Preface

The 28th instalment of the European Safety and Reliability Conference contributes to a long-standing tradition of sharing and learning in safety and reliability in Europe and beyond. Academics and professionals from all over the world meet in Trondheim to share the state-of-the-art in safety and reliability and discuss collaborations and future work.

The annual European Safety and Reliability Conference (ESREL) is an international conference under the auspices of the European Safety and Reliability Association (ESRA). It is one of the largest, and most important safety and reliability events in Europe and has become a recognized conference all over the world.

ESREL aims to be an inclusive event where safety and reliability students can meet renowned professionals and partnerships are forged between participants from all parts of the globe. This inclusiveness has been a characteristic for ESREL over many years and it contributes to the continued success of ESREL and ESRA.

NTNU is a university with an international focus, with headquarters in Trondheim and additional campuses in Ålesund and Gjøvik. NTNU has a main profile in science and technology, a variety of programmes of professional study, and great academic breadth that also includes the humanities, social sciences, economics and medicine. The Department of Marine Technology (IMT) is a world leader in education, research, and innovation for engineering systems in the marine environment. Areas of research include safety and reliability of marine systems, dynamic modeling, marine engineering, transport and production for oceans and the Polar Regions.

The programme of ESREL 2018 offers a variety of arenas for discussion. In invited and plenary lectures world leading scientists explain what their contributions are and share their view for the future of safe societies in a changing world. Internationally recognized university teachers, researchers and practitioners support sharing and discussion in topic sessions and special sessions focus on topics that are of interest to special interest groups. Industry challenge sessions offer an arena to industry professionals to discuss direct industry interests in the field of safety and reliability. And finally, talented young researchers have an opportunity to share their work.

This volume contains more than 400 abstracts of the scientific and industry contributions from the ESREL conference; it is ordered according to the methodologies that form the backbone of the ESREL conference. The full papers are published as Open Access papers on the following website: @@@@@@

Acknowledgment

We would like to thank many people for their support and contributions to ESREL 2018.

We gratefully acknowledge the members of the ESREL 2018 Technical Programme Committee for their support of the scientific programme. We gratefully acknowledge the European Safety and Reliability Association Technical Committee Chairs and Co-Chairs, for volunteering their time and expertise to provide feedback as part of the contributed paper review process and for chairing the sessions at the conference. And last but not least we thank all authors and reviewers who have willingly given some of their time to ensure a high quality of papers for this conference. Every paper was reviewed by anonymous reviewers.

We would like to thank colleagues who organised special sessions of contributed papers and colleagues who organised workshops. We also thank the ESREL 2018 Plenary Speakers for offering their unique perspectives on safety and reliability at this conference.

The support of the ESREL 2018 sponsors and exhibitors is gratefully acknowledged.

Finally, we would like to thank the respective organisations for supporting the conference: It has been made possible by the close collaboration of ROSS Gemini Center, NTNU and the European Safety and Reliability Association.

Comparing HFACS and AcciMaps in a health informatics case study—the analysis of a medication dosing error

O.O. Igene & C.W. Johnson
Department of Computing Science, University of Glasgow, Scotland

ABSTRACT: The utilization of Information Technology/software systems is considered a proactive measure for reducing medication errors, providing clinical efficiency and improving patient safety. However this has added a layer of risk that can potentially harm patients and compromise safety. A comparative study using specific accident models; the Human Factors and Classification Systems (HFACS) and Accident Mapping (AcciMaps) was utilized on a health IT related case study analysis of medication error relating to the Computer Provider Entry System (CPOE). The results (outcomes) of the analyses were compared using the usage characteristics criteria developed by Underwood and Waterson (2014). The usage criteria framework focuses on ease of learning (usability), data requirements, validity and reliability of analysis. The second objective of our study discusses the limitations of both models and proposes a way forward on enhancing the usability, validity of results and more importantly the reliability of the AcciMap approach for accident analysis in healthcare.

1 INTRODUCTION

The development and utilization of Information Technology (IT)/software systems within clinical settings in hospitals has helped to reduce medical errors and improve efficiency in health care delivery. However, its implementation and utilization has also introduced an additional layer of risks and unforeseen errors that can compromise patient safety (Koppel et al. 2005, IOM 2012, Magrabi et al. 2016). This is especially apparent within complex safety critical sociotechnical systems like healthcare (IOM 2012, Schneider et al. 2014). A sociotechnical system while regarded as an imprecise term (Klein 2014) consists of complex interactions between different entities (people, technology, process, organization and external environment) (Sittig & Singh 2010). Accident/errors can occur as a result of interactions involving people (clinicians/physicians) using software/IT systems. They typically stem from latent conditions (systemic factors) that stretch well beyond the "frontline" of healthcare service provision.

The development of accident causation methods has provided a means of investigating and analyzing failures. They focus on the subsequent development of counter measures to improve patient and system safety (Johnson 2004). These accident analysis techniques include but are not limited to linear/event, taxonomy and systemic based methods based on recognized accident causation theories like Swiss Cheese Model (SCM) (Reason 1995, Qureshi 2008). Systemic methods are considered to be more suitable for analyzing interactions in sociotechnical systems than linear and event based approaches (Qureshi 2008, Leveson 2011). One of such methods includes the AcciMap method (Svedung and Rasmussen 2000). Systemic analysis techniques are typically applied retrospectively in analyzing incidents/case studies and different outcomes are produced based on their component methods.

This paper presents a comparative study using a systematic taxonomy framework (HFACS) and AcciMaps on a published clinical case study report (Horsky et al 2005). The main purpose of the study is to identify the putative causes of errors resulting from interactions between the users and IT system. We are also motivated to identify contributing factors associated particularly at the systemic level to understand not only what happened but crucially why. Different components within the sociotechnical system cannot be analyzed in isolation from one another especially if system safety is to be achieved. The application of HFACS in healthcare incident analysis has been established but AcciMaps has not been utilized as an accident analysis tool for clinical investigation and analysis.

This paper is divided into sections highlighting the objectives of the comparative analysis,

the methodology applied as well as the description of an example clinical case study utilized. Each of the methods selected is also briefly described, applied to the case study and their respective results (outcomes) will be compared and discussed based on the usage characteristics (Horsky et al. 2005). Limitations of each method are highlighted leading to the discussion of the proposed method to address some of these limitations.

2 OBJECTIVES OF RESEARCH

The two methods were selected based on their differences in their methodological approach and systematic way of analyzing accidents. The objectives of the study are as follows:

I. Analysis of the medication dosing error case study involving the Computer Provider Order Entry system using the HFACS and AcciMap models.
II. A comparison of the resulting outputs of each accident method based on the usage characteristics criteria (Underwood and Waterson, 2014).
III. Identifying common causes and contributing factors from analyses relating to the adverse outcome.

3 RESEARCH METHODOLOGY

This study adopts a qualitative (case study) approach for identifying, understanding and analyzing a complex sociotechnical technical setting involving healthcare informatics. We aim to expose the contributing factors that are associated with an adverse event. A medical case incident was used in a comparative study of accident causation methods; the Human Factors and Classification Systems (HFACS) (Shappell & Wiegmann 2000) and the Accident Mapping (AcciMaps) method, a component of the broader Risk Management Framework (RMF) (Rasmussen and Svedung 2000).

