave radiative heat fluxes. Once icing rate is computed, the amount of energy released by freezing, i.e., q, is used for estimating the amount of energy to avoid icing (see Section 3.3).

Six model-input parameters including wind speed, air temperature, relative humidity, mean-sea level pressure, significant wave height, and significant wave period, are all derived from NOrwegian Reanalysis 10 km data (NORA10) (Reistad et al., 2011). Constant values of ship speed, sea-surface or water temperature, and incoming sea-water salinity, are applied.

As illustrated in (Samuelsen, 2017b – Figure 12 and 13), the sensitivity to these latter parameters in the normal range considered in marine-icing studies are relatively low compared to the former parameters, and thus, their medians are chosen as fixed model inputs. Incoming short-wave radiation, is here neglected, and incoming longwave radiation is parametrized by assuming that the atmosphere is radiating as a black body with a temperature equal to the air temperature at the level of the ship.

Furthermore, it is assumed that the winds and waves are coming from the same direction, and a constant angle is applied for the direction between the ship and wind equal to the median value of this angle derived from the icing reported by Samuelsen et al. (2017).

For simplicity, the trajectory model of water droplets used in is Samuelsen et al. (2017) skipped, and the droplet velocity is calculated from the relative velocity of the wind and ship in the horizontal direction, and an assumed terminal velocity of uniform droplets with a constant spherical size with a diameter of 2 mm. A detailed discussion on the MINCOG model, its underlying assumptions and constant values of input parameters are given in (Samuelsen, 2017a; Samuelsen, 2017b; Samuelsen et al., 2017).

3 LOGISTICS RISK INDICATOR MODEL: ANTI-ICING EXPECTED HEAT LOSS

In this work, energy consumption for anti-icing purposes and heat anti-icing heat loss are used equivalently. In order to calculate expected heat loss, a systematic procedure based on a non-sequential Monte Carlo simulation is suggested in this study, as shown in Figure 2. First, the trajectory is decomposed into several segments and coordinates of the origin and destination of each segment is determined. According to the vessel speed and the length of each segment, the time interval the vessel is sailing along segment is computed. In the second step, corresponding to those time intervals and for each segment, the occurrence of icing event and its rate is determined using the hindcast data, which will be used in the next step to extract the statistics of icing rates for those locations. Using determined distributions of icing events and rates for each segment, the occurrence of icing events and their associated icing rates are simulated for each segment at given times. This procedure is repeated for a sufficiently large number of times in order to estimate the statistics and determine the distribution of icing rate and heat loss for the whole trajectory.

3.1 *Vessel trajectory decomposition*

Let α and β denote, respectively, latitude and longitude, in degrees, of a geographical location on a map. Thus, vessel trajectory AB, is recognised by the coordinates of its origin A and destination point B, i.e., $A = (\alpha_A, \beta_A)$ and $B = (\alpha_B, \beta_B)$.

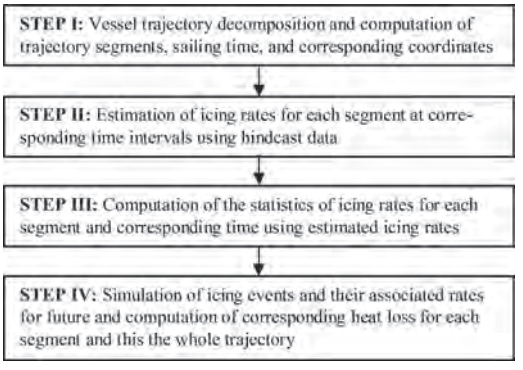

Figure 2. A systematic procedure for estimating expected heat loss for a given vessel trajectory.

Further, let trajectory $\overline{AB}$ be divided into N not-necessarily-equal segments $S_i = n_i n_{i+1}, i = 1, \ , N$, with length d_i and coordinates $n_i = (\alpha_{n_i}, \beta_{n_i})$, where,

$$n_1 = A \to (\alpha_{n_1}, \beta_{n_1}) = (\alpha_A, \beta_A) \tag{2}$$

$$n_{N+1} = B \to (\alpha_{n_{N+1}}, \beta_{n_{N+1}}) = (\alpha_B, \beta_B) \tag{3}$$

Note that, $\sum_{i=1}^{N} d_i = D$, with D being the rhumb line distance (Snyder, 1987) taken as the length of trajectory $\overline{AB}$ in km, given by (Alexander, 2004),

$$D = \frac{\pi R}{180} |\alpha_B - \alpha_A| \left| \frac{1}{\cos \omega} \right| \tag{4}$$

where, R = 6371 km is the earth's radius ω, in degrees, is the constant heading of trajectory $\overline{AB}$, i.e., the heading of rhumb line connecting A to B, clockwise from north. The constant heading is given by (Snyder, 1987),

$$\omega = \frac{180}{\pi} \tan^{-1} \left(\frac{x_B - x_A}{y_B - y_A} \right) \tag{5}$$

with,

$$x_A = \frac{\pi R}{180} \beta_A \tag{6}$$

$$y_A = R \ln \left[\tan \left(45 + \frac{\alpha_A}{2} \right) \right] \tag{7}$$

being rectangular coordinates of $A = (\alpha_A, \beta_A)$. While x_A lies along the equator, increasing towards east, y_A lies along the central meridian increasing towards north. Similar definitions stand for x_B and y_B.

In order to determine the coordinates of segment vertices, i.e., $n_i = (\alpha_{n_i}, \beta_{n_i}), i = 2, \ , N$, we can use the length of segment S_{i-1}, i.e., d_{i-1}, $i = 2, \ , N$, and the constant heading of trajectory $\overline{AB}$, ω, in degrees.

The latitude of the destination point of segment S_{i-1}, n_i, is given by (Kaplan, 1995),

$$\alpha_{n_i} = \alpha_{n_{i-1}} + \frac{180}{\pi} \left(\frac{d_{i-1}}{6371} \right) \cos \omega \tag{8}$$

where, d_{i-1} in km is the rhumb line distance between n_{i-1} to n_i. The longitude of the destination point of segment S_{i-1}, n_i, is given by (Kaplan, 1995),

$$\beta_{n_i} = \beta_{n_{i-1}} + \frac{180}{\pi} \left(\frac{d_i - 1}{6371 \cos \alpha_{n_{i-1}}} \right) \sin \omega \tag{9}$$

Once the coordinates $n_i, i = 1, \ , N+1$ are determined, the coordinates of midpoint of segment S_i, denoted by $n_i^* = (\alpha_{n_i^*}, \beta_{n_i^*}), i = 1, \ , N$, are determined by substituting half of segment's length into Equations (8) and (9), i.e., $d_{i-1} \leftarrow d_{i-1}/2$.

3.2 *Probabilistic representation of icing events and rates*

Probabilistic representation of icing events for a location includes representing two stochastic processes. In the first stochastic process, one predicts whether an icing event occurs, and during the second process, the amount of icing rate is predicted should the icing event occur. To this aim, assume that there exists sufficiently large number of icing event observations for a given location, using which both stochastic processes can be simulated.

For modelling the first process at a given location and time instant, let the probability of the occurrence of icing event be denoted by $\Pr(O = 1) = p$. Thus the complementary event (i.e., not occurrence of icing event) occurs with a probability of $\Pr(O = 0) = 1 - p$. For a given location and time instant, this process can be represented by a Bernoulli distribution, whose cumulative distribution function (CDF) is given by (Rausand and Høyland, 2004):

$$O \sim F_O(o) = \begin{cases} 1 - p & \text{for } O = 0 \\ 1 & \text{for } O = 1 \end{cases} \tag{10}$$

In order to simulate this process using a non-sequential Monte Carlo simulation, one can sample a random number form the CDF given by Equation (9). In other words, let $\zeta \sim U[0,1)$, then, icing event occurs if $\zeta \geq 1 - p$, and it does not occur, otherwise.

The second stochastic process initiates once the icing event occurs, i.e., $O = 1$. Once sufficiently large number of icing rate observations are collected, one can determine the empirical CDF of icing rate for a given location and time instant, i.e., $r \sim F_R(r)$, using which the amount of icing rate can be predicted.

3.3 *Heat loss estimation*

To estimate the amount of heat required for anti-icing, one can calculate the equivalent amount of heat released due to freezing, denoted by q_f in $\mathrm{Jm^{-2}\ s^{-1}}$ (Samuelsen et al., 2017),

$$q = L \cdot r \cdot \rho \tag{11}$$

where, ρ = 890 $\mathrm{kgm^{-3}}$ is ice density, taken constant, r is the ice accretion rate in $\mathrm{ms^{-1}}$, and the

$L = 2.3 \times 10^5$ Jkg^{-1} is the latent heat of freezing for saline-water ice (Samuelsen et al., 2017).

3.4 *Anti-icing expected heat loss for a given vessel trajectory*

Assume that the vessel departs from the origin A at time t_0. The vessel sails segment S_i with constant speed of V_i. By using the length of each segment and time of departure from origin, the time at which the vessel is sailing along segment S_i can be calculated accordingly.

By assuming that the vessel is exposed to the same level of icing continuously for the period it sails segment S_i, the amount of heat loss for segment S_i can be calculated by:

$$e_i = o_i \cdot q_i \cdot \frac{d_i}{V_i} \tag{12}$$

with $o_i = 1$ if icing event occurs, and 0 otherwise. By repeating the presented procedure for a sufficiently large number of times, an empirical CDF of e_i, $E_i \sim F_{E_i}(e)$, can be determined.

The amount of heat loss for the whole trajectory $\overline{AB}$, thus, will be given by:

$$e_{\overline{AB}} = \sum_{i=1}^{N} e_i \tag{13}$$

Mean, median, standard deviation, and quantiles of heat loss due to anti-icing can be extracted from empirical distribution of $e_{\overline{AB}}$ to represent the associate uncertainties with the occurrence and rate of icing events along the given trajectory. Another application of presented framework is identification of the most critical segment of the trajectory, from safety or heat loss viewpoint.

4 ILLUSTRATIVE CASE STUDY

Consider an operational site in the northern Barents Sea, 75.40N and 24.46E degrees, and Hammerfest 70.66N and 23.68E degrees; points B and A in Figure 3. A vessel leaves Hammerfest at 00:00 01.01.2018 towards location B. The aim is to simulate the occurrence of possible icing events along this trajectory and, in addition, simulate the expected heat loss associated with implementation of anti-icing measures.

4.1 *Data*

As discussed in Section 2, the MINCOG model is used in this study to model the sea-spray icing rate. As suggested by Samuelsen et al. (2017), median values of vessel speed $V = 4$ ms^{-1}, water temperature 2.5°C, and water salinity 35 ppt are chosen as

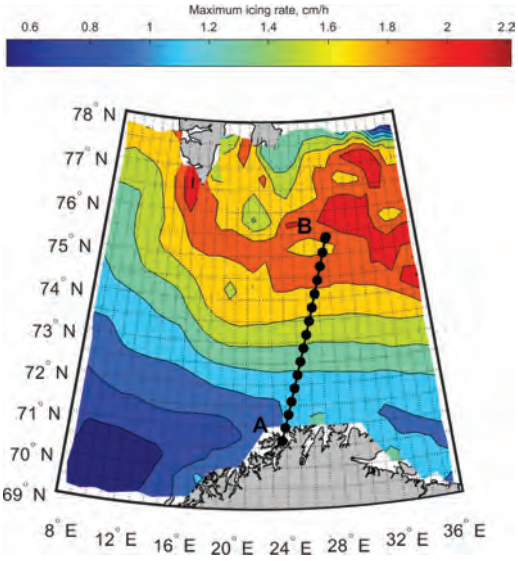

Figure 3. Maximum icing rate over the Barents Sea in January during 1980 to 2012. The solid black line shows the rhumb line of vessel trajectory $\overline{AB}$, decomposed into some segments showed by dark circles.

fixed input parameters. The main six input parameters including wind speed, air temperature, relative humidity, mean-sea level pressure, significant wave height, and significant wave period, are all derived from NORA10, obtained every 3 hours from 01.01.1980 00:00:00 to 31.12.2012 21:00:00.

4.2 *Analysis, results, and discussion*

The occurrence of icing events and their rates are subject to temporal and spatial variations over the Barents Sea due to changes in meteorological and oceanographic conditions. Figure 3 shows the maximum icing rate occurred in January during the period 1980 to 2012. As illustrated, the icing rate in the region is highest in the northeastern part. As shown, the maximum icing rate in January over the selected trajectory is also subject to considerable variations due to temporal and spatial changes in meteorological and oceanographic parameters.

Icing rate is lowest in the southwest due to higher air temperatures. This is only partly a result of the relatively high sea-surface temperature associated with the North Atlantic Current. However, the main reason is that these areas are located some distance away from the cold lands or sea ice, leading to the fact that the air has time to be sufficiently heated from below to avoid the high icing rates apparent in the other areas due to strong vertical mixing in weather situations in which icing occurs (Samuelsen and Graversen, 2017).

The icing rate is highest in the north and north-east due to lower air temperatures associated with strong winds and high waves that may arise during cold-air outbreaks from the ice. Since the ice edge normally is located just north of these areas exposed to severe icing, the air does not have time to be sufficiently heated from below in these areas to avoid severe icing. Sea-surface temperature alone does not have a large effect on icing (Samuelsen, 2017a). An interesting finding in Figure 3 is the maximum values obtained outside some of the fjords near the coast of Northern Norway. Such maximum values are associated with strong and cold gap winds out some of the large fjords generated in mountain wave situations during offshore flow from the Scandinavian archipelago described by Samuelsen and Graversen (2017). If using hindcast reanalysis data for atmosphere and ocean variables with higher spatial resolution than 10 km between the grid points, most likely this effect would have been more apparent. Thus, the maximum icing rates in these sea areas are probably underestimated.

In order to discuss the expected icing rate and heat loss over trajectory $\overline{AB}$, one needs to decompose it into different segments. The heading and length of trajectory $\overline{AB}$ is obtained using Equations (5) and (4), respectively, $\omega = 2.732$ degrees and $D = 653$ km. Thus, total sailing time of a vessel with speed of $V = 4$ ms^{-1} will be 45.35 h. Since the model input data are available every 3 hours, we divide the trajectory into equal intervals of d_i = 43.2 km, $i = 1,$,15, and d_{16} = 5 km (i.e., N = 16), and assume that the meteorological and oceanographic conditions remain constant during this time interval and along the segment. Coordinates of the vertices and midpoint of each segment are then computed using Equations (8) and (9). According to the vessel speed, one can determine at what time the vessel enters each segment and continues sailing towards destination.

MINCOG input data corresponding to each midpoint location, if existed, and the nearest location otherwise, are extracted from NORA10 database. Over the period 1980 to 2012, in total, 33 sets of input data are extracted corresponding to each coordinate and arrival time. Later, their corresponding icing rate is computed using MINCOG model. Figure 4 shows the frequency of the occurrence of an icing event, in per cent, at given locations and arrival times. These results are obtained based on the reanalysis hindcast data over the period 1980 to 2012 corresponding to certain arrival times at those specific locations. We assume that the probability of the occurrence of icing event, i.e., $\Pr(O = 1)$, in future is equal to its frequency, in per cent, over the past years, although this approach suggests that, for example

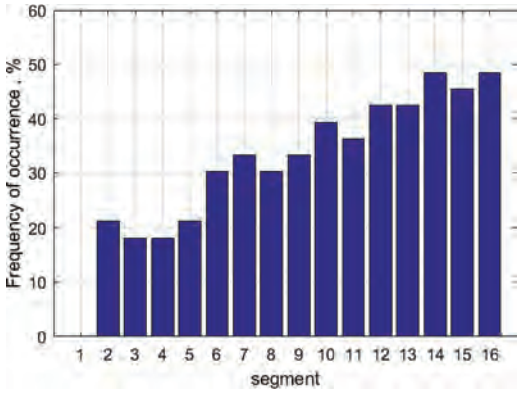

Figure 4. Frequency (probability of icing) in each segment at certain arrival times.

in segments S_{12} to S_{16} icing event occurs with certainty for specific arrival times to those segments. Thus, for instance, for segment S_2, the Bernoulli distribution of the occurrence of icing event can be given by,

$$O_2 \sim F_{O_2}(o) = \begin{cases} 1 - 0.2121 & \text{for } O = 0 \\ 1 & \text{for } O = 1 \end{cases}$$

Not that the overall trend of increasing icing rate in Figure 3, is also verified by the frequency of icing occurrence that increases from location *A* towards location *B*.

Empirical distributions of icing rates in each segment at given times, $F_R(r)$, is obtained by considering the occasions where $r \geq 0.05$ cmh^{-1} (Samuelsen et al., 2017). The modified box-plots in Figure 5 show the minimum, the 5th quantile, median, the 95th quantile, and maximum of icing rates in each segment. Segment S_1 is disregarded due to lack of weather data in its nearby locations.

The amount of heat loss for each segment is then calculated using Equations (11) and (12). For this purpose, a non-sequential Monte Carlo simulation is used, wherein, for each section, a realisation of icing event is sampled to simulate whether the icing event occurs.

Once an icing event occurs, another stochastic process is simulated and a random icing rate is sampled form the corresponding icing rate distributions, using which the required amount of energy for anti-icing applications is computed accordingly. This procedure is repeated for a sufficiently large number of times to obtain the statistics of the energy consumption for each segment, as the median, the 5th upper quantile and maximum values are presented in Table 1.

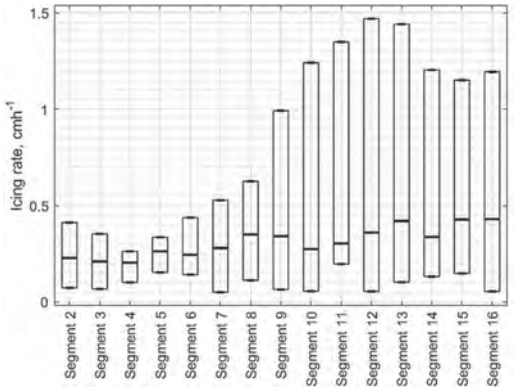

Figure 5. Box-plots showing the minimum, lower 5th quantile, median, upper 5th quantile and maximum values of icing rates for each segment at arrival times.

Table 1. Maximum, mean, and the 95th quantile of anti-icing energy consumption per area for each segment.

Segment, S_i	Energy consumption for each segment, e_i, MJm^{-2}		
	Maximum	Mean	95th Quantile
2	1.7283	0.2221	1.4708
3	1.6353	0.1745	1.3452
4	1.5429	0.1897	1.4747
5	1.7001	0.2966	1.6411
6	2.2691	0.4373	2.2318
7	2.0671	0.5098	2.8852
8	3.7993	0.6128	3.1980
9	4.0705	0.6325	3.0958
10	4.1505	0.6671	3.0741
11	4.0949	0.7177	2.9959
12	3.7782	0.7983	3.2998
13	4.0377	0.8963	4.0040
14	5.2738	1.0631	4.4079
15	5.0115	1.0447	4.0969
16	0.5971	0.1276	0.5574

Finally Equation (13) is employed to compute the overall expected energy consumption for all segments, i.e., trajectory AB, whose CDF is shown in Figure 6. Mean, median, the 5th upper quantile and maximum amount of energy consumption along trajectory AB are 8.40, 8.13, 15.00 and 29.24 MJm^{-2}, respectively. Depending on the decision-maker's risk perception approach and required safety guidelines, one may choose either maximum or some other statistics like the 95th quantile of expected energy consumption.

The maximum amount of icing rate and thus energy consumption, can be computed by adding up the required energy associated with maximum

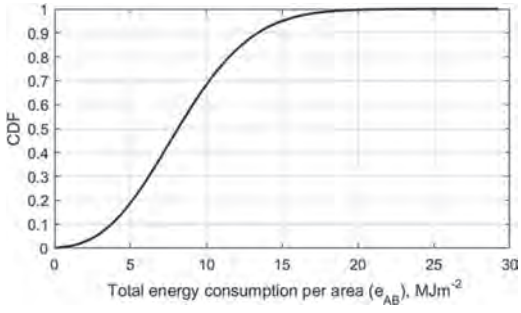

Figure 6. CDF of total expected energy consumption for anti-icing along trajectory AB.

icing rates computed using the data available for previous years. However, from a probabilistic viewpoint, the probability of having such a scenario is extremely low. Alternatively, a Monte Carlo simulation can be used to sample a sufficiently large collection of scenarios for icing events along the trajectory, based on which maximum amount of energy consumption for anti-icing is computed as around 29.24 MJm^{-2}.

5 CONCLUSIONS

In this study, a sea-spray icing rate prediction model, known as MINCOG, is employed to estimate the rates of icing events using reanalysis hindcast data. Such estimates are used to represent icing events and their rates probabilistically. Based on this procedure, a mathematical framework is proposed to simulate the icing events and their associated rates along a sea voyage through two stochastic processes. It further estimates expected energy consumption required to avoid icing on vessels. The results of this paper, illustrated by a case study, can be used in long-term decisions to be made in Arctic offshore logistics operations, such as scheduling and routing platform supply vessels, while reducing icing risks, operational costs, fuel consumption and CO2 emission. Future research on this area can be revolved around improving the simulation process of meteorological and oceanographic parameters, and thus icing events, by taking into account the effects of short-term patterns present in such parameters.

ABSTRACT: One of the design measures adopted for the risk reduction of machinery is the de-energization of all the components of the machine for assuring a "safe stop state". So, for gravity loaded axes, the risk of unintended gravity descent in the de-energized state has to be considered in the risk assessment. In case of power failure, the gravity loaded axes are held solely by the brake/counterweight systems, which are installed in the machine. The gravity loaded axes may drop down, if the existing brakes/counterweights do not provide adequate protection against unintended descent due to gravity.

In the paper first, a full analysis for this underestimated risk of today's very complex machines is presented. Than a description of the problem is illustrated and the resulting requirements are presented in terms of: design measures, information to be given to the end user and testing procedures to be assured for the new machines.

1 INTRODUCTION

While it can be assumed that during horizontal movements in the automatic production no hazards to persons occur due to gravity in the de-energized state, for vertical movements. However, the risks of unintended gravity descent have to be considered in the risk assessment, see DGUV (2012). These hazards particularly become obvious with linear robots for the handling of heavy parts (Fig. 1), but also with jointed-arm robots or inside machines, e.g. at vertical axes of any machine tools. If the existing brakes/counterbalancing systems do not provide sufficient protection against unintended gravity descent, control measures can contribute to reduce the risk of hazard in any case.

So, when the machine systems are in an energized state in any mode of operation, it can be usually assumed that the risk assessment performed by the machine builder assures a proper safety of the machine itself.

The aim of this article is to give a guide to machine builders for design of "state of the art" Gravity Load Axes (GLA) for machine tools. The risk assessment and the design solutions presented were mainly discussed during ISO standardization works of ISO 16090-1 (2017), but the results are of general applicability for all the types of machine tools.

The typical iterative three step method used for risk reduction, see ISO 12100 (2010) assures, in conjunction with the hypothesis of full disposal

Figure 1. Robot arm used for handling of heavy parts, from DGUV (2012).

of machine energy, the proper reduction of risk of uncontrolled descend of all the gravity loaded axes.

In case of power failure or energy removal (for example during maintenance), gravity loaded axes (weight-loaded, vertical, slant axes) are held solely by their brake/counterbalancing system installed in the machine.

The gravity loaded axes could descent in case of failure of the retention system and, usually, also the control/warning system, could be off-line due to the complete de-energization of the machine.

As is simple to understand, the risk reduction for this potentially unsafe condition cannot be satisfied also though some of the typical step two risk reduction means: "other protective measures", because they are also usually ineffective (e.g. light barriers, emergency stop buttons.…).

As an example, for vertical axes with braking systems the mechanical wear or oil-fouling may cause the braking torque/force of the brakes to fall below its nominal value which may result in an unintended descend of the gravity loaded axes.

In de-energized state the risk reduction cannot be achieved by machine builder through safety functions: only inherently safety design measures, physical guards, and information for the user are available. It is to say that, for the risk reduction of this potentially unsafe "state", the end user behaviour is essential during the utilization of the machine: correct procedures of maintenance and frequent inspections are essential for reduce probability, severity and occurrence of the risk of descend of GLA in de-energized state.

In the following paragraphs first, the risk analysis performed for safety standardization will be presented. Than the "state of the art" and future coming technical possible solution needs for risk reduction will be shown, using also an easy to be read table format.

This table format was preferred by the authors also during ISO standardization works to assure excellent clarity/effectiveness/brevity necessary to be understood to machine builder design departments.

Depending on the technical application and the risk to be reduced, different technical safety devices are suitable to prevent the unintended gravity descent of gravity-loaded axes.

Safety functions related to gravity loaded or slant axis will be also presented and discussed. At the end some examples of already in the marked design solutions will be presented for clarity. The presented design measures will be introduced in annexes of safety standards for machine tools such as the ISO 16090-1 (2017). This latter new ISO standard was published in December 2017.

2 RISK ANALYSIS FOR GLA

For the risk assessment the tables in new annex G of the ISO 16090-1 (2017) shall be used. The annex will help the designer to find the "perfect solution" for the necessary risk reduction. The tables cover the foreseeable operation of the machines as well as maintenance, cleaning and repair of the machines.

The risk for the GLA hazard started from precondition of machine design, i.e. the different safety condition of operators between all operational mode and maintenance. For more information see the table G.1 and G.2 on annex G of ISO 16090-1 (2017).

During maintenance no energy supply is present, so Numerical Control (NC) and Safety Function (SF) are not generally available. The safety of the workers it is accomplished during maintenance through inherent safe measures, such as mechanical support (e.g. using struts) of the axes loaded by gravity or equivalent measures.

Sometimes a direct safe support of the GLA is not the best technical solution because, as an example, it might not be possible, due to space limitation, to have adequate space left for the worker in the maintenance zone with the supported axis. In this case the mechanical locking of a different component directly connected to the GLA must be assured.

It is possible that:

- an appropriate mechanical support equipment (i.e. a strut) shall be designed and provided by the manufacturer of the machine, or
- a proper locking system (position) shall be designed and provided by the manufacture or
- at least, if no "special equipment/locking system is provided by the manufacturer, information on how to provide a proper support shall be given (see Table G.2 situation G1.3 and G1.4).

For all others operative modes, it was assumed that the most critical situation for hazard is full body access in the work area under a GLA (see G1.1).

Using as an example ISO/TR 14121-2 (2012) for risk assessment the authors stated that if only the upper limb stays under the GLA of the machine (G1.2) no serious (S2) injury is expected for the worker. Even if sometime the hypothetical severity is S2 than the velocity of the GL descending axis is not high, and the worker have not to fully move the body to escape to the risk. So, it is possible to avoid/reduce the harm and use A1 for possibility of avoidance/reduce the harm for risk the risk graph, see again Figure 3 of ISO/TR 14121-2 (2012).

Moreover, even if for some machines the hypothetical severity can be higher (S2), the necessity for cycling testing of "single channel/unsafe systems", such as a single brake (design V1 of Table G.1.), leads always to low occurrence of the hazardous situation (O1).

The hazard become a real risk only if:

- the machine goes in de-energized state and
- the worker is currently under the GLA and
- there is a not already evident failure on braking system, so we are between two cyclic tests. As one can see in table G.3. if the workpiece is manually loaded (i.e. frequent exposure to the risk without possibility to avoid it) the cycle testing time is 8h, otherwise for automatic loading of workpiece, so short presence, testing time is 48h.

It should be mentioned that, for correctly maintained/tested systems, usually the typical failure of braking of GLA are due, as an example, to wear and/or leakage (respectively for mechanical and/or pneumatic systems). So, no free falling of the GLA is expected.

At the end of this paragraph authors wants to emphasize that: a correct utilization/maintenance of the machine is a crucial point for safety of the workers for GLA risk. The defeating of the safety systems by the user is very dangerous for those systems.

2.1 *Safety functions for GLA*

It ought to be said clearly that it is not possible to design any SF for GLA in de-energized state of the machine, which is the main hazardous situation in operational field. As mentioned before, when the energy is lacking from the system only inherent safe measures shall be used if required.

When the machine is in de-energized state (often called the weak state) or by disturbance of the energy supply, only the mechanical braking system can work properly (e.g. brake, clamping etc.).

The faultless function of this mechanical braking system has to be checked in periodical distances (cyclic testing). However, this diagnosis function has no real SF according ISO 13849-1 (2008) but guarantees the faultless function for the weak state.

So, all the SF covering the hazard of GLA are designed in energized state of the machine. The matching safety functions (SF) are defined in the annex J, Table J.3 of ISO/FDIS 16090-1. For information on this annex see Bornemann A. & al. (2015a, 2015b).

As an example a "safe" stop function for a GLA, when only the upper limbs are under the GLA, can be accomplished in performance level c (PL_r = c, see ISO 13849-1 (2008)) with, at least, two different designs: the system is brought to a standstill, for example by the opening of an interlocked guard and is then held in position by a de-energized clamping or by an integrated SF category 2 stopping with a monitored SOS (see IEC 62061:2005 + A1 (2012)).

For more examples such as the prevention of unexpected start-up see Table J.3 of ISO 16090-1 (2017).

3 DESIGN OF BRAKING SYSTEM

The authors considered a lot of different braking systems for GLA, see the different design solutions in Table G.1. column 1, from V1 to V7.

The state of the art for machining centres is:

- single or redundant systems based on pure mechanical brakes. The redundant brake can be internal to the electrical motor or external to it. The internal redundant brake can be used for axis movements if no additional risks is foreseen. As an example, a fault of the electrical motor shaft due to fatigue. The mechanical parts of power transmission shall be at least designed with double weight load to withstand the occurring static and dynamic stresses. Moreover, if the same shaft is used for redundant internal brake the situation of full braking with only the redundant system (the added one) have to be taken into account for mechanical strength calculation, if a longer shaft is expected in this case (resulting in a greater torsional deflection). In order to prevent unnecessary wear of the

brakes, it is preferable to decelerate with the electrical drive controller instead of stopping with mechanical brakes.

- "hybrid systems" based on mechanical brakes in conjunction with counterweights. In this case the authors stated a difference between pure mechanical counterweights, usually designed by proper balancing masses connected to the GLA, and hydraulic/pneumatic counterbalancing systems. The reliability of pure mechanical counterweight is based on static/fatigue calculation of mechanical components, whose failure analysis is quite simple to be taken into account. There is a lot of literature for "usable safety". Safety coefficients, can be derived, as an example, from the design/safety of mechanical lifting systems. Conversely in pneumatic/hydraulic counterweight systems more non-return valves and other components were introduced in the field of "safety" system recently. Also "failure and effect methods" such as FMEA, see Stamatis, D.H, (2003), for those components is more complex with respect of simple balancing masses systems. So, it was decided that, if the manufacturer cannot explicitly justify the fault exclusion for hydraulic/pneumatic system (V6 of Table G.1), a hydraulic counterweight cannot be used when the worker whole body can be exposed to the hazard. An example of a proper hydraulic counterweight system for GLA where fault exclusion can be managed properly will be presented in paragraph 5 below;
- redundant system with one brake and one external clamping device (see V7 of Table G.1.). In this case the external clamping system is designed completely separate from the motor braking system. If a dangerous fault exclusion can be assessed from the designer the cyclic test can be avoided. It needs to be mentioned that, for external clamping, the cleanliness of every part of the clamping device is a key factor for a proper braking in a coolant environment of machine tools. In this case the cleanliness instruction should be properly defined in the instruction manual.

As one can see the V1 design is not suitable if whole body access is foreseen (situation G1.2). Due to simple tabular format it is not explained that this is not suitable due to frequent access during automatic mode because of frequent full body access without other measures possible.

For repair and maintenance additional measures are necessary, e.g., underpinning, mechanical locking, hanging as we will see in the next paragraph.

4 ADDITIONAL DESIGN MEASURES

As all safety engineers know that the inherent safe measures (see step 1 of risk reduction process of ISO 12100) usually are not sufficient to reduce the risk to a tolerable level. So other additional measures have to be assigned during the subsequent step 2 of risk reduction process.

Depending from the design of the braking system additional measures have to be selected. In Table G.2, the additional measures are described depending from the same situation (Gx.x) of the Table G.1.

The authors defined those measures using some guiding factors such as: minimize the gravity stored energy, maximize the stability of the system especially during maintenance. At least, information and measures for preventing the misuse during manual intervention on the system have to be provided by the machine manufacturer.

The locking of the GLA with a mechanical lock during maintenance is not only assuring that no intentional restart of the system is done, but also is a "guide" for the end user to stop the axis in the correct position (i.e. the correct maintenance location chosen by the designer of the machine).

It should not be forgotten at this point that parking the axis in the "lowest position" is the safest measure at all, because the axis cannot fall under this position.

Finally, according to step 2 of the risk reduction process, one or several warning signs shall be visibly fixed at the machine pointing out to hazards due to GLA and suspended loads. As an example, "Do not stay underneath the vertical axis!".

The same should be reported in the instruction manual giving also advice for safe working practices.

4.1 *Instruction for use, key role of the end user*

As all the national assurance of the workers reports shows, see as an example INAIL (2015), a lot of injuries are caused by workers defeating and/or misuse of the machine.

In the particular case of hazards related to GLA the user has a key role to maintain the safety of the system over the time. If the correct maintenance of the system is not performed also the safer redundant braking systems can by ineffective, especially for problem related to clean and wear. Also, small fluid leaks of hydraulic circuits that are not removed can cause an ineffective braking torque (force) of the system.

So, the machine manufacturer has to define, how normal operation, repair, cleaning shall be carried out safely by the machine user. It has to be remembered that maintenance, cleaning and repair works

are carried out at or next to the gravity-loaded axis. Usually a safe mechanical support of the gravity-loaded axis is easily feasible and consequently it has to be done for the sake of safety.

Operating instructions shall describe measures to protect the operator from a fall-down of GLA. These instructions shall also point out to hazards due to gravity-loaded axes and suspended loads. Also, the required skill level of the operators needs to be considered. If the brake is removed for maintenance, a support or a manual mechanical lock shall be used also in the designed system where fault exclusion can be done (see V3-V6-V7 in Table G.1).

For extensive additional measures required for the different operative/inoperative modes, see Table G.2.

4.2 *Cyclic testing and testing of torque/force*

The need of this diagnosis function is considered in the column "Requirement for cyclic test", see Table G.1. The maximum tolerable time span between tests depends mainly on frequency of exposure to the GLA risk for the worker, see Table G.3.

As mentioned before it is very important to understand that cyclic testing is not a SF itself and that it can be done with NC. The cyclic testing is always performed in safety condition (e.g. with machine doors closed). Cyclic testing is performed for the brake system, when fault exclusion cannot be done, at a predefined time span.

The test has to be able to measure the braking performance of the system over the time: a test torque/force is applied to the brake, e.g. motor brake or the clamping device.

Because the test condition of the ISO 13849-1 (2015) is not applicable for cat. 2 systems of braking test (i.e. mainly because we cannot test the brake 100 times before it is used again), a proper specification is defined in ISO/FDIS 16090-1 (2017). A sudden complete failure of a brake with the force actuated by a spring can be excluded because of the basic principles of the mechanical brake design of ISO 13849-2 (2012).

For torque/force testing the following requirements apply:

- 1 motor/1 brake (or clamping device) systems. The brake or the clamping device is charged with 1,3 times the maximum gravitational load for at least 1 s by the electric drive. If also a permanently present counterweight system is installed, the braking device is charged with 1,3 times the maximum gravitational weight minus the counterbalanced weight.
- 1 motor/2 brakes (or clamping device) systems. The braking devices are tested separately one after the other on 1,0 times the maximum gravitational load.
- 2 motors/2 brakes (or clamping device) system mechanically connected. The braking devices are tested together on 2,0 times the maximum gravitational load or one after the other on 1,0 times the maximum gravitational load.

All the requirements for brake test are defined in annex G of ISO 16090-1 v(2017), it is important to note that, again, the safety of the worker during the test is mainly defined by the GLA position:

- *before the test,* the GLA must be placed in a proper position where no hazard for the worker is foreseen, even if the test is failed,
- *during the test,* no additional hazard should arise from the failure of the test. As an example, the designer should take care of possible tools/parts breaking for undesired falling of the GLA during the test with sharp object contours,
- *after the test,* the machine must be placed in a safe state before any worker can enter inside the machine and further operation of the machine shall only be possible after a new successful cyclic test.

In case a fault detection occurs during the cyclic test the NC shall inform on the screen for a brake repair. In case of guards with closed and protective doors, a safe position shall not be approached until an unlock demand signal has been given. Again, further operation of the machine shall only be possible after a new successful cyclic test.

5 EXAMPLES OF EXISTING SYSTEMS

In this paragraph some design examples for GLA braking system are presented.

5.1 *Example of a single brake system—with or without fault exclusion*

In Figure 2 the typical V1 system of Table G.1 is presented. This system can be used only if the whole-body exposure to the GLA is not feasible during operative phases. Usually during setting, repairing works and so on, sometimes a staying for short time under the gravity loaded axis is necessary. Then a single brake with cyclic test is also a suitable design measure. It is to be remembered that during setting, as an example, usually additional measures have to be taken, such as, an operator pendant and/or reduced axis speed (leads also to shorter braking distance). Due to those latter additional measures a greater probability of avoidance of the accident is expected.

In Figure 3 the typical V2 system of Table G.1 is presented. A redundant brake system is safer with

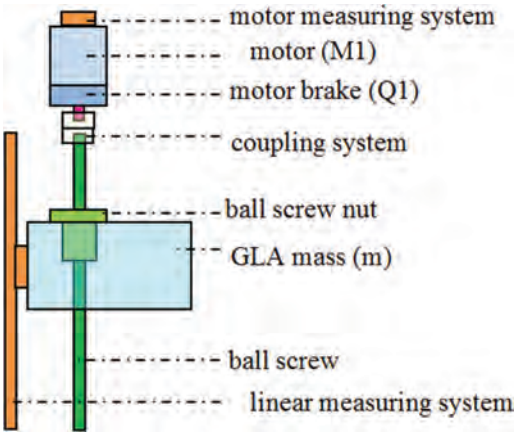

Figure 2. Single brake system without fault exclusion (V1).

respect to V1, even if no fault exclusion is made as in the redundant system V2. As one can see, all the parts of the braking system are redundant in this figure also the clamping stick attached to the fixed part of the machine. This is so, because all the possibilities of failures of braking cannot simply be excluded (as an example due to leaking of coolants lowering coefficient of friction).

It is very important that the risk assessment needs to be done for the V3 design under the condition of fault exclusion e.g. ISO 13849-2 (2010). However, if a single fault to a component cannot be excluded than a partial redundancy of the system is necessary.