This case incident details a sociotechnical scenario about risks relating to the house providers and the Computerized Provider Order Entry System (CPOE) (Horsky et al. 2009, IOM 2012). The selected accident methods were used to analyze the case incident and the outputs were further iterated, reviewed and validated with a HFACS and an AcciMap expert. The resulting outputs were then compared using the usage criteria framework consisting of its graphical representation, usability, validity and reliability (Underwood & Waterson 2014). Strengths and limitations of the methods applied are elaborated in section 8.

4 DESCRIPTION AND ANALYSIS OF CASE STUDY

The case study involves two providers (A and B) who were involved in the administration of Potassium Chloride (KCI) to a patient who was initially hypokalemic. The timeline of the events leading to the patient becoming hyperkalemic (receiving a high dosage of KCl) occurring over a period of three days are detailed in the work of Horsky et al. (2005). The patient was first examined by the first physician (Provider A) and administered an intravenous (IV) bolus injection thereby repleting the potassium. Provider A then realized that the patient already had an IV and so decided to administer the KCI as part of the treatment. The patient started receiving a higher KCI dosage than what was originally intended due to several events that took place. The initial dosage order was detected to be higher than what was allowed by the hospital's policy and was discontinued. A new dosage order had to be written. However this new dosage order was not entered correctly into the CPOE system and the maximum volume was not indicated for the fluid that was to be administered to the patient (Horsky et al. 2005).

A changeover between the first physician and the incoming physician (Provider B) took place the next day where the latter was notified about the patient's KCI levels from the system. However, the second provider did not know that the laboratory results were not current and it was before the last potassium repletion occurred (Horsky et al. 2005). This led to provider B to consider the KCI levels of the patient to be low and decided to order an additional IV injection despite the KCI still running. This eventually led to the patient to become severely hyperkalemic and the problem was immediately rectified and the patient was discharged (Horsky et al. 2005). Their study provided a comprehensive analysis of the contributing factors as a result of both human errors and system design issues that led to the patient experiencing an adverse event.

5 DESCRIPTION OF THE ACCIDENT ANALYTICAL METHODS

The methods selected for the case study are based on recognized accident causation theories and are briefly described below:

5.1 *Human Factors and Classification System (HFACS)*

The HFACS method is a systematic approach that is based on the Swiss Cheese Method (SCM) (Reason 1995). This approach compares different levels of 'causal categories' relating from active to

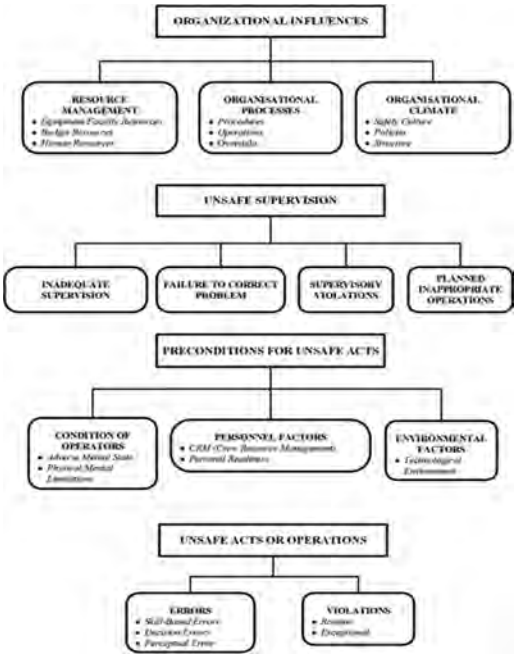

Figure 1. HFACS taxonomy (Shappell and Wiegmann, 2002).

latent conditions as shown in Figure 1 (Shappell & Wiegmann 2000). The categories include Unsafe Acts, Preconditions for Unsafe Acts, Unsafe Supervision, and Organizational Influences (Shappell & Wiegmann 2000). Each of them consists of specific subcategories that place emphasis on "who" and "what" rather than on "why" accidents or a significant adverse event occurred (Diller et al. 2013). This method can be utilized to analyze a comprehensive case study or a set of incidents to determine trends so as to develop countermeasures.

5.2 *Accident Mapping (AcciMaps) method*

The AcciMap method was developed as a component of the Risk Management Framework (RMF) and can be utilized as a standalone technique aside and as part of the broader RMF methodology consisting of the use of ActorMaps and Conflict Maps (Rasmussen & Svedung 2000). The AcciMap method allows analysts to graphically map causal relationships leading to an adverse event across each of the levels in a sociotechnical system (Branford 2011). The AcciMap levels as shown in Figure 2 depict interactions in a sociotechnical system and consist of Environment/Surroundings, Physical Processes/Actor activities, Organizational (Technical/Operational Management, Company

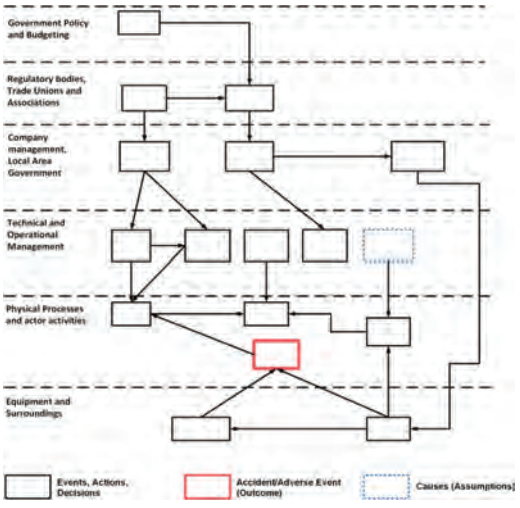

Figure 2. The AcciMap method adapted from Rasmussen and Svedung (2000).

management), and External (Regulatory bodies/ Trade unions, and Government Policy and Budgeting) (Rasmussen & Svedung 2000).

6 RESULTS

The resulting outputs from both methods are discussed below:

6.1 *HFACS output*

The results of applying HFACS were given to an experienced human factors specialist for verification and validation. The factors were identified and classified according to each level's defined categories and sub-categories of the HFACS taxonomy as shown in Figure 3 and described as follows:

6.1.1 *Unsafe acts*

Operators (clinicians) not using the CPOE system correctly was categorized under '*skill based errors*'. Lack of communication between the clinical providers (A and B) that led to the second provider administering additional KCI dosage to the patient is considered a '*decision error*'. While there wasn't any explicit evidence relating to '*perceptual errors*', violations regarding clinical handover procedures between Providers A and B was noted to have increased the risk of the patient becoming hyperkalemic.

6.1.2 *Preconditions for unsafe acts*

Several factors at this level include those relating to the design and usability of CPOE system

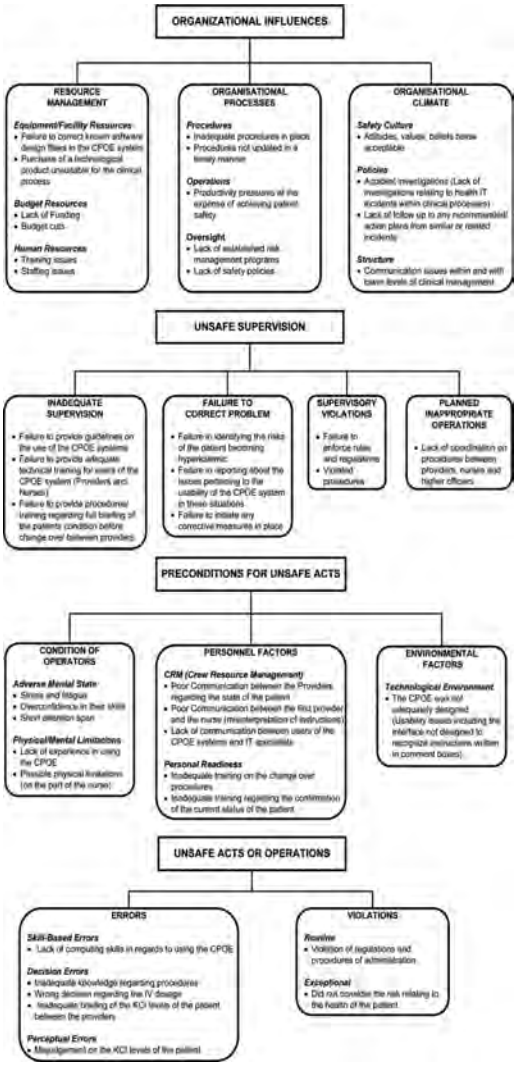

Figure 3. Application of the HFACS method on the medication dosing error incident.

(*Environmental factors*) and lack of user experience with the current version of the CPOE system (*Physical and Mental limitations*). Also at the '*Personal Readiness*' subcategory level, factors identified are attributed to issues regarding lack of communication between the providers as well clinical handover procedures not adequately carried out. This could be due to lack of effectiveness in training regarding the procedure.

6.1.3 *Unsafe supervision*

At both the '*supervisory violations*' and '*failure to correct problem*' subcategories, contributing factors arise from issues relating to inadequate training on the use of the current CPOE system. Furthermore, the system may not have been rigorously tested at the initial stage for its usability in a simulated environment (no explicit evidence in the case). In addition, there is a possibility of inadequate communication and coordination between the actors (providers A and B) and those at the management level including those responsible for IT systems which is classified under the '*Planned Inappropriate Operations*' subcategory.

6.1.4 *Organizational influence*

It was noted that within these subcategories, '*resource management*', '*organizational processes*' and '*organizational climate*', the case study did not indicate explicit evidence as to the contributing factors that enabled the accident. In examining the other subcategories within this category, it can be indicated that the organization may have underestimated the risks and severity relating to IT systems. In addition, there may not be any existing policies relating to testing the usability of the CPOE system within a simulated environment before its deployment. Other issues can include budget restrictions and low safety culture will be considered potential systemic factors.

6.2 *AcciMap output*

The original AcciMap method (Rasmussen and Svedung, 2000) and the standardized AcciMap format (Branford 2011) was applied on the case incident (See Figures 4 and 5). The latter was utilized by an experienced clinician (e-health pharmacy) and this method provided a simpler way of analyzing the case study particularly at the organizational level. The AcciMap outputs were externally validated by a human factors expert.

However for the purposes of study, the result of the AcciMap model is described using the original AcciMap format as follows:

6.2.1 *Equipment and surrounding*

In this case study, the equipment used here will be the CPOE system that allows providers to place orders regarding the administration of KCl to the patient. However human errors occurred as a result of issues relating to the design and usability of the system (relating to the interface of the system where instructions were difficult to read) leading to the eventual adverse outcome.

6.2.2 *Physical processes and actor activities*

This level refers to the actors involved in the adverse event (house providers, attending nurse and the patient). Here, provider A administered a high dosage of KCl which was entered incorrectly into the

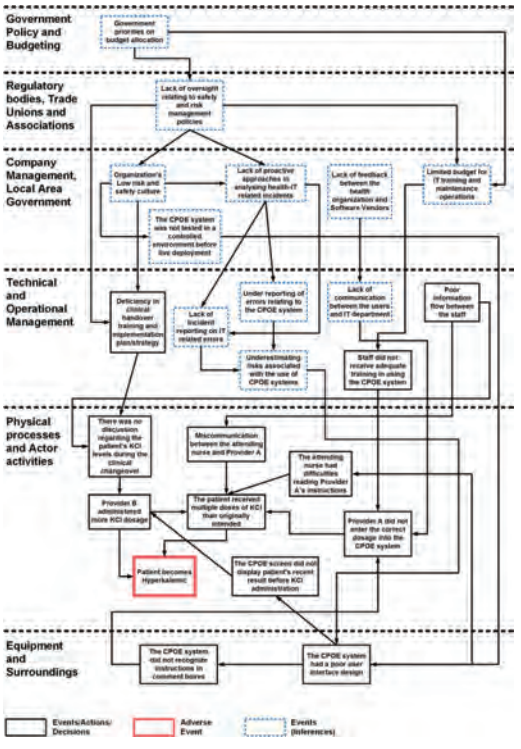

Figure 4. AcciMap analysis of the medication dosing error case study using the original format.

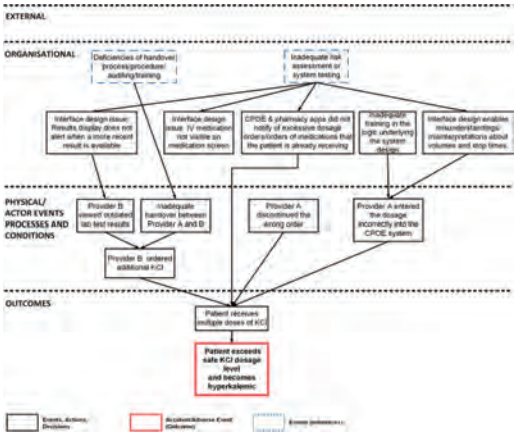

Figure 5. AcciMap analysis of the medication dosing error case study using Branford's standardized AcciMap format.

system. The second provider further implemented an additional dosage of KCl after failing to ascertain the current KCl levels of the patient by reading the outdated results from the CPOE system during the changeover process. Further problems occurred as a result of miscommunication between providers A and B on the patient's KCI levels during the clinical handover process and as a result, the patient became hyperkalemic.

6.2.3 *Technical and operational management*

At this level, issues relating to CPOE include specifically its interface design flaws which increased the probability of an error to occur. This could also be attributed to lack of rigorous software simulation testing of the system before it was deployed for clinical use. The IT vendor responsible for the development of the software may cite lack of training on the use of the software rather than the problem of the system design. Although this point can be inferred as a contributing factor, there was no explicit evidence from the reports that this was the case. Another inference that can be made is that similar incidents may not have been reported as an "IT-related" event and risks that can arise from system design of the CPOE was either underestimated or may not have been taken into consideration by the health organization.

6.2.4 *Company management and local government*

The case report did not contain explicit evidence regarding specific failures at this level. However, from the analysis of the preceding levels and some inferences, errors can occur due to lack of oversight, underestimation of the severity of risks associated with IT systems. Additionally, there may be issues relating to inadequate training and enforcement of existing polices relating to clinical handover process between providers can also contribute to the adverse event.

6.2.5 *Regulatory bodies, trade unions and associations*

At this level, contributing factors could include failure of implementing existing policies passed by the government and other relevant medical bodies carried out to ensure patient safety. Another inference could be that incidents relating to IT systems are not being adequately reported and lack of proactive measures may not be in place to handle such kind of incidents. However, it should be noted again that there was no explicit evidence in the case study to support these inferences.

6.2.6 *Government policy*

Issues like budget limitations, priorities on budget allocations and policies regarding the reporting of incidents relating to software/IT systems implemented in health organizations would be considered as systemic factors. However, a much more detailed report will need to include these systemic

factors that could contribute to the accident or any similar incidents. Based on the AcciMap outcome, there was no explicit cause indicated due to lack of evidence relating to systemic factors at this external level (government). This can be attributed to the fact that incident reports do not typically contain information especially on contributing factors in enabling the government to realize their role in creating latent conditions that can further enable similar incidents to occur again.