5.2 *Redundant brakes system*

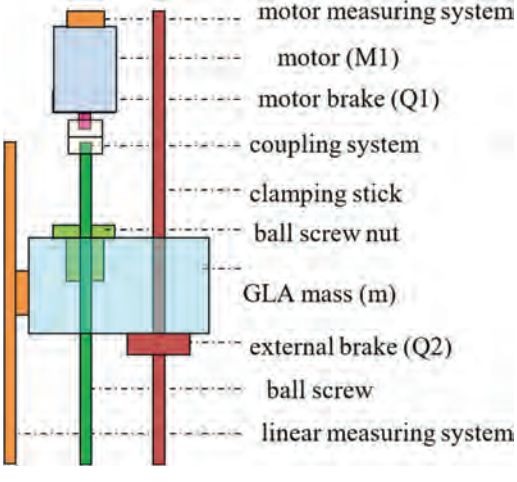

Figure 3. Redundant brake system without fault exclusion (V2).

5.3 *Counterweight systems*

As mentioned above a counterweight system is often used in machine GLA tools technology also to improve the dynamic capabilities of heavier axes. A GLA counterbalancing with a proper system results in small unbalanced masses to be moved. So, smaller motors can be used for axis movement and/or greater accelerations is foreseen with respect to the same GLA without counterbalancing system.

In Figure 4 a typical single counterweight system with external clamping is presented as an example of system V5.

Looking again to Table G.1. from V4 to V6 some simple conclusions can be derived:

- if it is not possible to prevent the staying of the full body of the worker under the GLA, it is not possible to use simple hydraulic/pneumatic system without fault exclusion, even if cyclic testing is performed,
- a mechanical counterweight without fault exclusion can be used in conjunction with a braking motor, but, in this case, a cyclic test is required. Basic and well-tried safety principles in the mechanics have to be used. Also, classical safety factors in the interpretation of the mechanic components, e.g., cable (rope), clamping device, bearing system have to be done. There is not safety control system for the counterweight that is required to be assembled only by mechanical parts. In this case the full system has 2 different and huge inertias to be supported, the system inertia and the counterbalancing inertia. The

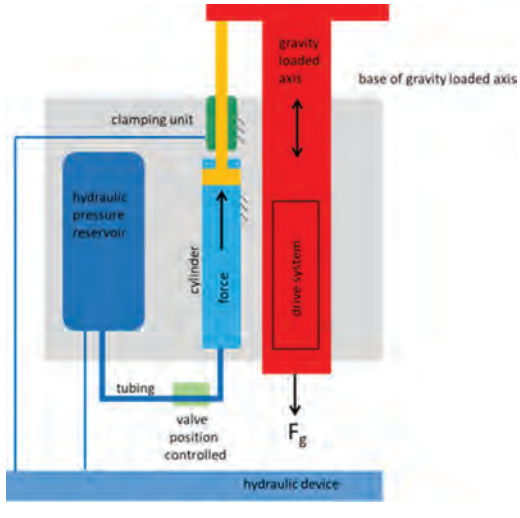

Figure 4. Single counterweight system based on hydraulic/pneumatic (V5).

validation has to be done, as usual, according to ISO 13849-2 (2012), annex "A" for mechanical systems.

For hydraulic counterweight systems the most important aspect to be considered is the requirement of fault exclusion for the non-return valves of the counterbalancing system.

Because it is considered possible a pressure leakage due to different events (breaking on a pipe, leakage of a valve, …), the piston(s) shall be sufficiently protected from non-closure of non-return valves.

Typical design measures to avoid dangerous failures (or dangerous interference on correct operational behaviour of the system) are:

- devices for fluid temperature monitoring (if hydraulic),
- device for pressure monitoring,
- devices for fluid pollution monitoring (filters up to 1 micron), because complete valves closure can be prevented by pollution particles dispersed in the fluids. For the faults related to problems of valves aging, see Schuster, U., (2004).

In Figure 5, a fully redundant counterweight system, with also redundant clamping unit, is shown.

If correctly designed this system could be appropriate for V6.

It has to be said that, during operative phases, the drive systems and the correct pressure of the fluid, assures GLA movements with counterbalancing. For safety aspects, the load capacity of the system with closed non-return valves is the crucial argument: during de-energization the balancing force is not acted through hydraulic system, but directly in the pressurized pistons by closed valves.

Depending on the applied principle for fault exclusion some of the double component of the system in Figure 5 can be avoided, such as the double reservoir.

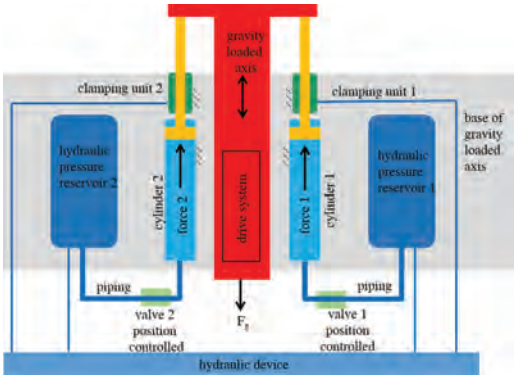

Figure 5. Fully redundant counterweight system based on hydraulic/pneumatic (V6).

As examples, the counterbalancing system with fault exclusion to non-return valves can be:

- a single piston, system capable to support with the non-return valves closed (with no motion/limited motion at low speed) the 1,3-full weight of the GLA. In this case, even if the motor or external clamping has a fault, the hydraulic system can stop the descending axis during the de-energized state. The valves closure shall be double monitored with cross monitoring. Moreover, it must be possible to make a fault exclusion to all relevant mechanic/hydraulic components of the system safety related (see below). Even if theoretically possible at the current state of the art a complete fault exclusion for this system is still difficult to be done.
- a redundant piston/brake system, each of them capable to support with the non-return valves closed (with no motion/limited motion at low speed) 1,3 the full weight of the GLA. Each valve closure shall be monitored with safety functions in $PL_r = c$.

In relation to non-returning valves, a fault exclusion of the mechanical spring of the valve shall be done by the valve manufacturer (the spring can be considered a well-tried component also for hydraulic, see Table B.6 of ISO 13849-2 (2012)).

For the validation of hydraulic system, e.g., failure exclusions for pipes related with safety according to ISO 13849-2:2012 Table "C.7" and failure exclusions for hydraulic connecting elements of Table "C.9" are necessarily in any case. Safety valves shall be firmly connected with the cylinders in order to avoid safety problems with connection pipes.

6 CONCLUSIONS

The risk analysis and the design measures presented in this article were initially developed as a part of the standardization works of ISO/TC 39/SC 10/WG4, "Safety of machining centres, milling machines, transfer machines for cold metal materials". The authors have been involved in this standard and they think that this risk assessment can be adopted also for other types of machine tools.

Because of its innovative subject for standardization purpose, the DGUV (2012) document has been taken as a basis for the discussion. This document needed to be clarified by the authors also with examples foreseeing the publication of a normative annex on GLA of a new standard. The authors believe that the risk analysis and technical

solutions presented in the paper provide an objective view of the state of the art and design solutions that can be used to effectively reduce the risk due to GLA.

The authors encourage the drafting of similar regulatory annexes for the C-type standards of forthcoming publication in the field of machine tools safety.

Risk significance assessment with operational events of Korea nuclear power plants

Seunghwan Kim, Sun Yeong Choi, Sang Hoon Han & Jaewhan Kim
Korea Atomic Energy Research Institute, Daejeon, South Korea

ABSTRACT: A handbook was published to document methods and guidance that NRC staff should use to achieve more consistent results when performing risk assessments of operational events by the U.S. NRC. Korea Atomic Energy Research Institute (KAERI) launched a research project to develop a regulatory purpose Level 1 PSA (Probabilistic Safety Assessment) model and framework for use in risk-informed regulation. To this end, we designed a regulatory risk model reflected regulatory purposes based on the real conditions and developed a regulatory software called RYAN (Risk Analysis for ASP/SDP of NPP) that enables the regulatory body to perform the overall safety assessment such as ASP/SDP (Accident Sequence Precursor/Significance Determination Process). In order to verify and validate the RYAN software, we investigated operational events occurred in domestic NPPs from databases such as OPIS (Operational Performance Information System for Nuclear Power Plant) and KRDB (Korean Integrated Reliability Database). From those nuclear event databases, we selected some component failures and IEs for the software verification and validation. We performed a sensitivity analysis for the various cases with the selected operational events. Based on the framework, it is expected that the regulatory staff can identify a nuclear power plant or SSC (Structure, System, and Component) for which safety performance has been decreased. For a further study, we are confirming the applicability of RYAN by performing a sensitivity analysis with more event data. In addition, we are to analyze the significance of each case with the AIMS-PSA to compare the results from RYAN and AIMS-PSA for ensuring the accuracy of the analysis results with RYAN.

1 INTRODUCTION

US.NRC provides the Risk Assessment of Operational Events Handbook (RASP Handbook) to assist NRC staff to achieve more consistent results when performing risk assessments of operational events and licensee performance issues. The methods and processes described in the RASP handbook can be primarily applied to risk assessments for Phase 3 of the SDP (Significance Determination Process), the ASP Program, and event assessments under the NRC's Incident Investigation Program. For example, Figure 1 depicts the criteria to determine the level of safety significance to characterize the safety significance of inspection findings for the NRC ROP by assigning a color to the inspection findings (U.S.NRC 2013).

Korea Atomic Energy Research Institute (KAERI) launched a research project to develop a regulatory purpose Level 1 PSA (Probabilistic Safety Assessment) model and framework for use in risk-informed regulation (J. Kim et al, 2017). The purpose of this research is to estimate the risk significance of initiating events and degraded conditions occurred in domestic NPPs (Nuclear Power Plants) and characterize the significance of an inspection finding consistent with regulatory response thresholds such as SDP (Significance Determination Process) of the US NRC.

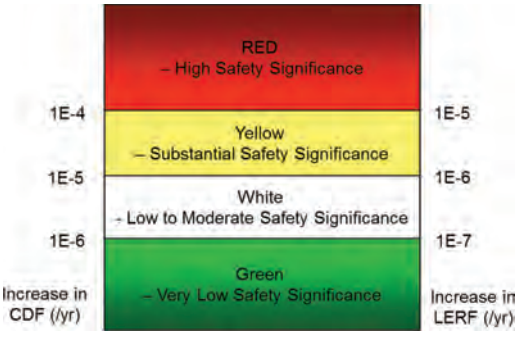

Figure 1. Criteria to determine the level of safety significance.

2 DEVELOPMENT OF A REGULATORY RISK ASSESSMENT ALGORITHM

As this research aims to estimate the risk significance and to characterize the significance of an

inspection finding consistent with regulatory response thresholds, it is essential to develop a regulatory risk assessment logic to satisfy the requirements of risk estimation for regulatory purpose.

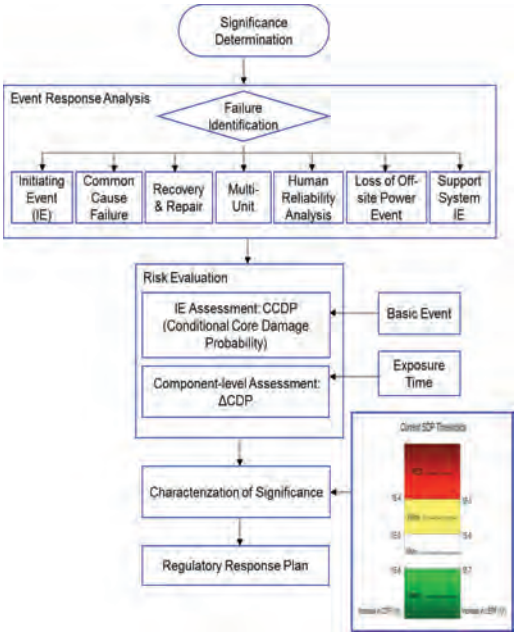

Figure 2. Schematic diagram of algorithm for regulatory risk assessment.

Figure 2 represents the schematic diagram of the algorithm for regulatory risk assessment. The analysis of the risk significance consists of the following procedures. First, the type of failure is determined by performing failure identification.

The types of failures include 'Initiating Event', 'Common Cause Failure', 'Recovery and Repair', and 'Human Reliability Analysis'. For example, the failure caused by one of initiating event or component failure. After the failure analysis is completed, a risk analysis is performed in which the associated failure calculates the Conditional Core Damage Probability (CCDP) for the initial event or evaluates the component level in case of failure in the unit of equipment.

At this time, the risk assessment is performed by modifying the basic event probability (BEP) for the initial event and the inoperable (out of service) time when the related component is exposed to the fault. Finally, the risk assessment is performed using the risk assessment results and a regulator response plan is determined.

Figure 3 shows the procedure for evaluating the risk increase due to reactor shutdown and SSC failure: 1) Calculate the delta CDF (Risk increase by Degrade SSC) by performing a PSA model modification to change the BEP and CCF values of the equipment for the SSC degraded condition including the SSC fault or out of service (OOS) due to maintenance. 2) Calculate the delta CDF (Risk increase by Degrade SSC) by performing a

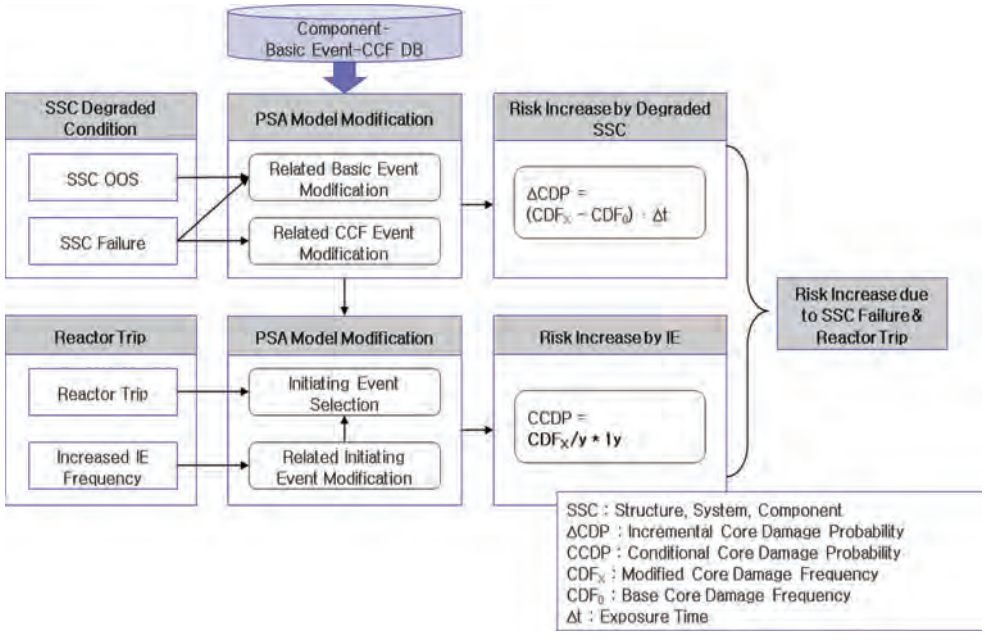

Figure 3. Process of increased risk evaluation due to SSC failure and reactor trip.

Table 1. CCDP calculation for sensitivity analysis.

Case	Calculate CCDP (Conditional Core Damage Probability)
Case 1: IE only	[1] CCDP Calculation – By setting the observed IE to 1.0 and all other IEs to 0.0
Case 2: IE & mutually exclusive SSC Unavailability (SDP only)	[1] CCDP Calculation [2] $\Delta CDP\ [(CDF_x - CDF_0)\Delta t]$ Calculation for the SSC unavailability – By setting the basic event associated with the SSC unavailability to TRUE [3] Total Risk Calculation, $\Delta CDP_{Total} = CCDP + [CDF_x - CDF_0]\Delta t$
Case 3: IE & Mutually Inclusive SSC Unavailability	[1] CCDP Calculation for the combined IE and SSC unavailability – By setting the observed IE to 1.0 and all other IEs to 0.0 – By setting the basic event associated with the SSC unavailability to TRUE [2] ΔCDP Calculation for the SSC unavailability only [3] Choose the highest of the CCDP or ΔCDP result
Case 4: SSC Unavailability Increases the IE frequency (No IE Occurred)	[1] Baseline system failure prob. estimation by solving an applicable FT [2] Calculate the system failure probability factor (or ratio) – By setting the basic event to TRUE – Calculation of system failure probability factor (new value/baseline system failure probability) [3] The modified initiating event frequency calculation – By multiplying system failure probability factor with the baseline IE frequency [4] Calculate ΔCDP for degraded condition

PSA model modification to change the BEP and CCF values of the equipment for the SSC degraded condition including the SSC fault or OOS due to maintenance.

In order to carry out these procedures, the following cases are evaluated. From those nuclear event databases, we selected some component failures and IEs for the software verification and validation. We performed a sensitivity analysis for the four kinds of cases with the selected operational events. Table 1 shows the CCDP calculation method for each case

- Case 1: IE only
- Case 2: IE & mutually exclusive SSC Unavailability (SDP only)
- Case 3: IE & Mutually Inclusive SSC Unavailability
- Case 4: SSC Unavailability Increases the IE frequency (No IE Occurred)

3 SDP ASSESSMENT SOFTWARE (RYAN)

3.1 *Development of RYAN Software*

The SDP importance assessment can be performed using full-scale quantification programs such as AIMS-P. However, the importance evaluation using AIMS-P is possible by PSA experts who have knowledge of PSA model. Therefore, it is necessary to develop software that provides Non-PSA Expert with the ability to roughly estimate the risk increase due to incidents / accidents. To solve this problem, this study developed RYAN, which is a SDP evaluation program for regulatory verification.

RYAN provides a simple sensitivity analysis interface that can easily assess RISK changes to events/accidents resulting from plant shutdowns and equipment failures. In the case of detailed evaluation, PSA Expert can evaluate using AIMS-PSA. By using this, the regulatory body can establish regulatory standards for the change of the risk of the power plant. We called the software for a regulatory PSA model RYAN (Risk Analysis for ASP/SDP of NPP) which is for a significance assessment of incidents/accidents in domestic NPPs (Nuclear Power Plants).

The assessment of the importance of incidents/accidents is based on the evaluation of the increase in risk due to them, and is divided into the following: risk increase by an IE (Initiating Event) assessment and risk increase by a conditional assessment due to damaged SSC. Figure 4 shows the risk assessment concept for RYAN (S. Y. Choi et al, 2017) (S. H. Han, 2017). RYAN is a user-friendly interface tool developed under Windows environment using the PSA model provided by the AIMS-PSA (Advanced Information Management System for PSA) which is a software for integrating various types of PSAs including typical external and shutdown PSAs (S. H. Han, 2016).

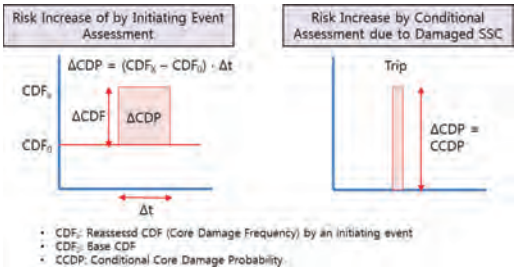

Figure 4. Risk assessment with RYAN.

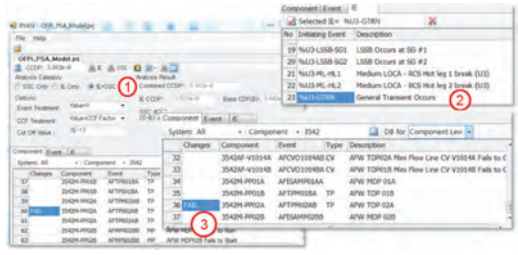

Figure 6. An example of SDP calculation with RYAN.

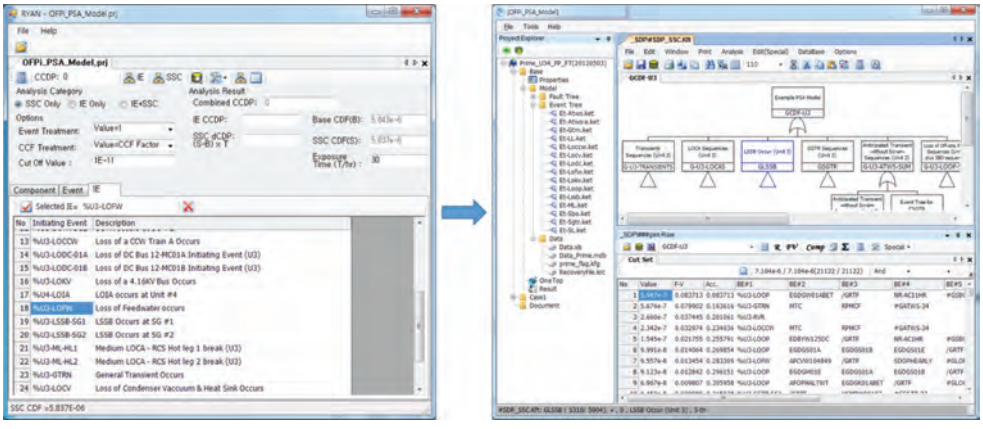

Figure 5. An example of RYAN analysis interface.

Figure 5 shows an example of RYAN analysis interface to quantify risk increase of an accident. To evaluate the increased risk due to an accident, the user should input damaged SSC information and IE information when the damaged SSC affects an IE. Then RYAN automatically changes the PSA model to quantify the increased risk.

3.2 *Example of SDP Calculation with RYAN*

In order to verify and validate the RYAN software, we investigated operational events occurred in domestic NPPs from databases such as OPIS (Operational Performance Information System for Nuclear Power Plant) and KRDB (Korean Integrated Reliability Database) (OPIS, 2017) (S.Y.Choi et al, 2005). Figure 6 shows an example of SDP analysis using RYAN.

Assumptions for the analysis are as follows.

– IE: General Transients
– Failed SSC component: Fail to Start of AFWS-PP02 A (T/D Pump)
– Exposure Time: 720 hours

As shown in the figure, the analysis is performed in the following order.

Table 2. Result of sample calculation.

Option	Component	IE CDP	SSC CDP	Total
Event Level	Comp = Fail Value = 1	2.52E-06	1.39E-06	3.91E-06
Comp Level	Comp = Fail Value = 11	4.05E-06	3.15E-06	7.20E-06

1. Select the analysis type as the initial event + SSC analysis.
2. Select the initial event as General Transient.
3. Change the BE of the failed SSC to Fail.
4. Set the OOS Time to 720 hr.

Table 2 shows the results of SDP analysis in this example and indicates that the SDP analysis using RYAN has been performed properly.

4 CONCLUSION

In this research, KAERI developed a regulatory purpose Level 1 PSA model and framework for use in risk-informed regulation. The purpose of this research is to estimate the risk significance of

initiating events and degraded conditions occurred in Korean NPPs and characterize the significance of an inspection finding consistent with regulatory response thresholds. To this end, we designed a regulatory risk model algorithm reflected regulatory purposes based on the real conditions and developed a RYAN (Risk Analysis for ASP/SDP of NPP) that enables the regulatory body to perform an overall safety assessment such as ASP/SDP of U.S.NRC. To verify the applicability of RYAN, we investigated operational events occurred in domestic NPPs from databases such as OPIS (Operational Performance Information System for Nuclear Power Plant) and KRDB (Korean Integrated Reliability Database), and performed a sensitivity analysis for the selected operational events. Based on the framework, it is expected that the regulatory staff can identify a nuclear power plant or SSC (Structure, System, and Component) for which safety performance has been decreased. For a further study, we are confirming the applicability of RYAN by performing a sensitivity analysis with more event data. In addition, we are going to analyze the significance of each case with the AIMS-PSA to compare the results with RYAN for ensuring the accuracy of the analysis results of RYAN.

Risk dimensions of fish farming operations and conflicting objectives

S.M. Holen, I.B. Utne & X. Yang
Institute of Marine Technology, NTNU, Trondheim, Norway

ABSTRACT: Operations at sea-based fish farms can be challenging, and several risk dimensions are of concern during operations. Sea lice represent a challenge for the fish farmers who are required to perform delousing when the infestation levels rice above a set value. Delousing operations are frequently performed and require the use of heavy machinery operated from service vessels moored to the net-cages. Operators are exposed to hazards that may cause severe injuries and fatalities. Escape of salmon, which is a substantial environmental risk, has occurred in relation to delousing operations. Chemicals used during the operations may cause negative environmental consequences. Other safety related issues are the fish health and welfare. In this paper, a delousing operation on a fish farm is discussed with respect to different dimensions of risk, and potential conflicting objectives are discussed.

1 INTRODUCTION

The operators on fish farm localities have to navigate and make decisions in an environment where their own safety is lined up against other factors, such as fish welfare and prevention of escape of salmon. The workplace is exposed to forces from the environment, such as waves, current and wind, and maintaining focus on safety is crucial in all operations. Authorities with different regulatory responsibilities require risk assessment of prevention of fish escape, environmental impact and fish welfare (Holmen et al., 2017). Identification of hazards and risk assessments are measures implemented to avoid accidents. Holistic and systematic risk management is a prerequisite for safe operations, however, the fragmented regulation might work against this (Utne et al., 2017).

Projects related to the evaluation of risks in fish farms have identified critical operations, such as lice counting, well boat operations and operations involving cranes (Sandberg et al., 2012). Technology, the physical working environment, work-load, work pressure and safety management are found to be among the factors influencing escape events (Thorvaldsen et al., 2015). External pressures on operations, such as time, costs and weather conditions also puts constraints on operations.

Lice infestations has become a major sustainability challenge in Norwegian fish farming, and has also become the main delimiting factor for future growth in the industry (Svåsand et al., 2017, Norwegian Ministry of Trade Industry and Fisheries, 2017). The fish farming industry in Norway uses up to NOK 4,5 billion in anti-lice measures (DN, 2017). Treatments to remove lice are decreed in regulations (Norwegian Ministry of Trade Industry and Fisheries, 2012), and has become an operation frequently performed in fish farms. Delousing is an operation where several factors identified as critical or risk-influencing are present, see Table 1.

In this paper, the first three risk dimensions are presented and compared with the purpose of identifying examples of potential conflicting objectives in the fish farming operation delousing. Conflicting objectives is an accident perspective, and highlighting consequences of the different pressures the human operators are exposed to in aquaculture, risk-reducing measures can be developed.

2 RISK DIMENSIONS IN A CONFLICTING OBJECTIVES' ACCIDENT PERCPECTIVE

The concept of conflicting objectives is described by Rasmussen's migration model (Rasmussen, 1997a). It explains how accidents may happen when decisions in an organization are made based on different objectives and constraints. One example is the decisions made by management to minimize costs, while operators may focus on making the operations as efficient as possible. These sometimes competing, or conflicting, objectives may eventually lead to a migration towards the boundary of a functionally acceptable performance. As the decisions are made local at separate levels, the side effects of the decisions may eventually set the stage for an accident (Rasmussen, 1997b). The operators can be seen to be at the sharp-end, close to the hazard sources, while management can be seen to be at the blunt end, removed from the hazards (Rosness, 2001, Rosness et al., 2010a).

Table 1. Risk dimensions present in the fish farming operation delousing. Adapted from (Yang et al., 2017).

Risk dimension	General description	Relation to delousing operations
Risk to personnel	The Norwegian fish farming industry has one of the highest fatality and accidents rates when compared to similar industries (Aasjord, 2010). Accident statistics show that the fish employ ees are among the most exposed workers with regards to injuries and fatalities (Holen et al., 2017a).	Frequent use of safety critical equipment during delousing operations.
Risk to environment	The escape of salmon represents a hazard for the stock of wild salmon living in the rivers and fjords of Norway (Svåsand et al., 2017). The use of chemicals in delousing operations and on the net-cage to avoid fouling may affect the environment around the fish farm. Waste that accumulate under the fish farms due to fodder spill and organic matter and may have benthic impacts and on species living around the fish farm (Holmer, 2010).	Risk of net-tear is present during delousing operations. Medical treatment chemicals are released after operation.
Risk to fish welfare	Fish welfare in fish farms are under pressure due to sea lice and diseases (Hjeltnes et al., 2017).	Delousing operations require handling of the fish and may cause harm. The chemicals used in delousing may cause discomfort and wounds.
Food safety	Food safety is a general concern due to the accumulation of toxins in the fish meat.	Chemicals used for treatment of fish are not seen as critical for food safety (Norwegian Veterinary Institute, 2016).
Risk to material assets	Risk to material assets (e.g., net-cages, service vessels, workboats etc.) in fish farm operations may have severe economic consequences, mainly to the fish farm company. This risk dimension has not gotten much attention in the literature (Xue, Yang et al. 2017).	Structural damages of net during delousing may lead to escape of salmon which is a risk dimension already included.

Safety is an emergent property of a system and risk should be considered in a systems perspective where all factors that can influence safety, should be analyzed. Control can be made by increasing the safety margin, increase awareness of the boundary, or make the boundaries explicit. Making visible the limits on acceptable risk by establishing criteria for critical decisions or other ways of establishing clear lines as to when the safety margin is small should encounter challenges with conflicting objectives. Managers should also communicate openly about the existence of conflict of interest (Rosness et al., 2010b).

Fish farming is an industry dealing with production of livestock, thus requiring knowledge about biology, welfare, and diseases. In addition, operations are increasingly resource demanding and large production equipment requires special expertise for safe handling. The fish farms are mainly placed in the fjords where the operations may impact the fauna and wild animals living around the fish farm. These are all risk dimensions of concern for the operators at the sharp-end, and in some situations trade-offs between the risk dimensions must be made. In this paper these are seen as conflicting objectives. An example of a situation where operators are faced with having to choose between prioritizing risk objectives is provided by Størkersen (2012). The operators have to choose between fixing a net cage damage immediately after discovery, or use valuable time to provide the appropriate safety equipment to do the repair according to safety procedures. In the case presented, the operators do not hesitate to improvise and make the repair without the required safety equipment. Thus, the risk of escape is reduced, while the operators face a greater personal risk by down prioritizing their own safety (Størkersen, 2012).

The management at the blunt end is also making choices that affect the risk in operation, by allocating resources, like personnel, equipment and timeslots to operations. Management decisions influenced one of the biggest single escape event in Norway, which happened in relation to a delousing operation in 2011 where 176 000 salmon escaped (Soknes, 2012). The delousing operation had been ongoing

for two continuous days in order to finish the operation as quickly and efficiently as possible. The company later claimed that the responsible operator was disloyal to the company when breaching procedures to get the job done. However, a court case ruled that the employee had loyally tried to fulfill the management's expectations and that there had been a great time pressure on the employees, and no willingness from the company to compensate economically for extra personnel (Soknes, 2012).

Time pressure is a risk-influencing factor mentioned by personnel at fish farms in relation to both escape events, fish welfare and personnel safety (Thorvaldsen et al., 2015, Hjeltnes et al., 2017, Fenstad et al., 2009). Time pressure is not only created by allocation of resources by management, but also unforeseen weather changes puts this constraint on operations.The regulation of the fish farming industry is characterized by being fragmented and the authorities have developed separate regulations to ensure the different values being protected (Holmen et al., 2017). Fish farmers state that the focus in planning for safety in operations will be towards the area were they experience pressure from the authorities (Skjærvik, 2017). In line with Rasmussen's framework of distanced decision-making, some unforeseen consequences might be the result. For example, the strict regulations on delousing according to infestation levels may lead to both unsafe situations concerning escape and reduced welfare for the fish.

3 THE DELOUSING OPERATION

3.1 *Anti-lice measures*

The sea lice, or salmon lice, is a parasite, which only have salmonids as hosts. The last five stages of the life cycle of the sea lice are parasitic to the salmon, when it feeds of the mucus, skin and blood. The sea lice may cause fish welfare problems both to farmed and wild salmonids, and may ultimately cause fish death. The sea lice has become a major issue in the fish farming industry where large outbreaks of the parasite is made possible by the high density of salmon in the fish farms along the coast. The sea lice is sensitive to temperature, and infestation levels change according to the season; the lowest levels are registered in the spring and the levels increase during summer and fall (Svåsand et al., 2017). This have led to frequent delousing in periods of the year.

As the sea lice mainly lives in the higher levels of the sea some preventive measures to sea lice have been developed, e.g., a skirt placed around the net cages with a depth up to 3 meters preventing the sea lice to enter in the area where the salmon are (Lien et al., 2014). The skirts around the net are the most used preventive measure (Svåsand et al., 2017). Also a "snorkel"-solution, where the fish are held in an semi-enclosed net cage, only with access to water air through a "snorkel" with a diameter around 6 meters (Stien et al., 2016). In 2017 over 27 million wrasse was captured, mainly used for delousing purposes in fish farming (Directorate of Fisheries, 2017).

The main mode of combating the sea lice have been medicinal products. These can either be introduced to the fodder, or the salmon are exposed to the medicament in bath-treatments. In bath treatments, the salmon are exposed to medicinal products added to the seawater after the salmon is gathered in an enclosed area, in either a well vessel or using a tarpaulin around the net cage. The bath treatments require major resources and is one of the most demanding operations that is carried out in fish farming.

In addition to the bath-treatments, some new technologies have been developed to remove sea lice from farmed salmon. These methods have been developed mainly due to resistance in the salmon lice of the medicaments used. The new treatments use mechanical aids, such as water jets, higher temperature and brushes. These new methods are seen as the main cause in the large drop in prescribed anti-lice treatment medicaments from 2015 to 2016. There is a concern that the new methods might be a risk to fish welfare, and that they have not been sufficiently tested for welfare before they have been put to use (Hjeltnes et al., 2017). In addition, signs of possible resistance to these new anti-lice treatments have been discovered.

3.2 *Steps of a bath treatment operation*

Figure 1 show the steps of a fish farm operation using tarpaulin. This approach is representative for all methods of delousing, only the step "Perform delousing" differs according to the method and technologies used.

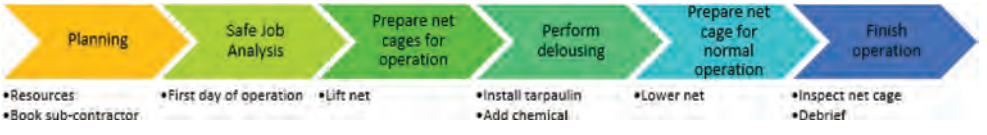

Figure 1. Steps of a delousing operation using tarpaulin.

- Planning

Delousing must be carried out when the critical level of lice is reached. The operation is planned by the operations manager on the fish farm, sometimes in cooperation with higher level onshore area managers. The operations are in most cases performed by or in co-operation with service providers who have both required equipment and expertise.

- Safe Job Analysis (SJA)

Most fish farmers conduct a preparation meeting the day the operation starts. An integral part of this meeting is to perform a SJA, where hazards in the operation are identified and responsibilities for tasks during the operation are assigned.

- Prepare net cage for delousing (Lift net)

It is necessary to make the volume of the net cage smaller so that the fish is easily accessible in the upper layers of the sea. Lifting is demanding and time-consuming, and requires the use of crane and winches from work vessels. If a well vessel or a type of barge is used in the treatment, a "crowding" of the fish is also necessary. This is done by using an extra net to push the fish together in an even more confined area.

- Perform delousing

Bath-treatment are either performed with tarpaulin in the net cage or in a well vessel. New types of mechanical treatments are performed on specialized barges.

- Prepare net cage for normal operation (Lower net)

After the treatment, the fish is put back in the net or the tarpaulin is removed, depending on the type of treatment. Then the net needs to be lowered to its normal position. This is done in a reverse manner to the lifting of the net. Careful lowering of the net and ropes are necessary to avoid any damage.

- Finish operation

After the operation is finished, an underwater inspection should be made by either divers or a ROV. Debrief-meetings will ensure that any adverse events during the operation are discussed and subsequent changes implemented in safety management systems.

4 RISK DIMENSIONS OF DELOUSING OPERATIONS

In this section, the three first dimensions of risk in Table 1 (Yang et al. 2017) are presented and discussed for the delousing operations.

4.1 *Risk to personnel*

Delousing operations are demanding operations where the operators on fish farms are exposed to several hazards. Most of the delousing techniques require use of cranes when preparing for the operation. In accident statistics from the fish farming industry, the use of cranes are found to contribute to several of the blow by object and entanglement injuries (Holen et al., 2017a). Work operations are also an increasing contributor to fatalities in the fish farming industry (Holen et al., 2017b). As service vessels are an important part of the operation, also man over board accidents is in important risk to consider. In addition, the chemicals used in delousing operations may present a hazard to the operators. In some delousing operations, extra oxygen is used, and explosions may happen.

4.2 *Risk to the environment*

In general, two types of hazards to the environment should be assessed in relation to delousing operations; (i) the effects from escaped farmed salmon, and (ii) the release of treatment chemicals, which may have an effect on organisms around the fish farms.

4.2.1 *Risk of escape*

The main causes to escape from fish farms are due to structural failures including net tearing. Net tearing can happen during operations and from abrasion from related components (Jensen, Dempster et al. 2010). Abrasion from the sinker tube chain is the most common cause for net tearing, while handling of net weights, including the sinker tube is the second largest cause (Føre and Thorvaldsen, 2017). Handling of net weights must be done in all delousing operations, as part of the preparation before the operation, and after the operation has been completed. Organizational factors influencing escape events are found in Thorvaldsen, Holmen et al. (2015).

The consequences of escaped salmon are related to introgression of genes and the spreading of diseases, which both may influence the wild salmon. Introgression of farmed salmon genes is unwanted because of the genetic differences in farmed salmon and wild salmon (Taranger et al., 2015). The long term consequences of introgression may lead to "changes in life-history traits, reduced population productivity and decreased resilience to future changes" (Glover et al., 2017).

4.2.2 *Risk of treatment chemicals on surrounding environment*

The medical chemicals used for bath treatment of sea lice may affect other animals, especially crustaceous animals as the sea lice belongs to this type of animals. The chemicals used for bath treatments are Azametifos, Deltametrin, Cypermetrin and Hydrogrenperoxid; the three first chemicals are mainly used in tarpaulin treatments, while the last

is used in well vessels. When the bath treatment is made with tarpaulin, the chemicals are directly released into the sea at the fish farm; when well boats are used the chemicals can be transported away (Svåsand et al., 2017). The different chemicals have different levels of toxicity, where Deltametrin have been shown to be very toxic for some non-target organisms, such as plankton, and may also be bound up in seaweeds. Hydrogen peroxide have the least effect on organisms in the surroundings of the fish farm (Svåsand et al., 2017). In a five-year study of effects of sea lice medicine to the receiving environment in Scottish sea lochs, no long-term effects could be found (Scottish Association for Marine Science, 2005). Chemical release in the case of vessel capsizing may also be a risk.