7 USAGE CHARACTERISTICS CRITERIA

The HFACS and AcciMap methods utilized for the case study is briefly described and the resulting outputs are discussed below:

7.1 *Data requirements*

The use of both methods requires data which can be collected in various formats including case incidents or a detailed case report of significance. Other data sources include documentations, interviews with actors (frontline workers, management) involved in the incidents and observing the events in a sociotechnical scenario. Both methods require a great deal of details from the actors directly involved in the incident and at the higher (organizational) levels to be to identify valid causes and contributing factors to accidents.

7.2 *Graphical representation of the accident*

HFACS and AcciMaps differ in this category. The HFACS only used a set of defined categories that classify causes to the accident and so lacks a way of graphically representing contributing factors and their relationships. However, the AcciMap method provides this advantage by enabling analysts to use different graphical symbols to represent different meanings; adverse event (accident), causes (evidence), causes (inferred) in relation to the adverse outcome (Branford 2011, Salmon et al. 2012). AcciMaps also allow the causes identified to be represented using causal relationships (represented by arrows) within and between each level of the sociotechnical system.

7.3 *Usability of method*

The use of both HFACS and AcciMaps is relative to the level of skill and experience of the analysts. While both methods require understanding of the accident causation theories they are built on, the HFACS method provides a framework of failure categories built for classifying failures according to the Swiss Cheese Model from either singular or multiple incidents. The AcciMap method provides users the basic understanding of the causes that interconnect in a vertical manner to enable understanding of why the accident took place. However, the use of these methods can be relatively time-consuming depending on the complexity and comprehensiveness of the case study, and due to its subjective nature of analysis from multiple users.

7.4 *Validity of method*

Each of the outputs from HFACS and AcciMaps were reviewed by an experienced and expert user of both methods for both content and face validity (hence external validation being required). As both methods have differing methodological approach (each based on a recognized accident causation theory), its results will only reflect the methods perspective as to the analysis of the accident and possible safety recommendations needed to be in place.

7.5 *Reliability of analysis*

In previous studies, the HFACS method was noted to provide a considerable measure of reliability due to the defined failure categories (Salmon et al. 2012, Ergai 2013). However as was demonstrated in the case study, the AcciMap method is limited in terms of considering failure categories that can exist at different levels including the external level as it relates to this case study. This is the reason why reliability of the AcciMap method is considered to be low, due to the subjective nature of its analysis (Salmon et al. 2012, Underwood & Waterson 2014) especially because multiple analysts can produce different causal outcomes from the same case incident. There is also the issue of bias including hindsight bias as to what contributed to the adverse outcome.

8 DISCUSSION

The implementation of both HFACS and AcciMaps shows both strengths and limitations they offer regarding accident analysis. Drawbacks of the AcciMap method include its subjectivity of analysis and the lack of failure categories in each of the levels (Salmon et al. 2012). The issue of subjectivity is due in part to lack of existing standard guidelines in addition to the need for external validation of results generated. This can ultimately affect the type of safety recommendations that are needed, and how effective they are in preventing an occurrence of the accident. Although Branford made an attempt to solve that issue through the development of the standardized AcciMap format,

it still lacks a formal way of classifying failures into specific categories. This limitation makes the AcciMap method not suitable for analyzing multiple incidents (Salmon et al. 2012, Goode et al. 2017). There is also the issue of bias including hindsight and outcome biases, which can also affect the results of the accident analysis, especially in determining why the adverse event occurred (Johnson 2004).

In comparing outputs from the analyses, similar causes from the analyses include communication issues between the actors (Providers A and B), software design issues with the CPOE system, issues relating to clinical handover process between the providers and inadequate/ineffective training relating the use of the current CPOE system. The difference however lies in identifying contributing factors at the higher levels especially as to how these factors at external levels (Regulatory bodies and the Government) can systemically contribute to the occurrence of the accident. For example, based on the AcciMap result, inferences was made as to why there was ineffective feedback between the health organization (i.e. IT department) and the software vendor responsible for the design of the CPOE system. Another inference could be made regarding inadequate policies relating to testing the software product (albeit in a simulated environment) before it was deployed live for clinical purposes. While both methods assist in identifying causes and contributing factors in a systematic way, the AcciMap method is not restrictive in terms of identifying and placing causes at each level while in the case of HFACS, the causes need to be classified according to the defined framework of failure categories (based on Reason's Swiss Cheese Model of accident causation). The HFACS taxonomy is also considered a generic-based method (initially developed for investigating accidents in the aviation system), but has also been adopted in the healthcare system (Diller et al. 2013). However, one of the limitations attributed to HFACS method is in the restrictive nature of the categories within the HFACS taxonomy. There is also the need to expand and adapt the taxonomy within specific healthcare scenarios including the addition of higher level related factors (External) (Salmon et al. 2012) as well as any other factors not included in the original format. The advantages of HFACS and/or any similar health-based error taxonomies and AcciMaps can potentially be combined together to improve the latter's reliability. This step was explored in investigating multiple led outdoor incidents through the development of an incident reporting and learning system based on the UPLOADS (Understanding and Preventing Led Outdoor Activities Data Systems) taxonomy (Salmon et al. 2015). Each AcciMap level had failure categories based on contributing factors identified from multiple incident reports as it related to the actors/decision makers in each of the level. Causal relationships, which are a very important feature of the AcciMap method, were also depicted between contributing factors (relating to the actors identified in the system) within and between each AcciMap level (Salmon et al. 2015, Goode et al. 2017).

This similar approach can potentially be applied in investigating significant incidents and near misses as a result of software issues within the healthcare context. This could not only potentially improve the validity of results but can also enhance its usability for accident analysis and adoption by safety practitioners in healthcare systems. This approach can also be utilized to investigate IT failures or near misses so that lessons learned can be used as a way of improving safety culture towards the implementation and utilization of health IT systems by its operators.

9 LIMITATION OF STUDY

This study has limitations in its identification of causes and in the validation of outcomes/recommendations from the analysis. It was particularly challenging identifying systemic factors at the higher levels (in the case of the AcciMap analysis) due to lack of evidence in the report; especially dealing with governance. Another issue is the knowledge and application of the methods. especially for first time users in identifying causes that are valid and that actually contributed to the occurrence of the adverse event. The last point is very important for the development of effective safety countermeasures and to which level this countermeasure is applied to. Future studies will require the use of a more structured approach by involving a multidisciplinary team ideally from all sociotechnical levels. This will involve safety practitioners, IT specialists, users of software systems, vendors and expert opinions in the analysis of health IT related accidents.

10 CONCLUSION

Both methods allow for a systematic identification and analysis of accidents in complex sociotechnical systems like healthcare. The purpose of the study was not to indicate that one method is better than the other, but to highlight the advantages and limitations of each method in the analysis of the case study. Isolating software related problems and taking steps to improve the functionality and reliability of the system does not necessarily improve

patient safety. Accidents where software systems played a role must be analyzed from a sociotechnical perspective. This is why human factors engineering plays a very important role as it involves analyzing complex interactions between clinicians and software systems utilized, and determining latent conditions based on decisions at the systemic level.

11 FUTURE WORK

Beyond the objectives of this present study, a current study is underway focusing on the development of a health-specific AcciMap taxonomy model. This model will then be used to analyze cases/incidents relating to software/IT related accidents in healthcare settings. The development of the model will comprise of examining existing health based error taxonomies similar to the HFACS and contributing factors framework. This will then be synthesized within the levels of the standardized AcciMap method. The purpose of this approach will be to determine if both the reliability and validity of the AcciMap method will be improved through the use of defined failure categories in a taxonomic structure.

ACKNOWLEDGEMENT

The HFACS result was reviewed by Dr. Suzanne Shale, trained in the use of the HFACS method by Scott Shappell, who offered comments and approach to analysis. Further acknowledgement goes to Dr. Kate Branford, a human factors and AcciMaps expert as well Mr. Iain Bishop, an e-Health Pharmacy Adviser, Information Technology of the National Services Scotland (NSS).

Possibilities of using simulation software to estimate losses of industrial facilities and installations—critical analysis

J. Ryczyński, P. Mastalerz, K. Ksiądzyna & T. Smal
Tadeusz Kosciuszko Military University of Land Forces, Wroclaw, Poland

ABSTRACT: In the paper, simulation of severe failure of fuel terminal is presented. Results of the simulation are compared to the real situation, that took place on 11th December 2005 in Hertfordshire Oil Storage near the M1 motorway in England. That comparison shows how beneficial an accurate simulation of the accident is. Next, the risk analysis is presented. The Preliminary Hazard Analysis (PHA) and the fault tree are methods that show possible cause of the accident. Using simulation, the course of action before and during failure could be traversed. That kind of research shows how important is to do the simulation before the accident occur and assess the possible consequences of the adverse situation. That simple method is significant to increase awareness of the fuel terminal workers and anyone who is related to the technical process safety.

1 INTRODUCTION

It is commonly known, that already high demand for fuel products is growing year by year. What is more, this kind of products has to be stored properly and transported in special conditions. Because of that, the authors decided to look into this topic. Analysis of previous petrochemical failures shows, that most of accidents with fuel products occur during loading and unloading of the materials. Those operations are crucial and cannot be omitted during the whole transportation process. Thereupon, both operations, loading and unloading, should be performed in a way that ensures no unwanted situation occurs. To fulfill the safety rules and eliminate the possible risk, series of complex theoretical analysis are made before the transportation of the fuel products is possible. Nowadays, computer simulations are used to estimate possible consequences of failure. Simple computer programs are able to show many indicators, like the dangerous zones range, which is helpful especially for personnel responsible for safety of the technological process.

According to data, the requirement for fuel products rises year by year, hence the need to store and transport it. Without the suitable stock of liquid fuel storage the whole transportation would not be able to function. Security in each of these processes is a crucial element. Unluckily, it is often not possible to forecast events that menace safety in general, including the safety of fuel terminals. Figure 1. introduce the dependence of oil manufacturing and consumption of crude oil products

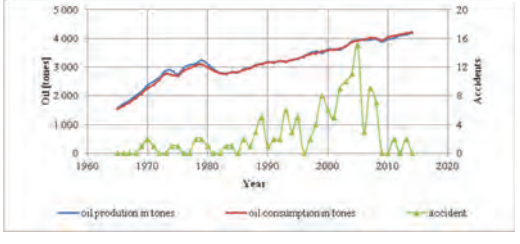

Figure 1. Oil production with consumption and amount of accidents between 1960 and 2016 (BP, Statistical Review of World Energy June 2016, edition 65-th).

on calamity rates between 1965 and 2016. Because of that, multi-stage risk analysis presents such a vital role in the petrochemical industry.

For risk analysis to reveal reality precisely, different databases including industry cases are utilized. In Poland there are two programs: the System Pomocy W Transporcie Materiałów Niebezpiecznych—transport of dangerous goods aid system (SPOT) and the Safe Chemistry, as an covenant between the Polish Chamber of Chemical Industry and the leading plants in the chemical industry in the Republic of Poland. One of the crucial elements of this collaboration is, among others, to form a common disaster database as a ground for sharing requests for unfavourable events.

The European equivalents are the Major Accident Reporting System (eMARS), Analyse, Recherche et Informations sur les Accidents (Aria) and Failure and Accidents Technical information

System (FACTS). This sort of database should be kept topical with new industry incidents, establishing a kind of precedent. The high consumption of fuel products and the evident safety magnitude have led the authors to become interested in the matter of fuel terminals.

In this paper, a simulated malfunction of the fuel terminal was shown via the usage of computer modeling. The simulation outcome was compiled with the positive situation that occurred on the Hertfordshire Oil Storage near the M1 at Hemel Hempstead in Hertfordshire in Europe (Mannan et al., 2009). This approach permit a similitude of both situations to project the accuracy of modeling. Based on the scores, we generated an assumptive simulation of the detonation of the whole storage base in order to settle the possible implications in the event of non-trip events in this type of facility.

2 SAFETY IN STORAGE LIQUID FUELS

Storage liquid fuels safety depends primarily on the proper storage infrastructure, legitimate handling of loading and unloading actions and compliance with minimum tank distance provisions (Ryng, 1989). Additionally, it is significant to notice that, in spite of expanded automation, qualified and experienced personnel are the major determinants of workplace safety.

High haze volatility, continuous fire and explosion hazards necessitate the precaution against exorbitant loss of stored substance. These losses are mainly caused by the so-called 'breathing tanks'. Attempts to limit the losses include (Ryng, 1989):

- the usage of "tanks operating under pressure within the limits held by valves";
- maintaining the maximum filling condition of the tank;
- protective coatings that reflect sunlight;
- the usage of isolating tanks;
- placing underground tanks.

Flammable liquid tanks are fitted with safety attachments, which can comprise of:

- respiratory valves protected with valves with a fire stop;
- fire fuses;
- throats for feeding foam from the fire extinguishing system;
- Pouring and Emptying Devices (PED) installations;
- control and measuring apparatuses;
- double bottoms;
- fire alarm systems (mechanical and automatic);
- sprinkler systems;
- Faraday's grids;
- tank control systems—Distributed Control System (DCS);
- emergency pools.

3 THE FUEL TERMINAL FAILURE IN BUNCEFIELD—COMPARATIVE SIMULATIONS

In Hertfordshire, at the daybreak of the 11th of December of 2005, a fuel terminal failure arose. The consequence of this event was the loss of about 1/3 of the entire stockpile of about 10 million liters of liquid fuels. The effects of the explosion of the gathered medium were considerable damage of up to 10 km from the site (several houses were grievously damaged, while hundreds had incurred smaller, non-injurious damages). Accordingly, there were no fatalities, but over 3,000 direct casualties are estimated (no fatalities, with more than 2,000 homes and 92 businesses evacuated in the neighborhood). As an outcome of the fire, massive amounts of smoke were emitted, spreading over southern England. The fire has been burning for 3 days and to quench it, gargantuan amounts of water and foam were spent. 180 firefighters took part in the rescue operations by at the peak of the event. The course of events (Buncefield major incident investigation. Initial Report, Hemel Hempstead, on 11 Dec. 2005, p. 7):

1. At around 3:00, the fuel gauge for tank 912 (Figure 2) indicated a steady level of filling, even though the tank was filled with 550 m^3/h; Around 5:20, the tank began to overflow as a result of overfilling.
2. At 5:38, approximately 300 t of gasoline flowed through the roof of the tank to the emergency pool, resulting in an explosive mixture (approx. 5:38 of the emergency pool).
3. About 5:50 mass flow of fuel to the tank was 890 m^3/h.
4. At 6:01 am the first explosion occurred, resulting in the fire of 20 storage tanks.