4.3 *Risk to fish welfare*

Fish welfare is affected by the salmon louse itself and the anti-lice treatments carried out to remove the lice. Normally the damage to the farmed salmon is not high because treatment is required before a critical number of lice is reached (Svåsand et al., 2017, Norwegian Ministry of Trade Industry and Fisheries, 2012). However, substantial injuries in some areas where the salmon lice infection pressures have not been possible to control have been reported (Hjeltnes et al., 2017). The larger wounds caused by sea louse may lead to dehydration, electrolyte balance and increased influence on physiological functions with the fish (Svåsand et al., 2017).

Anti-lice treatment represents a significant negative welfare challenge to the fish (Hjeltnes et al., 2017). Especially handling and crowding of fish, which is done in relation to the treatment, will have an impact on welfare of the fish. The stress and fear-levels increase in the fish during these operations and if the fish is weak, heart failure may occur. Open wounds, scale and mucus-loss and stress are factors caused by handling which might also increase the risk of other infections in the fish (Svåsand et al., 2017). The chemicals used in treatment may be overdosed and give toxic effects. Observed fish behavior during delousing operations may indicate that the fish experience the treatment chemicals as uncomfortable (Oppedal et al., 2011).

Bath treatments have been the primary method of delousing, but new methods and technologies, which does not use chemicals, are increasingly in use, mainly due to resistance of chemicals in the salmon louse. Mechanical delousing using heated water, water jets or a combination of water jets and brushes are reported to give welfare issues related to reduced appetite, eye injuries, reduced mucus production and poor skin health, amongst others. These new methods of anti-lice treatment are of great concern to fish welfare as they are not sufficiently tested for effectiveness and welfare (Hjeltnes et al., 2017). Heated water treatment has caused mass-fatalities of salmon (Heraldscotland, 2016).

4.4 *Conflicting objectives of the risk dimensions*

Some examples of how each risk dimension may influence the others during the delousing operation are presented below. Especially, risk to personnel safety, risk of escape, and risk to fish health may come in conflict. All these dimensions are also under the constraints introduced by management decisions like allocation of resources, such as personnel, equipment and timeslots to operations.

4.4.1 *Prioritizing personnel safety*

Personnel safety has been given increasing focus in the fish farming industry. Major hazards for personnel are especially present during operations using heavy machinery. For delousing operations, this type of machinery is used in preparation of the delousing, and after the operation when net is lifted and lowered. Handling of the net also involves hazards with regards to tearing of net and following escape. In stressful situations, due to limited attention span, there could be a need to focus on one of the risk factors. Situations where focusing on personnel safety may cause higher risk with regards to escape may also occur after operations when inspections of the net cages should be done to ensure that the nets have been correctly lowered. Inspections by divers or cameras must be done so that potential holes caused during operation are discovered. In cases where there may be risk of injuries because of, e.g., weather conditions, personnel safety must be prioritized over prevention of escape.

Stopping operation too soon or too late in cases of risk to personnel may cause the delousing treatment not to work adequately. The operation must then be repeated later, which represents an extra strain to fish welfare, which must undergo handling again in a short time. If operation is not completed the net may not be lowered in between operations which also means that the fish must be kept “crowded”.

4.4.2 *Prioritizing fish welfare*

Fish welfare has traditionally been given high priority. Fish welfare is important to management as it affects earnings. Cases when fish welfare may influence personnel safety or prevention of escape during operations, may occur if delousing with tarpaulin must be abruptly stopped due to, e.g., too low oxygen levels in the net cage. Stressful

situations and a focus on fish welfare may lead to hazardous situations by personnel. The choice of delousing methods may also have an influence on the fish welfare. Bath-treatments with tarpaulin include some more hazardous tasks using crane compared to bath-treatments in well vessels. Whereas well vessels may include more welfare issues due to "crowding" and pumping of the fish in and out of the vessel.

4.4.3 *Prioritizing prevention of escape*

Prevention of escape is a major focus of the fish farming industry. This focus may also have been at the sacrifice of personal safety in procedures and risk assessments. An inadequate focus on hazards that may cause personnel injuries when planning operations and in safe job analysis performed before delousing may contribute to accidents.

If a hole in the net is discovered, fish may be kept crowded longer than normally to keep the fish away from hole in the net. This will be at the expense of fish welfare.

4.4.4 *Prioritizing limited consequences for environment*

When using well vessels for delousing operations, chemicals used during operations may be transported out of the fjords into designated "drop zones". The choice of using well-vessels may have an influence on fish welfare in operations. Some of the new delousing methods do not use chemicals and, in this regard do not represent a challenge to the environment. Emissions to the environment of the chemicals used in delousing operations are an integrated part of the operation, especially when using the tarpaulin. The consequences of the release of chemicals into the fjords is a controversial issue between the stakeholders.

5 DISCUSSION

Several risk issues are present during fish farm operations, and delousing is no exception. Accidents, such as escape, serious personal injuries and major fish deaths, have happened in relation to the activities in delousing operations. In the accident perspective of conflicting objectives, one of the measures towards avoiding accidents is to make visible the limits of acceptable performance. It is important to assess how prioritizing one risk issue may affect other risk aspects and dimensions. During delousing operations both personnel safety, fish welfare and fish escape are concerns, which require attention. It is not possible to eliminate the conflicting objective as they, in today's methods available for delousing, are inherent in the operation. However, means to avoid accidents due to conflicting objectives are to highlight the conflicts themselves and the possible consequences of giving priority to one aspect in operations. Visualizing the different risk dimensions, which may give rice to hazardous situation, gives an opportunity for operators and management to gain awareness of possible hazards in the operation.

Possible risk mitigating actions could be to assign some operators the main responsibility to follow whether one risk issue is given an unbalanced focus. The different steps of the operation may also be more hazardous with regards to one type of risk. For example, the beginning of preparation of the net cage is hazardous related to tearing of the net, while the last part of preparation may be more hazardous to personnel injuries because of excess chains suspended from the crane. In addition, correct lowering of the net after operation is a critical part of the operation concerning escape events.

Risk avoidance of some of the measure might also have mutual positive effects. One example of this is to not starting delousing treatment in harsh weather, as this might present hazards to both personnel and fish welfare (Størkersen, 2012, Fenstad et al., 2009).

In almost all situations during operations where one risk issue might be prioritized over a different one, management decisions, such as time pressure, costs and weather may influence the decisions made during an operation. Stress due to time limits and limited resources will affect how choices are made, and violation of procedures might be done if that is what seems most rational in the moment. When evaluating how risk mitigating measures might work, one should be aware off the mechanisms of the socio-technical system where different actors will make decisions according to their respective constraints and options, and that some interpretation of rules will be made at lower levels of the organization (Rasmussen, 1997b). Within the aquaculture company, the operators are in the sharp-end in close proximity to the hazard, and they make decisions within different frames of what the land based organization with higher level of authority and distance to the hazard do. Without the possibility of always seeing the whole picture decisions on both ends are made on "local rationality". Often, it is explicitly said that safety should be prioritized, but tacitly opposite messages are sent through planning, follow-up and resource allocation. Measures should be implemented in and continuously monitored by the management systems to ensure that safety is not compromised.

In this paper, the immediate risk issues that arise during an operation due to conflicting objectives has been in focus. In a broader perspective, other risk issues would also be relevant to consider with regards to conflicting objectives such as resistance

of sea lice to the different treatments and the influence of regulations on the different risk issues. The decisions made on higher level may have more impact to the risk picture, than the decisions made by operators during operations. The regulations that specifies the limits for the acceptable lice level may challenge fish welfare as it leads to frequent delousing (Hjeltnes et al., 2017). This is seen as a challenge to the welfare and in some cases the levels of lice might be more acceptable to welfare than performing repeated treatments which cause strain and stress to the fish. Repeated delousing operations will also increase the possibility of escape due to handling of the net.

6 CONCLUSION

Sea lice is a major challenge to the fish farming industry and delousing is decreed by the authorities. The delousing operation involves risk dimensions with regards to personnel safety, the environment and fish welfare, all issues including severe consequences. Conflicting objectives may arise during the operation. Prioritizing one risk dimension at the expense of others may lead to situations, such as: (i) focusing on personnel safety may hinder the discovery or repairing holes in the net, or (ii) operator stress to finish operation due to fish welfare, may cause hazardous situations for personnel. Higher-level management decisions also influence the risk during operations through, e.g., timely allocation of resources. Unforeseen accidents may happen if conflicting objectives are not visible to management and operators, and they should be openly discussed to ensure safety in operations.

The future of driver training and driver instructor education in Norway with increasing ADAS technology in cars

G.B. Sætren, J.P. Wigum, R. Robertsen, P. Bogfjellmo & E. Suzen
Road Traffic Section, Business School, Nord University, Stjørdal, Norway

ABSTRACT: On average, more than two people are killed or severely injured every day in Norway in road traffic. Hence, elements that benefit a decrease in this number will be welcomed, such as "Advanced Driver-Assist System" (ADAS) technology. However, increasing technology in cars might require new driving skills compared to those taught today and the transition to more and new technology could potentially increase the accident rate. In the safety industry, it is well known that training for new and more automated technology is important. This raises a question: How does the transition to new, more complex and more automated technology affect driver training and the education of driver instructors? At the present time, there are no clear answers to this question. However, it seems that there is a need for a discussion and potentially a redefinition on which driver skills should be required, and how to implement these skills. This is what we attempt to discuss in this paper.

1 INTRODUCTION

In 2016, there were 135 road deaths in Norway. The number for 2015 was 117, and for 2014 it was 147. However, if you include the number of accidents resulting in severe injuries, the number was 791 in 2016, 810 in 2015, and 821 in 2014 (SSB 2018a). This means that, on average, more than two people are killed or severely injured every day due to traffic accidents in Norway. Compared to any other high-risk sector, the number is high, but the trend over the past decades is that the number is decreasing. The Norwegian government bases the National Transport Plan (NTP) on a vision of zero. This vision means zero dead and zero severely injured in road traffic. The objective for this period of NTP (2014–2023) is to halve the number of road deaths and severe injuries, and that, in 2020, there should be no more than 775 killed and severely injured in road traffic in Norway, that is about two people per day on average. Strategies to achieve this objective in Norway are, for instance, to design safer roads, to encourage safer behaviour from road users, and to encourage the development of technology to produce safer vehicles (NTP 2014–2023). Norway is not alone in such objectives as this is also in accordance with the EU objective, which is to halve the number of people killed in road traffic during the period 2010–2020 (European Commission 2015a). In order to achieve this, the EU has developed seven strategies: (1) improve education and training of road users, (2) Increase enforcement of road rules, (3) safer road infrastructure, (4) safer vehicles, (5) promote the use of modern technology to increase road safety, (6) improve emergency and post-injuries service, and (7) protect vulnerable road users (European Commission 2010). Technological innovation is one of the seven strategies, in addition to improving education and training of road users. However, what we know from other industries regarding humans interrelating with increased automation (e.g., Lee 2006; Sætren and Laumann 2015), it is not a certainty that the numbers of killed and severely injured will continue to decrease with an increase in technological solutions. Reasons such as lack of standardisation in technological solutions, mode confusion, lack of situational awareness, overreliance, complacency and so forth, could all be reasons why the interrelation between humans and technology have a possibility of not going according to plan (Young and Stanton 2007). One of the reasons is a lack of focus on training for automation (Sætren and Laumann 2015). Regarding the technological development in cars, new technology is implemented at a fast tempo, but little attention is given to training in using the technology to new and existing drivers. Research shows for instance that only 24% of buyers were given instructions from the car dealer when cars with an "Advanced Driver-Assist System" (ADAS) were bought in The Netherlands (Harms and Dekker, 2017). Even less attention seems to be placed on teaching driver instructors how to teach driving skills with this vast variety of technology. In addition, we have found no literature on this topic from a pedagogy aspect. For this

reason, we would like to look at training for automation when it comes to driving cars.

How will ADAS technology in cars potentially affect driver training and driver instructor education, and which new skills might be needed for a driver?

In order to answer this, the driver training program and the driver instructor education in Norway will be presented first, before we present issues regarding automation and training. After this we discuss ADAS technology in cars and how it would affect driver training and driver instructor education. Next, we look at which new skills a driver might need. Then, we present our conclusion.

2 DRIVER LEARNING PROGRAM AND DRIVER INSTRUCTOR EDUCATION IN NORWAY

The Norwegian driver education model is very comprehensive and systematic (Rismark and Sølvberg 2007) and it normally takes about two years to become a driver with the program which contains detailed curricula for content, progression, and teaching methods (NPRA 2013). This two-year education is a module based training program consisting of four modules that include both individual and group tutorials that are both theoretical and practical. In addition, accompanied driving with someone who has had their driving license for a minimum of five years is highly recommended and thus it is common, from the age of sixteen to drive with a parent as a passenger.

Driver instructor education in Norway is also an extensive education as it is a two-year university education with an emphasis on traffic pedagogy, road traffic law, and traffic psychology in addition to physics and technology (Nord universitet 2017). This two-year education includes both theory and practice and emphasises operational, tactical and strategic driving skills (Michon 1985), and the GDE framework (Peräaho, et al. 2003). However, in the future we might see a reduced need for an extensive focus on these elements, which until now have been viewed as basic. As future in-car technology might replace some of the information retrieval, assessments and decisions previously made by the driver, we might see a shift in which are the knowledge and skills that are important for driving instructors to develop.

3 AUTOMATION AND TRAINING

There are a number of different systems, ranging from basics such as automatic windscreen wipers to more advanced technology such as lane departure tracking, automatic braking systems and even more enhanced levels of automated driving functionality. Such systems are for instance autopilot (Tesla), distronic plus steering assist (Mercedes), and intellisafe (Volvo).

Increased automation in cars will probably lead to an eventual decrease in the numbers of accidents (Elvik and Høye 2015; Wilmink et al. 2008). Some reports indicate that traffic fatalities could be reduced by as much as 90% (Bertanocelli and Wee 2015). Further, levels of automation in cars will most probably increase as a result of the increased digitalisation of the transport sector, and brands such as Volvo, BMW, and Tesla, all popular brands in Norway, expect to have self-driving cars on the roads within the next five years (TechEmergence 2017). However, it is expected that the leap from where we are today to all cars being self-driven, is remote, and that semi-automation with in-built ADAS technology seems to be a reality for some time to come, considering that age of the motor vehicle population in Norway in 2016 was, on average, 10.6 years (SSB 2018b). The number for Europe is 10.7 years (ACEA 2017).

There are several different taxonomies trying to capture the essence of the development of advanced technology in cars, and the most common seems to be the SAE's levels of automation (SAE 2014). This approach is based on six levels of automation ranging from "No automation" (level 0) to full automation (level 5). In levels 0–3 the human driver has the responsibility for the driving, and in levels 4–5 the car takes on this responsibility. Examples of technology at each level, according to Banks et al. (2017) are for instance level 1: Adaptive Cruise Control (ACC), level 2: Tesla Autopilot, level 3: Audi A7 prototype, level 4: Toyota Highway Teammate, and level 5: Google self driving car. Today, most ADAS technology equipped cars are at level 1. Furthermore, seen from a drivers perspective (Banks and Stanton 2017), there are different roles for the driver within automated systems. As an example, a Driver Driving (DD) is defined as an operator responsible for completing basic operational, tactical, and strategic tasks (Michon 1985). However, the Driver Not Driving (DND) would expect an automated system to have full control of these tasks. That being said, the transition is not straightforward, and during the middle phases of automation, Driver Monitoring (DM) should be assumed. A challenge is that in level 2 the driver operates the vehicle, which assumes a transition between DD and DM and in level 3 the driver, to a larger degree, supervises the vehicle but needs to intervene if needed assuming a transition between DM and DND (Banks and Stanton 2017). The cars with the most advanced

driver assist systems will be additional to the many cars that have less advanced technological equipment on the roads. However, this middle phase is, according to human factors and safety research, a phase where the human interference is relied upon, but the human is not very reliable (Wickens et al. 2016; Son and Park 2017). Human interrelationship with semi-automated technology is known to potentially result in serious unwanted incidents in a wide range of sectors such as petroleum (Sætren and Laumann 2015), aviation (Billings 1997; Parasuraman and Byrne 2003), and road transport (NTSB 2017). Research has found there are several causes for this, for instance the issue of trust, overreliance, or complacency (Sætren and Laumann 2015; NTSB 2017), situational awareness (Kaber and Endsley 2007), mode confusion (NTSB 2014), or lack of optimal training (Salas et al. 2006; Sætren and Laumann, 2015). Additionally, news items concerning ADAS technology in cars seems to share a common misperception that when more automation is introduced, human error will disappear (e.g. NRK 2017). This gives rise to the idea that training is not necessarily needed. Human factors research advises against not training for the use of new complex technology (Lee 2006; Salas et al. 2006; Sætren and Laumann 2015), as there will always be a human in the technology loop, for instance in use, maintenance or design.

It might even be an issue that increased automation might increase the level of competence required for the operator, as an operator must know both how to handle the system more or less manually, for instance if the sensors in a car turn off due to bad weather, and additionally know how to handle and supervise the advanced technology.

So, as driving skills decrease, the need for potentially taking over the car will occur in more difficult scenarios such as in bad weather conditions like slippery roads, heavy snow, and so forth, because such conditions could be difficult for ADAS technology to handle. One example is Adaptive Cruise Control (ACC). A driver who uses ACC, that works most of the time, does not get much training in driving without it. Then, when it is time for the driver to take over control, for instance because the weather conditions are too harsh for the system to operate, the driver might lack optimal skills to handle the driving. Research has indicated that ACC technology leads to a reduction in mental workload and thus problems with regaining control of the vehicle in failure scenarios (Stanton and Young 1998). ACC is one of the technologies that might be turned off in, for instance, heavy rain without advance warning, implying in that the driver must be skilled in handling bad weather conditions while driving, and be able to take control of the car straight away.

During a transition period where there will be cars on the roads with very little to no ADAS technology in combination with cars with a large variety of ADAS technology. There is the important question of which skills should be taught in a driver training program and in driver instructor education. The introduction of more automation in cars will lead to a change in the skills needed for the driver, and hence will bring about a need for a change in the competence of the driver instructor. This, in turn, will probably affect driver instructor education.

4 AUTOMATED AND ADVANCED NEW TECHNOLOGY IN CARS IN REGARD TO DRIVER TRAINING AND DRIVER INSTRUCTOR EDUCATION

There are some obvious strengths regarding more automation in cars as opposed to fully manual cars. First of all, the workload will decrease for the human driver. With more technology taking over tasks such as changing gears, keeping the speed stable, avoiding collisions with pre-crash systems, navigation, and so forth, the driver can pay attention to other aspects. However, it is commonly known that when humans supervise a system as opposed to being an active participant, attention seem to fall (e.g. Yerkes and Dodson 1908). Even though there are many benefits such as the probability of a lower accident rate, there are also several concerns regarding automation. Most of these concerns are about when the driver needs to take over a vehicle, for instance in critical conditions (Son and Park 2017) or intention to use/user resistance (Kyriakidis, et al. 2015; König and Neymar 2017). When technology takes over many of the tasks, and works most of the time, driver skills will decrease. This is because maintaining skills without practice is probably not possible. However, very little information exists on driver training in regard to how to learn to drive with new technology as a new driver, or driving cars with new technology as an experienced driver (Harms and Dekker 2017). The topic of learning to use the technology is not even mentioned when opportunities and barriers on a societal level are considered (Fagnant and Kockelman 2015). However, the use of the technology on the market today, such as, for instance, lane assist and Adaptive Cruise Control (ACC) should perhaps be taught after proper driver skills are acquired. For instance, technical driving using lane assist could be perceived as uncomfortable as the technical reaction of the car is generally slower compared to a driver. When turning, for instance, the car is often too far out the curve before the turn is performed and this can

be repeated several times during the turn. If this was the behaviour of a learner driver during a lesson, the instructor would not have considered the technical driving skills to be adequate. This means that the driver must be skilled in order to understand that the car's behaviour is not adequate, and respond accordingly. The driver requires both good driver skills and an understanding of how the technology works, together with its advantages and limitations. On the other hand, technology such as lane assist could probably be of support in the event that an unexpected incident occurs and the driver loses control of the car. As single vehicle off the road together with head-on accidents are the most frequent accidents with the highest death rate in Norway for the past decades (SSB 2018a), this technology could potentially save lives. However, perhaps, it should not be trusted for use on a regular basis. In driver instructor education today, the teaching is that when driver assistance systems take over, the driving is not optimal. Thus, the systems could be there as a backup, but not trustworthy enough to be used regularly. The driver should drive the car. Furthermore, if such systems are to be used while driving, there are other considerations involved. For instance, regarding ACC, it is a technological system that perhaps works better in some driving conditions than in others. As an example, on icy roads, or in higher density traffic in a more complex driving environment, it might be a better solution to control speed manually. Making the correct decisions on when to use, and when not to use, technology while driving requires good driving skills.

Regarding driver instructor education and driver training, it seems that the introduction of ADAS technology requires that elements are added to the education and training rather than removed. Additionally, operating these technologies should perhaps be a larger part of driver training, driver testing, and hence driver instructor education.

Technology has always had an impact on the content of the Norwegian driver education curricula. For instance, driving on slippery roads has been a mandatory part of driver training in Norway since 1975. In the early days, the learner drivers were trained to manually adjust the brake pedal in different ways to minimise the braking distance, on ice and snow, as much as possible. After the ABS braking system was introduced and became common in most cars, the content of driver training on slippery roads changed and focused more on letting the learner drivers experience that the ABS system enabled them to brake as hard as they could and to simultaneously use the steering wheel to control the car (NPRA 1995; NPRA 2005). However, the main difference between the ABS brakes transition and the present technological transition, is that ABS brakes became common in many cars and used the same way of braking in all brands of car. The driver needed to change how to move the foot while braking, but the brakes were in the same place, the basic movement was the same, and most brands of car had the same system. Nowadays, new technological solutions such as ACC, are different in different makes of car where some brands for instance have a switch on the right side of the steering wheel, while others have a button on the front or on the left side of the steering wheel. This lack of standardisation could be confusing and hence could distract the driver. All kinds of different solutions such as these, and different software solutions in touchscreens in new cars may have as a result that it may not be as easy as previously to drive a car that the driver has not driven before, due to a wide variety of technological solutions. It could be difficult to know which technological solutions are included in the car, and difficult to know how to use the technology. Currently, distractions for the driver are about to increase due to in-vehicle devices. This runs counter to the necessity of keeping an eye on road (Wickens et al. 2004).

There is a possibility that the answer to this is to have differentiated driving licenses and not a standardised license such as we are used to today, because technology in cars is too varied and unstandardised. It should be a matter for discussion as to when cars are so different from each other that a standardised driving license is no longer good enough.

Increased technology has affected the training situation for a long time, and, in Norway, one example of an aspect that is in a transitional phase, is the trend that new cars are not equipped with manual gears. There are two important aspects to this situation. First, we see that the educational system does not keep up with the speed of technological development. Toyota for instance, sold more than 99% of new cars equipped with automatic gears so far in 2017, in Norway (Korsvoll 2017). Thus, the driver will not need to learn how to use manual gears as automatic gears will most probably become the new normal. However, in Norway, driver training is based on manual gears, and the education of driver instructors is based on vehicles equipped with manual gears. Perhaps the driver instructor program should focus instead on other tasks rather than teaching new drivers how to drive with manual gears. If a technology as basic as gears is hard to keep up with regarding a transition from manual to more automation, it could be a challenge when now even more technologically equipped cars enter the market.

Second, the gearing system is an example where different technological equipment in cars requires

different types of license for the driver. In Norway, as in the EU, you are allowed to drive an automatic car if your license is for manual gears, but not the other way around. You are not allowed to drive a car with manual gears if your license is for automatic driving (FOR 2017). For this reason, many driving schools only have manual gears in their cars, as for instance learner drivers know that they will probably buy a cheaper car with manual gears when they have their license. A solution such as this might also include more ADAS technology in the years to come. There could be different licenses based on the technology in the car you drive.

The rapid speed of introducing new technology seems to be happening faster than the changes in the educational system. Furthermore, if you have received your class B driving license, there is no retesting or system to update your driving skills, so there is a question as to how these drivers should learn how to operate new technology properly. Additionally, for driver instructors who are already authorised, there are no mandatory courses for updating their competence, so another question could be how they should get the necessary skills to teach new and existing learner drivers. If the two-year university education to become a driver instructor in Norway adjusts today, the market will not change completely for many years. Nevertheless, the rapid speed of technological progress will continue.

5 NEW DRIVER SKILLS REQUIREMENTS

In order to know which skills a driver must have, we need to know how the car works. For example, the GDE matrix has been the basic understanding of the driving skills that is necessary for a driver to have and thus, one of the central elements in the driver instructor education. The GDE-matrix consists of five levels, where the lowest level is vehicle manoeuvring, the second level is mastering traffic situations, the third level is goals and context of driving, the fourth level is goals for life and skills for living (Keskinen 1996 in Hatakka et al. 2002), and the fifth level is social skills (Keskinen 2014; Keskinen et al. 2010). However, the situation regarding new technology in the car is also changing the skills needed for a driver. It seems to be time to redefine which competence a driver must hold, and the GDE matrix may not be the optimal way to define the necessary skills in the future. If cars become more or less self-driving and automated, perhaps the lower stages of the GDE matrix might not correspond with the actual skills that are needed to drive a car.

Another example is the driving process, which might be explained using a basic information processing model (e.g. Wickens and Carswell 2006). This model assumes that information is *perceived*, then *processed* before *decisions* are made based on how the information is processed and *action* is then taken. In regard to the driving process, the question is who is collecting the information and who is responsible for collecting which information, the car or the human? As an example, when driving with ACC, the driver needs to monitor the environment and collect information on driving conditions as the car does not collect information, for instance, on the road conditions such as rain or ice or dry asphalt. Furthermore, the system does not correspond with any other systems in the car, so, for instance, if the car skids and the traction gets the car back on track, the ACC does not take the slippery road condition into consideration, and will only work to get the car back to the required speed or distance from the car in front. This assumes Driver Driving and Driver Monitoring with this technology (Banks and Stanton 2017). Regarding another technology, lane assist, the same aspect occurs as, for instance, lane assist will not work without proper road markings. Therefore the driver must pay attention to whether the road is properly marked or not. This is information a driver normally would not need to pay that much attention to if driving the car, as the driver would most likely hold the steering wheel and stay on her/his side of the road regardless of the quality of the road marks. The technology could thus make the driver pay attention to the road closer to the vehicle rather than paying attention to the road traffic environment further ahead. Additionally, regarding decision making, it could be questioned as to whether it is the car or the driver that makes the decisions. For instance, with ACC, if the car does not collect information on the road conditions, it cannot be responsible for making decisions in this regard. The driver must monitor and make decisions based on the information gathered and processed. Finally, the question is who takes action based on the information and decisions? If the car does not make decisions or gather relevant information, it probably cannot take appropriate action, meaning this would be the driver's responsibility.

So, what do we hand over to the car and what is left to the driver? The question will have different answers for different technologies. If, for instance, using the same scenario as with the ADAS technology, adaptive lighting, there is a different situation. Here the car gathers information on for instance the light conditions in the environment, and oncoming cars, and makes decisions based on the information gathered and takes action to turn lights on or off or chooses the degree of brightness. Thus, the driver will not need to use as much cognitive capacity for this operation.

Another issue that complicates which driving skills are needed is the lack of standardisation between the car manufacturers on how the new technology should interact with the driver. For instance, there are several different solutions to touchscreen software in cars. So, the skills of the driver need to correspond to the actual car the driver will be driving, the technological solutions in the car and how the technological solutions interact with the driver.

It seems that training needs adjustment in order to meet the new digitalisation of the future. However, in order to change what we teach to the learner drivers, we probably need to start with the educational institutions who educate the driver instructors. In addition, there is the question of if and how to re-educate driver instructors who are already certified as driver instructors for traditional driving. In Norway alone, there are more than 1,000 driving schools, and providing courses for the instructors in all of these schools will take time and effort. This time does not seem to be available at the speed at which changes are happening today.

One solution could be that the manufacturers are responsible for the specific technological training for drivers, and license drivers for their technology. A solution such as this also requires consideration as to what training and testing for such a license should involve, in addition to who is responsible for the training and testing. Today it is the National Road Authorities in Norway who conduct the testing of learner drivers in order for them to qualify for a driving license. Therefore, to maintain the driver skills requirements, the testing could be the responsibility of the authorities. This testing could include drivers ability to drive and supervise the systems in addition to how to respond to alarms and warnings. Therefore, one could think of driver education that comes in two levels. In that case, a standard learner driver could learn how to handle a manual car as level one in a standard driving school, but also learn how to operate and supervise a car of the future as level two. How to drive a car with technological solutions could, with this system, be up to the manufacturers to teach properly to all drivers, and be tested by the road authorities.

We see in aviation, for instance, that pilots are trained in simulators in order to uphold the required skill level to fly an aircraft. This is partly because flying with a high level of automation decreases flying skills. This could be a solution for drivers as well. In order to keep their driving license, drivers could be required to have a certain amount of simulator training in order to uphold driving skills because their cars have ADAS technology. However, this will require an increase in simulators for one, and in Norway today there are between 5–10 simulators for driving license B. Furthermore, retraining to uphold skills requires a system where everyone holding a driving license in Norway has training. A system will also be needed to deal with the bureaucratic aspects. Thus, there are some obvious obstacles to such a solution in regard to costs and resources in addition to the issue of how society would respond to it and if there will be public acceptance for such a system, and the political will to implement it.

6 CONCLUDING REMARKS

How will ADAS technology in cars potentially affect driver training and driver instructor education and which new skills might be needed for a driver? This was the question we wanted to examine closely in this paper.

We must be honest and admit that today, we do not know how to provide general training for more technology equipped cars, or even for self-driving cars. To be able to assess a good training program, it is essential that we know what we are training for. Today, however, with the vast variety of technological solutions on the roads, the lack of standardisation of the software and devices in cars, in addition to a future which seems to have new technological solutions happening quickly, it seems difficult for the driver instructor industry to prepare and come up with an optimal solution in the short run.

Hence, we recommend that the content of driver training and driver instructor education should preferably be increased, not decreased, as good driving skills are still needed in addition to good understanding on how to operate the technology. This is because, as of today, ADAS technology in cars seems to result in more rather than less work for the driver.

ABSTRACT: Improving performing and safety of the aircraft operation is one of the most important issues addressed by experts. Such improvement can result not only in the less frequent loss of equipment but primarily in the protection of health or saving lives of both crew members and others involved. Reducing such risks or minimizing impacts is possible by analyzing events, which had already occurred. In this paper, our main motivation consists in developing an effective and intelligent decision support system based on data mining techniques. In this context, data mining classifying algorithms with large datasets have been utilized to assess and analyse the risk factors statistically related to aircraft incidents in order to compare the performance of the implemented classifiers such as decision tree, discriminant and random forest. To underscore the practical cost, i.e., effectiveness of our approach, the selected classifiers have been implemented using statistical programming tools with datasets taken from the operation process. This analysis is expected to find the algorithm, which can support the decision taking.

1 INTRODUCTION

1.1 *Formulation of the problem*

Following the increasing requirements of flight safety and cost reduction, the problem of finding the optimum between the economic demands and acceptable level of risk arises in terms of reliability. Modern control systems equipped with computerized processes and extensive diagnostic tools do not often use all the information collected from the hardware level (Tloczynski 2017b). Moreover, some of the relations between events are often ignored or neglected. The article presents a new approach to increasing reliability of aircraft operations by predictive data analysis and increasing acceptable levels of safety.

2 FORMULATION OF THE PROBLEM - A STATISTICAL APPROACH TO SAFETY AVIATION PREDICTION

This article deals with the needs of the usage of statistical tools and methods of artificial intelligence, which enable to discover the relations between events stored in the database.

2.1 *Decision trees*

Decision trees are a class of predictive data mining tools which predict either a categorical or continuous response variable. They get their name from the structure of the models built. A series of decisions are made to segment the data into homogeneous subgroups. This is also called recursive partitioning. If presented graphically, the model can resemble a tree with branches (StatSoft Inc. 2013).

A decision tree is composed of nodes and splits of the data. The tree starts with all training data residing in the first node. An initial division is made using a predictor variable, segmenting the data into 2 or more child nodes. Divisions can then be made from the child nodes. A terminal node is the one where no more divisions are made. Predictions are made based on the behaviour of terminal nodes (Mueller et al. 2017).

Decision trees offer many advantages. One important advantage is the ease of interpretation

of a decision tree. While the tree can be complex, involving a large number of splits and nodes, users can interpret the model (Sedlacik & Cechova 2016). Additionally, making model predictions does not involve mathematical calculations as in General Linear Models. The predictions are based on decision rules. In classification problems, the user can specify misclassification cost. Decision trees tend to give good predictive accuracy and can allow for missing data in deployment (Hinz et al. 2017a).

2.2 *Logistic regression*

The statistical methods have been used so that the safe performance of the aviation operation could be determined. The logistic regression and the decision trees have been implemented as the most promising methods to reach this goal. The regression logistics model is based on the similar assumption as the model of linear regression; however, the former can be used in case the predicted variable is in binomial form (Babiarz 2016).

Logistic regression is a mathematical modelling approach that can be used to describe the relationship of several independent variables X_s to a dichotomous dependent variable, such as outcome - decisions D (Kleinbaum & Klein 2010). Other modelling approaches are possible as well; however, logistic regression is by far the most popular modelling procedure used to analyse epidemiologic data when the illness measure is dichotomous (Vintr & Valis 2011).

Formally, the model logistic regression model is as follows (Valis, Zak, & Pokora 2014):

$$\log \frac{p(x)}{1-p(x)} = \beta_0 + x \cdot \beta \tag{1}$$

where
p – logistic function of the probability,
β_0, β – constant terms representing unknown parameters.

Solving for p, this gives:

$$p(x) = \frac{e^{\beta_0 + x \cdot \beta}}{1 + e^{\beta_0 + x \cdot \beta}} = \frac{1}{1 + e^{-(\beta_0 + x \cdot \beta)}} \tag{2}$$

It should be noted that the overall specification is a lot easier to fathom in terms of the transformed probability that in terms of the untransformed probability (Shalizi 2013, Hinz et al. 2017b).

3 EXPERIMENTAL STUDY OF STATISTICAL METHODS

In order to carry out experimental studies, flights performed on a third generation fighter aircraft of two types were considered. The data were derived from the last 8 years of operation exploitation process in Poland. Flights were analysed in terms of incidents or undesirable events occurrences.

Table 1. Flight parameters.

Variable name	Unit	Type
Time after sunrise	min	Continuous
Time after sunset	min	Continuous
Month		Continuous
Aircraft type		Categorical
Age of aircraft	day	Continuous
Atmospheric conditions		Categorical
Name of the military department		Categorical
Real time in air	min	Continuous
Number of crew members		Continuous
Flight-hour of the first pilot	hour	Continuous
Flight-hour of the first pilot performed on a given aircraft type	hour	Continuous
Year of the promotion of the first pilot		Continuous
Subsequent departure of the first pilot on a given day		Continuous

Table 1 presents variables, which represent the examined flight parameters.

3.1 *Decision trees results*

Evaluation of the performance of a classification model is based on the counts of test records correctly and incorrectly predicted by the model. These counts are tabulated in a table known as a confusion matrix. Although a confusion matrix provides the information needed to determine how well a classification models perform, summarizing this information with a single number would make it more convenient (Bořil & Čičmanec 2016). This can be done using a performance metric such as accuracy, which is defined as follows:

$$\text{accuracy} = \frac{\text{Number of correct predictions}}{\text{Total number of predictions}}$$

$$\text{error rate} = \frac{\text{Number of wrong predictions}}{\text{Total number of predictions}}$$

Figure 1 shows the obtained results with the use of decision tress.

In this analysis, 80% of the cases were selected as the testing samples.

Tables 2 and 3 shows the percentage of correct decisions for the training sample and the learning sample, respectively.

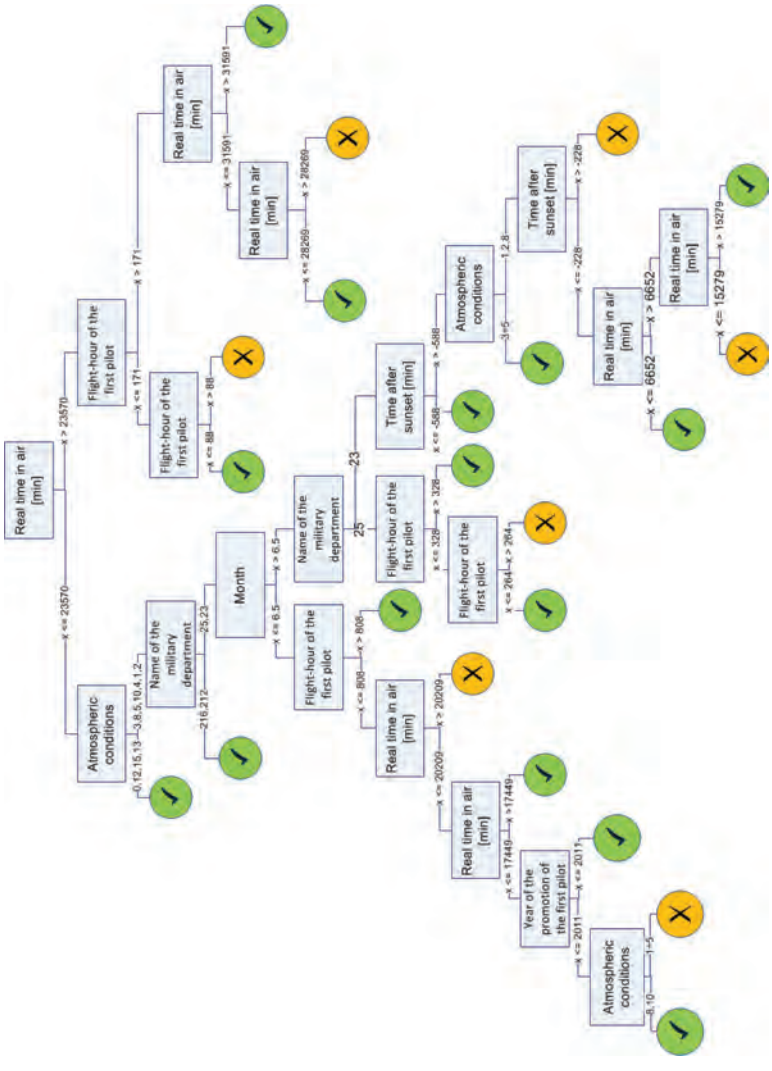

Figure 1. Sketch of the decision tree.