Simulations have been performed, based on the post-accident studies data, to determine three phases of toxic cloud formation. In (Krawczyszyn et al., 2017), authors used Buncefield case to show accompanying phenomenon and consequences of the accident, such as formation of release zones, the floodplain area prior to the explosion and explosion itself. In this paper, Buncefield catastrophe is used to introduce consequences for humans. It should be emphasized, that each result shown in this work is assumed, because there were no fatalities and injured in Buncefield accident. What is more, the topology of the area was not considered in current work. Possible injuries in case of fire in

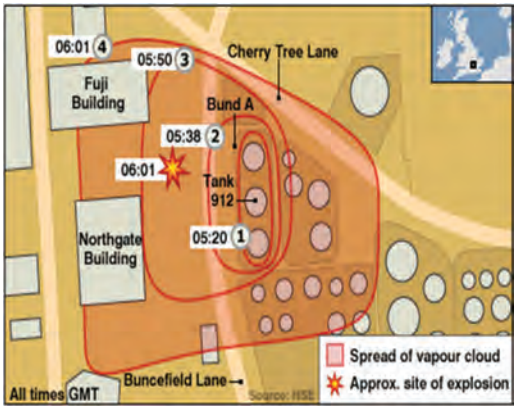

Figure 2. The spread of the toxic cloud according to accident reports (Mannan et al., 2009).

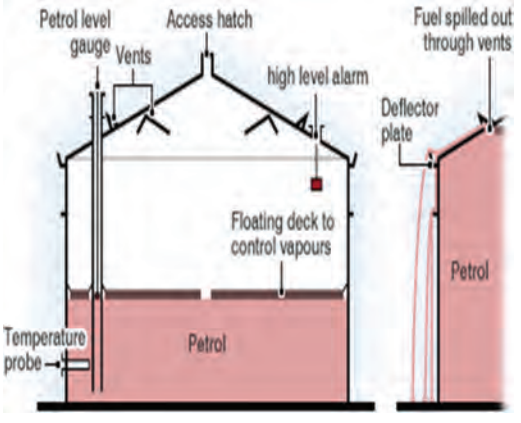

Figure 3. The spread of the toxic cloud according to accident reports (Mannan et al., 2009).

different stages of fuel spread are presented. Next part of the paper illustrates scathes that could be received during Buncefield catastrophe.

4 FIRST SIMULATION

Figures 4, 5 and 6 show dependence of burns degree in percent in function of exposure duration for 2 kW/m^2, 5 kW/m^2 and 10 kW/m^2 radiation heat. The mathematical model is based on value of probit function and percentage measure relation (Committee for the Prevention…, 1989):

$$Probit = -38.48 + 2.56 * \ln\left(t * q^{4/3}\right) \quad (1)$$

where: t–time of exposure (s), q–heat-flux absorbed (Wm^2).

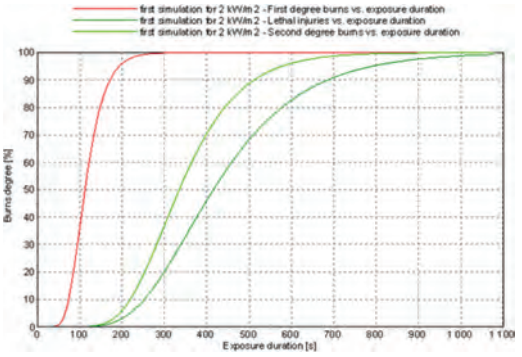

Figure 4. Burns degree in percent to exposure duration for 2 kW/m^2.

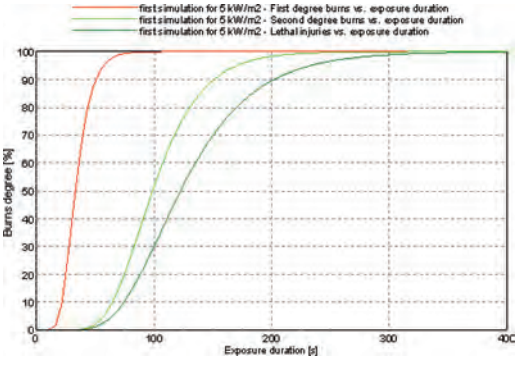

Figure 5. Burns degree in percent to exposure duration for 5 kW/m^2.

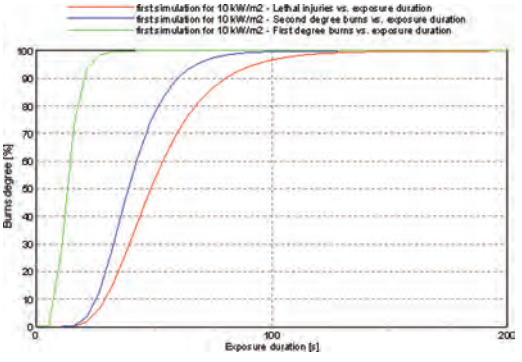

Figure 6. Burns degree in percent to exposure duration for 10 kW/m^2.

In all cases increase in exposure time generates higher burns degree. According to the figures, people exposed to the 10 kW/m^2 are more likely to get severe damages in shorter time (lethal injuries after 16 s) than people exposed to lower radiation heat (for 2 kW/m^2 lethal injuries after 130 s).

The graphs 4–6 depict that increase in first degree burn grown quicker than other injuries. The saltatory change of body damage appears in a different values for each simulation, the first degree burn curve saturate soonest and the lethal injuries curve has gradual transition and gain the plateau much later.

For 2 kW/m^2 the first degree burns plateau is gained after 328 s, the second degree burns after 900 s and the lethal injuries after 1080 s.

For 5 kW/m^2 the first degree burns plateau is gained after 98 s, the second degree burns after 280 s and the lethal injuries after 370 s.

For 10 kW/m^2 the first degree burns plateau is gained after 50 s, the second degree burns after 100 s and the lethal injuries after 125 s.

5 SECOND SIMULATIONS

The second simulation shows explosion of the entire fuel terminal and consequences for people. The average weight for man is 80 kg, and for woman – 55 kg. The calculations are based on Netherlands organization for applied scientific research (TNO) methodology (Committee for the Prevention…, 1989). The probit function for lung damage:

$$Probit = 5.0 - 5.74 * \ln S \tag{2}$$

$$S = \frac{4.2}{\bar{p}} + \frac{1.3}{\bar{i}} \tag{3}$$

$$\bar{P} = \frac{P}{P_0} \tag{4}$$

$$\bar{i} = \frac{i}{P_0^{1/2} * m^{1/3}} \tag{5}$$

where: P_0–atmospheric pressure, P–pressure exerted on the body, m–mass of the body.

The probit function for hearing damage:

$$Probit = -12.6 + 1.524 * \ln P_s \tag{6}$$

where: P_s–peak overpressure in the incident.

The probit function for the impact with the whole body:

$$Probit = 5 - 2.44 * \ln S \tag{7}$$

$$S = \frac{7.38 * 10^3}{P_s} + \frac{1.3 * 10^9}{P_s * i_s} \tag{8}$$

where: i_s–impulse of the incident pressure.

Figure 7 represents dependence of percentage of body damage and pressure in bars for average man, whereas Figure 8 depicts dependence of percentage of body damage for average woman. What is more, Table 1. Introduces comparison of body damage for average man and woman. Based

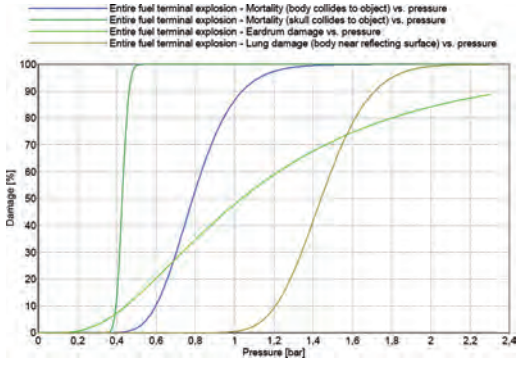

Figure 7. Percentage of body damage and pressure for average man.