Table 2. Cross tabulation for training sample.

Reality \ Model	No incident	Incident
No incident	62.34%	31.46%
Incident	0.29%	5.91%

Table 3. Cross tabulation for testing sample.

Reality \ Model	No incident	Incident
No incident	60.15%	34.21%
Incident	3.01%	2.63%

3.2 *Logistic regression results*

In order to analyse the significance of parameters, not all available flight data were included. For the analysis, the entire data from the operation process with the recorded incidents were used, and the same number of randomly selected flights without an incident was considered.

In the proper statistical model all of the parameters should be quite different from zero (Koucky & Valis 2007). There are cases when the model has to comprise parameters that are not statistically significant however, the decision has to take them into account. Such a justification may be either theoretical knowledge of a phenomenon or experience from another, similar analysis. Wald statistics

Table 4. Cross tabulation for generalized linear model results.

Reality \ Model	No incident	Incident
No incident	31%	18%
Incident	23%	29%

Table 5. Cross tabulation for generalized linear model results – backward elimination.

Reality \ Model	No incident	Incident
No incident	33%	18%
Incident	25%	25%

can be used for the predictors determination and the associated test probability level p. The simplest way to obtain a model with all statistically relevant parameters (Table 7) consists in removing those parameters from the model which are not significant; this model is presented in Table 6. The strategy of construction of the model was achieved by backward elimination. The elimination starts with the entire model and then the most probable variables (test probability level p) are eliminated. The elimination finishes at the moment when the model comprises only statistically significant variables.

Tables 4 and 5 show the percentage of correct decisions for the model with all parameters and for the model with all statistically relevant parameters, respectively.

In the present analysis, the logit node with implementation was applied, and the choice of predictors has been made with automatic execu-

Table 6. Assessment of the parameters significance.

tion. The logit model is linear and its complexity is determined by the number of independent variables included in the design (Valis et al. 2016, Tloczynski 2017a). The more variables there are, the greater the risk of failure of the model is.

4 CONCLUSIONS

The work was carried out by the three research groups: University of Defence, Air Force Institute of Technology and Polish Air Force Academy as a part of the activities of the recently international cooperation between military universities and the institute.

In this article the comparison between the results of two models, regression model and decision trees, is presented. It was shown that both of them are giving similar results around 60% of accuracy. Results calculation should consider the fact they are slightly different for various models; the process of the training sample selection has to be consider as well.

The algorithms give us, step by step, importance of predictors, which can be used in the processes of decision taking.

This particular analysis resulted in finding the first, general algorithm, which can support the decision taking. Moreover, this algorithm is general, and could be used for different type of aircraft. In order to reach better accuracy, further calculations are expected.

ACKNOWLEDGEMENTS

The work of first author presented in this paper was supported within the project for "Development of basic and applied research developed in the long term by the departments of theoretical and applied bases of FMT (Project code: DZRO K-217) supported by the Ministry of Defence of the Czech Republic.

ABSTRACT: This paper presents the experiences from applying SysML models as support for establishing the safety requirements specification of a new safety-related railway application. The new railway application is a software-based system for securing work areas, meaning it prevents railway traffic in areas along the track allocated to maintenance. The experiences are collected within the Safety Assessment Framework for Efficient Transport (SafeT) project managed by Bane NOR. Bane NOR is the government agency that owns, operates and develops the Norwegian railway infrastructure. The objective of the SafeT framework is to offer a systematic, reusable way for creating system wide conceptual design models and based on them, creating a common risk model, which in turn will facilitate safety assessment, establishing the requirements specification, and safety demonstration of the system under consideration. The paper introduces the SafeT project as context of the work and presents experiences on the application of SysML for the conceptual system design of the new securing work areas application. The paper also discusses whether SysML models fit the SafeT framework's objectives.

1 INTRODUCTION

The SafeT project aims at developing a framework that supports the implementation of EN 50126 (CENELEC, 2017) and thereby of the Common Safety Methods for Risk Assessment (CSM RA) (EU, 2013). Figure 1 illustrates which phases of EN 50126 that is within the scope of the current SafeT work and this paper, annotated by a dark grey rectangle.

The current focus is on the development phases 1 to 4 of EN 50126. In these phases of a systems life cycle, Bane NOR takes a lead role in the development while successive development phases to a large extent are outsourced. The SafeT framework intends to support the development of the core artefacts within the system life cycle. In the early stages of the life cycle, in the part of the framework that concerns the in-house conceptualisation, the core artefacts are: 1) the conceptual system design model; 2) common risk model; and 3) requirements specification.

The main objective of the SafeT framework is to offer a systematic, reusable way for creating system wide conceptual design models and based on them, creating a common risk model, which in turn will facilitate the safety assessment, requirements specification and safety demonstration of the system under consideration, throughout the system's lifetime.

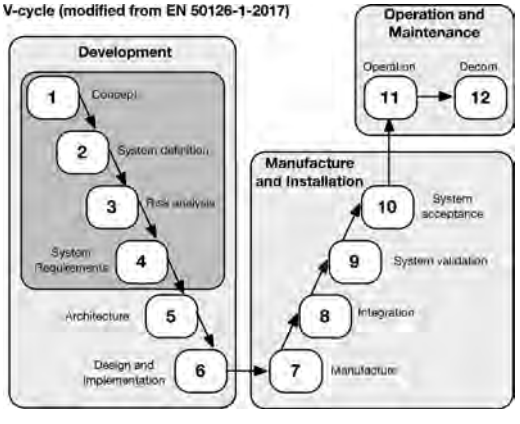

Figure 1. Scope of paper and relationship to EN50126.

2 RELATED WORK

International safety standards, such as EN 50126, provide requirements and guidance on how to carry out safety demonstration and assessment. Although most safety standards often view the safety of a system as a function of the reliability of its components, little guidance is provided on how to derive safety requirements and acceptable risk for components whose failure rates are not known. Particularly, it is often difficult to derive safety requirements for logical components such as the software. The problem can be formulated from a consideration of the following two important tasks in the development of safety critical systems: (1) *establishing the requirements to the system*, and (2) *ensuring that the system fulfils these requirements.* The safety requirements should be established through risk assessment and hazard analysis, and fulfilled through the use of techniques and measures adequate for the risk level. The framework proposed in SafeT has much of its inspiration from theoretical aspects of international safety standards such as IEC 61508 (IEC 61508). The novel part of the framework is fivefold: reusability, modularity, unification, transparency and argumentation.

Next, many past projects that relate to the topics of SafeT are briefly introduced. The OPENCOSS project provides a common language for both safety-case and standards-based approaches for certification. The CHESS project seeks to improve Model Driven Engineering practices and technologies to better address safety, reliability, performance, robustness and other extra-functional concerns while guaranteeing correctness of component development and composition for embedded systems, and offers a modelling language and editor. The CHESS modelling language and editor is a collection-extension of subsets of standard OMG languages such as UML (UML), MARTE (MARTE) and SysML (SysML).

The EU funded project MODSafe provides a risk analysis method purposed to combine potential hazards, safety requirements and functions, and link these elements to a generic functional and object-oriented structure of a guided transport system. The SaferCer project (Björnander, 2012) provides a generic process model for integrated certification and development of component based systems, including an overall picture of the development and verification of components and systems. ASCOS (Roelen, 2014) focuses on safety and certification of new aviation operation and systems, including advices on methods and tools for safety based design. ModelMe! (Falessi, 2011) provides a tool-supported traceability framework where the tool automatically extracts the safety-related slices of SysML design models.

Another approach is the AltaRica Language (Griffault, 1998). AltaRica is an object-oriented modelling language dedicated to performance evaluation of complex systems. The main motivation for its creation was the difficulty to design, to share and most importantly to maintain safety and reliability models such as fault trees, event trees, Markov chains or stochastic Petri nets. The application and further development of the language is a continuous research activity at NTNU (Legendre 2017).

Of relevance is also CORAS (Lund, 2013; Gran, 2004) which provides a methodology for model-based risk assessment, integrating aspects from partly complementary risk assessment methods and state-of-the-art modelling methodology.

The SafeT project has also reviewed a number of ongoing and past industrial experiences among the project partners related to the use of design and risk models to facilitate the safety assessment and demonstration of complex systems. Some of the challenges observed in these projects have also been reported earlier within aviation (Gran, 2007). Finally, the CHASSIS method (Raspotnig, 2018) utilizes UML use cases and sequence diagrams with HAZOP guidewords to integrate safety and security considerations for early requirements determination.

3 CONCEPTUAL MODELLING

3.1 *The role of models*

An important aspect of SafeT is the role of system modelling in the RAMS process defined in EN 50126, in particular for supporting the risk assessment process and the identification of safety requirements. An example of a modelling task related to the RAMS life-cycle phases is the introduction of the system under consideration in a model at the railway system level (phase 1). In phase 2, the model can be refined as necessary to support the description of system objective, mission profile, boundaries and external interfaces and interactions. In phase 3, the model can be further refined to support the establishment of the risk model, followed by a refinement in phase 4 to support the specification of requirements and application conditions for the system under consideration. In addition to the system models, there is also a need to establish risk models that capture the relations between the different hazards, causes, barriers, accidents, and consequences identified in the hazard identification performed at the different system levels. SafeT looks into the possibilities to enhance the system and risk modelling tasks by the appropriate application and combination of techniques evaluated against a set of criteria derived from the relevant standards.

SafeT intends to support the implementation of EN 50126 by giving guidance on what kind of models can be used, and how they can be utilized, in the life cycle phases within the standard. In this paper, we focus on the application of models. In another paper, we focus on the risk assessment part (Skogvang, 2018). An important research problem in the SafeT project is how the use of models throughout the life cycle of a system can be integrated in a way that facilitates the overall safety demonstration and assessment. The models will serve different needs, related to the analysis of system, risk, requirements, etc. SafeT aims at arriving at a set of techniques that covers the modelling needs in the different life cycle phases, with a current focus on the first four phases aimed at establishing the requirements specification. Some examples of the prospective use of models are:

- describing and analysing the static structure of a system and its constituent parts, down to the system level and the level of detail necessary to support analysis, independence demonstration, etc.;
- describing and analysing the behaviour of a system, internally as well as through its boundaries;
- describing and analysing a system's interaction with its environment, and how it affects, and is affected by, agents involved in its operation;
- supporting the activities involved in risk assessment and hazard control, including the identification of hazards at all system levels, their causes and possible consequences;
- supporting the derivation of the safety requirements needed to handle the hazards at the overall system level as well as technical hazards at any system level; and
- communicating the different design and risk aspects, as well as the safety argumentation as such, to the different stakeholders involved.

3.2 *Requirements to models*

To facilitate the selection of design and risk models, an initial set of 58 requirements to be fulfilled by the models is established within SafeT. The requirements were derived by reviewing the process requirements in the CENELEC standards EN 50126, 50128 and 50129 (CENELEC 2017, 2011 and 2003). The set of requirements acts as the evaluation criteria supporting the selection of techniques to be used in the development of the desired models. The identified modelling needs were reformulated in terms of requirements to the models as such and categorised as requirements concerning

- Structure: to model the static aspects of a system at any system level, e.g. the possibility to support any hierarchy of system levels, and describe any system level at the appropriate level of detail without introducing unnecessary detail and complexity at other system levels;
- Behaviour: to describe the dynamic aspects of a system at any level, e.g. the possibility to show how the behaviour and state of a system depends on, and changes with, the functionality of its sub-systems and components;
- Interaction: to describe the reciprocal impact between a system and its environment, e.g. the possibility to show how the environment can influence, or be influenced by, the system, including anything to which the system connects mechanically, electrically or by other means;
- Risk: to carry out the risk assessment and hazard control, e.g. the possibility to facilitate the identification of hazards associated with the system and events leading to these hazards, the determination of the risk associated with the hazards, and the identification of possible further safety requirements needed to reduce the risk to an acceptable level, at any system level;
- Requirements: to identify and specify safety requirements, e.g. the possibility to provide the details necessary to explain and understand the requirements to the functions to be provided by the system, as well as any additional requirements that are necessary to ensure proper functioning, including contextual and technical requirements;
- Design: to analyse the safety aspects of a design, e.g. the possibility to identify the need for, and analyse the effectiveness of, safety functions or any other barrier; and
- Quality: to assure clarity, unambiguity, consistency, etc., e.g. the possibility to review the models for completeness of the identified safety requirements.

For each requirement, SafeT provided an explanation to guide the application of the requirement on models to be used in the RAMS life cycle. An example is shown in Figure 2.

Requirement: The models must support the breakdown of a system into its constituent parts, in terms of system, sub-systems, and components.
Explanation: A system generally consists of a hierarchy of subsystems and components, each of which can be understood as a system itself. It is therefore meaningful to speak about the different levels of a system, and represent these levels in such a way that the details presented for each level are adequate for this level. Furthermore, it should be possible to study the details at any system level by recursively opening up the system model down to the subsystem or component of interest.

Figure 2. Example of a requirement and its explanation.

3.3 *The use of models in the RAMS life cycle*

The 58 requirements to models reflect needs identified from an analysis of the tasks to be performed in the different phases of the RAMS life cycle. The requirements can therefore relatively easily be interpreted in this context by describing how they apply to the modelling needs in the first ten RAMS phases. The different requirements were gradually introduced along with possible procedures and flow charts. Concerning modelling, the concept phase can be carried out in accordance with the following procedure:

1. Describe the needs and how these are met today without the system.
2. Make a first informal description of the system and its environment.
3. Make a first model of the system and its environment.
4. Define the aspects to be analysed, including the aspects defined in EN 50126.
5. Select an aspect for analysis.
6. Analyse the aspect, refining the model to make it adequate for the analysis.
7. If necessary, refine the model to make it represent the analysis result adequately.
8. Repeat from step 5 for the remaining aspects.

The RAMS life cycle is initiated with the concept phase. The main objective of the phase is to investigate the overall system and its environment, confined to (1) scope, context and purpose, as well as (2) physical, interface, legislative and economic issues. This means that there already is some idea of a "system under consideration", and some idea of the functionality that shall be offered, and most likely some constraints. The purpose of a model in this phase would therefore be to facilitate this investigation. Even if the system has not yet been defined in a proper sense, it will usually be possible to introduce the system as a black box, and concretize the aspects to be investigated. It might already in this phase even be possible to decompose this black box into a set of connected subsystems, each with its specific scope, context and purpose.

Requirements posed to models in this phase demand the ability of the models to support different needs, for example:

- support the breakdown of a system into its constituent parts, in terms of system, sub-systems, and components;
- facilitate the treatment of systems, sub-systems and components as black boxes, for which the details on architecture, design and implementation can be kept out of consideration, evaluating functions and hazards only at the boundaries;
- describe the system as contained in its operational environment;
- show how the environment can influence, or be influenced by, the system, including anything to which the system connects mechanically, electrically or by other means;
- show how man and organization can affect, or be affected by, the operation of the system;
- use clear and intelligible means of description, such as formal notation for logical functions, natural language for introductions, justifications and representations of intentions, graphical representations of examples, semantic definition of graphical elements, and directories of specialised words;
- be possible to communicate to the different stakeholders;
- be understandable in themselves;
- be understandable to the prospective user.

4 APPLYING SYSML

The Concept phase and System definition phase are focused on preparing the conceptual system model. The model acts as an input to the Risk analysis phase (see Figure 1). The first activity of the Risk analysis phase is the Hazard Identification (HI). This was the focus of a workshop in the SafeT project (see section 4.5) using the model-based description of an example case described in section 4.1.

Related to the use of models, two questions were investigated: (1) whether the modelling technique selected on the basis of theoretical considerations (the identified requirements to models based on the standards) is also practical for phase 1 and 2, and (2) whether the model-based description prepared is practical for the hazard identification activity.

4.1 *The securing work areas case*

In order to realistically evaluate existing techniques and develop the SafeT framework, the project chose a case example based on a concept of a new solution for securing work areas (Sivertsen, 2014). The problem concerns the need to protect maintenance workers from accidents caused by the interference with the railway traffic. The concept involves the development of a software-based system for securing the work areas from such interference. The basic requirements to such a system are to identify the workers' position correctly, effectively block the correct work area, and prevent a premature unblocking of this work area.

In the proposed solution (see Figure 3), a safety guard uses a smartphone both for the interaction with the train dispatcher and for identifying the works areas under consideration. The smartphone contains a dedicated application with functionality

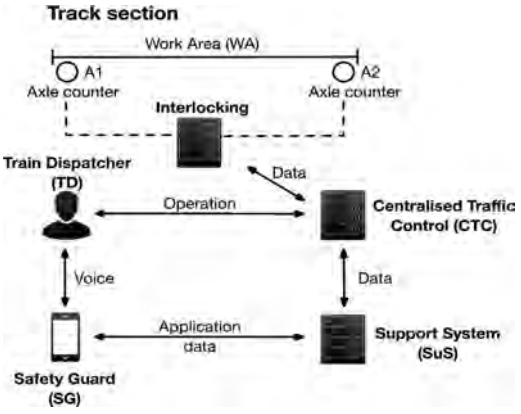

Figure 3. The securing work areas case.

to manage the securing and releasing of the work areas. Some of the characteristics of the functionality are:

- The main Safety Guard (SG) selects the functions from the application on his smart phone, e.g. secure a Work Area (WA).
- The scanning of the associated QR-code of a WA identifies both the SG and the WA.
- The application communicates with the Support System (SuS), which communicates with the Centralised Traffic Control (CTC) and other applications.
- The SuS supervises the associated protocols.
- The SuS supervises the secured WAs, and prevents the Train Dispatcher (TD) from prematurely unblocking them.

4.2 *SysML*

UML (Unified Modeling Language) was initially selected to be applied for modelling in phases 1 and 2 as it fulfils all of the related requirements to models in these phases. However, UML's focus is on supporting software analysis and design, while the system in our example case is not limited to software. Another important consideration was that the first RAMS phases are carried out at a higher system level ("the railway system level"), requiring a focus on the system as such and not merely on its software. Hence, we used SysML (Systems Modeling Language) instead which supports system engineering.

SysML is an extension of a frequently used subset of UML, and thus is expected to comply with most of the requirements to models that UML complies with. A SysML model is usually developed in a tool that stores the model entities with their characteristics and relations. The model entities can then be used in diagrams to present graphical views on specific aspects, e.g. structural or behavioural aspects.

Because of this unified model in the core of UML and SysML, they can be considered as a single but complex modelling technique. Furthermore, they offer different kinds of diagrams where each kind can be considered as a modelling technique in itself.

4.3 *Modelling the conceptual design*

Within the concept phase, modelling of the system and its environment with respect to the following aspects are required: (1) scope of the system, (2) (application) context of the system, (3) purpose of the system, and (4) environment of the system (anything that could influence, or be influenced by, the system, including people and procedures). All of these aspects are expected to be considered in the context of RAMS performance. The system definition phase requires extending the model with:

- functions and elements which need to be considered in the risk assessment;
- interfaces and interactions with the physical environment, other systems, humans, and other organisations;
- operational requirements influencing the system, including a description of conditions, constraints, logistics;
- existing safety measures and assumptions that determine the limits for the risk assessment.

The modelling was performed by an IT and dependability specialist with some experience in UML modelling, using a tool. A short textual description of the proposed system was the input to the modelling, and was analysed according to the needs of the two phases described above. The models were developed in an iterative process including consultation with the system owner.

Diagrams were prepared for a HAZOP workshop, e.g. Block Definition Diagrams (**BDD**) about Work Area and related concepts (see Figure 4), Internal Block Diagrams (**IBD**) about the internal communication and interfaces of the Support System (see Figure 5), Use Case diagrams (**UC**) of the main functions of the Securing Work Area application, State Machine diagrams (**STM**) about the registerable states of a Work Area (see Figure 6), and Sequence Diagrams (**SD**) about the main functions of the application.

4.4 *Using the models to meet the needs of the concept phase and the system definition phase*

The concept phase modelling needs can be mainly fulfilled by using BDDs and IBDs since those needs

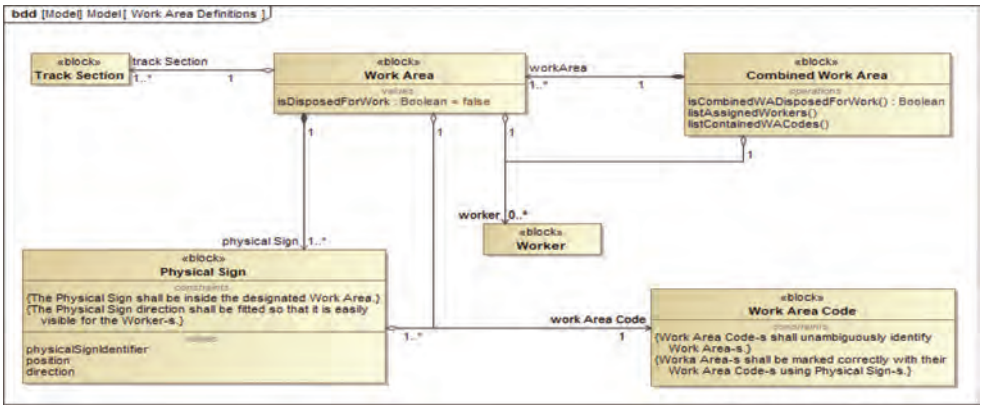

Figure 4. Example BDD defining the work area and related concepts.

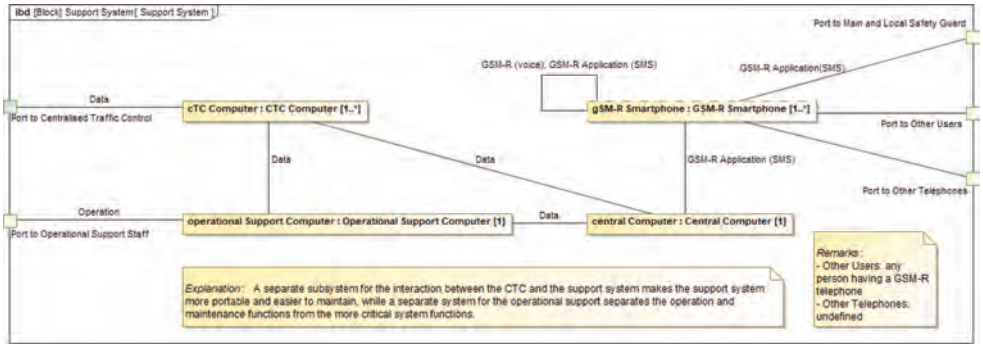

Figure 5. Example IBD of the internal structure of the support system.

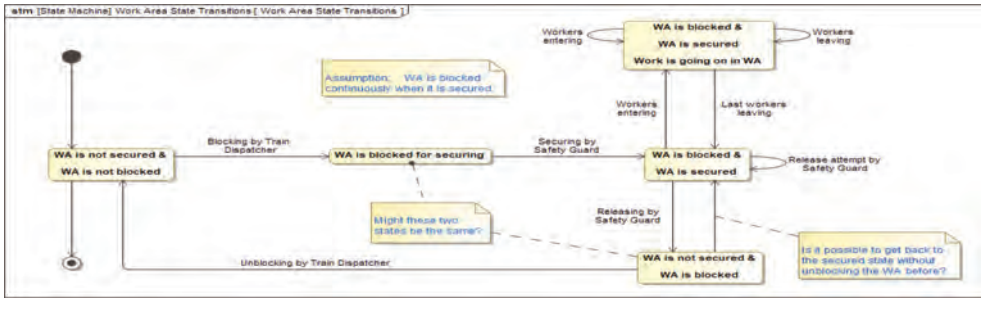

Figure 6. Example STM with the different states of a work area from the securing point of view.

require to represent the system with its elements and environment, and their static, conceptual relations. BDDs can depict an ontology. For example, the BDD in Figure 4 identifies the main concepts connected to work area in the proposed solution, their relevant characteristics, and their relations. IBDs can visualize internal structure, lines of communication and interfaces. For example, the IBD in Figure 5 depicts the internal structure of the Support System with it interfaces. The central computer communicates with the applications via its GSM-R receiver and transmitter; the operational support computer is used by the operational support staff to operate the system; the CTC computer ensures the correct interaction between the central computer and the CTC system. Another SysML diagram type not utilized by us is the Requirement Diagram (REQ) which could have

been useful for embedding the requirements in the model if a structured requirement specification had been available.

The system definition phase modelling needs can be partially fulfilled by using all 5 mentioned diagram types. BDDs and IBDs can be used when the system is further detailed (i.e. elements and interfaces in the system definition description). UC and STM diagrams as well as SDs are useful for depicting the dynamic, behavioural aspects (i.e. functions and interactions). For example, Figure 6 presents an STM with the different states of a Work Area from the securing and releasing functions point of view. This diagram shows for example that the states of the Work Area (as seen by the system) were unclear between "before securing"/"after releasing" and when it was "secured". Whether these states ("WA is blocked for securing" and "WA is not secured & WA is blocked") are the same, whether a transition from the second directly back to the state of "WA is blocked & WA is secured" is possible, triggered lots of discussions in the workshop.

Operational requirements were mostly not included in the model, but they can be added through REQ diagrams and by defining constraints. Existing safety measures were not specifically identified as such in the model, they were depicted as regular parts of the diagrams. However, there are suggestions in this direction, for example extending UC and SD for safety and security considerations (e.g. Misuse Cases, Failure Sequence Diagrams, Misuse Sequence Diagrams; an overview can be found in (Raspotnig, 2014)). Assumptions were either depicted as notes in the diagrams (e.g. see Figure 6), or as constraints. In summary, SysML has the potential to fulfil the needs of the concept and the system definition phases with respect to the requirements to models connected to these phases.

One experience was that the modelling process *helped identifying unclear and missing parts* of the case description which were necessary to develop an understanding for persons not familiar with the planned system. It is quite hard for a person involved in a task to evaluate what pieces of information are necessary for understanding the task by another person with different expertise working on another aspect of the task. The necessary amount of information is usually underestimated, which is also reflected by the related system descriptions. Modelling helps overcoming this gap but it does not guarantee the completeness of the information provided.

Another experience was that modelling with SysML sometimes demands more details than available or expected in the conceptual design phase. In other words, it *might be hard to draw the line between the conceptual design* (defining the "what") *and detailed design* (defining the "how"). For example, the conceptual design might stop at the level where the actors and systems of the New Solution are identified, maybe including the subsystems of the Support System. However, including the SWA App in the model required some further details since it resides in the software part of the Smartphone, which is a subsystem of the Support System. SafeT will need to specify clear criteria or guidelines regarding the detailing of models at the different phases of the development of a planned system.

4.5 *Using the models in a HAZOP workshop*

Two workshops utilizing HAZOP for hazard identification (HI) were organized, one using only a textual description as input and the other using a model-based description as input. The hazard identification related experiences of the workshops are presented in paper (Skogvang, 2018). Here, we focus on the modelling related experiences from the model-based workshop. A description utilizing the diagrams with limited text and explanation of the modelling language, was sent out one week before the workshop.

Even though modelling helped identifying unclear and missing parts from the modeller's perspective, it gave no guarantee that these identifications covered every necessary detail for HI. This became clear since the workshop participants had many questions outside the scope covered by the model but important nevertheless for their understanding of the context and for identifying hazards. A conclusion is that, for a better coverage of the hazard identification, relevant details in the model and the diagrams are desired. This could be achieved for example by a preparatory workshop focusing on eliciting such information, or by involving a RAMS expert in the modelling.

Constructs in models can become complex, and so their visualization. According to the experiences in the workshop, after a certain level of visual complexity (e.g. when not the whole diagram can be shown at once or if it is shown then it becomes unreadable), understanding of the diagram and following the track of thought becomes cumbersome. One related problem was following the flow of logic in SDs when branches and parallel activities were involved. Modularization might help with this issue.

During the workshop, an example of the physical outline was drawn ad hoc as an illustration which was used a lot in the discussions. This suggests that a physical outline diagram could be part of the model. SysML has no obvious means for this, therefore another modelling technique might be required as support. Another consideration is that modelling specific, representative cases (e.g. application of the planned system at a specific work area) might be a necessary supplement to the

general model of the planned system. In our case, a specific, representative train station could be considered. The model-based description also missed some information, e.g. preconditions of the main functions of the software application, necessary for understanding how the system was intended to work. A question related to this is whether the workshop would have been able to process and utilize the information requested by the participants (defined terminology and roles, description about the old and current solutions, etc.). This needs to be taken into account when considering the use of models with other techniques. SafeT needs to prepare guidelines on how to use HAZOP in combination with specific SysML diagrams.

5 CONCLUSIONS

In this paper we have elaborated on the experiences on using SysML diagrams as support for the concept and system definition phases. To the question of whether the modelling technique selected on the basis of theoretical considerations is also practical for the two first phases, we can answer affirmatively based on the experiences. The concept phase modelling needs can be fulfilled by using BDDs and IBDs since those needs require representing the system with its elements and environment, and their static, conceptual relations. BDDs can depict an ontology. The system definition phase modelling needs can be partially fulfilled by using all five mentioned diagram types.

However, further investigations and fitting guidelines will be necessary. Whether the model-based description prepared was practical for the hazard identification activities were not concluded, but the HAZOP workshop suggests that the use of SysML models requires good preparation of the HAZOP, and the participants should be familiar with such modelling to benefit from the models.

ACKNOWLEDGMENT

The SafeT project is funded by the Norwegian Research Council (project number 257167/O80) and Bane NOR, and has beside participation by Bane NOR and IFE, also participation from Indra Navia AS, Avinor, Solvina AB, Safetec Nordic AS, NTNU, VTT and Beijing Jiaotong University.

A framework for modeling of multiple system failures—recoveries through multi-dimensional distributions in dynamic event trees

C. Picoco

ABSTRACT: Dynamic Event Tree (DET) methodology has been developed to overcome the limitations of the traditional Event Tree approach by taking timing of events explicitly into account through communicating with the system model that describes its dynamic behavior in event sequence construction. In addition, more rigorously accounting for process/hardware/software/human interactions, this capability allows including recoveries within the sequence analysis. Furthermore, particularly for long term scenarios, DET would be able to model multiple failures and recoveries for a given system with this capability. From probabilistic point of view, modeling multiple failures and recoveries introduces a major challenge since failure and recovery distributions for a given system can be correlated. Use of a multidimensional distribution is proposed to address this challenge.

1 INTRODUCTION

Dynamic Probabilistic Risk/Safety Assessment (DPRA/DPSA) methodologies are those methodologies that, by using simulator for the system under analysis, are able to explicitly model time dependent system evolution along with its stochastic behavior under accident conditions (Aldemir, 2013). Among these methodologies Dynamic Event Tree (DET) is perhaps the most popular one, given its similarity to the static event-tree (ET) approach, but with capability to model the interaction between stochastic events (e.g., failures, recoveries, etc.) and the dynamic evolution of the system as a consequence of these events.

A DET consists of an initiating event (e.g., station blackout, loss of offsite power, etc.), and a set of events that initiate system evolution in different directions, called branching conditions. Each branching point is defined by the analyst, and consists of a stochastic event described by (Alfonsi, 2013):

- values of process variables or thresholds, and,
- corresponding probability distributions (e.g., the exponential distribution of the failure time).

When, during the simulation, the thresholds corresponding to the branching points are met, branches are generated that give rise to the typical ET structure. Figure 1 shows a typical DET structure with thresholds defined for values 0.33 and 0.66 of the relevant cumulative distribution function (Cdf).

The scheme presented in Figure 1 refers to one of the codes currently used for generating DETs (i.e., RAVEN (Rabiti, 2016)).

Since the timing of the events in the sequence is explicitly modeled with a DET, failure recovery can be included within the analysis by assigning a probability distribution to the recovery time. The modeling of system failure and recovery becomes particularly important when long term scenarios

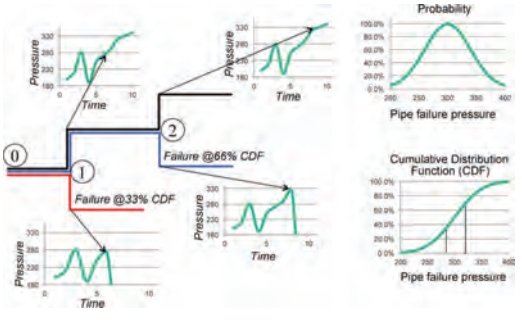

Figure 1. DET scheme (Alfonsi, 2014).

are considered. In these cases, multiple failure/recovery cycles for a given system become possible within the mission time.

The modeling of recoveries, however, introduces two main issues to consider. On one hand, as previously mentioned, failures and recoveries for a single system can be multiple along the accident sequence. On the other hand, recovery and failure time distributions can be interdependent since, from a causality point of view, a recovery can occur only after a failure.

Let us consider a system made up by different components, each with a characteristic failure and recovery distribution. The recovery time distribution for the overall system will be dependent on the failure time distribution for the system itself, through the failed components. Each event from the first recovery afterwards will depend on the previous one. Second recovery time will depend on second failure time, second failure time will depend on first recovery time and finally, first recovery time will depend on when the system has first failed. Therefore, in order to realistically represent the behavior in this example, we need to use a 4-dimensional distribution to be sampled according to the branching conditions.

The case of multiple failures and recoveries presents a unique challenge. In terms of physical states of the system, the multiple failures and recoveries can be represented as a two-way transition between two discrete states: an ON state and an OFF state (Picoco, 2017a). However, from a probabilistic point of view, each single transition (e.g., first failure, first recovery, second failure, etc.) could correspond to a different probability distribution.

In this work, we address these two aspects of DET generation: failure/recovery behavior (potentially multiple) and use of multi-dimensional distributions.

The paper is organized as follows. In Section 2, the framework for DET generation with multi-dimensional distributions is presented. In Section 3 some conclusions are drawn.

2 FRAMEWORK TO MODEL MULTIPLE FAILURE/RECOVERY BEHAVIOR IN DET

In order to generate a DET, a driver coupled with a simulator is needed. Different couples driver—simulator have been presented in literature such as ADAPT—MELCOR (Hakobyan, 2006), ADAPT—MAAP4 (Rychkov, 2015), RAVEN—RELAP7 (Alfonsi, 2013), MCDET-MELCOR (Hofer, 2002), ADAPT-SAS4-SASSYS-1 (Jankovsky, 2015), RAVEN-MAAP5 (Picoco, 2017b).

In the coupling, the driver is the code responsible for taking care of the probabilistic aspects. Generally, the driver requires for each branching condition the definition of a probability distribution. The branching conditions are expressed as a grid of thresholds, defined in either values of the process variables/system configuration or Cdfs. The driver is responsible for generating the different branches and managing their run. Driver also collects the results from the simulator, and, for some drivers, perform desired post-processing analysis, if any, set by the analyst.

The simulator provides the branch consequences and simulates the plant evolution as the different branchings occur. In nuclear field, the simulator (e.g., MELCOR (Summers, 1981), MAAP5 (MAAP5, 2015), RELAP7 (Anders, 2012)) is able to predict the behavior of the reactor under several accident conditions as the different branches occur. The control logic of the simulator is often used to model operator actions, and possible interactions among the different branches.

The driver and the simulator usually exchange information during the DET generation in order to create the different branches, based on the plant state.

Overall, the DET generation process is the following (the process can slightly vary depending on the driver-simulator couple used):

1. Simulation starts: the first branch is run.
2. The simulation stops when a branching point is met.
3. Two (or more) branches are created by the driver, each corresponding to a different new simulator instance, and run in parallel.
4. The simulation of each branches progresses until the next branching point is met.
5. When all the branches simulated are completed, the DET is generated.

In order to define each branch, as previously mentioned in Section 1, a probability distribution is needed.

In case of multiple failures and recoveries, a first approach would suggest to treat these conditions independently, defining a different distribution (and corresponding branching points) for each event. However, this type of modeling will not account for their intrinsic correlated behavior.

Since most of the drivers, so far, require definition of branching points in terms of 1-dimensional distributions and 1-dimensional grid for each variable as a first approach to face the use of N-dimensional distribution, we propose the following framework:

1. *From the N – dimensional distribution, define the corresponding N 1-dimensional marginal distributions*. It is worth recalling that, starting from a joint *N*-dimensional distribution, the marginal of a variable describes the corresponding probability distribution of that variable only. Formally, given the N – dimensional probability distribution function $f(x_1, x_2, \ldots, x_n)$, then the marginal for the generic x_i is

$$f_{X_i}(x_i) = \int \ldots \int f(x_1, \ldots, x_n) dx_1 \ldots dx_{i-1} dx_{i+1} \ldots dx_n \quad (1)$$

   The general concept of multidimensional distribution and corresponding marginal is shown in Figure 2, referred to the case of a bivariate normal distribution. In Figure 2, the two marginal distributions for x_1 and x_2 are $f(x_1)$ and $f(x_2)$, respectively.
2. Once 1-dimensional distributions for each variable are obtained, it is possible to use them with the driver and define for each variable the grid of the branching points independently, as is current practice with DET generation.
3. Run the simulation and generate the DET.
4. Once the DET has been generated, post-process the results to recalculate the probabilities of each history based on the values of the multidimensional distribution rather than on the marginal.

This approach allows to account for correlated probabilities without necessity to re-run the DET, and by defining the branching conditions as is the case for 1-dimensional distributions.

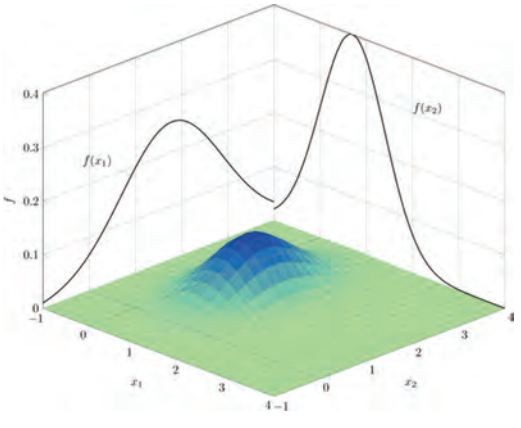

Figure 2. Two-dimensions distribution and corresponding marginal for a bivariate normal distribution.

3 CONCLUSIONS

DETs are currently used to analyze the possible evolution of an accident scenario starting from a given initiating event. In general, as in traditional ET, only failures of the different systems involved in the accident evolution have been considered. By explicitly modeling time, DET has the capability to include recoveries within the model. Including recoveries, and even multiple failures and recoveries for the same system, becomes particularly important when long mission times are considered.

In this paper, we have presented a framework for dealing with the DET generation in case of multiple failures and recoveries for a given system modeled by multidimensional distribution. In summary, the approach proposed in this work consists in the following: a) variables are sampled starting from their marginal distributions, and, b) the DET is generated using the marginal distributions. Then history probabilities are recalculated based on the values of the *N*-dimensional distributions.

This framework represents a first approach for the use of multidimensional distribution in DET. The approach is valid in regular cases (e.g., multidimensional uniform, multivariate normal), however, the sampling from the marginal can potentially lead, in some cases, to weak density of sampling points in probabilistically relevant regions of the multi-dimensional distribution.

Using an enterprise architecture model for assessing the resilience of critical infrastructure

Gonçalo Cadete & Miguel Mira da Silva
Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal

ABSTRACT: Assessing the resilience of Critical Infrastructure (CI) is a complex problem. Complexity becomes especially high when hybrid threats are considered and, additionally, crisis span interdependent sectors and sovereign borders, with time-variable cascading effects. Models may help address complexity, since they are simplified representations of systems, intended to promote understanding within some domain of discourse. Furthermore, Enterprise Architecture (EA) allows for managing and visualizing integrated model repositories. In this paper, we propose an EA model to assist resilience assessments, performed using a Resilience Assessment Framework (RAF). To ensure that the framework was fit for purpose according to the evaluators' needs, a new version of an existing RAF was designed and tested, using a Design Science Research Methodology (DSRM) process model. To measure the value of the EA model, we performed a comparative evaluation of the new RAF's usefulness—i.e. with and without assistance of the EA model. We conclude that the proposed EA model is useful for assisting resilience assessment initiatives for CI. The main scientific contributions of this paper are the validation of the EA model's usefulness, a set of EA viewpoints for assisting resilience assessments of CI, as well as an evaluation of the new version of the RAF.

1 INTRODUCTION

Assessing the resilience of Critical Infrastructure (CI) presents both conceptual and implementation challenges. At the conceptual level, frameworks and standards are required to align terminology (ISO 2009, 2012), provide reference models (ISACA 2013a), enable consistent audit and assurance programmes (NIST 2014, ISACA 2013b), as well as to facilitate communication, cooperation, and collaboration. At the implementation level, adequate methods and tools are required to enable effective and efficient assessment initiatives.

Models are important to address the complexity of resilience assessments, since they are simplified representations of the system of interest. Also, as we demonstrate in this paper, models may help clarify conceptual and methodological ambiguities. Furthermore, Enterprise Architecture (EA) allows for managing and visualizing integrated model repositories (Lankhorst 2013), thus enhancing the performance of assessment initiatives – when compared with the exclusive use of spreadsheet-like artifacts, informal diagrams, and natural-language descriptions.

In this paper, we propose an EA model to assist the implementation of resilience assessment initiatives. The EA model's usefulness was evaluated using a demonstration, evaluation questionnaires, and group sessions, to measure the efficacy, generality, consistency, simplicity, and clarity of the artifacts. For the demonstration and evaluation, we used a new version of an existing Resilience Assessment Framework (RAF) – from Cadete et al (2017).

We conclude that the proposed EA model is useful for assisting resilience assessment initiatives, by helping to achieve three framework objectives: provide a logical link between management and operational indicators for resilience, clarify conceptual and methodological ambiguities, and facilitate the implementation of resilience assessment initiatives.

2 METHODOLOGY

In this paper, we performed two iterations of a Design Science Research Methodology (DSRM) process model (Peffers et al 2014), for guiding the construction and evaluation of the architectural artifacts.

DSRM incorporates principles, practices, and process models which are adequate to conduct design science research in applied research disciplines, whose cultures value incrementally effective solutions (Hevner & Chatterjee 2010). The design science paradigm seeks to create and evaluate

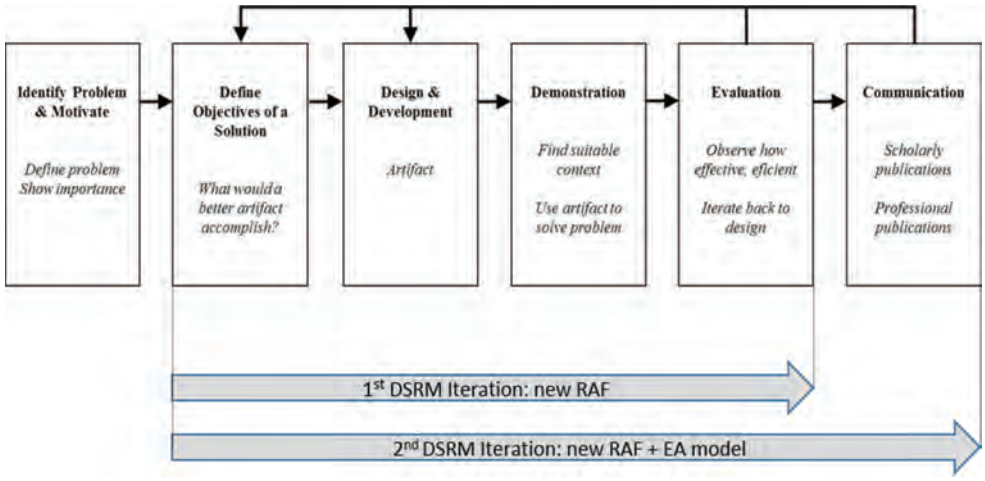

Figure 1. DSRM process model used in this paper. Two DSRM iterations were performed: in the first DSRM iteration, a new conceptual model for the RAF was designed and tested; in the second DSRM iteration, an EA model for the new RAF was designed and tested.

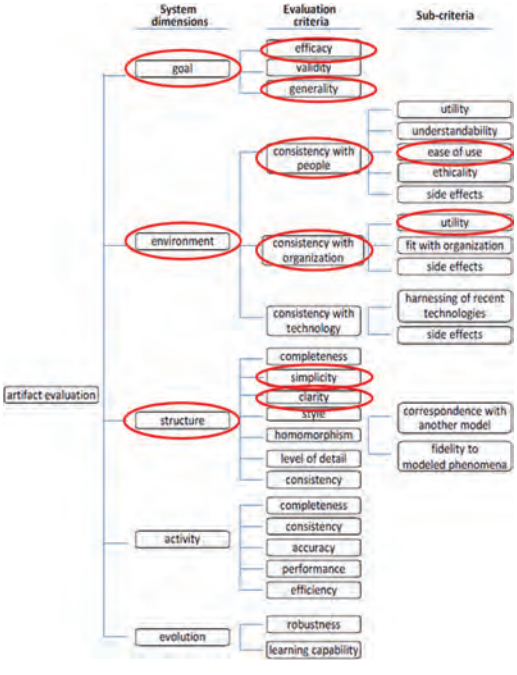

Figure 2. Evaluation criteria, taken from Prat et al (2014). The evaluation criteria used for evaluating the new RAF are highlighted with ellipses.

"what is effective" in the problem space (Hevner et al. 2004).

The first DSRM iteration (Fig. 1) was performed to ensure that the framework was fit for purpose according to the evaluator's needs. Had

Table 1. Evaluation objectives for the new RAF.

System dimension	Evaluation criteria/ sub-criteria	Objectives for the new RAF
Goal	Efficacy	Integration of disaster risk management aspects
		Risk is associated to effect/ impact on relevant objectives
		Indicators are relevant for risk management
		Management indicators relate to operational indicators
	Generality	May be tailored for any CI organization
		Is not overly prescriptive
		Cross-sector generality
		Cross-border generality
Environment	Consistency with organization/ utility	Useful for CI organizations
	Consistency with people/ ease of use	Easy to implement for CI managers
Structure	Simplicity	Is simple to communicate and understand
	Clarity	The concepts and methods are clear and unambiguous

this iteration been omitted, the evaluators' ratings might have been negatively affected by perceived deficiencies in the reference framework design (Cadete et al. 2017). In the second DSRM iteration, an EA model was designed, for modeling the new RAF that resulted from the first DSRM iteration. This strategy allows for comparing the two sets of DSRM results, ensuring that the evaluation rating differences (i.e. between the first and second DSRM iterations) are a reasonably good measure of the benefits of using the EA model.

As shown in Fig. 1, the DSRM process model includes an evaluation activity. For both DSRM iterations, we adopted the same evaluation criteria (see Fig. 2), as well as the same evaluation objectives (see Table 1), that were used for evaluating the RAF from Cadete et al (2017) – based on the evaluation taxonomy from Prat et al (2014).

3 RESEARCH PROBLEM

In Cadete et al (2017), the RAF evaluation results showed relatively weak ratings, regarding the achievement of three objectives:

- Consistency with people, ease of use: easy to implement for CI managers;
- Structural clarity: the concepts and methods are clear and unambiguous;
- Generality: may be tailored for any CI organization.

In related work, EA artifacts were used successfully to assist business continuity planning (Gomes et al. 2017) as well as to represent process-based frameworks (Vicente et al. 2013). Also, EA is recommended as best practice for guiding the creation and maintenance of the governance and management enablers for information systems and related technologies (ISACA 2012a). Finally, it is important to note that when holistic frameworks are represented, complex graph-like structures of entities and relationships emerge due to the variety of concerns (e.g. many sectors, many countries, and many areas of expertise), as well as due to the complex networks of dependencies. Such complex graph-like structures may be represented and managed using EA methods and tools.

These facts lead to the hypothesis that EA techniques and artifacts might help address some of the implementation issues identified previously by the RAF evaluators in Cadete et al (2017).

The research problem is therefore to find and validate an EA solution to address the RAF conceptualization and implementation shortcomings, namely regarding goal efficacy, environmental consistency, and structural simplicity and clarity.

4 DESIGN AND DEVELOPMENT

To help improve the design of the new RAF, we selected senior evaluators from the defense sector,

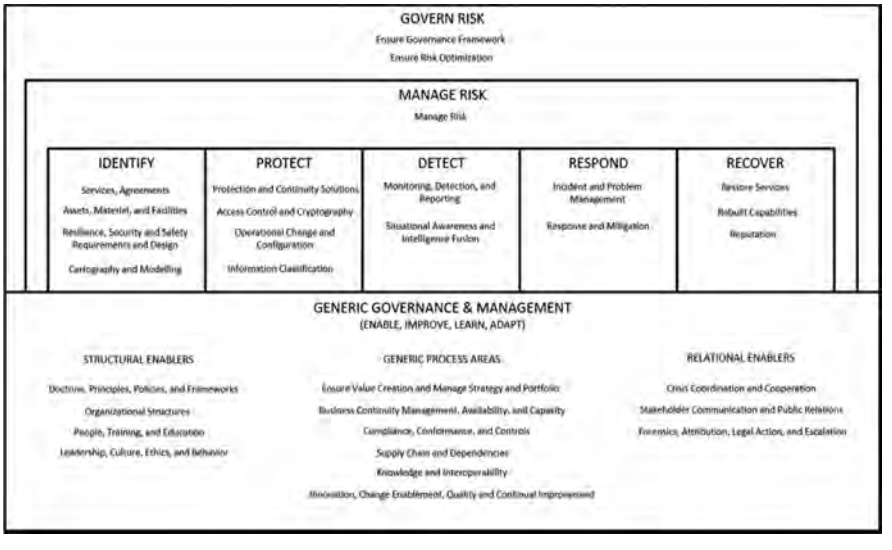

Figure 3. The new RAF Process Reference Model (PRM) design, resulting from the first DSRM iteration. This artifact was used in both DSRM evaluations (first and second). This new design ensured that the RAF framework was sufficiently fit for purpose, according to the evaluator's needs –thereby minimizing negative bias in the evaluator's ratings, regarding the EA model's usefulness.

with cyber-physical expertise. This selection differs from the evaluators selected for evaluating the reference RAF, who were experts from civilian sectors (ICT, water and water waste, and financial sectors).

To improve the fit for purpose of the RAF artifacts, according to the evaluator's needs, the first DSRM design and development activity was dedicated to producing a new RAF design, shown in Fig. 3. The differences between the reference RAF design and the new RAF design concern the Process Reference Model (PRM), and are the following (see Fig. 3):

- 6 new process areas were added to the PRM:
  - Doctrine, Principles, Policies, and Frameworks;
  - Organizational Structures;
  - People, Training, and Education;
  - Leadership, Culture, Ethics, and Behavior;
  - Crisis Coordination and Cooperation;
  - Stakeholder Communication and Public Relations.
- The generic governance and management areas were sub-divided according to:
  - Generic process areas;
  - Structural enablers;
  - Relational enablers.

Essentially, these additions relate to standard defense planning capabilities (DOTMLPF-I, the acronym standing for Doctrine, Organization, Training, Materiel, Leadership, Personnel, Facili-

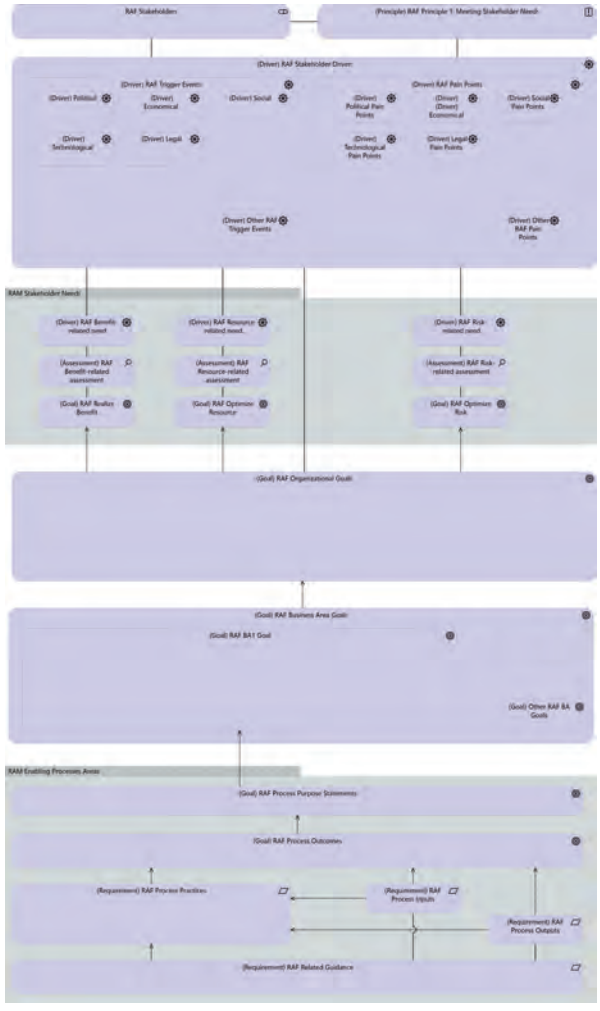

Figure 4. The RAF Goals Cascade and PAM model (modeled using ArchiMate). The organizational drivers, needs, and goals cascade to a representation of the PAM elements (process purpose, outcomes, practices, inputs, outputs, and related guidance).

ties, and Interoperability), as well as to COBIT5 enablers (ISACA 2012b).

The Process Assessment Model (PAM), the Process Measurement Model (PMM), and the Goals Cascade Methodology (GCM) remained unchanged in the new RAF design.

For the second DSRM iteration, an EA model was created, to model the new RAF framework that resulted from the first DSRM iteration. The ArchiMate (The Open Group 2016) modeling language was used for the EA representations. An open source EA tool (Archi 2017) was used for providing an integrated EA repository, as well as the ArchiMate views. The viewpoint representing the goals cascade and the PAM is shown in Figure 4. Note that this viewpoint clearly shows the relation between the goal cascade elements (stakeholder drivers and needs, organizational goals, business area goals, and enabling process goals), as well as the relations between all their subcomponents. Also, note that the graphical arrangement intuitively conveys the notion of top-down and bottom-up alignment – important for relating management and operational concerns.

5 DEMONSTRATION

For demonstration purposes, we used Fig. 4 (goals cascade and PAM) as well as ArchiMate artifacts taken from Gomes et al (2017) (Figs. 5, 6). These artifacts provide an EA model that instantiates the RAF for the following resilience assessment scenario:

- RAF goals cascade Business Area (see Fig. 4):
  - COBIT5, information and related technologies.
- RAF PRM process area:
  - "Business Continuity Management, Availability, and Capacity" (see Fig. 3).
  - Corresponding COBIT5 process: DSS04 Manage Continuity (see Fig. 5).

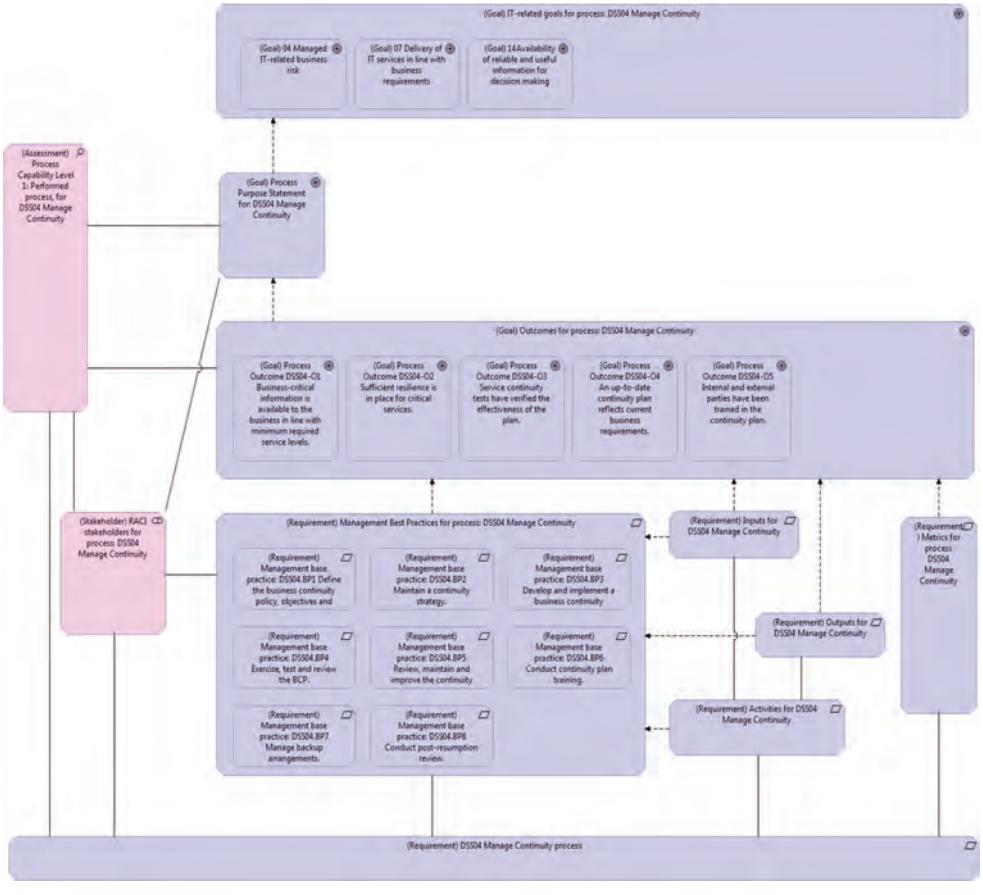

Figure 5. Viewpoint for the COBIT5 manage continuity process, for process capability level 1 assessments. Taken from Gomes et al (2017).

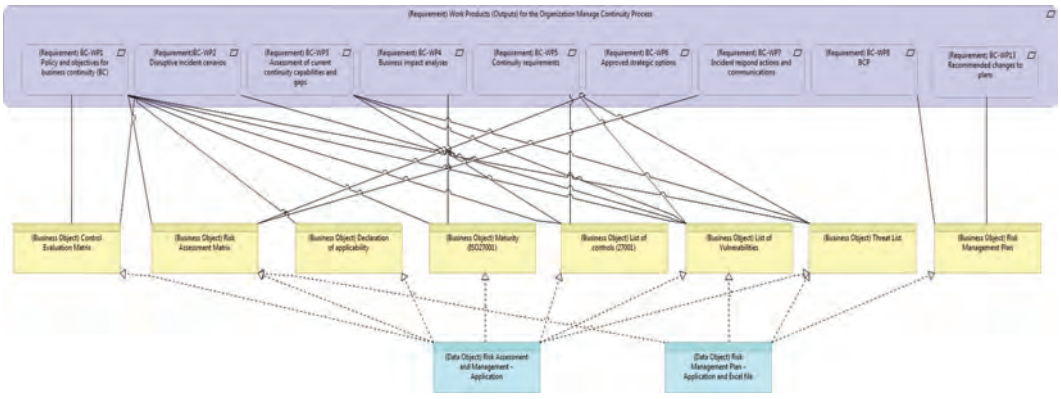

Figure 6. Resilience assessment evidence (middle-row and lower-row elements) mapped to outputs (upper-row elements) of the Manage Continuity COBIT5 process. Taken from Gomes et al (2017).

– RAF PAM process capability level:
  – Process capability level 1 (see Fig. 5).

In other words, in this scenario we are assessing process performance (i.e. achieving process goals) for the process area "Business Continuity Management, Availability, and Capacity", focusing on information and related technologies' concerns. For adequate coverage of such informational concerns, we have used the state-of-the-art COBIT5 governance and management framework.

Real-world formal assessments must be justified and documented using evidence. We demonstrated the instantiation of resilience assessment evidence using the ArchiMate view in Fig. 6, that represents the mapping between the evidence (middle-row and lower-row elements) and the outputs of the Manage Continuity COBIT5 process (upper row elements). This demonstration artifact was taken from Gomes et al (2017).

6 EVALUATION

The evaluation results are shown in Table 2. For rating the achievement of RAF objectives, we used a standard ordinal scale that is used for assessing outcomes (ISO 2015):

– "FA" = fully achieved
– "LA" = largely achieved
– "PA" = partially achieved
– "NA" = not achieved

In the right column "*Gain*" we show the added value of using the EA model (i.e. difference between the second DSRM and first DSRM ratings). Each "+" sign accounts for one rating improvement (e.g. from PA to LA, or from LA to FA). A change from PA to FA is thus represented with two "+" signs. Where no rating changes occurred, an "=" sign was used.

In the "Research Problem" section, we reported three issues that were found in the reference RAF:

– Consistency with people, ease of use: easy to implement for CI managers;
– Structural clarity: the concepts and methods are clear and unambiguous;
– Generality: may be tailored for any CI organization.

From the results presented in Table 2, we can observe only a minor improvement in achieving the objective "*may be tailored for any CI organization*". However, higher gains were obtained for the objectives "*management indicators relate to operational*", "*easy to implement for CI managers*", and "*concepts/methods: clear and unambiguous*".

Using an EA model (introduced in the second DSRM iteration), we have thus obtained significant gains in the system dimensions:

– Goal efficacy: management indicators relate to operational;
– Environmental consistency: easy to implement for CI managers;
– Structural clarity: the concepts and methods are clear and unambiguous.

For all the remaining objectives, no achievement degradation was observed.

These results are consistent with the hypothesis that EA models are useful to assist resilience assessment initiatives, since the only difference between the first and second DSRM iterations is, precisely, the use of the proposed EA model.

Table 2. Evaluation ratings for the two DSRM iterations. The column "*Gain*" shows the benefits of using the EA model: each "+" accounts for one rating improvement, e.g. from PA to LA, or from LA to FA. A change from PA to FA is thus accounted for using two "+" signs.

Objectives for the RAF	1st DSRM	2nd DSRM	Gain
Disaster risk management aspects	FA, FA, FA, FA	FA, FA, FA, FA	=
Risk is associated to effect on objectives	FA, FA, FA, FA	FA, FA, FA, FA	=
Indicators are relevant for risk management	FA, FA, FA, FA	FA, FA, FA, FA	=
Management indicators relate to operational	FA, LA, LA, PA	FA, FA, FA, FA	++++
May be tailored for any ci organization	FA, LA, LA, LA	FA, LA, LA, FA	+
Not overly prescriptive	FA, FA, FA, FA	FA, FA, FA, FA	=
Cross-sector generality	FA, LA, LA, FA	FA, LA, LA, FA	=
Cross-border generality	FA, LA, LA, FA	FA, LA, LA, FA	=
Useful for ci organizations	FA, FA, FA, FA	FA, FA, FA, FA	=
Easy to implement for ci managers	LA, LA, PA, PA	FA, FA, LA, LA	++++
Simple to communicate and understand	FA, FA, FA, FA	FA, FA, FA, FA	=
Concepts/methods: clear and unambiguous	LA, LA, LA, LA	FA, LA, FA, FA	+++

Interestingly, the efficacy objective "*management indicators relate to operational*" received maximum ratings in the second DSRM iteration (i.e. with EA model), a significant upgrade from the first DSRM ratings (i.e. without EA model). These results reflect the expressiveness benefits of the EA model, that provided an integrated representation including all levels the assessment rationale (from high-level organizational drivers and needs, down to low-level assessment evidence) in a graph-like conceptual structure.

Note that these EA representations may be stored in an integrated EA repository, which means that they can be reused in several assessment initiatives, as well as integrated in the larger EA landscape of the CI organization.

However, during the group sessions, the evaluators commented that additional ontological artifacts – such more thorough formal definitions for entities and relationships, as well as ontological mappings – are needed to further clarify the framework's semantics, as well as to ease real-world implementation initiatives in critical infrastructure operators.

7 CONCLUSION

Assessing the resilience of Critical Infrastructure (CI) is a complex conceptual and implementation challenge. Modeling artifacts such as languages, methods, and tools, are instrumental to address such complexity. Furthermore, EA models, methods, and tools allow for managing and visualizing integrated model repositories, thus providing a powerful complement to representations based on spreadsheet-like artifacts, informal diagrams, and natural-language descriptions.

It is important to note that this work does not prove that the new RAF is an improved version of the reference RAF from Cadete et al (2017). Also, no claims are made in relation to the relative benefits of the proposed ArchiMate artifacts used in the demonstration, vis-à-vis other EA modeling languages. Future work may address optimization of the RAF and related EA models, to assist actual assessment initiatives.

However, the evaluation results are consistent with the hypothesis that EA models are useful to assist resilience assessment initiatives. Such results are also consistent with the informal feedback elicited during the group sessions.

Regarding limitations, the evaluators commented that additional ontological artifacts are needed, namely for achieving higher ratings for the generality goals (such as achieving cross-sector, cross-border, and tailoring for any CI organization), as well as to improve the framework's conceptual clarity and ease of implementation.

Also, EA models may not be as useful for frameworks that are based on simple checklists or matrices of indicators. For these cases, spreadsheet-like artifacts and natural-language descriptions may be sufficient to assist the assessment initiatives. Note, however, that such simple artifacts may not provide the optimal solution for assisting holistic frameworks that comprise several points of view (i.e. many related concerns, many sectors, many countries, and many areas and levels of expertise) and account for complex networks of dependencies and interdependencies. In these cases, a complex graph-like structure emerges and may be successfully be addressed with adequate EA models, methods, and tools.

A secondary contribution of this paper is the new version of the resilience assessment frame-

work, as well as its set of evaluation ratings. This new version and evaluation ratings may be used to inform design, development, and testing for future DSRM iterations.

The main contributions of this paper are the validation of the EA model's usefulness for assisting resilience assessment initiatives, as well as a set of EA viewpoints that may be reused, improved, or adapted for actual resilience assessment initiatives.

ABSTRACT: The life and recovery factor of already existing subsea gas fields and infrastructure may be increased by installing boosting facilities to compensate for declining well pressures. The installation of such boosting facilities subsea has often been identified as more cost-efficient than installation topside. A recent example is the Åsgard Subsea Gas Compressor installed and started up in 2016 on the Norwegian Continental Shelf. The compressor system is highly complex, involving, beyond the compressor itself, numerous pipes, valves, sensors, a liquid removal facility and a liquid pump. The design of control and safety systems is based on requirements in regulations and key standards, many of which build on topside philosophies for process safety and protection. An ongoing research in the Centre on Subsea Production and Processing (SUBPRO) is to investigate if new requirement formulation methods can verify if the current subsea safety and control philosophy is adequate. A motivation is to investigate areas of improvement for future subsea installations or similar systems. One such method is the Systems-Theoretic Process Analysis (STPA), a method that has been developed specifically for hazard identification in system control architectures. The main advantage of STPA over other hazards identification techniques is its ability to capture system failures that may arise from the communication between equipment in the control architecture, and this insight can be used to build more robust and reliable systems. STPA has already been adopted in many different sectors and domains, but has not yet been tested for subsea processing systems. The main objectives of this paper are: (1) to apply STPA to a subsea processing system; a subsea compression system; (2) to discuss opportunities and challenges of applying STPA to subsea compression systems, and; (3) to extend the discussion to the general use of STPA and necessity to improve the method.

1 INTRODUCTION

1.1 *Background*

The life and recovery factor of a subsea gas reservoir depends on the reservoir pressure and pressure loss in the production system. The reservoir pressure is typically higher than the pressure loss in the first period of gas production, so that the production rate can be maintained (Monsen et al., 2012). However, at some point during the field life, installation of a boosting facility may be needed to compensate for declining well pressure and extend the plateau production (Baggerud et al., 2007). In other cases, long distance transport increases pressure loss, and consequently, the gas production can be sustained at lower pressure.

One traditional and proven solution in these cases is topside gas compression, but subsea gas compression has often been identified as more cost-efficient than topside gas compression. Subsea gas compression can sustain higher production rates with lower power consumption, because the compressor is closer to the well (Lima et al., 2011). In addition, unmanned operation of subsea gas compression reduces operation costs (Lima et al., 2011). On the other hand, the application of subsea gas compression has been technically challenging due to large electrical power consumption, the

need for fast acting control and use of complex equipment (Baggerud et al., 2007).

To prevent hazardous events of subsea gas compression systems, the control and safety systems of subsea gas compression are designed in accordance with regulations and key standards. However, many of the regulations and key standards of subsea gas compression systems build on topside philosophies for process safety and protection (Kim et al., 2016). Research is currently underway in the Centre on Subsea Production and Processing (SUBPRO) to investigate whether new requirement formulation methods can help verify adequateness of subsea safety and control philosophies (SUBPRO, 2017). One such method is the Systems-Theoretic Process Analysis (STPA), a hazard identification method that was recently developed based on the Systems-Theoretic Accident Model and Processes (STAMP).

STPA has widely been adopted and used in cyber security (Young and Leveson, 2013, Salim, 2014, Young, 2014, Schmittner et al., 2016), aerospace (Ishimatsu et al., 2010, Nakao et al., 2011, Leveson, 2014), aviation (Leveson et al., 2014, Chen et al., 2015, Allison et al., 2017), medical device (Antoine, 2013, Samost, 2014, Proctor et al., 2015, Zhang et al., 2017) and so on. However, there are limited number of studies on STPA application in the oil and gas industry, and only one conference paper investigated the application of STPA to subsea systems (Rachman and Ratnayake, 2015). To the best of our knowledge, no study has conducted STPA on subsea processing systems and discussed opportunities and challenges of applying STPA to subsea processing systems.

1.2 *Objectives*

The main objective of this paper is to apply STPA to a subsea gas compression system and discuss associated opportunities and challenges. This main objective is further developed into three sub-objectives:

- To conduct STPA analysis on a general subsea gas compression system and summarize the results
- To discuss opportunities and challenges applying STPA to subsea processing systems, based on the results of the analysis
- To extend the discussion to the general use of STPA and necessity to improve the method

1.3 *Structure of the paper*

The remainder of this paper is organized as follows: subsea gas compression system is introduced in Section 2, and STPA is applied to a typical subsea dry gas compression system in Section 3. Summary of the analysis results and discussions follow in Section 4.

2 SUBSEA GAS COMPRESSION SYSTEM

2.1 *Subsea processing*

Any handling and treatment of the produced hydrocarbon fluids prior to reaching the platform or onshore can be defined as subsea processing, e.g. subsea boosting, subsea separation and subsea gas compression (Bai and Bai, 2012). Compared with topside processing, the advantages of subsea processing are (Bai and Bai, 2012):

- *Accelerated and/or increased production and/or recovery;*
- *Enabling marginal field developments, especially fields at deepwater/ultra-deepwater depths and with long tie-backs;*
- *Extended production from existing fields;*
- *Enabling tie-in of satellite developments into existing infrastructure by removing fluid;*
- *Handling constraints;*
- *Improved flow management;*
- *Reduced impact on the environment.*

2.2 *Subsea gas compression*

Since the late 1980s, several oil companies and research institutions tried to develop and commercialize subsea gas compression technology (Vinterstø et al., 2016), because a well can produce at lower wellhead pressures with subsea gas compression, thereby accelerating gas production and/or increasing recovery rate (Kuhnle et al., 2015).

However, it was considered that subsea gas compression requires *extensive further technology maturing* until 2005, while the other subsea processing were classified as *mature technology* or *high technical maturity level* (Fantoft, 2005).

On 16th September 2015, the world's first commercial subsea gas compression station was started-up on the Åsgard field, and it was followed by the Gullfaks (Vinterstø et al., 2016, Wadel-Andersen and Moe, 2016).

There are currently two different solutions for subsea gas compression: dry gas compression and wet gas compression (Tønnessen and Romanello, 2017). The former was applied at the Åsgard subsea gas compression station, while the latter is the concept for the Gullfaks subsea compression project. In dry gas compression, gas and liquid in the well stream are separated and boosted by a compressor and a pump respectively. In the wet gas compression, on the other hand, the well stream is boosted directly by a multiphase wet gas compressor without

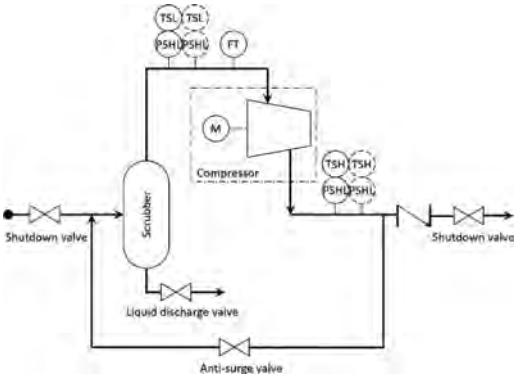

Figure 1. A typical subsea dry gas compression system (API RP 17V, 2015).

separation (Tønnessen and Romanello, 2017). Dry subsea compression is considered the standard solution, because it adopted some common principles from conventional topside compression (Dettwyler et al., 2016, Tønnessen and Romanello, 2017). Similarly, wet compression is called *well-stream compression* (Dettwyler et al., 2016).

2.3 *General configuration of subsea dry gas compression system*

API RP 17V (2015) provides a diagram that includes subsea dry gas compressors with typical safety devices, and a liquid discharge valve and a flow transmitter were added for the analysis of this paper as shown in Figure 1.

Abbreviations in Figure 1 are

- M: Motor
- FT: Flow Transmitter
- TSL: Temperature Safety Low
- TSH: Temperature Safety High
- PSHL: Pressure Safety High and Low

3 STPA FOR SUBSEA GAS COMPRESSION

3.1 *STAMP and STPA*

Leveson (2012) proposed a new accident causation theory, called Systems-Theoretic Accident Model and Processes (STAMP), whose main idea is that major accidents in today's complex, software-intensive, and sociotechnical systems are mainly caused by control problems rather than reliability problems. The three main concepts of this theory are safety constraints, hierarchical control structures, and process models.

Based on the STAMP theory, Leveson (2012) developed a new approach to hazard analysis, called Systems-Theoretic Process Analysis (STPA). The main reasons for developing STPA were to include new causal factors of STAMP that are not identified by traditional hazard identification techniques and to provide guidance to the users in getting good hazard identification results. STPA can identify more causal factors and hazardous scenarios, which are related to software, system design, and human behavior, than the other methods (Leveson and Thomas, 2013).

3.2 *STPA procedure*

The STPA procedure consists of one preparatory step (step 0) and two main steps (step 1 and 2) as described below (Leveson and Thomas, 2013):

- Step 0: *Establishing the system engineering foundation*
- Step 1: *Identifying unsafe control actions (UCAs)*
- Step 2: *Identifying the causes of the unsafe control actions*

Sub-steps with associated outcomes of each step are summarized in Figure 2. This paper follows this procedure to conduct STPA analysis for a subsea gas compression system.

3.3 *STPA analysis for subsea gas compression system*

3.3.1 *STPA Step 0*

In this step, we first identified system-level accidents (SLA), system-level hazards (SLH), and system-level safety constraints (SLSC) to define the scope of the analysis. Any unsafe control actions not relevant with defined SLHs were excluded in the further analysis.

The definition of a *hazard* in STPA is significantly different from traditional definition. The accidents and hazards in STPA are defined as below (Leveson and Thomas, 2013):

- *An accident is an undesired and unplanned event that results in a loss, including a loss of human life*

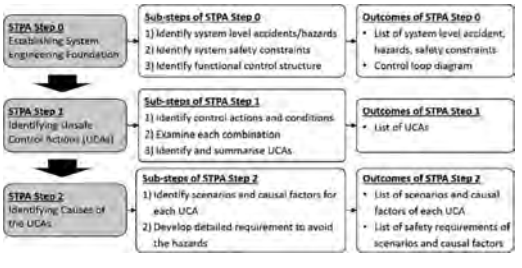

Figure 2. STPA procedure.

or human injury, property damage, environmental pollution, mission loss, financial loss, etc.
– *A hazard is a system state or set of conditions that together with a worst-case set of environmental conditions, will lead to an accident (loss).*

In subsea gas compression, large amounts of gas release can lead to loss of human lives (due to explosion on topside installations or loss of buoyancy of a vessel on the surface during a gas leak) or environmental pollution. In addition, significant economic loss may occur due to damage of costly subsea component or reduced gas production rate. The SLAs, SLHs, and SLSCs of subsea gas compression are summarized in Table 1. It is assumed that the compression system is designed inherently safe, so that the system can endure the pressure of the well stream and the compressor.

The next step was to identify functional control structure of the system. The high-level functional control structure of subsea gas compression system can be illustrated as shown in Figure 3. The system consists of Human Operator, Control System, Subsea Gas Compression (SGC) Unit,

Table 1. System-level accidents, hazards, and safety constraints of subsea gas compression.