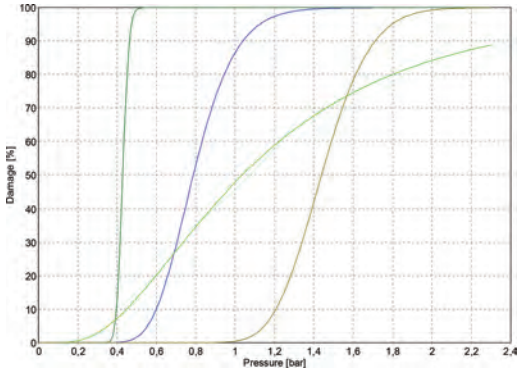

Figure 8. Percentage of body damage and pressure for average woman.

Table 1. Comparison of body damage caused by pressure for average man and woman.

Body damage	Man	Woman
Lung damage when body is perpendicular to blast direction (%)	18,88	19,2
Lung damage when body near reflecting surface (%)	99,97	100
Whole body displacement (when body collides to object) (%)	100	100
Whole body displacement (when skull collides to object) (%)	100	100
Eardrum damage (%)	88,78	88,78

on information in Table 1. We could assume, that potential explosion would have a similar effect on damage to the bodies of a woman and a man, there would be a slight discrepancy in the lung damage.

6 CONCLUSIONS

The purpose of the paper was to introduce the potential results of a fuel terminal failure. Choosing the Buncefield fire incident allowed to establish the correct mathematical model for a simulation of this type. The overriding goal was to identify potential consequences for people who were exposed to radiation heat generated in the event of an explosion of the entire storage base. Detailed analysis of the data and implementation of the risk analysis allowed the authors to view the issue of storage of dangerous substances in a tangible way.

It should be mentioned, that based on available data, authors were not able to define all parameters needed for the simulation, nor to fully anticipate the failure mechanism. Even though, it is valid to make such analysis and computer simulations to help us better understand the nature of the production process.

Analyzed simulations show, that humans near the centre of explosion would be suffer serious injuries or even death. What is more, there is only slight difference between percentage of body damage sustained by average man and woman exposed to pressure in the centre of the explosion. Probable cause is hidden in program limitation, because weight was the only factor that could be set to distinguish between man and woman. Such parameters as height or physique are not included and could potentially influence the results of simulation.

Analysis on factors of subway incidents for signal system maintenance improving based on a hybrid model

S. Zhang, T. Tang & R. Niu
State Key Laboratory of Rail Traffic Control and Safety, Beijing Jiaotong University, Beijing, China

F. Yan
National Engineering Research Center of Rail Transportation Operation and Control System, Beijing Jiaotong University, Beijing, China

L. Yue & L. Wan
Communication and Signaling Branch affiliated with Beijing Mass Transit Railway Operation Corp. Ltd., Beijing, China

ABSTRACT: Signal system is widely used to improve the safety and efficiency of subway system, while signal failure of it may lead to a huge breakdown of subway capacity. Most signaling operation and maintenance team still use the outdated checklists while signal operation and maintenance is proved to be a more and more difficult task because the internal and external interactions. This paper proposes hybrid accident/incident causal model of bowtie and cybernetic control loop to guide the design of incident data model. After that, the database is demonstrated on Beijing subway line No. 5. Based on the analysis, statistical characteristics of incidents are concluded. The trend of these factors could help companies improve the performance of subway system and the process of this analysis give them a new manner to record and learn from incident data.

1 INTRODUCTION

Many big cities rely on subway to solve the traffic problem, including Beijing. There are now 21 million people living in this city and 6 of the 18 subway lines have a passenger volume for over one million every working day (Beijing Mass Transit Railway Corp. Ltd., 2017). Signal system is widely used for the safety and efficiency in subway. While the advanced block mode and automatic controls provided by signal system can achieve shorter train interval that makes it possible for more trains operating at the same time, the failure of this system may lead to a breakdown of subway capacity.

An event with a single over-5-minute-delay train is classified as an operation accident by Beijing subway operation cooperation. Statistic shows that there were 36 operation accidents caused by signal failure of Beijing subway in the year 2016, which caused great social repercussions. For example, a failure of track circuit of Beijing subway Line No. 5 happened to January 26, 2016. Before the trouble removal 37 minutes later, the subway had to operate by telephone block, which caused 53 trains' over-5-minute-delay. So it is of vital importance to reduce the signal failure and control the loss during recovery period.

Learning from incident data is a way to help subway companies improve system performance and prevent an accident. While operation accidents seldom happened and learning from old accidents cannot catch up the operation state of the system, it is a good choice to reduce accident by analyzing minor incidents and minimizing the number of it according to Heinrich's Law (Jehring, 1959). There are papers that analyze subway incident with data. Zhang et al. (2016) builds a database to collect and analyze time, location, severity, causes and staff data of near misses in Shanghai subway. Ding et al. (2017) uses fault log database for safety management of subway. The data model of these databases is built based on existing incident record provided by subway companies and no safety science theory was mentioned to explain why they use this data and what other data could also be collected. Moreover, these databases are designed for the whole subway operation, concerning about aspects like fire, passenger fall downs, explosions, train collisions, vehicle derailments. And there is no database that illustrates the prevention and recovery of signal failure.

Signal operation and maintenance are proved to be a more and more difficult task not only because electronic equipment is sensitive to sever environment but because the interactions among signaling systems, surrounding equipment and human operators become much more complex. However, most signaling maintenance teams still use the outdated checklists, and only inspects and records the parameters of signaling itself. The lack of records of the working environment, related interfaces and operations makes it difficult to do incident cause-tracing and maintenance dynamic adjustment.

Accident/incident models provide insight to analysis the causes of an accident/incident. This paper proposes a signal system operation and maintenance database based on hybrid accident/incident causal model of bow-tie and control loop, in which the former provides an overview of what process should be under controlled to keep the performance of the system and mitigate the loss and the later explore how the control processes failed. Cooperated with Communication and Signaling Branch affiliated with Beijing Mass Transit Railway Operation Corp. Ltd., this research is based on real subway operation data. By the approach of building a signal-related incident database, this analysis is aimed at helping reduce the failure rate and improved recovery efficiency of signal system in the daily operation and maintenance of Beijing subway.

The structure of this paper is as follows. The literature review is in Section 2. Section 3 describes the proposed model and the demonstration of this data model in Beijing subway is in Section 4. Finally, Section 5 is the discussion and Section 5 is the conclusion of this paper.

2 LITERATURE REVIEW

2.1 *Bow-tie model*

Bowtie models demonstrate accidents and incidents as cause consequence diagrams. Nielsen (1971) invents the earliest bowtie by combining a fault tree and event tree into one diagram, in which the fault tree explains the cause and the event tree explains how the consequence happens. A top event (also called critical event) is put in the center of this kind of diagram while elements in the left end are causes and elements in the right end are called the consequences. Haddon (1973) put the concept of barrier to keep hazards from impacting a target, after which Reason (1990) use barriers as layers in his Swiss Cheese Model to explain the weakness in a system. Barrier then becomes an important part in bowtie models to explain the linear causal relationship between top event and causes or consequences. Indeed, fault tree and event are often abandoned in many bowtie models to be more suitable for qualitative analysis (Visser 1998, Zuijderduijn 1999, Ruijter et al. 2016). Fig. 1 displays a basic structure of Bowtie model. The barriers at the left of the critical event are control barriers and these at the right side are recover barriers (Visser 1998).