System-level accident	System-level hazard	System-level safety constraints
SLA1: People die or are injured due to large amount of gas release	SLH1: SGC unit continues to supply gas when gas leaks to the environment	SLSC1: SGC unit must stop compressing gas when gas leaks to the environment
SLA2: The sea is polluted due to large amount of gas release		
SLA3: Valuable subsea components are damaged	SLH2: Compressor operates outside normal operation conditions	SLSC2: Compressor must be protected from extreme operating conditions that can damage the compressor
SLA4: Production is reduced or interrupted unnecessarily	SLH3: SGC unit stops compressing gas when not necessary	SLSC3: SGC unit must never stop compressing gas when not necessary
	SLH4: Compressor operates outside optimal conditions	SLSC4: SGC must be operated within optimal conditions

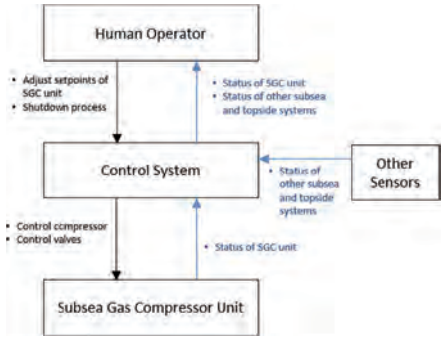

Figure 3. High-level functional control structure of subsea gas compression system.

and Other Sensors. The Human Operator provides *adjust setpoint of SGC unit* and *shutdown process* commands to the Control System, and the Control System provides commands to the compressor and valves of Subsea Gas Compressor Unit. The Control System receives feedbacks about *status of SGC unit* and *status of other subsea and topside systems* from Subsea Gas Compressor Unit and Other Sensors respectively, and these feedbacks are finally delivered to the Human Operator.

Based on the high-level functional control structure, a detailed model can be further developed as shown in Figure 4. The *Control System* consists of Variable Speed Drive (VSD), Process Control System (PCS), Process Shutdown (PSD) System, Subsea Control Unit (SCU), Subsea Control Module (SCM), and Subsea Electronic Module (SEM). VSD, PCS, PSD System, and SCU are located topside, while SCM and SEM are installed subsea. The Subsea Gas Compressor Unit is composed of Subsea Gas Compressor (SGC), Shutdown Valves (SDVs), Anti-Surge Valve (ASV), Liquid Discharge Valve (LDV), and Sensors. Responsibilities and process models of each controller are summarized in Table 2.

3.3.2 *STPA Step 1*

After establishing the functional control structure with responsibilities and process models, we could identify unsafe control actions (UCAs) by examining combinations of control actions and associated process models identified in Step 0.

Table 3 shows an example of how to identify UCAs of the system. One of responsibilities of PCS is to automatically control LDV depending on the level inside the scrubber. If the level inside the scrubber is too high, then liquid may flow into gas compressor, resulting in severe damage of the compressor. PCS should therefore open or close LDV to control the level of liquid in the scrub-

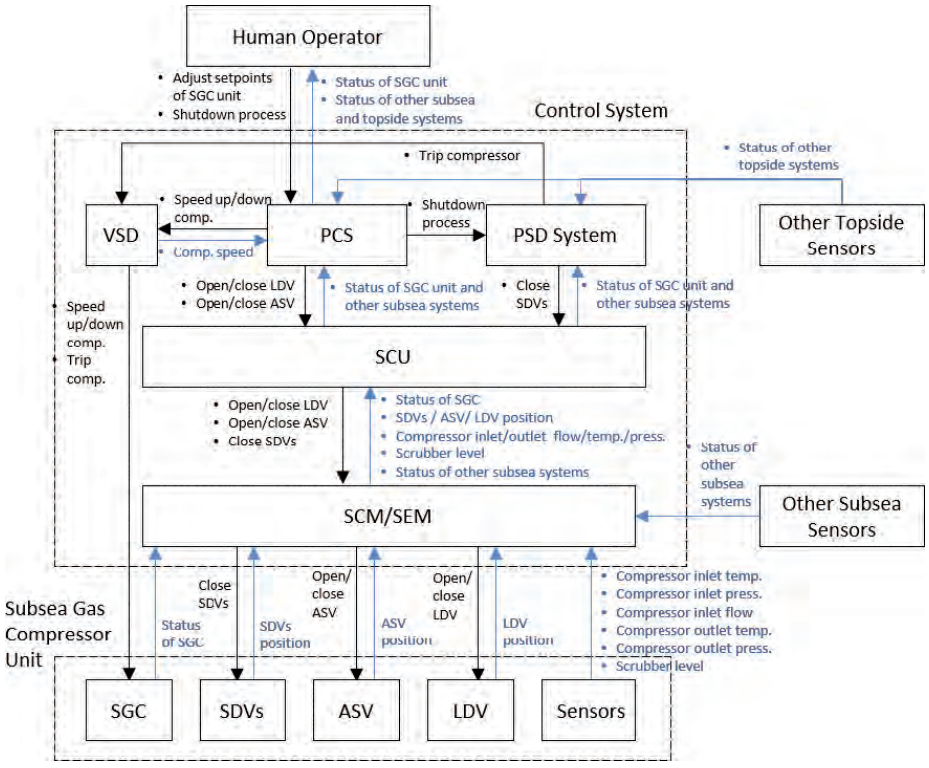

Figure 4. Detailed functional control structure.

Table 2. Responsibilities and process models of each controller.

Controller	Responsibilities	Process models
Human operator	– Adjust setpoint to maximize the efficiency of SGC unit – Shutdown process when needed	– Compressor inlet temperature/pressure/flow (low/normal/high) – Compressor outlet temperature/pressure (low/normal/high) – Status of other subsea and topside systems (normal/gas leak)
PCS	– Deliver *shutdown process* command from human operator to PSD system – Automatically adjust compressor speed – Automatically open/close LDV – Automatically open/close ASV	– Setpoints (optimal/not optimal) – Compressor inlet temperature/pressure/flow (low/normal/high) – Compressor outlet temperature/pressure (low/normal/high) – Scrubber level (low/normal/high)
VSD	– Deliver *speed up/down* and *trip* command from PCS and PSD to SGC	– Control command from PCS (speed up/down) – Control command from PSD (trip compressor)
PSD	– Trip compressor and close SDVs based on shutdown command from human operator – Automatically shut down process when needed	– Control command from PCS (shutdown) – Status of other subsea and topside systems (normal/gas leak)
SCU	– Deliver control commands from PCS and PSD system to SCM/SEM	– Control commands from PCS (open/close LDV, open/close ASV) – Control commands from PSD (close SDVs)
SCM/SEM	– Distribute control commands to each component	– Control commands from PCS (open/close LDV, open/close ASV, close SDVs)

Table 3. Identifying UCAs of open/close LDV command.

Controller: PCS								
No	Control action	Scrubber level	Not provided	Provided	Too early	Too late	Too short	Too long
1	Open LDV	High	***Unsafe [SLH2]***	Safe	Safe	***Unsafe [SLH2]***	***Unsafe [SLH2]***	Safe
2		Normal	Safe	Safe	Safe	Safe	Safe	Safe
3		Low	Safe	***Unsafe [SLH2]***	N/A	N/A	N/A	N/A
4	Close LDV	High	Safe	***Unsafe [SLH2]***	N/A	N/A	N/A	N/A
5		Normal	Safe	Safe	Safe	Safe	Safe	Safe
6		Low	***Unsafe [SLH2]***	Safe	Safe	***Unsafe [SLH2]***	***Unsafe [SLH2]***	Safe

Table 4. Scenarios, causal factors, and safety constraints of a UCA.

UCA.PCS001: Open LDV command is not provided when scrubber level is high		
Scenario	Associated causal factors	Safety constraints
PCS receives wrong measurement of scrubber level	Drift of scrubber LT	SC.PCS001.01 Scrubber LT must be calibrated periodically SC.PCS001.02 Scrubber LT must have 2003 configuration
PCS receives no measurement of scrubber level	No power supply to scrubber LT	SC.PCS001.03 PCS must generate an alarm when no signal is received from scrubber LT SC.PCS001.04 Scrubber LT must have UPS
	Broken signal wires from scrubber LT to PCS	SC.PCS001.03 PCS must generate an alarm when no signal is received from scrubber LT SC.PCS001.05 Signal wires must be inspected periodically
PCS receives correct measurement, but PCS does not provide open LDV command	Wrong logic inside PCS	SC.PCS001.06 PCS logic to generate open LDV command must be fully demonstrated during commissioning period

ber. In this case, control actions are *open LDV* and *close LDV*, and the process model is *scrubber level (high/normal/low)*.

UCAs can be identified by examining combinations of control actions and associated process models. For instance, if the *open LDV* command is not provided when the *scrubber level is high*, then this is a UCA that can cause SLH 2 identified in Step 0. On the contrary, it is a safe control action if *open LDV* command is not provided when the scrubber level is low. UCAs identified in Table 3 are

UCA.PCS001 Open LDV command is not provided when scrubber level is high
UCA.PSC002 Open LDV command is provided too late when scrubber level is high
UCA.PSC003 Open LDV command is provided too short when scrubber level is high
UCA.PSC004 Open LDV command is provided when scrubber is low
UCA.PSC005 Close LDV command is provided when scrubber level is high
UCA.PSC006 Close LDV command is not provided when scrubber level is low
UCA.PSC007 Close LDV command is provided too late when scrubber level is low
UCA.PSC008 Close LDV command is provided too short when scrubber level is low.

Similarly, other UCAs can be identified by combining control actions and process models of each controller.

3.3.3 *STPA Step 2*

The last step of STPA was to identify scenarios, associated casual factors, and safety constraints of each UCA. STPA provides less help for this step, and therefore, the analysts must rely on brainstorming with their own background knowledge and prior experiences (Leveson and Thomas, 2013).

An example of identified scenarios, causal factors, and safety constraints of an UCA are summarized in Table 4.

4 RESULTS AND DISCUSSION

4.1 *Results*

In this study, a total of 129 high-level UCAs have been identified for a subsea gas compression system. SCU and SCM/SEM have the largest number of UCAs, while the Human Operator is associated with the smallest number of UCAs. 66 out of 129 UCAs are related with SLH2, *compressor operates outside normal operation conditions*, while only nine UCAs can cause SLH3, *SGC unit stops compressing gas when not needed*. The number of UCAs of each controller and system-level hazard are summarized in Table 5.

Human operator's main responsibility is to adjust setpoints, so most of UCAs of human operator are related with SLH4, *compressor operates outside optimal conditions*. On the other hand, the main function of PSD system is to shut down the process when there occurs a gas leak, so the greater part of UCAs of PSD system are connected to SLH1, *SGC unit continues to supply gas when gas leaks to the environment*.

The main responsibility of PCS is to automatically control LDV and ASV to prevent the compressor from being damaged due to operating outside normal operation conditions, and therefore, UCAs of PCS are mostly relevant with SLH2, *compressor operates outside normal operation conditions*.

Table 5. Results of the analysis.

Controller	Total UCAs	UCAs to SLH1	UCAs to SLH2	UCAs to SLH3	UCAs to SLH4
Human Op.	10	2	0	1	7
PCS	30	2	10	1	17
PSD	12	8	0	4	0
VSD	15	2	0	1	12
SCU	31	2	28	1	0
SCM/SEM	31	2	28	1	0
Sum	129	18	66	9	36

SCU and SCM/SEM have the same number of UCAs, because the responsibility of SCU is to deliver control commands from PCS and PSD system to SCM/SEM.

Most of the control actions in the subsea gas compression system are to prevent compressor damage and/or operate the compressor in optimal conditions, rather than to prevent or stop gas leaks, because these functions are already covered by emergency shutdown (ESD) system with shutdown valves. Therefore, the subsea gas compression system has a large number of UCAs related to SLH2 and SLH4 compared to SLH1 and SLH3.

4.2 *Discussion and concluding remarks*

When applied to a subsea gas compression system, STPA provided a systematic and structured way of identifying UCAs in STPA Step 0 and 1. STPA provides, on the other hand, less help to identify scenarios and causes of UCAs, and relies on brainstorming in STPA Step 2. However, this is not only a problem of STPA. Other traditional hazard identification methods also have the same limitation. For instance, hazard and operability (HAZOP) studies provides guide words and parameters to identify hazards, structured what-if (SWIFT) uses checklists and what-if questions to identify hazards, and failure modes, effects, and criticality analysis (FMECA) utilizes system breakdown and functional analyses to identify hazards. However, once hazards are identified, all these methods rely on brainstorming to identify causes of the hazards. As Leveson and Thomas (2013) mentioned, STPA can provide more help for STPA Step 2 in the future, because there are common flaws that lead to accidents.

One of the distinct characteristics of subsea systems is the remoteness of control actions. The control commands for subsea systems are provided from topside installations or onshore that is sometimes hundreds of kilometers away from the subsea facilities. Therefore, there are some equipment that collect control commands and distribute the commands to associated components, like SCU and SCM/SEM in Figure 4. Accordingly, appropriate transmission and handling of control signals becomes important for the operation of the subsea systems, and STPA is well suited for addressing hazards in such distributed control structures.

However, only looking at the system from the perspective of the control units and flow of control commands and signals during operation can lead to omission of important hazards. To be fair, STAMP does consider a wider range of accident causes, including unhandled environmental disturbances or conditions, unhandled or uncontrolled component failures, unsafe interactions among

components and inadequately coordinated control actions by multiple controllers (Leveson and Thomas, 2013). Also, Leveson uses the term control in a broad sense, to include control by design (i.e. to prevent or protect against component failures or unsafe interactions), control processes (including developmental, manufacturing maintenance and operational processes) and social controls (i.e. legal requirements, cultural norms, or other interests that constrain behaviour) (Leveson and Thomas, 2013). However, although STPA may in principle cover a wide range of hazards, it is not necessarily the best method or easiest method to apply for identifying or analyzing all types of hazards. Other methods, such as HAZOP and FMECA also have their advantages and may be more familiar to safety engineers and risk managers. For example, while STPA takes the working system as point of departure and then identify flaws that could cause hazards, FMECA starts from the failure modes of subsystems to identify system effects, and HAZOP focus on deviations from normal operations that could cause hazards. Often these failure modes and possible deviations are known and STPA is not needed to identify them. Rather, the question is how critical they are for the system operation and safety, and if there are system hazards *not* covered by these subsystem-oriented approaches. In the latter case STPA may add important additional insight into system hazards.

The oil and gas industry has widely adopted risk-based safety philosophies, where safety is regarded as tolerable risk. In contrast, STAMP and STPA views safety as a control problem, where hazard can be eliminated by imposing control measures and constraints, or by modifying the system. STPA does not provide a method for describing, ranking or comparing the risk associated with identified unsafe control actions. In reality, imposing constraints and controls to eliminate unsafe control actions will have a cost and will not be perfectly reliable or remove hazards completely. While STPA is good for identifying inadequate control and suggesting additional controls, it does not provide stop criteria for when the control is sufficient. Eventually, the need for prioritization of resources will necessitate an evaluation of the associated risk to ensure that resources are spent optimally and that safety of the system represents a tolerable risk.

In conclusion, if the goal is to identify as many hazards, unsafe control actions and dangerous scenarios as possible, it is useful to view a system from several different perspectives, and not insist on using only one method. Hence, rather than replacing other methods, STPA should be used as a supplement, providing a control perspective on safety.

Enhanced condition monitoring of the machining process using wavelet packet transform

L. Mao & L.M. Jackson

ABSTRACT: Tool wear in machining processes can have a detrimental impact upon the surface finish of a machined part, increase the energy consumption during manufacture and potentially, if the tool fails completely, damage incurred may require the part to be scrapped. Monitoring of the tools condition can therefore lead to preventative steps being taken to avoid excessively worn tools being used during machining, which could cause a part becoming damaged. Several studies have been devoted to condition monitoring of the machining process, including the evaluation of cutting tool condition. However, these methods are either impractical for a production environment due to lengthy monitoring time, or require knowledge of cutting parameters (e.g. spindle speed, feed rate, material, tool) which can be difficult to obtain. In this study, we aim to investigate if tool wear can be directly identified using features extracted from the electrical power signal of the entire Computer Numerical Control (CNC) machine (three phase voltage and current) captured at 50 KHz, for different cutting parameters. Wavelet packet transform is applied to extract the feature from the raw measurement under different conditions. By analyzing the energy and entropy of reconstructed signals at different frequency sub-bands, the tool wear level can be evaluated. Results demonstrate that with the selected features, the effects due to cutting parameter variation and tool wear level change can be discriminated with good quality, which paves the way for using this technique to monitor the machining process in practical applications.

1 INTRODUCTION

Tool wear and subsequent failure of tools during the manufacturing process will have a significant impact on the economics of machining, and about 25% of machine down time can be attributed to the direct results of tool wear failure (Altintas & Yellowley 1989). Moreover, the development of tool wear will give rise to inconsistencies in surface finishes and geometric tolerances, affecting the quality of manufactured products. Therefore, a series of studies have been devoted to monitoring systems detecting underperforming tooling and improving machining efficiency and productivity.

The monitoring techniques for tool wear can be divided into two categories, direct and indirect methods (Bhattacharyya & Sengupta 2009, Teti et al. 2010). With direct methods, tool wear is evaluated by analyzing the cutter itself, such as measuring the surface roughness and flank wear, etc. On the other hand, indirect methods apply either model-based or data-driven techniques to the measurements like cutting force, tool vibration and output power for evaluating tool wear conditions. It should be noted that due to the restrictions of direct methods such as stopping requirements during production, indirect methods are more suitable for industrial applications (Zhu et al. 2009).

With indirect methods, different measurements can be collected and analyzed to evaluate the tool condition, including acoustic emission (Prickett & Johns 1999, Karimi et al. 2013, Hass et al 2013), cutting force (Dimla & Lister 2000, Li et al. 2006, Deng et al. 2013, Lee et al. 2006), vibration (Yesilyurt & Ozturk 2007, Zhang & Chen 2007, Lamraoui et al. 2014), temperature (Byrne 1987, Davoodi & Hosseinzadeh 2012), spindle power/current (He et al. 2017, Li et al. 2000, Simoneau & Meehan 2013), etc. However, several of these methods often require expensive sensing equipment (Nouri et al. 2015) and can be difficult to install due to the need for close proximity to the cutting tool and workpiece, meaning they can be impractical for large production environments. Additionally, the classification of tool wear from the collected data is challenging due to the high sensitivity of data to the cutting parameters (i.e. spindle speed, feed rate, depth and width of cut, material, tool type). Thresholding of time domain data has been used as a method of classifying tool wear (Shao et al.

2004), however, this requires large amounts of calibration and training data which is time consuming to collect and reduces the robustness of the system to a limited set of cutting conditions. Several studies of investigated frequency and time-frequency domain analysis to reduce the sensitivity to classification to cutting parameters (Kuljanic et al. 2009, Liao et al. 2007, Huang et al. 2010, Lauro et al. 2004], however, most of these methods require specialist monitoring equipment which pose the challenges described above.

Within this research we investigate the potential of a low cost, non-invasive sensing approach which is also cutting parameter agnostic to the problem of tool condition monitoring, which has so far not been identified within existing literature. The investigated solution uses current and voltage sensors across electrical three phase input to the machine to monitor the overall machine power consumption, whilst classification of the signal is conducted though time-frequency analysis using wavelet packet transform.

In Section 2 the diagnostic approach using the wavelet analysis is described. Section 3 details the experimental methodology and results, and Section 4 concludes the findings and highlights limitations and future work.

2 DIAGNOSTIC APPROACH

Although several studies have been performed for condition monitoring of the milling process using wavelet transform [Choi et al. 2004, Li et al. 2008, Zhong et al. 2010], these have mainly used vibration or cutting force measurements in the analysis instead of electrical power consumed by the machine. Moreover, the effectiveness of wavelet transform in discriminating tool wear level operated at varying cutting parameters still requires further investigation.

In this study, wavelet packet transform (WPT) is selected to evaluate the tool wear level. The reason of using WPT is that compared to wavelet transform, which only filters the signal to get the low-pass results (approximation), WPT can filter the signal to obtain both low-pass and high-pass (detailed) results (depicted in Figure 1). Therefore, more information can be extracted from the original signals using WPT [Torrence & Compo, 1995]. The extracted wavelet coefficients $C_{j,k}$ can be expressed using Eq. (1).

$$C_{j,k} = \int f(t)\psi_{j,k}(t)dt \tag{1}$$

where $f(t)$ is the original signal, $\psi_{j,k}$ is the wavelet function, j and k are the scale and shift parameters, this can be expressed in Eq. (2).

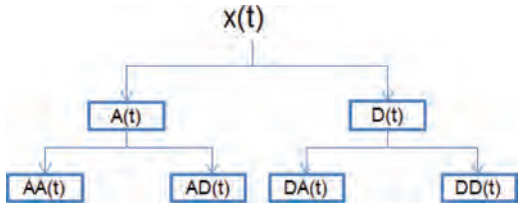

Figure 1. Two-level wavelet packet transform, where A and D are the approximation and detail by filtering the signal at the previous level.

$$\psi_{j,k}(t) = \frac{1}{\sqrt{j}}\psi\left(\frac{t-k}{j}\right) \tag{2}$$

It can be seen from Figure 1 that the application of WPT provides a sub-band filtering of the original signal into progressively finer equal-width intervals with the extracted packets of wavelet coefficients, i.e. the i^{th} packet of wavelet coefficients at j^{th} level represent the information of original signal within the frequency sub-band of $\left[iF_s/2^{j+1}, (i+1)F_s/2^{j+1}\right]$, where F_s is the sampling frequency.

With wavelet coefficients, the time-history of signals at different frequency sub-bands can be reconstructed using Eq. (3).

$$f_j(t) = C\sum_k C_{j,k}\psi_{j,k}(t) \tag{3}$$

where C is a constant independent of signals.

With these constructed signals, energy and entropy are calculated from each signal using Eqs. (4) and (5).

$$E_s = \int \left| f(t)f(t) \right| dt \tag{4}$$

$$H_s = -\sum_{i=1}^{N} p(x_i)\log_{10} p(x_i) \tag{5}$$

where E_s and H_s are the energy and entropy of the signal, $p(x_i)$ in Eq. (5) is a probability of the signal with value of x_i.

The energy of reconstructed signals represents the amount of information within different frequency sub-bands, while entropy of reconstructed signals can indicate the signal disorganization at the frequency sub-bands. It is expected that these two features would be sensitive to the change of cutting parameters and cutting tool wear level, thus can be used for the discrimination of cutting tool levels. This will be further investigated in the following section.

It can be seen that with the use of WPT, the original signals can be decomposed and reconstructed

at different frequency ranges, from which the frequency information can be related to the signals in the time domain, and better used for the feature extraction and fault diagnosis.

3 PERFORMANCE OF DIAGNOSTIC APPROACH

3.1 *Experiments*

In the study, HSS-Co8 is selected as the end milling tool due to its ease of wear measurement, which is a high speed steel containing 8% cobalt with 4 flutes. Two end milling tools with different diameters are selected herein for the analysis. Table 1 lists the characteristics of these end milling tools, where LOC refers to the tool's length of cut.

In the experiments, each end mill was assigned a work piece of dimension 150 mm × 120 mm × 30 mm, and the plate material was selected as commercial aluminum grade 6082 T651, which is a common alloy used in manufacturing.

Cutting parameters used in the tests were selected according to the manufacture's recommendation, which are listed in Table 2.

For the duration of each cutting session the energy monitoring device was connected to the system, which collected the current and voltage measurements at a sampling frequency of 50 kHz. During each session, the tools were used to perform climb milling on the work pieces. The number of passes, cut depth and cutting radius are selected as 10, half of the cutter diameter, respectively.

It should be mentioned that after each cutting session, the tools were used to machine the carbon steel to induce wear (40 min initially, subsequently 20 min), and this process was repeated until 100 min, where full tool wear was observed. Table 2 lists the cutting parameters used for different cuts and corresponding wear measurements.

Table 1. Characteristics of end milling tools.

Mill Dia. (mm)	Shank Dia. (mm)	LOC (mm)	Overall length (mm)	No. teeth/ flutes
8.0	10	19	69	4
10.0	10	22	72	4

Table 2. Cutting parameters and corresponding wear measurements.

Dia. (mm)	Cut no.	Time (min)	Spindle speed (RPM)	Feed rate (m/min)	Localized tool wear (mm)
8	1	0	4000	580	0
8	2	40	4000	580	0.182
8	3	60	4000	580	0.279
8	4	80	4000	580	0.327
8	5	100	4000	580	0.493
10	1	0	3100	600	0
10	2	40	3100	600	0.185
10	3	80	3100	600	0.434
10	4	100	3100	600	0.582

3.2 *Discrimination of different cutting tools with different wear level*

In this section, the current and voltage from two end milling tools with 8 mm and 10 mm cutting diameters are collected at 0 min and 100 min, which represents the intact and fully worn tools. The reason of selecting these measurements is that the collection process will not interrupt the machining process, and the installation of sensors will not add complexity of monitoring systems, thus the results can be better applied in the practical machining process.With current and voltage measurements, the instantaneous power can be calculated using the following equation.

$$P_{ins}(t) = v(t)i(t) \tag{6}$$

where $v(t)$ and $i(t)$ are the collected voltage and current measurements at time t.

Figure 2 depicts the instantaneous powers for 8 mm and 10 mm tools at intact and fully worn conditions. It should be mentioned that only power from single pass cutting is illustrated herein, as the powers of 10 passes have a similar trend. In the current study, only the power from a single pass is analyzed. Table 3 lists the average and maximum instantaneous power at each condition. It can be seen from the table that the instantaneous power will be increased with cutting tool wear.

From the instantaneous powers shown in Figure 2, the cutting tools with different diameters and cutting parameters, and the same tool with different wear levels cannot be discriminated easily in the time-domain, as the signals from different conditions have a similar shape, thus the four different conditions cannot be discriminated using only the power amplitude variation.

As described in section 2, WPT is applied to the instantaneous power to extract wavelet coefficients and reconstruct signals at different frequency sub-bands. In the current study the WPT is used to decompose the original signal over 8 levels. This decomposition level is selected by considering both the range of frequency sub-band and computational time. In the current study the Shannon wavelet

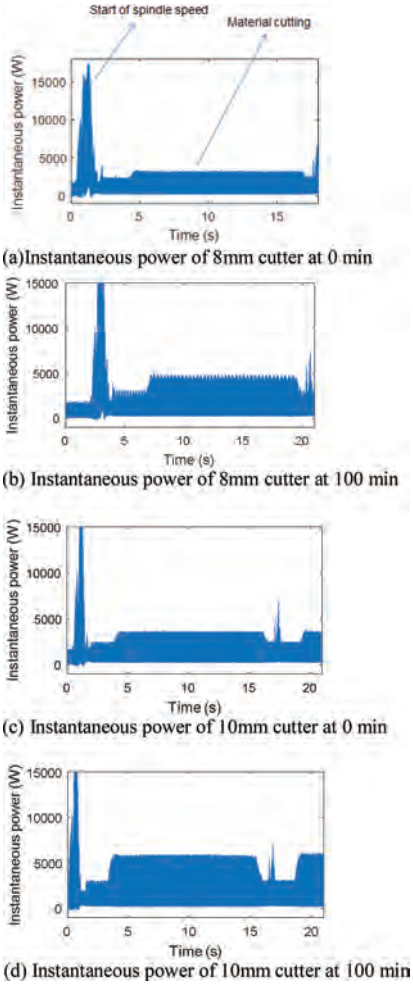

Figure 2. Instantaneous power of two cutters at intact and fully worn conditions.

Table 3. Average and max instantaneous power.

Condition	Average power (W)	Max power (W)
8 mm tool at 0 min	1593.7	3277.4
8 mm tool at 100 min	1989.6	4890.1
10 mm tool at 0 min	1712.3	3827.7
10 mm tool at 100 min	2537.5	5971.5

function is used in the WPT analysis, which can be written as follows:

$$\Psi_{j,k}(t) = \sqrt{j}\,sinc(jt)e^{2\pi ikt} \tag{7}$$

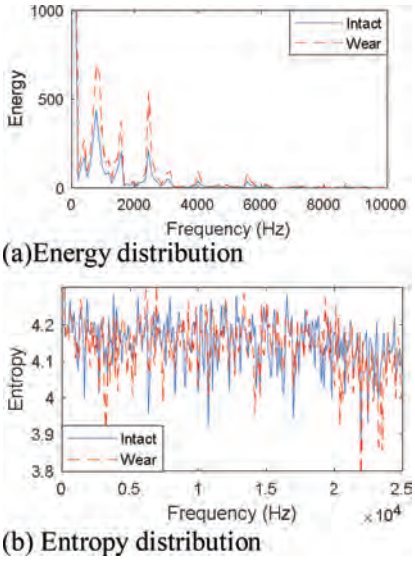

Figure 3. Energy and Entropy distributions of 8 mm cutter at intact and worn conditions.

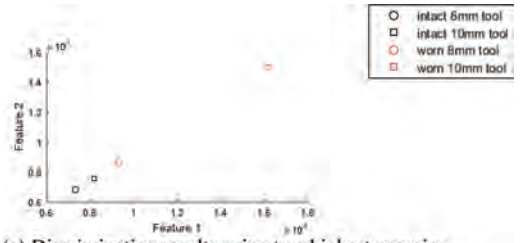
Energy and entropy are then calculated from each reconstructed signal. Figure 3 depicts the distribution of energy and entropy over the whole frequency range. It should be noted that as the distributions are similar for the two end milling tools, only energy and entropy distribution from the 8 mm tool are illustrated herein.

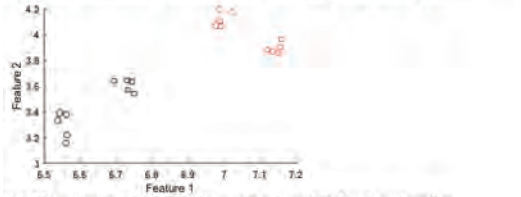
It can be seen from Figure 3 that the energy distribution shows similar trends for both intact and worn conditions, and the maximum energy is concentrated at around 700 Hz. However, the entropy distributes well along the whole frequency range, and the entropy distribution at intact and worn conditions shows clear variation. This indicates that the energy features can provide more consistent results, while entropy features are more sensitive to the change in the cutting parameters.

In this study, the two highest energies and entropies at the intact condition are selected for the discrimination, as they represent the most information and disorganization in the original signal. Figure 4 depicts the discrimination results. It should be noted that each point in Figure 4 represent the feature calculated with a two-second length instantaneous power signal.

From Figure 4, it can be seen that with selected energy and entropy features, all four different states, i.e. two end milling tools with two wear levels, can be discriminated with good quality, indicating that not only the worn condition can be identified clearly for the same cutting tool, but the different cutting tools with similar worn levels can also be separated accurately.



(a) Discrimination results using two highest energies



(b) Discrimination results using two highest entropies

Figure 4. Discrimination results using two highest energies and entropies.

When this approach is used in practical applications, the state of the end milling tool can be determined with the minimum Euclidean distance between features (two highest energies or entropies) of instantaneous power from the unknown state and the features shown in Figure 4. It should be mentioned that as the analysis is computational efficient (only taking about 20 seconds to gain the results), this approach can be used in the practical application for on-line monitoring purposes.

3.3 *Discrimination of different cutting tools with different wear level and similar instantaneous power*

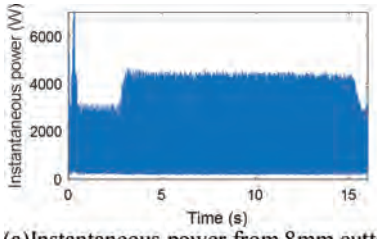
The performance of WPT in discriminating cutting tool conditions is further investigated using the data from the end milling tools at different cutting parameters but having similar instantaneous power, which makes it extremely difficult for discrimination using time-domain techniques.

In this study, two sets of data are used for the analysis, including end milling tools with diameters of 6 mm and 10 mm at different wear levels and cutting parameters. Table 4 lists the cutting parameters of these two end mill tools and the corresponding wear measurements.

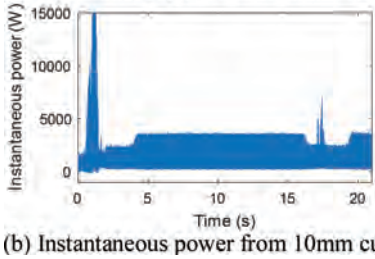
Figure 5 depicts the instantaneous powers from these two end milling tools. Similar instantaneous power can be observed due to the combination of different wear levels and cutting parameters. The average instantaneous powers from these conditions are listed in Table 5. It can be seen that these two conditions will provide similar average instantaneous power, while clear variation is observed in the wear level, which is listed in Table 4.

Table 4. Cutting parameters and corresponding wear measurements.

Dia. (mm)	Spindle speed (RPM)	Feed rate (m/min)	Time (min)	Wear measurement (mm)
8	4000	580	60	0.279
10	3100	600	0	0



(a)Instantaneous power from 8mm cutter



(b) Instantaneous power from 10mm cutter

Figure 5. Instantaneous powers from 6 mm and 10 mm diameter end mill tools.

Table 5. Average and max instantaneous power.

Condition	Average power (W)	Max power (W)
8 mm tool at 60 min	1810.1	4461.2
10 mm tool at 0 min	1712.3	3827.7

WPT described in section 2 is applied to extract the wavelet coefficients over 8 levels, and signals at different frequency sub-bands are reconstructed. The two highest energies and entropies are then selected for the discrimination. Results are depicted in Figure 6.

It can be seen from Figure 6 that with the selected energy and entropy, the two end milling tools can be discriminated with good quality, indicating the effectiveness of the proposed approach in identifying the states of different end mill tools at varying cutting parameters.

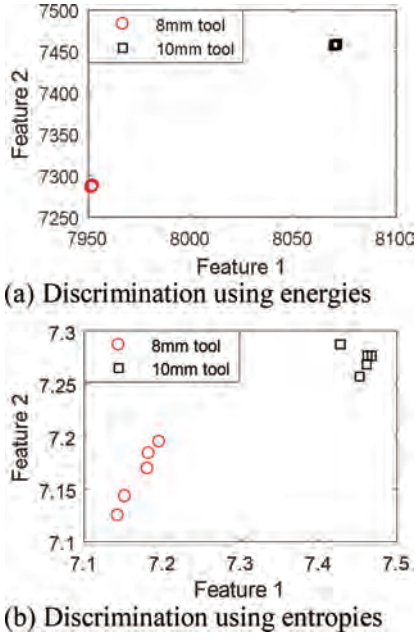


Figure 6. Discrimination results of 6 mm and 10 mm tools at different conditions.

4 CONCLUSIONS

In this paper, the discrimination of end mill tools with different diameters, wear levels, and cutting parameters is investigated. Wavelet packet transform is applied to extract wavelet coefficients from the original signal. Signals at different frequency sub-bands are then reconstructed using wavelet coefficients from which energy and entropy are calculated. The two highest energies and entropies are selected to discriminate different cutting tool states.

Two cases are used in this study to investigate the performance of the proposed method; cutting tools with different diameters and wear levels, and cutting tools with different diameters and wear level but similar instantaneous powers. Results demonstrate that with the proposed approach, the state of the cutting tool can be discriminated with good quality, both the tool wear level and cutting parameters can be discriminated.

Whilst these initial results are promising further work is required to expand the analysis over a wider range of cutting parameters to establish if the methodology holds. Additionally, refinement of the sensor measurement and tool monitoring service is required. At present signal analysis is performed off-line, whilst data is captured at higher frequency (50khz) increasing the cost of equipment and time of analysis. Optimization of this methodology is required in order to enable on-line monitoring.

Risk from cyberattacks on autonomous ships

Jan Erik Vinnem & Ingrid Bouwer Utne
Department of Marine Technology, NTNU, Norway

ABSTRACT: The vulnerability of technological and administrative systems to cyberattacks has been shown to be high in several cases, which has led to different unwanted consequences. Autonomous ships will also be exposed to the threat of cyberattacks, due to their need for connecting to operational, management and administrative systems onshore. The most critical hazards are possibly not associated with consequences for the ship itself or its cargo, but the threat to infrastructure along the coast and offshore if a ship under alien command is used as a "battering ram" to cause major structural damage. Even relatively small autonomous ships may pose a real threat, and ships sailing in international waters may come from distant locations. This implies that all autonomous ships may be considered as possible threats. This paper outlines the risk for some infrastructure systems. Even though the probability may be low, such events cannot be ruled out in the future, and the design of autonomous ships must involve a series of risk reducing actions and designs.

1 INTRODUCTION

Maritime security has come on the agenda the past decade. In 2004, the U.S. presented a national maritime security policy. The Sept. 11th attacks also put maritime terrorism on the agenda. The increase in piracy attacks in 2008 and 2011 outside the coast of Somalia contributed to even more attention to maritime security globally. In 2011, maritime security became one of the objectives in The North Atlantic Treaty Organization's (NATO) Alliance Maritime Strategy. The UK, EU and the African Union proposed maritime security strategies in 2014 (Bueger, 2015). The Maritime Safety Committee (MSC) in the International Maritime Organization has recently published guidelines on maritime cyber risk management (IMO, 2017a).

There is an increased focus on developing autonomous ships. A motivation is reduced building and operational costs, because the ships can be redesigned. Research projects, such as the Maritime Unmanned Navigation Through Intelligence in Networks (MUNIN) (Rødseth & Tjora, 2014) and Advanced Autonomous Waterborne Applications (AAWA, 2016) focus on the development of technological specifications and designs for autonomous ships. Industry projects aim at realizing the first autonomous ships in the next 1–3 years, e.g., Yara Birkeland (Kongsberg Maritime, 2017).

Autonomous ships will be exposed to the threat of cyberattacks, due to their need to connect to operational, management and administrative systems onshore. The most critical hazards are possibly not associated with consequences for the ship itself or its cargo, but the threat to infrastructure along the coast and offshore if a ship under alien command is used as a 'battering ram' to cause major structural damage. Even relatively small autonomous ships represent a high kinetic energy when travelling at full speed and may thus pose a real threat to infrastructure systems. Ships sailing in international waters may come from distant locations. This implies that all autonomous ships may be considered as possible threats. It will not be sufficient to ensure that the high-quality classification societies have stringent requirements; all classification societies or IMO need to focus on such threats.

We may think that the probability of cyberattacks may be low, but such events cannot be ruled out in the future. We therefore believe that it is important, before autonomous ships are built and commissioned, that the marine and maritime industry at large, consider this threat and takes necessary actions to implement sufficient risk control actions.

A cyber-attack may have some parallels with the terrorist attack on USS Cole, the United States Navy guided-missile destroyer, on 12th October 2000, while it was being refueled in Yemen's Aden harbor (US Navy, 2001). 17 sailors were killed and 39 injured, due to the attack from a small fiberglass boat carrying explosives and two suicide bombers. The boat approached the port side of the destroyer in bright daylight, and exploded, creating a 12 by 18 m gash in the ship's port side from what was estimated to 180–320 kg of explosives.

The objective of the paper is to discuss the implications of the vulnerability of autonomous ships to cyber-attacks, the threats that a ship under alien control may represent for infrastructure systems, and how such risk should be mitigated in general. There are also other activities and sectors in the society where cyber-attacks may be a potential threat. One incident known from the petroleum industry is described in Section 2.1. Some incidents in the energy sector are briefly mentioned in Section 2.3. Autonomous cars are another such sector, see further descriptions in Section 2.2. Experiences from other sectors can be used as a basis for assessing risk and developing relevant risk mitigation measures for autonomous ships.

Traditional risks to ships, which also apply to autonomous ships, such as collision, grounding, foundering, etc. are outside the scope of the paper, and are therefore not discussed. These risks are still important, and are subject to attention by several researchers. The risks to infrastructure systems are special in the sense that catastrophic consequences may cascade outside the industry itself.

The paper considers unmanned autonomous ships primarily, but differences between unmanned and manned autonomous ships are also considered.

2 REVIEW OF CYBER THREATS IN COMPARABLE SYSTEMS

2.1 *Petroleum industry*

It is not easy to collect experience data about cyber-attacks. Statoil corporate management was invited to give a university lecture about cyber threats to their systems and operations in October 2016 (Statoil, 2016). The incidents presented during this lecture are presented in Section 2.3 below. No incidents were mentioned in the lecture from Statoil's own operations. Three weeks later it was revealed through media that there had been a serious unintended incident at Statoil's Mongstad refinery in May 2014, as described in the following. Through the subsequent handling of this incident, it became clear that Statoil has had many more incidents of probably different severity. What was revealed by media a short while after the guest lecture puts the lack of openness in the university lecture in a special light.

The most well-known incident in the petroleum industry is from the downstream part, where maintenance on a server by an IT specialist in Hindustan Computers Ltd. (HCL) in India disrupted the loading of a gasoline tanker at the Statoil operated Mongstad refinery just outside Bergen in Norway on 21st May 2014. An input error by the operator gave him access to a server he should not be able to access. It should not be possible to stop the server in question remotely, but the HCL specialist inadvertently accessed the server through a 'back door', according to media.

The operations of certain IT systems, including the Mongstad refinery, was outsourced by Statoil to HCL in India in 2012, after a risk assessment. The incident referred to here did not affect safety directly, but could potentially have affected safety functions and barriers, according to the audit report by Petroleum Safety Authority (PSA, 2017).

The NRK broadcasting company in Norway found 29 incidents where information and communication technology (ICT) employees from India had accessed servers they should not have access to in Statoil. Anonymous sources in Statoil have commented that the problem was more extensive than what the journalists found.[1]

The PSA audit was initiated after the incident was known in the public domain, almost 2.5 years after it occurred. The audit considered the handling of incidents associated with ICT and information security by Statoil in general. PSA considered several ICT related incidents, as well as Statoil's technical requirements to information security for industrial automation and control systems. The wording of the PSA audit report is such that it indicates that other incidents have occurred that are unavailable in the public domain.

Statoil was criticized by PSA for failing to notify the authorities about the incident at the time it occurred, which according to Statoil's own assessment could have had consequences, such as failure of safety functions or barriers, according to media reports (see footnote[1] above).

Statoil informed in mid 2017 that they had cancelled all outsourcing contracts that affected safety critical systems. They had concluded that the outsourcing of these systems represented too high risk for unwanted influence on the systems.

From the media, it is known that Statoil was the target of a massive attack over three days in 2013, where hackers tried to install dangerous code into Statoil computers[2], apparently an unsuccessful attack.

2.2 *Autonomous vehicles*

Autonomous cars are expected to become an important part of the transportation system within the next decade. Self-driving vehicles will

[1]https://www.nrk.no/norge/xl/tastefeilen-som-stoppet-statoil-1.13174013.

[2]http://www.newsinenglish.no/2014/08/28/statoil-held-off-hacker-attack/.

be shared by several users (Lyche, 2017). Autonomous buses may be realized in the near future with operators in control centers remotely overseeing several buses. In specific circumstances, the operators may take over control and remotely operate the buses if needed (Lyche, 2017). This means that the autonomous buses will operate in different autonomy levels, with shared control.

A major challenge is the increasing interconnection that may expose safety-critical systems to security threats. Cars are no longer physically isolated machines controlled mechanically and locally (Macher et al, 2017). They have become computers with various electronic control units (ECU) and hackers may take control over brakes, engine, the steering wheel, radio, and lights. Recently, it was discovered that one million cars could be hacked simultaneously (Kibar, 2017; Slovik, 2017).

A car's vulnerability to hacking depends on what kind of remotely connection the car has, the configuration of the car's internal computer network, and how external digital commands may affect physical components (Kibar, 2017). Press (2017) discusses how cars can become weapons of mass destruction on the road. It will not be sufficient to install firewalls or intrusion detection systems. The UK Government states that Wi-Fi connected cars along with autonomous cars are getting increasingly vulnerable to hacking and data theft. They recently published key principles of vehicle cyber security for connected and automated vehicles to support the industry (GOV.UK, 2017). These principles are (quote):

1. Organizational security is owned, governed and promoted at board level.
2. Security risks are assessed and managed appropriately and proportionately, including those specific to the supply chain.
3. Organizations need product aftercare and incident response to ensure systems are secure over their lifetime.
4. All organizations, including sub-contractors, suppliers and potential 3rd parties, work together to enhance the security of the system.
5. Systems are designed using a defence-in-depth approach.
6. The security of all software is managed throughout its lifetime.
7. The storage and transmission of data is secure and can be controlled.
8. The system is designed to be resilient to attacks and respond appropriately when its defences or sensors fail.

The connectivity means that the vehicle is integrated in a global ad-hoc network system where external information are important for decision making. Security has become an important aspect to include in systems safety engineering. The development of these novel transportation systems means that systematic approaches taking both safety and security aspects into consideration are needed (Macher et al, 2017).

Standards relevant for the automotive domain are increasing their focus on security. IEC 61508:2010 mentions that security threats may be identified during hazard analysis. Nevertheless, the security threat analysis is not specified or detailed. The SAE J3061:2016 is a guideline for cybersecurity engineering. Among other things, it focuses on defining a process for implementing cybersecurity in the design, considering a vehicle's lifecycle and providing basic guiding principles on cybersecurity.

2.3 *Energy sector*

Some other cyber-attacks on the energy sector that are known in the public domain are the following (Statoil, 2016):

- Attacks on Technical network
  - Stuxnet: Iran's uranium enrichment facility 2010
  - German Steel Mill 2014
  - Ukrainian power network 2015
  - German nuclear plant 2016
- Attacks on Office network
  - Shamoon incident: Saudi Aramco office network 2012
  - Energetic Bear: Energy industry in the US and Europe 2012 →
  - Cleaver (recon): Energy infrastructure several countries around the globe 2012 →

The Gundremmingen nuclear power plant in Germany, located about 120 km northwest of Munich, is run by the German utility company RWE. It was found to be infected with computer viruses, but they appeared not to have posed a threat to the facility's operations because it is isolated from the Internet, according to press reports.[3] The viruses, which included "W32.Ramnit" and "Conficker", were discovered at Gundremmingen's B unit in a computer system retrofitted in 2008 with data visualisation software associated with equipment for moving nuclear fuel rods, RWE said. Malware was also found on 18 removable data drives, mainly USB sticks, in office computers maintained separately from the plant's operating systems. W32.Ramnit is designed to steal files from infected computers and targets Microsoft

[3]http://www.telegraph.co.uk/news/2016/04/27/cyber-attackers-hack-german-nuclear-plant/.

Windows software, according to the security firm Symantec. Conficker has infected millions of Windows computers worldwide since it first came to light in 2008. It is able to spread through networks and by copying itself onto removable data drives, Symantec said.

The 'Energetic Bear' is a Russian virus that let hackers take control of power plants. Over 1,000 energy firms have been infected, according to media reports.[4]The hackers obtained access to power plant control systems, and could have disrupted energy supplies in affected countries, if they had used the sabotage capabilities open to them, according to Daily Mail.

In October 2017, it has been revealed by media[5] that Russians have jammed the GPS signals in Northern Norway in September 2017, as a deliberate action by Russian militaries during a cyber warfare exercise.

3 CYBER RISKS FOR AUTONOMOUS SHIPS

3.1 *Hacking of autonomous ships*

The technological advancements towards ships operating without an onboard crew is enabled by the developments in ICT in recent years. ICT provides data connection and on-board intelligence and data connection capabilities. The ships may operate in different levels of autonomy. In a high level of autonomy, ships may be supervised by human operators in Shore Control Centres (SCC). Whenever necessary, the operator (supervisor) may intervene. A SSC could take responsibility for overseeing specific phases of a ship's operation or voyage, for example, maneuvering in and out of port, which then means that the ship would operate in a lower level of autonomy. The connectivity between the ship and SSC must have high capacity and availability and is crucial for the realization of autonomous ships (AAWA, 2016; MUNIN, 2015).

The increasing usage of networked ICT technology makes it possible to access systems through net-work interfaces and gain unauthorized remote capability to control ship systems in undesired manners (AAWA, 2016). Security threats that are relevant for ships are piracy and highjacking, smuggling of goods, human trafficking, damaging of ship or port facility, vandalism, sabotage, such as intentional jamming or spoofing of the ship automatic identification system (AIS), GPS signals and communication systems, and use of the ship as weapon for terrorist activity (AAWA, 2016; MUNIN, 2015).

The security challenge of shipping has been addressed by the International Maritime Organization (IMO) Maritime Safety Committee and The Facilitation Committee, who recently issued guidelines on maritime cyber risk management (IMO, 2017a). The guidelines give high-level recommendations on security risk management to protect shipping from current and emerging threats. Five functional elements are presented consisting of identification, protection, detection, responding and recovering. Vulnerable systems that are mentioned in the guideline are bridge systems, cargo handling and management systems, machinery and propulsion systems, control systems, passenger servicing and management systems, passenger public networks, crew welfare systems, and communication systems. IMO states that cyber risk management should be integrated into ship safety management within 2021 (IMO, 2017b).

To protect a ship against cyber threats means that vulnerabilities in the ICT infrastructure need to be eliminated and effective measures for intrusion prevention must be implemented. It is also necessary to consider that hackers may become more skillful over time with more advanced techniques available. This means that cyber security needs to be dynamic and proactive. Classification and encryption of data, user identification, authentication, authorization, protection of data integrity and connectivity, as well as activity logging and auditing are examples of typical cyber security methods that are expected to be needed (AAWA, 2016).

MUNIN (2015) presents a risk matrix, including both safety and security aspects. The highest ranked threats are found to be jamming, spoofing or hacker attacks of AIS, GPS signals, or communication systems, leading to collision with other ships, or ship grounding in critical areas.

3.2 *Autonomous ships used as threat to infrastructure systems*

The control over an unmanned ship which is hacked may be lost completely, which is the most severe situation. It is assumed that complete loss of control is impossible if there is a small crew onboard. It is assumed that a small crew may be able to deactivate external control and take over control locally. If this fails, they should at least be able to shut of power and let the ship drift until they may be able to take back control locally.

But without local crew such possibilities are not available, and control may be lost completely, at least for some time. In theory, control may be

[4]http://www.dailymail.co.uk/sciencetech/article-2675798/Hundreds-European-US-energy-firms-hit-Russian-Energetic-Bear-virus-let-hackers-control-power-plants.html.

[5]https://www.nrk.no/finnmark/e-tjenesten-bekrefter_-russerne-jammet-gps-signaler-bevisst-1.13721504.

reestablished by boarding the ship, for instance by helicopter, such as police helicopter or naval helicopter. This will take time in any case, and if the vessel is far from shore, a helicopter may not be able to reach the ship until it comes closer to shore, and then it may be too late.

It is therefore possible that an unmanned, autonomous ship that has been hacked may be used to ram into infrastructure systems. This is discussed further below. A similar scenario could also occur with a conventional manned ship, if the ship is highjacked, but this is outside the scope of the present discussion.

Let us first consider if a hacked, unmanned ship may be a threat to other ships in open seas. This may be possible in principle, but if the other ships are conventional, manned ships, they may be able to avoid the hacked, unmanned ship through maneuvering away from the threat. This may fail if the threat is not observed, but should normally be successful. It the second ship is an unmanned, autonomous ship, control from shore should be able to observe the threat in a similar manner.

A special case occurs if other ships represent potential extreme catastrophic consequences, for instance if the other ship is a cruise ship with many thousands of cruise passengers. Or if the other ship is a very (or ultra) large crude carrier, capable of transporting in order of 2,000,000 bbls of crude oil. These ships would not be autonomous, and should normally be able to avoid attack.

But infrastructure installations are usually stationary and not able to relocate to avoid the threat. By infrastructure systems in this context one may first of all think of bridges crossing fjords and bays and other seawater open areas which are found in almost all coastal areas worldwide. Other systems may be offshore petroleum installations, which are found far away from shore in several parts of the world; the North Sea, Gulf of Mexico, Atlantic Sea off the coast of Brazil, several African countries, Newfoundland, Shetland as well as the Pacific in some areas off Australia and the South China Sea.

There are considerable differences with respect to impact resistance to external impact in the various types of infrastructure systems. In Norway for example, there has been a study project ongoing to establish possible concepts for fjord crossing of some of the largest fjords on the West coast of Southern Norway. For a possible fjord crossing of the Sognefjord, a floating bridge concept has been specified to have 1563 MJ kinetic energy resistance, corresponding to a ship of about 31,500 tdw, travelling at a full speed of 17.7 knots (Statens Vegvesen, 2013). Smaller bridges along the coast are believed to have resistance at least one order of magnitude lower, but the consequences of a collision against a smaller bridge may be less extensive.

When it comes to offshore structures, the traditional resistance has been designed to take the impact from a drifting service vessel. Typically, this was a value of 14 MJ for many years (Vinnem, 2013), but is in recent years increased to around 50 MJ (Yu & Amdahl, 2018), due to increasing size of service vessels used for these installations. The largest offshore structures, the concrete gravity based structures (so-called Condeep structures), which we commonly installed in the North Sea some 20 years ago, have a push-over resistance about 200 MJ (Vinnem, 2013). This is almost an order of magnitude lower than the specified resistance of the bridge for the fjord crossing of the Sognefjord. Most of the offshore structures have capacity in the order of 50 MJ or less.

Floating offshore structures may in theory move away, if threat is detected sufficiently early. If the hacked ship is used with the intention to ram into a structure, it may be able to follow the movements of the offshore installation.

Even a small ship with a mass of 5,000 tons, travelling at a speed of 12 knots, has a kinetic energy of roughly around 200 MJ, which is excessive in relation to structural capabilities of most offshore structures; only the Condeep structures could be expected to survive. Larger ships will be a threat to all offshore structures.

The largest offshore structures are usually manned with up to a few hundred persons, implying that many lives are at risk. In addition, comes the blowout potential. Here the fixed installations are the most vulnerable, because the equipment to isolate the wells are mainly on deck. If the installation is wiped out, very long-lasting blowouts may occur as a result, in addition to the death toll.

4 FEASIBILITY OF RISK REDUCTION

4.1 *Approach to risk control*

The previous sections have shown that hacked autonomous unmanned ships may be a considerable threat to offshore installations, and to infrastructure elements along the coast unless particularly strengthened.

It is considered that further strengthening of constructions is not relevant. First of all, this is impossible for existing structures, and further strengthening of future structures is not relevant due to excessive costs. The risk control actions will need to be focused on prevention of the threats to cause incidents.

Traffic surveillance is one of the solutions adopted by the offshore oil and gas industry for protection of offshore installations against collision threats by passing vessels. For the Norwegian sector, there are several centers; two operated by off-

shore companies and several government operated centers along the coast. The main principle is to detect a ship on collision course as early as possible, to give the possibility to communicate with the ship and warn it to alter its course. If contact is not established, the approach implies to warn the installation sufficiently early, such that safe evacuation of all personnel may be completed. In addition, available resources may be used to try to establish contact with the vessel, if communication fails.

But the approach in this case assumes that the vessel does not want to collide. If on collision course, this is due to lack of knowledge, or in some cases with intent for a certain period, with a planned future course change. This approach is not correspondingly well suited if the ship is on collision course by intent. Communication is not going to change anything, nor the use of vessels or other resources to achieve physical contact. Still, the detection of a ship on collision course will imply that evacuation of personnel may be possible, if the procedures to start evacuation in a timely manner are adhered to. This will not protect the installation, though.

Keeping a small crew onboard is the most effective risk control action. It was assumed above that a small crew may be able to deactivate external control and take over control locally and mechanically. If this fails, they should at least be able to shut of power and let the ship drift until they may be able to take back control locally or assistance from shore has arrived.

A small crew would not need to be onboard al the time, the duration could be limited to where there are critical infrastructures.

If keeping a small crew onboard is infeasible, then the only option is to ensure as far as possible that there are no possibilities for hackers to gain access to the control of an autonomous unmanned ship.

Another option would be to limit the operational area of an unmanned autonomous ship for instance by limiting the available fuel stored onboard. This is to some extent used for aircrafts, although the main approach in this case is to limit the weight the aircraft is carrying. But this would be an option with some other risks. If the ship due to weather or other unforeseen events is significantly delayed, it could run out of fuel, if this is limited. If such risks are judged to be tolerable, however, it may provide an effective manner to avoid that hackers turn a ship into a threat to goals far away from the intended route. A battery powered ship will have such limitations in any case.

4.2 *Principles of prevention of threats*

If the ship is completely unmanned, it will be essential to avoid any opportunities any vulnerabilities in the control and communication systems onboard that may be used in a cyber-attack to gain control over the ship. This implies that complete control over the construction, procurement, management, operation and maintenance of autonomous ships without manning of the ship for any purpose is necessary. At all times, no unauthorized organizations nor individuals should get the opportunity to install software or hardware which may provide a "backdoor" into the control system and software available to hackers.

4.3 *Responsibilities*

Even though the probability for a cyber-attack against an unmanned autonomous ship may be low, such events cannot be ruled out in the future, and the design of autonomous ships has to involve a series of risk reducing actions and designs. Requirements to completely non-vulnerable control and communication systems may pose extreme restrictions to the construction, management, operation and maintenance of a completely unmanned ship, perhaps to the extent that the advantage of zero manning by far is overridden by costs increases associated with such restrictions.

4.3.1 *Role of ship owners*

It will be the responsibility of the ship owner who is commissioning the construction of an unmanned, autonomous ship that no alien software or hardware is allowed on board, which may be used in a cyberattack.

This will imply that every aspect of construction, procurement, management, operation and maintenance of such ships is controlled in extreme detail. All suppliers, vendors and component manufacturers and all their personnel will have to be scrutinized in order to ensure that no one has illegitimate purposes. This would be an extreme control system.

In the late 1970s, the possibility to construct nuclear power plants in Norway was considered by specialists and politicians. For a lot of the people who were against, the most fundamental argument was that there would need to be so strong requirements to control of the personnel who would operate and maintain nuclear power plants. Such very strong restrictions and surveillance of personnel were completely unacceptable to many persons.

To prevent successful cyber-attacks to autonomous ships, it will be crucial to maintain control and sufficient quality assurance over the whole software development process. This might become costly and reduce some of the expected cost savings related to autonomous ships.

4.3.2 *Role of designers and ship builders*

It is still the responsibility of designers and ship builders to implement the very strict control outlined above.

4.3.3 *Role of classification societies*

The classification societies will have to provide assurance that no alien software or hardware has been installed at any time during construction. This will require quite extreme housekeeping and control activities. It will not be sufficient to ensure that the high-quality classification societies have stringent requirements, all classification societies (high quality and low quality) need to focus on such threats.

Such assurance will need to maintained also after commissioning, due to software updates, etc. verification of software and software updates therefore becomes even more important and challenging.

4.3.4 *Role of IMO*

It is required to establish very stringent international requirements to control the risk of cyberattacks on autonomous ships. Any ship from anywhere in the world can travel international waters all over the globe and become a threat in very distant waters, provided it has sufficient amount of fuel (or operates on solar power!). All ships will therefore need to follow strict requirements.

It would be expected that the following were high-level IMO requirements for two alternative categories of autonomous ships, with and without manning:

1. Autonomous ships that always require a small crew onboard to operate
   a. Ships to have function which deactivates mechanically external control and replaces it with local control
   b. Ships to have a global power off function which as a last resort gives a dead ship
2. Autonomous ships that may operate without any crew members onboard
   a. Ships to have a function which limits the stored fuel to the distance between ports with a small margin, or
   b. Take steps to ensure fully that nobody has opportunity to install hardware or software that may be used in cyberattacks against the ship.

5 CONCLUSIONS

This article discusses cyber-attacks and its potential threat to autonomous ships. Experience from other sectors are presented and discussed. A hacked autonomous ship may be used as a weapon and ram offshore oil and gas systems, infrastructure systems along the coast, or collide with, cruise ships or oil tankers.

Infrastructure systems along the coast may be considerably more robust against collision impact compared to offshore structures. Typical offshore structures may have a resistance up to 200 MJ, which corresponds to a 5,000 tons ship with a speed of 12 knots, and are thus quite vulnerable.

Keeping a small crew onboard is the most effective risk control action, assuming that the crew may be able to deactivate external control and take over control locally and mechanically.

An option to keeping a small crew onboard is to ensure, as far as possible, that hackers cannot gain access to the control of an autonomous unmanned ship. This implies that there will have to be complete control over the construction, procurement, management, operation and maintenance of autonomous ships.

Another option would be to limit the operational area of an unmanned autonomous ship, for instance, by limiting the available fuel stored onboard. But this would be an option involving some other risk: if the ship due to weather or other unforeseen events is significantly delayed, it could run out of fuel, if this is limited. If such risks are judged to be tolerable, however, it may provide an effective manner to avoiding that hackers turn a ship into a threat for objectives far away from the intended route.

It is required to establish very stringent international requirements to control the risk of cyberattacks on autonomous ships. As ships may travel all over the globe and become a threat in very distant waters, all ships will therefore need to follow strict requirements. There will have to be different requirements to ships which require a small crew onboard than those without any crew.

An evaluation of the Functional Resonance Analysis Method (FRAM) as a practical risk assessment tool within a manufacturing environment

S. Albery, S. Tepe & D. Borys
RMIT University, Melbourne, Australia

ABSTRACT: The objective of this research was to evaluate a risk assessment process based on the Functional Resonance Analysis Method (FRAM) (Hollnagel, 2012) as a practical tool within a manufacturing environment. Instead of focusing on the activities and events which can cause adverse outcomes, known as a Safety-I approach, this study uses risk assessment for detecting the sources of variability within activities and how this may lead to both negative and positive outcomes within the system; Hollnagel (2012) refers to this as a Safety-II approach. Four examples of work process from an upholstered seat manufacturer were assessed using a risk assessment process involving consultation with workers to determine sources of variability in the 'work-as-done'. The data was mapped onto the FRAM six aspects to envision instantiations. The method provided a means of clearly articulating gaps in the system design impacting safety and productivity. FRAM was found to be an effective mechanism for revealing aspects of variability but required a greater resource commitment over regular risk assessment tools.

1 INTRODUCTION

Despite their wide spread use, risk assessment tools such as risk matrices have documented pitfalls (Gadd et al., 2004). Due to restricted requisite variety, their effectiveness is limited in the identification and control of hazards (Conant and Ross, 1970) and as a result, limit the benefit they provide to both employees and organisations. Further, the use of a linear causal relationship to describe hazards generates a concentration on negative outcomes and lower order controls, limiting stakeholder learning and cross disciplinary engagement (Cox, 2008).

This research proposed to challenge this Safety-I archetype (Hollnagel, 2014) and replace it instead with the perspective of Safety-II (Hollnagel, 2014), principally to look beyond isolated hazard management to the consideration and optimisation of the greater system within which the hazards exist. The objective was to investigate if the pitfalls associated with linear risk assessment methods could be mitigated by using a tool with greater requisite variety.

The research evaluated four work systems within a manufacturing environment. The systems were selected based on work-as-imagined descriptions of characteristics key to both Safety-II and FRAM assessments, being: (i) variability in functions, (ii) the level of acknowledgement and control of that variability, and (iii) the couplings between functions within the systems, as well as (iv) couplings to upstream and downstream systems.

1.1 *Safety-I and Safety-II*

Hazard management is based on the definition of risk, the perception of risk, the tools employed to measure risk, and the respective controls identified as a result of the risk assessment process (IEC, 2009). The type of tools used for risk assessment will also influence the type and number of hazards identified, the controls for management of those hazards, and the capacity for organisational learning (Lundberg et al., 2009).

In line with this practice, the risk matrix is a tool used for the assessment of risks based on the likelihood and consequence of negative outcomes (IEC, 2009). The risk matrix is widely accepted as an industry tool because of its simplicity to use and understand, and it is recommended by regulators such as Australian Governments (Worksafe, 2014).

In contrast to current Safety-I based practice, Safety-II seeks to understand why things go right even when there is variability in the system which would otherwise lead to error states (Hollnagel, 2012b). This creates a focus on 'work-as-done' (the way work is actually done, as opposed to the documentation which describes work-as-imagined) and how the system may adapt to emerging situations to prevent the occurrence of negative outcomes.

The adoption of a Safety-II perspective does not mean that the principles of Safety-I should be discarded. Safety-II provides a different lens to question the way work-as-done is understood and Safety-I is a subset of Safety-II (Hollnagel, 2014). The trade-off of looking at everything that goes right, as opposed to just that which goes wrong, is the need to look at all activity not just specific outliers.

Further to this line of thought, the Safety-II concept recognises that workers adapt to situations that do not function as intended, interpreting the conditions of the environment and adjusting their own output accordingly (Hollnagel, 2012b). Recognising that a system is unlikely to be completely defined or closed, humans play an important role in bringing together elements that could not otherwise manage the variability of an open system (Woods et al., 2010).

1.2 *The Functional Resonance Analysis Method (FRAM)*

The degree of variation that a Safety-I tool such as a risk matrix can describe is insufficient to characterise the degree of variation needing to be understood or controlled in the physical system being interrogated (Hollnagel and Woods, 2005). Conversely, the FRAM may have a greater requisite variety due to its ability to better model the environment being investigated and thus its regulation (Conant and Ross, 1970).

Unlike a risk matrix assessment which only looks at likelihood and consequence, a FRAM assessment requires four steps. The first two steps focus on understanding and defining work-as-done, the third examines emergent system states that result from system variability and the fourth considers managing these unwanted system states (Hollnagel, 2012a).

In conducting a FRAM assessment, the system is divided into key functions which either directly or indirectly affect the outcome of the activity as it would usually be performed. In FRAM, functions have up to six aspects which define their characteristics and how they are coupled within the system: inputs, outputs, preconditions, resources, time constraints and controls. Potential variability is then described within the functions in terms of the way a function would typically vary in normal working conditions, and from where that variability originates.

This information constitutes a FRAM model which may then be used to recognise emergent states or instantiations of the system. When variability leads to system states which are not considered normal activity, the variability is construed as uncontrolled, and resonance is said to have occurred.

By observing the relationship between instantiations and emergent system states, it is possible to identify sources of variability and how they may be managed. These may be tabulated to qualitatively aggregate all sources of variability within an instantiation (Hollnagel, 2012a), thus forming a diagram of the relationship between functions through coupled aspects (Hill, 2015).

From the perspective of risk assessment, the Safety-II objective is to identify and assess the sources of variability within a system, so they may be damped to stop the occurrence of resonant system states which otherwise would generate negative outcomes.

A small automotive manufacturing site was selected which had a range of different material processing and fabrication systems, all involving different degrees of worker and technology adjustments, based on work-as-imagined descriptions. By definition, systems with low technological precision required more human adjustment and where thus expected to contain higher variability. Comparatively, systems with a high technological precision required less human adjustment and where thus expected to contain lower variability.

Based on work-as-imagined descriptions from written procedures, four manufacturing systems were selected which contrasted both technological and human precision. The systems were selected as two coupled pairs so that the upstream and downstream relationship of variability could be observed on the overall systems (Table 1).

System 1A required two workers to move carpet stock through a number of automated stations to convert raw carpet stock into a moulded three-dimensional shape with plastic-welded components. The output of System 1A was fed into System 1B which required another two workers to move the

Table 1. Perceived level of adjustment (precision) in manufacturing activities based on work-as-imagined descriptions of technology and human action; resulting in potential output variability.

Imprecise = high adjustment for success;
*System B is downstream of System A.

stock through further automated stations, initially adding a foam backing before waterjet cutting the stock to a required shape for stillaging.

System 2A required a worker to assemble many individual pre-welded steel components into a fixture inside a robotic weld station, producing a welded sub-assembly. The welded sub-assembly of System 2A was then fed into System 2B which required a second worker to construct a finished structure from several different sub-assemblies.

At each of these workstations, four question sets were employed (Albery et al., 2016) to discuss each of the systems with the workers thus collecting the necessary data required to perform FRAM analyses.

Workers, supervisors and quality engineers were asked the four sets of questions. All participants had been in their respective roles greater than a year and were skilled in their roles. The question sets were applied as a semi-structured interview process, focusing discussions on the precision of each of the systems in the workers' own language (Louise Barriball and While, 1994).

Aggregate variability was determined qualitatively from participant responses to the question sets. Alignments and misalignments between work-as-imagined and work-as-done were recorded within the precision of respective aspects.

Notes from the data collection were subsequently transcribed into a template adapted from the FRAM (Hollnagel, 2012a). This qualitative coding formed the basis of the aggregation of variability described for each system in Tables 2 through 5.

For each system the variability associated with normal work (N) was recorded as instantiation "0" for each aspect of each function. Normal work was considered an alignment between work-as-imagined and work-as-done where the required adjustments were considered in the system design.

When the response to the questions revealed either an increase (I) or reduction (R) in variability for the same aspect, this was construed as a unique instantiation and "1, 2, …" was recorded, signifying that a different level of precision was required to manage the variability within the system.

Finally, visualisations of the systems then constructed based on this information.

2 RESULTS

The first instantiation of System 1A, System 1A.0 was considered "normal work". It revealed that the shape of the carpet through the process from start to finish was heavily dependent on its temperature. If the carpet temperature dropped two low at any stage in the process it would become incompatible with the other functions. This placed a reliance on human precision to carefully maintain the system cycle time (Table 2. and Fig. 1.).

Instantiation 1A.1 identified time delays moving the stock between stations in upstream functions; this caused a temperature drop in the carpet

stock which led to the carpet border, or perimeter, being geometrically incompatible with the downstream functions.

Specifically, the geometric border change meant that the carpet stock was incompatible with machine fixtures, meaning (i) it could not be correctly welded and (ii) the foam backing material could not be correctly applied as the last stage before entering the next system (Fig.2).

To force the welding and foam backing functions work successfully, workers compensated by hand cutting the carpet borders as a hidden upstream sub-function.

Instantiation 1A.2 identified that approximately 50% of carpet stock was a recycled material which was stiffer than the normal carpet and incompatible with the system temperature range. The recycled material was imprecise and required additional heating time as well as a hidden hand cutting operation to remain compatible with the other functions (Fig. 3).

Instantiation 1A.3 identified that workers were exposed to minor burns manually handling the hot carpet between each of the functions (human, imprecise). This resulted in the carpet becoming soiled and rejected during the foam backing process (Fig. 4).

The first instantiation of System 1B, System 1B.0 was considered "normal work". Workers advised that when the system was functioning correctly, a sufficient carpet temperature was maintained and there was no rejected stock from the previous System 1A (Table 3, Fig. 5). If the workers in System 1A could achieve the 'minimum' temperature meant the carpet stock could successfully pass through each function without hidden worker adjustments, such as also cutting the boarder as described in System 1A (Fig. 2).

Instantiation 1B.1 resulted from a delay in instantiation 1A.1. This resulted in the introduc-

tion of a second precise hidden function required to hand cut the carpet for the waterjet function to succeed (Fig. 6).

Instantiation 1B.2 was also caused by the upstream instantiation 1A.1. As the carpet was at the wrong temperature (technology imprecise) when entering instantiation 1B.1 the foam backing

N – Normal variability; I – Increased variability.

ances, human or technology imprecise), impacting all functions within this system, and those downstream from it (Fig. 10). This meant stock was either rejected as it could not be welded, or was welded and rejected in a downstream function.

The first instantiation of System 2B, System 2B.0 was considered "normal work". The system required workers to manually assembly a number of sub-assemblies into a station, including sub-assemblies from System 2A. These were then bolted together (human precise). The system was reliant on workers continually adjusting their control of the processes and timing between each of the functions to ensure the total aggregate variability was successfully managed (Table 5, Fig. 11).

Instantiation 2B.1 resulted from welded stock from instantiation 2A.1 entering this system. Workers could not confirm if the 2B.1 part was geometrically incorrect (human, imprecise) until checking the final assembly at which point it was rejected and must be returned to the first system input for re-assembly (Fig. 12).

Instantiation 2B.2. resulted from using stock from instantiation 2A.0 that had misaligned hardware. Like Instantiation 2B.1, the assembly was returned to the first system input for re-assembly (Fig. 13).

Finally, instantiation 2B.3 resulted from using stock from instantiation 2A.1 that was welded correctly but was geometrically incorrect. However, the assembly was not detected and rejected initially;

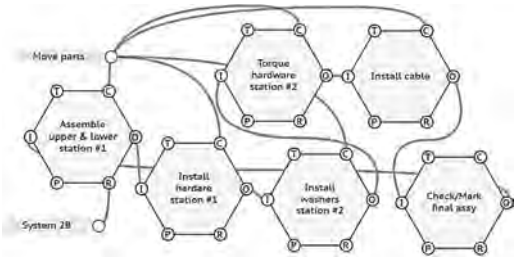

Figure 11. System 2B/Instantiation 0 (2B.0). Normal work.

so the variation was carried into downstream functions and then rejected in the last function.

3 DISCUSSION

The key learning associated with each instantiation was the identification of variability introduced by upstream plant process where technological precision was expected but absent. Subsequently reactive human precision was introduced to manage variability and maintain successful outcomes (Dekker, 2006). The adjustments to the introduced variability led to the subsequent creation of hazards to workers (Table 6).

Further upstream variability was observed to have downstream effects on quality and productivity, as demonstrated by any increased output variability described within tables of the results section. This was best typified as reject stock output from each of the systems. These learnings contrasted the initial work-as-imagined evaluations of each of the four systems (Table 7).

Acknowledging that each of the systems has a reliance on human precision to manage variability a summary of the main source of variability in each of the systems is provided (Table 8). Interestingly, downstream functions could be improved with no action other than better managing unwanted variability in the upstream functions.

Two specific interventions which would has an impact on the aggregate variability of the systems

2B.1	Resource, Output	Instantiation 2A.1
2B.2	Resource, Output	Instantiation 2A.1
2B.3	Resource, Output	Instantiation 2A.1

discussed above are (i) for system 1A, ensuring the system cycle time is compatible with the required raw material forming temperature, and (ii) for system 2A, tightening the tolerances on raw stock prior to welding sub-assemblies.

It is hoped that both of these simple examples serve to emphasise the importance of addressing or damping unwanted variability at its source.

Further to these points, the FRAM analysis of each of the functions aligns each of the sources of unwanted variability with potential hazards to workers. This is significant as traditional risk assessment tools do possess the requisite variety to understand the detail of the systems they seek to control (Gadd et al., 2004). This said, the cost and training required to develop a level of analysis similar to that described within this paper maybe potentially greater than many standard risk assessment tools (IEC, 2009), possibly deterring some safety practitioners.

4 CONCLUSION

Using a Safety-II lens it was found that for each of the systems analysed, work-as-imagined was reliant on worker adjustments for success. These adjustments were conscious actions made in response to introduced variability in each of the systems. From a safety viewpoint, this highlights that collaboration with other stakeholders is required to identify systemic solutions which look beyond the prevention of only localised hazards to those which emerge from the system design (i.e. systemic upstream issues that are not proximal to the worker).

It is concluded that the use of the FRAM provides deeper learnings of system performance in the management of variability as well as the impact of precise and imprecise control. The Safety-II perspective potentially involves greater time and practice to develop more meaningful output than a traditional Safety-I approach; however, this perspective is necessary if it is desirable to increase requisite variety and thus knowledge of the system.

These conclusions are limited by the sample size and findings of the systems considered in this research. However, the case studies presented indicate that a degree of variability and adjustment exists in all of the systems investigated. Further to these learnings, it would be of value to extend this type of analysis to (i) a greater sample size and (ii) coupled systems in other disciplines.

ABSTRACT: This paper presents the experiences from applying hazard and operability analysis (HAZOP) as support for establishing the safety requirements specification of a new safety-related railway application. The new railway application is a software based system for securing work areas, meaning it prevents railway traffic in areas along the track allocated to maintenance. The experiences are collected within the Safety Assessment Framework for Efficient Transport (SafeT) project managed by Bane NOR. Bane NOR is the government agency that owns, operates and develops the Norwegian railway infrastructure. The objective of the SafeT framework is to offer a systematic, reusable way for creating system wide conceptual design models and based on them, creating a common risk model, which in turn will facilitate safety assessment, establishing the requirements specification, and safety demonstration of the system under consideration. The experience collected on applying HAZOP is done through two workshops with different formats on the documentation. The objective was to collect guidance on how HAZOP can be supported in the SafeT framework.

1 INTRODUCTION

The project "Safety Assessment Framework for Efficient Transport" (SafeT) aims at developing a framework that supports the implementation of EN 50126 (CENELEC, 2017) and thereby of the Common Safety Methods for Risk Assessment (CSM RA) (EU, 2013) in the railway industry, in particular how the railway infrastructure may support efficient transport.

This paper presents ongoing results from the case studies, while the results from the modelling is presented in another paper (Karpati et al, 2017). Figure 1 illustrates which phases of EN 50126 that is within the scope of the current SafeT work and both papers, annotated by a dark grey rectangle. Some of the related work (chapter 2) is therefore relevant for both papers, and the case (chapter 4)

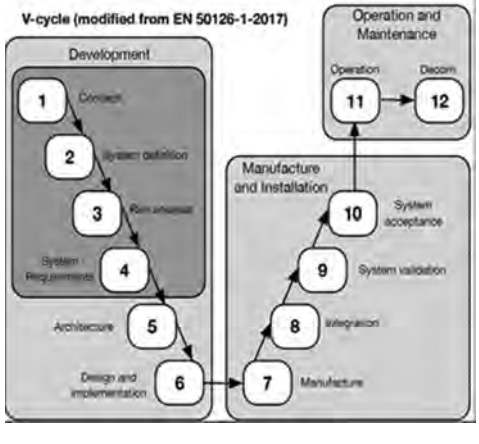

Figure 1. Scope of paper and relationship to EN50126.

is applied throughout the SafeT project. The aim of the paper is to show differences, advantages and disadvantages for two different approaches for hazard identification, applied on the new safety-related railway application.

The current focus in the SafeT project is on the development phases 1 to 4 of EN 50126. In these phases of a systems life cycle, Bane NOR takes a lead role in the development while successive development phases to a large extent are outsourced. The SafeT framework intends to support the development of the core artefacts within the system life cycle. In the early stages of the life cycle, in the part of the framework that concerns the in-house conceptualisation, the core artefacts are: 1) the conceptual system design model; 2) common risk model; and 3) requirements specification.

The main objective of the SafeT framework is to offer a systematic, reusable way for creating system wide conceptual design models and based on them, creating a common risk model, which in turn will facilitate the safety assessment and safety demonstration of the system in focus, throughout the system's lifetime.

2 RELATED WORK

International safety standards, such as EN 50126, provide requirements and guidance on how to carry out the assessment process. Although most safety standards often view the safety of a system as a function of the reliability of its components, little guidance is provided on how to derive safety requirements and acceptable risk for components whose failure rates are not known. Particularly, it is often difficult to derive safety requirements for logical components such as the software. The problem can be formulated from a consideration of the following two important tasks in the development of safety critical systems: (1) *establishing the requirements to the system*, and (2) *ensuring that the system fulfils these requirements.* The safety requirements should be established through risk assessment and hazard analysis, and fulfilled through the use of techniques and measures adequate for the risk level. The framework proposed in the project has much of its inspiration from theoretical aspects of international safety standards such as IEC 61508 (IEC 61508). The novel part of the framework is fivefold: reusability, modularity, unification, transparency and argumentation.

In the following, a number of past projects that relate to the topics of SafeT are briefly introduced. However, most of them relates to the need of establishing models and providing support for a safety case, see related work presented in the other Safe-T paper (Karpati et al, 2017).

The EU funded project MODSafe provides a risk analysis method purposed to combine potential hazards, safety requirements and functions, and link these elements to a generic functional, and object structure of a guided transport system. ASCOS (Roelen, 2014) focused on safety and certification of new aviation operation and systems, and included among other advices on methods and tools for safety based design. ModelMe! (Falessi, 2011) provides a tool-supported traceability framework where the tool for example automatically extracts the safety-related slices of SysML design models (SysML).

The AltaRice Language (Griffault, 1998) is an object-oriented modelling language dedicated to performance evaluation of complex systems. The main motivation for its creation was the difficulty to design, to share and most importantly to maintain safety and reliability models such as fault trees, event trees, Markov chains or stochastic Petri nets. The application and further development of the language is a continuous research activity at NTNU (Legendre, 2017).

Of relevance is also CORAS (Lund, 2011; Gran, 2004) which provides a methodology for model-based risk assessment integrating aspects from partly complementary risk assessment methods and state-of-the-art modelling methodology.

The SafeT project has also reviewed a number of ongoing and past industrial experiences among the project partners related to the use of design and risk models to facilitate the safety assessment and demonstration of complex systems. Some of the challenges observed in these projects have also been reported earlier within aviation (Gran, 2007). Finally, the CHASSIS method (Raspotnig, 2018) utilizes UML use cases and sequence diagrams with HAZOP guidewords to integrate safety and security considerations for early requirements determination.

3 APPLYING DIFFERENT APPROACHES FOR HAZARD IDENTIFICATION

3.1 *The role of the hazard identification*

There may be a number of different motivations for performing a hazard identification. Among them are avoiding loss of value, life and property, optimizing performance and reducing costs. The motivation for studying hazard identification in the SafeT project is to make sure that relevant hazards associated with development and use of software are evaluated, risk mitigation is in place, and the methods used for hazard identification are applicable and useful, with a basis in case studies that are carefully selected together with Bane NOR.

The purpose and method of a hazard identification and operability study (HAZOP-study) is well described in the literature, for example in *Risk assessment* (Rausand, 2011) and *IEC 61882:2016 (HAZOP studies)* (IEC 61882). The hazard identification and operability study is performed by a group review using structured brainstorming to identify and assess potential hazards. The group of experts starts with a list of tasks or functions, and next uses keywords such as none, reverse, less, later than, part of, more. The aim is to discover potential hazards, operability problems and potential deviations from intended operation conditions. Finally, the group of experts establishes the likelihood and the consequences of each hazard and identifies potential mitigating measures. The analysis covers all stages of project life cycle. In practice, the name HAZOP is sometimes (ab)used for any "brainstorming with experts to fill a table with hazards and their effects". Many variations or extensions of HAZOP have been developed.

Hazard identification can be defined as the process of identifying and listing the hazards and accidents associated with a system (DEF-STAN 00-56, 2007). There are numerous different definitions of the term *hazard* described in standards and the literature. In the following, we will combine the definitions used in EN 50126 and EN 50129 and define hazard as "*a physical situation or a condition that can lead to an accident*".

3.2 *Hazard identification in the RAMS lifecycle*

Throughout the European Union, railway signalling and interlocking projects are carried out on the basis of the CENELEC standards EN 50126 (CENELEC 2017), 50128 (CENELEC 2011) and 50129 (CENELEC 2003). The set of standards provide a consistent, European approach to the management of reliability, availability, maintainability, and safety, denoted by the acronym RAMS. In order to demonstrate that a technical system is safe to take into use and suitable for its intended application, the CENELEC standards require that the system under consideration is described and analysed in its intended context, in particular with respect to its relationship to hazards that can occur in this context and how these hazards can be controlled through the system design. This requires good models of both system design and risk that capture the relations between the different system levels and between hazards, causes, barriers, accidents, and consequences. Of particular importance to the safety demonstration is the utilization of common risk models that include the results from the hazard identifications at the different system levels, from an overall railway system down to the separate subsystems (Sivertsen, T. 2016). The use of models to support the safety management is central to SafeT, which therefore focuses on criteria for the choice of modelling techniques and how they can be combined, adapted and further developed to satisfy the modelling needs. These needs are associated to the analyses at the different system levels and its context, the risk associated to the application, and the requirements established to control this risk.

Hazard identification, operability studies, analysis and evaluation of the risks are key activities in phase 3, but they are also relevant for all the following RAMS-phases, shown in Figure 1, and in accordance with 50126-1 (CENELEC 2017):

#	Phase
1	Concept
2	System definition and operational context
3	Risk analysis and evaluation
4	Specification of system requirements
5	Architecture and apportionment of system requirements
6	Design and implementation
7	Manufacture
8	Integration
9	System validation
10	System acceptance
11	Operation and maintenance
12	De-commissioning and disposal

As part of continuous improvement work as described in the ISO 9000-family of standards (ISO 9001), identification and evaluation of potential hazards should also be done as a continuous activity throughout the system's whole life cycle. For all steps and phases, there may be numerous hazards that can compromise the RAMS performance of the system.

4 CASE EXAMPLE DESCRIPTION

4.1 *Introduction to the case example of securing work areas*

The introduction of axle counters for train detection necessitates a new solution for securing work areas. The current solution, on track sections without axle counters, is to use a contact magnet to induce a short circuit in a manner similar to how an axle of a train induces a short circuit and thereby is detected. The short circuit induced by the contact magnet triggers a state change in the interlocking that prevents the train dispatcher from locking routes through the affected section until the contact magnet is removed by the safety guard.

In the proposed solution for securing work areas (see Fig. 2 and Fig. 3), a safety guard uses a

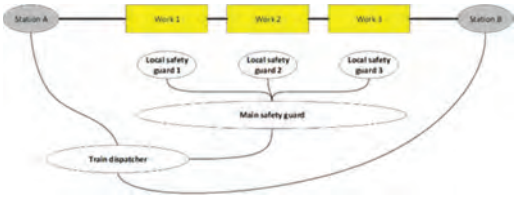

Figure 2. Work areas and roles.

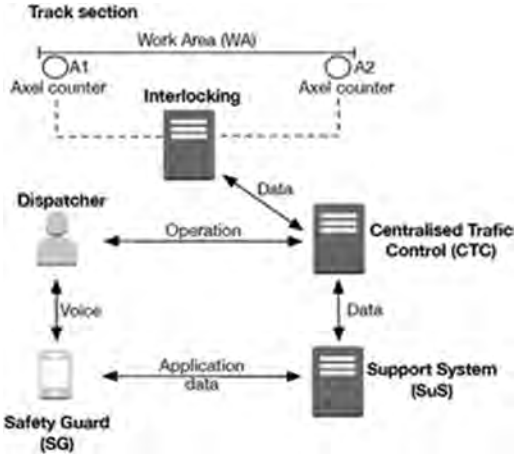

Figure 3. The securing work area case.

smartphone to interact with the train dispatcher. Besides allowing voice communication with the train dispatcher, the smartphone also contains a dedicated application with functionality to manage the securing and releasing of work areas.

In the Norwegian infrastructure, the train detection has usually been performed with different variants of track circuits. Axle counters were introduced in the infrastructure just a few years ago, and gradually replace the existing track circuits.

Irrespectively of the train detection system used, there is a need to protect workers along the track from trains unintentionally moving into the work area. A work area is a track section (possibly more than one track) that can be disposed for work, without any trains entering or leaving the area (Figure 2). The work area and the surrounding tracks can be protected by points, derailers, main signals, shunting signals, and regulations.

While the train dispatcher in either case has the possibility to block the work area, a basic safety principle in Norwegian railway operation is that the workers should be able to prevent the train dispatcher from unblocking the work area before the work is finished. Basically,

- the workers' position must be correctly identified;
- the correct work area must be effectively blocked; and
- the work area must not be unblocked prematurely.

One of the challenges with the introduction of axle counters has been that the existing methods to secure the work area no longer worked. This applies both to the correct identification of the workers' position and to the barriers against hazards caused by premature unblocking of the work area. Since a track circuit short-circuits when a train is present in the track section, the presence of trains can be imitated by short-circuiting the track circuit with other means, viz. the *contact magnets*. In this way, the workers along the track can indicate their position to the train dispatcher, who can block the section to prevent trains from entering. The contact magnet furthermore works as a barrier to hazards caused by premature unblocking of the area (trains entering the work area), since the track section is considered occupied by the interlocking.

The current solution in Norway for securing the work area when axle counters are used for the train detection involves removing a physical key for the relevant work area from its lock when the train dispatcher has blocked the work area and released the key. The train dispatcher is prevented from unblocking the work area until the safety guard has put the key back. While this certainly works, the solution is both expensive and inefficient due to the need for additional physical equipment along the track, and physically interlocking this with the signalling system. There is therefore a need for a system that can replace the current use of physical keys.

This is the background for the invention of the concept described in the next section.

4.2 *A concept of a new solution for securing work areas*

The concept involves the development of a software based system for safe interaction and supervision related to the protection of maintenance workers from accidents caused by the interference with the railway traffic. The solution is planned to require no other physical measures in the infrastructure than simple marking along the track in terms of a barcode or QR-code identifying the work area.

The proposed solution for securing work areas (see Fig. 3) consists of a software-based solution whereby a safety guard uses a smartphone to interact with the dispatcher. Besides allowing voice communication with the dispatcher, the smartphone also contains a dedicated application with functionality to manage the securing and releasing of work areas.

The safety guard identifies the work area by scanning the code on site. This identification of the work area is required at certain steps in the operation. Some of the characteristics of the functionality are:

- The main safety guard selects the functions from the application on his smart phone.
- Scanning the work area identifies both the safety guard and the work area.
- The application communicates with the support system, which communicates with the CTC and other applications.
- The support system supervises the protocol associated to each function.
- The support system supervises the secured work areas, and prevents the train dispatcher from prematurely unblocking the work area.

The solution gives several advantages, like less intervention in the infrastructure, no physical key to be kept and replaced, more convenient inspection, improved safety locally, additional functionality, larger flexibility, and simpler maintenance.

For simplicity, the interfaces between the operational support staff and the other roles are not shown in the figures. The operational support is not mentioned in the descriptions of the main functions, but a separate analysis of the support functions should be part of a complete analysis of the system. The responsibilities of the operational support include

- correcting errors or operational problems;
- keeping the support system updated with respect to information about known faults or operational problems; and
- keeping the support system data updated.

For the purpose of the risk assessment at the railway system level, all the functions can be described by considering only the interfaces between the applications and the safety guards, between the applications and the support system, and between the support system and the CTC.

Twelve main functions have been specified for the system (T. Sivertsen, 2014):

1. Log in: Logging into the system, thereby getting access to the other main functions.
2. Log out: Logging out of the system, thereby being prevented from using other functions before a new login.
3. Join: Enrolling in a work area, thereby preventing the safety guard in charge to release the work area.
4. Resign: Withdrawing from a work area, thereby allowing the safety guard in charge to release the securing of the work area.
5. Secure: Securing a work area, thereby preventing the work area from being unblocked.
6. Release: Releasing a secured work area, thereby allowing the work area to be unblocked.
7. Set time: Setting the time available for work in a work area, thereby allowing an automatic countdown of the time available.
8. Time: Reading the time available for work in a work area, thereby facilitating management of work in the work area.
9. Status: Reading the status a work area, thereby facilitating management of work in the work area.
10. Takeover: Requesting takeover of responsibility for a work area.
11. Full takeover: Requesting takeover of another safety guard's responsibilities.
12. Overview: Overview of the work areas the safety guard is in charge of or enrolled in.

For each of these functions there is a list of tasks that is performed by one or more of the involved actors in the process of securing and releasing the work areas, as showed in Figure 3.

5 TESTING TWO ALTERNATIVE APPROACHES FOR HAZARD IDENTIFICATION ON THE CASE

In order to evaluate the importance of the system description in relation to the result of an analysis, two alternative system descriptions were applied in two different HAZOP workshops with different participants.

The aim was to evaluate if different ways of presenting the system would result in different findings. In the first workshop, the basis for preparation and discussion was a graphical model of the system, while the other used a textual description. The same type of competence was present in both workshops, however, not represented by the same individuals.

The participants in the two workshops were mainly academics, with theoretical knowledge of the new and current system and of different approaches for risk assessment. There were no participants with practical experience with using the existing system for securing work areas, or other roles involved when performing such tasks. Most participants were familiar with the railway infrastructure in general and had experience with the HAZOP technique. All participants in the workshop where familiar with the new concept for securing work areas, through either the graphical representation of the system or the textual description.

5.1 *HAZOP based on a graphical model*

As preparation, a description of the case utilizing SysML diagrams with limited text and explanation

of the modelling language was sent out to the participants one week before the workshop. In the workshop the participants had many questions outside the scope covered by the model, there were also questions related to the meaning of some of the modelling symbols. During the workshop, an example of the physical outline was drawn ad hoc as illustration, and it was used a lot in the discussions. The facilitator had guidewords on hand, but they were not applied actively, as the participants constantly came up with new questions related to system achitecture or potential problems. The HAZOP resulted in the identification of two hazards, a large number of potential hazards and potential situations leading to down-time. The large number of the identified potential hazards was due to uncertainty and lack of detailed system procedures.

5.2 *HAZOP based on a textual description*

A textual description of the case was provided in advance as input to the HAZOP workshop (a summary of the textual description is given in chapter 4.1). The participants had one week to familiarize themselves with the textual description of the system before the workshop.

The following guide words were used in the meeting: early, late, before, after, wrong place, missing and wrong. The guidewords were not used actively for each function, but were presented on a separate marker board throughout the whole workshop. Each of the main functions was discussed in the HAZOP workshop, in accordance to the order given in chapter 4.2.

5.3 *Experiences from testing the two approaches*

A textual description is, compared to a model description, a well-known and common way of presenting systems for most people. A textual description may therefore be less time consuming to understand and is easy to present in a meeting. However, the textual description was not detailed enough to present the system logic and all the preconditions in depth. Hence, an illustration including the sequence of main functions and roles involved in each function was made by one of the participants in the workshop.

The illustrations were found to be useful complements, and indicated that the textual descriptions alone were not able to provide sufficient information. In specific, it was found that understanding the correct sequence of functions performed by the different roles was critical to the hazard identification, and this was not easily covered and captured by the textual description.

Constructs in models can become complex and thus their visualization as well. According to the experiences in the workshop based on graphical models, the models became difficult to understand after a certain level of visual complexity (e.g. when it is no longer possible to present the whole system in *one* single and readable screen diagram), it becomes more difficult to find support in the visual representation). One specific related problem was following the flow of logic in diagrams when branches were involved. Modularization of the visual representation added to the textual descriptions (if meaningfully possible) might help here.

Both workshops included a physical description in addition to the text or models provided on beforehand. This suggests that a physical outline diagram could be part of the models, or an addition to textual descriptions. Another consideration is that modelling or describing specific, representative cases (e.g. application of the planned system at a specific work area) might be a necessary supplement to the initial descriptions of the planned system. In our case, a specific, representative train station could be considered.

Even though participants in both workshops helped identifying unclear and missing parts, both workshops pointed to a number of potential hazards due to uncertainty about how the system was intended to work. Some of these details were contained in only one of the descriptions, but a number of descriptions were missing in both workshops, for example: preconditions of the main functions of the securing work area app, defined terminology and roles, description about the old and current solutions etc. A question related to this is whether the workshops would have been able to process and utilize the information requested by the participants. This needs to be taken into account when considering the use of HAZOP. In particular, there is a need to find models supporting the balance between the two considerations: giving sufficient descriptions, but not drowning the participants in details.

Based upon one workshop with models, we cannot conclude on the question of whether the model-based description prepared is practical for the hazard identification. There were, as described above, many other influences in the workshop independent from the modelling. However, it is clear that SafeT will need to prepare guidelines on how to use HAZOP in combination with specific SysML diagrams. Another question is if other models could have provided the same.

The two workshops came up with the same hazards. The only differences lay in how they were identified in the two workshops. This is in accordance to what one should expect. Since the textual and graphical descriptions were based upon the same source of knowledge within Bane NOR, differences in the assessment would typically point to

flaws in one of the descriptions. Another reason for having the same results is that the two workshops had rather homogenous group of knowledge and experiences. None of the groups had participants with practical experience, such as train dispatchers or safety guards. This is also illustrated by the high number of potential hazards. It is assumed that by having additional competence in the workshop, some of these potential hazards would be closed as not possible, while others would be confirmed. One interesting observation is that most of the potential hazards are not closed by just adding the graphical and the textual description. The uncertainty lies in what is not presented in any of the two workshops. If the experiment would have included only one HAZOP, we could falsely have concluded that the solution was simply to add the graphical or the textual description.

Both for the model based and the text based descriptions there is a need to supplement the descriptions by all the following different visualisations, to compensate for their inherent advantages and disadvantages:

- High-level visualisations—everything on one drawing.
- Modularised visualisations—to explore the details where and when needed.
- Sequences—to get necessary understanding on the order and timing of activities and tasks.
- Visualisation of interactions: man–machine/technology–organisation–environment.

A conclusion from this is that a better coverage of relevant details for the hazard identification could have been included in the model and the diagrams. This could also have been achieved by a preparatory workshop focusing on eliciting such information, or by involving a RAMS expert in the modelling beside the system modeller and the system owner.

There are several sources of uncertainty in the conclusions relating to relevant hazards identified in the two workshops. The uncertainty related to the sum of competencies covered by the participants in the workshop is crucial. That means that whatever approach, the sum of competencies is of great importance. It is not possible to compensate for lack of competence by choosing the other approach, or adding more time for each participant's preparations.

Applying these two approaches to the case identify basically the same hazards. This means that the conclusion is not that one of the approaches is preferable. On the contrary, both approaches give different nuances and different perspectives, resulting in a broader risk picture, which may be useful when it comes to communicating, evaluating and mitigating the risk.

How sensitive these findings may be to the chosen case is not investigated. This means that if the case was a totally different one, we do not know whether the two approaches would end up with similar hazards. Anyway, the findings in the HAZOPs from the two approaches, and the findings from the comparison of the two approaches, both indicate that the case is complex enough for an experiment like this.

When introducing new technologies or new applications of existing technologies, it is important to assess the risk by using not only one approach, but rather apply different approaches to get a broader understanding of the potential hazards.

6 CONCLUSIONS

In this paper we have elaborated on the experiences on using a graphical model presented as SysML diagrams in comparison with an ordinary textual description as a basis for hazard identification.

The model-based description is a practical and useful supplement for the hazard identification activities, but the HAZOP workshops point out that the use of SysML models requires good preparation of the HAZOP. SafeT will need to prepare guidelines on how to use HAZOP in combination with specific SysML diagrams. The participants should be familiar with such modelling to benefit from the models. A textual description is a mode of communication that most of the potential participants in the HAZOP workshop will be familiar with and trained in on beforehand. Graphical models, pictures and drawings are necessary and useful supplements for getting a broader understanding on the case that is subject for analysis.

ACKNOWLEDGMENT

The SafeT project is funded by the Norwegian Research Council (project number 257167/O80) and Bane NOR, and has participation by Bane NOR and IFE, also participation from Indra Navia AS, Avinor, Solvina AB, Safetec Nordic AS, NTNU, VTT and Beijing Jiaotong University.

Analysis of the risk of pipe breaks based on hydraulic model

E. Bartkiewicz & I. Zimoch
Institute of Water and Wastewater Engineering, Silesian University of Technology, Gliwice, Poland

ABSTRACT: The Water Supply System (WSS) distributes and supplies water to customers, which is used for consumption, production, maintenance of sanitary conditions and extinguishing fires, i.e. activities necessary for life. For this reason, hydraulic conditions of the WSS and the water quality must be maintained. One of the most common problems encountered in underground infrastructure is pipe failure, which has a major impact on WSS performance and water quality. To avoid such incidents, a safety plan should be developed. The WSSs safety plans requires some steps for risk assessment and decision-support systems. This system should use all the information resources stored in the databases. Currently, water supply companies have a number of network monitoring systems, however these are more warning rather than preventing systems. The risk is defined as undesirable situations that may occur, and therefore the preventing system should be more complex and based on historical operational events. The basic tools for building such a system are mathematical models that simulate the operational states of the WSS at different time intervals and during accidently situations. There are two kinds of models—hydraulic to simulate operating condition of the water pipe network such as pressure and velocity of water flow and- quality model, that show changes in water quality at different time intervals. The article presents a hydraulic model of a real WSS, created in WaterGEMS. This software uses historical data of pipe breaks in Pipe Break Analysis function, to compute a pipe break score for each pipe. The article presents the results of the analysis and risk assessment, presented in matrix form.

1 INTRODUCTION

Water Distribution Systems (WDS) are technical systems with a spatial structure, which the purpose is the continuous supply water to customers with appropriate quality, quantity and pressure. Unfortunately, water supply companies are increasingly faced with aging and unreliable network infrastructure, which contributes to water supply interruptions. These interruptions may be caused by pipe damages, pump failure and equipment failures [1]. Pipeline failures are a common problem depending on many internal and external effects that cause the pipe break. These effects include pipe factors (material, age and diameter), operational factors (pressure, corrosion, external stresses) and environmental factors (temperature, rainfall, soil conditions) [2, 3, 4, 5, 6]. The Figure 1 shows a few examples of conditions that may cause pipes break. Pipes failures cause economic losses (leakages) and threats to consumer health [7, 8, 9]. In small systems (often branched), pipe failures cause interruptions in water supply, which causes risk in public health places (hospitals, hotels, kinder gardens, schools), whereas in large systems reveal itself as water leaks. Determining the type of recipient is an important element in risk assessment. Every year, 32 to 48 billion cubic meter of water is lost all around the world through leaks that correspond to the total annual cost of water loss of more than 14 billion US dollars [10, 11]. Through cracked pipes, the system gets contaminated soil (by pesticides or animal and human waste) that causes water borne diseases outbreaks [12, 13]. For these reasons, the analysis of pipe failures should be included in the

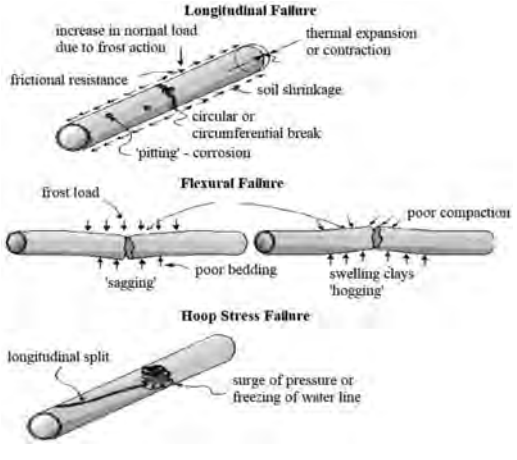

Figure 1. Causes for pipe break [2].

Water Safety Plans, as one of the elements enabling the determination of water contamination areas. World Health Organization (WHO) wrote in the Water Safety Plans: "*Understanding the nature of sources of contamination and how these may enter the water supply is critical for assuring water safety*" [14], which means that every risk analysis is crucial to the protection of human health.

There are two categories of pipe failure modeling: physical and statistical. Physical methods are designed to describe the physical mechanisms underlying the failure of pipelines. However, the mechanism of physical pipe cracks is often very complex and difficult to determine accurately. The reason for this is the fact that the pipes are buried, and the records from the failure are insufficiently accurate. Acquiring data to determine the physical causes of failure requires expensive investments, which is why statistical methods are more often used. Statistical methods use different characteristics of water networks, usually data that can be easily obtained, as pipe age or the number of failures [2]. The aim of statistic approach was to determine the deterioration of the pipes condition and creating a forecasting model to assess the risk of failure [11, 15]. Statistic methods can be divided into three categories: deterministic, probabilistic multi-variates and probabilistic single-variate. Models considering uncertainties related to input data are probabilistic models, otherwise, these are deterministic models, while models based on more parameter then pipe age are multidimensional [16]. The deterministic methods ware described by Shamir and Howard as a prediction model that relates a pipe's breakage to the exponent of its age [17]. Examples of probabilistic methods include, among others models defining the time of failure occurrence, such as the Cox proportional hazard model, accelerate failure models [18]. Table 1 presents sample models of pipe failure estimation. Analysis of the risk of pipe breaks is related to the concept of reliability. Reliability of WDS systems is defined as a property that relies on the system's ability to perform its functions under certain conditions of existence and exploitation and within the assumed time. Which means that the reliability of WDS is determined as the probability of supplied all demand nodes [4, 19, 20]. Based on the actual behavior of the network, study the reliability of water distribution network is planning to accurate operation and management of WDS. Taking into account pipe failure prediction models and models of WDS reliability, a Water Safety Plans supporting system can be created.

Forecasting pipe failure requires the collection and analysis of historical data. One of the most commonly used system to collect data is the GIS (Geographic Information System) database, which enables the integration of multiple data sources (including location data of dangerous locations, geodemographic features and vulnerable populations), the use of spatial analysis techniques (including buffering and overlap), potential spatial integration models and geographical presentation of complex data in a cartographic format [22]. However, the GIS database is used to collect data

Table 1. Pipe failure models.

Author	Year of study	Objective	Explanatory variables	Model type
Shamir Howard	1979 [17]	pipe breaks and other structural degradation	pipe length, pipe age, breakage history	Deterministic
Walski Pellicia	1982 [21]	pipe breaks and other structural degradation	pipe length, pipe age, breakage history	Deterministic
Kettler Goulter	1985 [16]	pipe breaks and other structural degradation	pipe length, pipe age, breakage history	Deterministic
Cox	1972 [18]	time between failures or time to the next failure	pipe length, operating pressure, pipe age, break rate, soil corrosivity	Probabilistic
Constantine Darroch	1993 [16]	pipe breaks and other structural degradation	operating pressure, pipe diameter, soil type, overhead traffic conditions	Probabilistic
Accelerated failure models	[18]	time between failures or time to the next failure	pipe age, pipe diameter, pipe length, pipe material, traffic loading, soil acidity, soil humidity, number of breaks	Probabilistic

and not to acquire data, for this purpose various devices and systems enabling reading information from these devices are using. SCADA (Supervisory Control and Data Acquisition) belongs to such systems. The WDS commonly used SCADA systems to transmit data flow and pressure in real time, which is why it also using as early warning systems (e.g. in the event of pressure/flow drop or increase). In combination with a telemetry system, SCADA can be used to find water leaks and detect the place of failure. These systems enable transferring and storing data, network models are used to predict (simulate) failures. Mathematical models of water distribution network allow the simulation of water flow and pressure in the system during "normal" and partially failed system as well it can generates failure rates and repair events according to specified probability distributions [23]. Using the collected historical data and supporting systems (e.g. hydraulic models), decision systems can be created, which can then be used in the Water Safety Plans. Water Safety Plans are based on risk assessment and risk management. Risk issues provide answers to three questions: What can happen? How likely is it to happen? and Given that it occurs, what are the consequences? [24]. To answer these questions, a risk analysis should be carried out using the matrix method. In order to answer these questions, a risk analysis should be carried out using a matrix method in which probabilities and consequences weights are assumed, and the product of these weights will determine the risk [25].

2 RESEARCH OBJECT

The subject of the study is the selected subsystem of the biggest collective Water Distribution System (WDS) in Poland, which is located in the southern-west of Poland in Silesian region. Analyzed WDS is composed of four local Water Treatment Plants (WTP A, B, C and D) with a total average daily production of 72 577 m^3, and four storage tanks (E, F, G and H) with the total capacity of 155 200 m^3 (Figure 2). The area under consideration is additionally fed by a pumping station (located outside the research area), which supplies water in the amount of 60 000 m^3 per day. The average daily water consumption of this area is 102 000 m^3. The study area is characterized by high altitude variability from 240 m to 364 m above sea level. The central point of the subsystem is the storage tank E (345 m above sea level), which are supplied from two directions (WTP A and Pump Station I) and delivers water to the largest number of customers in north area. Tanks G (315 m above sea level) and H (364 m above sea level) collect water and if necessary provide a water supply. WTP C and B

Figure 3. Material structure of water pipe network.

Figure 4. Age structure of water pipe network.

supply the smallest part of north-west area, while WTP D works occasionally in a case of higher water demands.

Analyzed subsystem of WDS is a widespread system covering about 100 km^2 of the area with a total water pipe length of 256 km. Water pipe network is made mainly of steel, as well as polyethylene (PE) and ductile iron (Figure 3) with pipe diameters from 55 mm to 1600 mm. The oldest pipes that build this subsystem come from 1929 (Steel) and the latest from 2016 (PE) (Figure 4).

The analyzed network is located in the area of intensive exploitation mining areas where there are mining damages and shocks. The reason for this is the collapse of the terrain and cracks in the urban infrastructure. Figure 2 shows the location of existing and inactive mine shafts in the considered area.

3 RESEARCH METHODOLOGY

The hydraulic model of the subsystem was used for the analysis. The network topology was exported

from the GIS database to the WaterGEMS software. The model was calibrated to average values of water demand from 2016 (102 000 m^3). While the validation was carried out for the operation conditions during three days (17–19.10.2016). For this model we obtained a high correlation of computed values and observed values, for pressure 99.4% and for flow 99.0%. Failure data form mentioned area has been entered into the software from the 5-year period (2012–2016). Table 2 shows the total number of pipe cracks for a given year.

Based on length, number of breaks and break history (duration of break history) WaterGEMS calculate predict rate of failure. The results that are calculated by the Pipe Break Analysis include:

– failure rate λ_{IB} (breaks/yr/km)- number of breaks for individual pipe, according to the pattern:

$$\lambda_{IB} = \frac{N}{L \cdot t'}, \text{break/yr/km} \quad (1)$$

where N = number of breaks; L = length of pipe (kilometer); t = period of analysis (year).

– pipe group failure rate λ_{GB} (breaks/yr/km) – number of breaks for a given pipe group, according to the pattern:

$$\lambda_{GB} = \frac{N}{L \cdot t'}, \text{break/yr/km} \quad (2)$$

where N = number of breaks for the group; L = total length of pipe in the group (kilometer); t = period of analysis (year).

Based on the total length of the network, the number of failure and the length of the failure time, one group break rate was created for calculations for all pipes.

– projected failure rate λ_{PB} the product of the scaled break rate, the projection period and the length of pipe. Estimate of the number of breaks over the projection period assuming that past break rates persist, according to the pattern:

$$\lambda_{PB} = a \cdot \lambda_{IB} + (1-a) \cdot \lambda_{GB} \quad (3)$$

where a = index of the share of damage intensity.

Due to the creation of only one pipe break group, the index value *a* was chosen at 0.8.

The studied network is a main network supplying water to cities and industry, so every water customer will belong to a critical group (hospitals, food production, etc.). Any interruption in water supply can have a major impact on the functioning of customer group. The task of this work is to determine the impact of pipe breakage on the efficiency of water supply. For this purpose, the water flows calculated in the hydraulic model and the predicted number of pipe failure were used. The results of the analyzes were presented in the form of a risk matrix.

Table 2. Number of pipe failure for a given year.

Year	2012	2013	2014	2015	2016
Number of pipe failure	313	226	232	303	210

4 RESULT AND DISCUSSION

Figure 5 shows the average water flow in the water supply system, the lowest flow values (below 50 m^3/h) are marked in dark blue color, while the highest values by red color (above 600 m^3/h).

The number of failure for individual pipe was determined, zero values were obtained for 2533 sections (sections without a failure during the considered period), the minimum value of failure rate was 0.098 (break/yr/km) and maximum 452. Failure rate for pipe group was obtain for all section in analyzed network and was 1.06 (break/yr/km). Based on these rates, projected failure was calculated. The result of simulation a base map representation of the failure risk of pipes in the network. Figure 6 is a map of these pipes and their corresponding risk levels. The largest number of expected pipes failures was achieved for the section located east of the Tanks E and the section located north of the Tanks G. They constitute 2.5% of the analyzed network. The biggest part (90%) is the probability of occurrence of up to 4 failures per year, while the smallest part is the probability of the number of failures between 12 and 16 (1%).

The values of the predicted pipe fractures were calculated for each segment. The smallest value of failure rate is 0.001, while the highest is 20.0. Based on the obtained simulation results, a risk matrix

Weight of projected failure rate W_2	Weight of consequences of flow rate W_1				
	1	2	3	4	5
1	1	2	3	4	5
2	2	4	6	8	10
3	3	6	9	12	15
4	4	8	12	16	20
5	5	10	15	20	25

Figure 7. Risk matrix of pipe failure.

Table 3. Flow rate division into weight classes.

	Categorization due to the flow rate				
Water flow [m^3/h]	0–50	50–200	200–400	400–600	>600
Weight scale	1	2	3	4	5

Table 4. Projected breaks division into weight classes.

	Categorization due to the intensity of failure rate				
Projected failure rate	0–4	4–8	8–12	12–16	>16
Weight scale	1	2	3	4	5

was created (Figure 7). Based on the analysis, a five-stage categorization of the effects of damage based on the volume of water supplies was made. The ranges of water flow values and failure rate were assigned to individual weight classes from 1 to 5 (Tables 3 and 4).

For risk analysis, a risk matrix was developed, which takes into account the consequences of failure occurrence expressed by the flow rate and the intensity of failures. Defined risk is expressed by the formula (4):

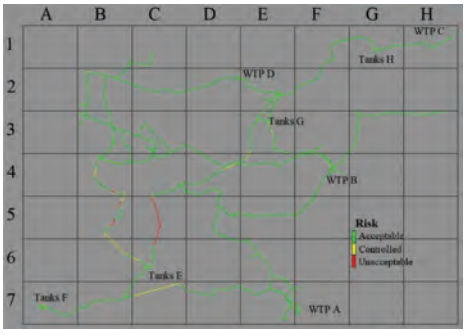

Figure 8. The distribution of risk on the network map.

$$R = W_1 \cdot W_2 \quad (4)$$

where W_1 = weight of flow rate; W_2 = weight of projected failure rate.

Risk value varies from 1 to 25. For this risk, a three-class classification was made: acceptable risk, control and unacceptable risk.

Three risk classes have been classified: Acceptable risk – weight 1–4 (green color), Controlled risk – weight 6–10 (yellow color) and Unacceptable risk – weight 12–25 (red color). Green color indicates a low impact of pipe failure on network operation, yellow – medium, and red – high. Figure 8 shows the distribution of risk classes in the network. The result of the risk assessment of damage to the pipe section allows for easy identification and classification of pipes, which need to be modernized. Based on the impact levels, areas with the highest risk of lack of water supply/reduction of water supply to the largest number of customers were designated. In areas located in cells 4B, 5B, 5C and 6C there is the highest impact of pipe failure on water supply, so the pipes in these areas must have the highest priority for modernization. Pipes in the mentioned cells distribute water to the largest number of customers and the failures of these pipes will cause water shortages in the largest area. Pipes located in cells 4B, 5B, 6B, 6C, 7C, 4D, 3E and 4E belong to the medium impact, therefore rehabilitation should be considered later. The remaining pipelines are the least affected and do not pose a threat.

5 CONCLUSION

The water distribution system is an extremely important infrastructure enabling the functioning of various social zones. Lack of water supply, reduced amount of water supply or contamination of water can lead to the risk of human life. An important element of network management is the determination and assessment of risk. These analyzes may concern various aspects related to the operation of the water

supply network, among others chlorine disappearance, secondary water contamination or pipe failures. Data sets and decision support systems are important for risk management. These systems certainly include the GIS and SCADA databases that acquire and provide data, but also a useful tool are hydraulic models that allow to perform various simulations. Based on the conducted simulations, so-called "sensitive" areas can be identified, for which different types of risks can then be determined. Knowing the risks, waterworks companies can save money and time to plan future investments.

Understanding and including the dynamics of extreme natural hazard event uncertainty within the overall offshore wind farm project risk assessment using a causality-based graphical modelling approach

R. Zamora, J. Qin, A.S. Kristensen, S. Mehmood & S. Ahmed
Danish Center for Risk and Safety Management, Aalborg University, Esbjerg, Denmark

Ørsted, Fredericia, Denmark

ABSTRACT: Offshore wind structures are subject to the combined action of wind and wave loads. A change of these loads may significantly affect the integrity of the structural elements. Increased instabilities in the Earth's climate system could increase the frequency of extreme events (e.g. rogue waves) well beyond the frequency values currently recommended within structural design standards. Inherent to extreme event modelling is the need to use expert (subjective) judgement and sparse data sets. In this context, a Bayesian Belief Network (BBN) can be applied to describe the effect of these changes on the frequency of rogue waves within wind farms located in shallow water depths of 20–60 metres. This graphical modelling approach provides the structure to effectively communicate, among others, parameter uncertainty, causality across multiple risk factors, quantitative definition of assessment subjectivity or potential impact of a change in rogue wave frequency relative to that described in current design standards.