Control barriers prevent the cause from occurring as well as prevent the cause from leading to a top event. Recover barriers prevent the top event from leading to an undesired loss and mitigate the loss.

A bowtie model combines a cause consequence diagram with barriers, which means linking barriers of all operation process in the system. As is widely used for decision making purpose (Ruijter et al. 2016, Visser 1998, Rathnayaka et al. 2014), bowtie models can model the operation of an integrated system and provide an overview of what varieties of barriers should be placed.

2.2 *Control loop*

Control loop is a form of information flow diagram in the system, which aimed to ensure the outcome of a process can follow a specified target or setpoint. The basic structure of a control loop is shown in Fig. 2.

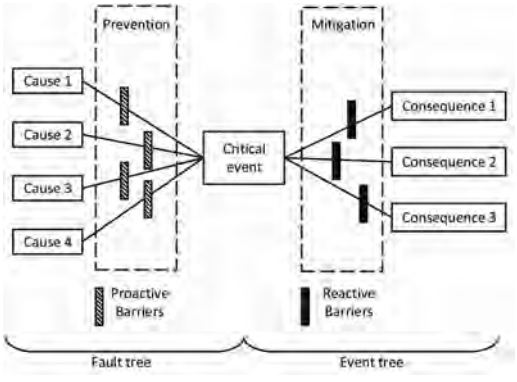

Figure 1. A basic structure of bowtie model.

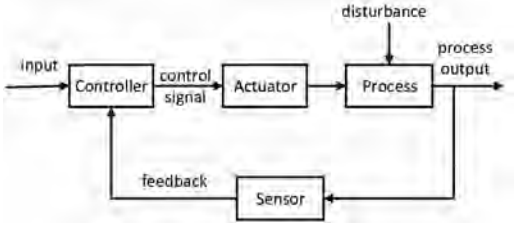

Figure 2. A basic structure of control loop.

Kuhlmann (1986) states that safety can be understood as a cybernetic problem because of the interactions among machine, human and environment. Behavioral cybernetic theory. Smith, K.U. (1972) and Smith, T.J. (1987) maintains that human behavior is guided as a closed-loop, feedback controlled process. Cybernetics control loops are used to analyze the performance of complex, socio-technical systems in which individuals and organizations operating together with advanced technology systems (Smith, T.J. et al., 1995). Sonnemans (2006) uses the control loops in accident analysis of the chemical industry to exam the control mechanism inside organizations. Dijkstra (2007) uses a cybernetics management theory in aviation to model the organizational structure of communication which should be able to adapt the changing environment. Kontogiannis (2012) uses control loops based on VSM to look into general patterns of breakdown related to structural vulnerabilities and gradual degradation of performance in an accident from a Helicopter Emergency Medical Service.

The control loops are also used in railway. Appicharla (2011) analyzes the system interfaces of railway with cybernetics loops because cybernetics studies organization, communication and control in complex systems. Kohda (2007) uses control loops in the accident analysis of railway protective systems. As can be seen, control loops can model a control process, providing details of subjects in the process and details of interactions among human, equipment and environment in a complex system, such as railway signal system.

3 METHOD PROPOSED

Beijing subway Line No. 5 is an important subway line in Beijing subway system, which contains 23 stations and 27.6 km mileages, providing over one million passenger trips every working day. While Line No. 5 is the 4th busiest line in Beijing, it takes the top in signal system failure records and in operation delay in incident records in the past 4 years. From the 2016, RCS lab of Beijing Jiaotong University has been working with Beijing Subway to improve the performance of the signal system and subway Line No. 5 is chosen to be the research subject in this paper.

3.1 *A hybrid data modeling method proposed*

Bowtie and control loop are combined into a hybrid model in this paper.

Signal system can guarantee the shortest train interval under the normal operation mode, while signal degradation resulting from signal failure could cause a traffic jam on track. The signal-related incidents have different causes and different degree of loss but all of them have an event that the normal operation mode of signal system failed. The responsibility of operators and maintainers is to keep signal system working under the normal mode and to recover the operation if a signal failure happens. A bowtie model divides an incidents into causation and effect and signal failure is put in the middle of it. Then the operation and maintenance tasks can be recognized as barriers besides the top event. Bowtie models can be valuable at high level to guarantee all various kinds of data is taken into consideration for the target incident data model.

Signal system is a complex social-technical system and the operation and maintenance can be influenced by the complex interactions among human, equipment and environment. While the bowtie model is built with high abstraction level and less specific information, the management of barriers takes the view from the whole picture to more detail of the system. Thus control loops can be used as a model for the management of barriers could tell what detail data should be collected or recorded for the database.

The hybrid model can be established by the following two steps:

Step 1 Establish a bowtie model based on practical subway operation and maintenance situation and gain the barriers.
Step 2 Establish a control loop specific for every barrier gained in the bowtie model.

The steps are carried out as follows.

3.2 *Establish the bow-tie model*

A qualitative bowtie model is used in this hybrid model, in which there is no fault tree or event tree. Various types of signal failure of normal mode are placed at the middle of the model as top events. Component failures of the system are placed at the left end of the bowtie as the cause of the top event while the loss is placed at the right end of this model. Then there should be a way to determine the barriers of the bowtie model.

RAMS concept is widely used in mainline railway and subway domain, which is defined in terms of reliability, availability, maintainability and safety and their interaction (CENELEC 1999). It provides a guide to assess and improve the quality of service. The RAMS is influenced in three ways, which are system conditions, operating conditions and maintenance conditions. Thus the three conditions can be used in the bowtie model to determine the categories of barriers of subway signal system.

These three conditions can be directly put on the left side of the top event to control the causes and can also be used in the right side of the top event for recovering within more specific scenarios. Thus, the six barriers include system conditions, maintenance conditions and operating conditions as well as degradation conditions, emergency maintenance conditions and operational response conditions.

The system conditions barriers focus on the maintainability and technical characteristics of the system, which are the inherent attribute of the system, as well as the internal and external disturbance of the system.

Maintenance conditions barriers include maintenance procedures such as the conditions of preventive maintenance and corrective maintenance, logistics, and also human factors in the maintenance.

Operating conditions barriers are a question of the operation parameter of the system before the signal failure. Factors like operation time, train interval and passenger flow volume can affect the system and human factors like driving manners and dispatchers' intervention can also contribute to signal failure.

Degradation conditions describe the system conditions without the normal operation mode. The trains have different driving modes and the ground system has different block modes. When the signal failure happens, it is important that a backup mode is ready for operation.

Emergency maintenance conditions are corresponding to maintenance conditions. After a failure happens, it is important to report, diagnose, and repair the system as quickly as possible. Enough well-trained maintainer in the nearby and sufficient spare parts help a lot.

Operational response conditions are corresponding to operation conditions while emphasize the recovery operation procedure. The operational response under the command of dispatchers should decide and carry out methods like degradation, making trains offline, canceling trains and detain trains at stations.

The cause consequence diagram and the 6 categories of barriers are combined and the bowtie part of the hybrid model is shown in Fig. 3.

3.3 *Establish the control loops diagram*

There is no unified control loops diagram for the six categories of barriers. The control loops diagram can be different for different systems and the complexity of these loops depends on how far the analysis is intended to go. The six categories of barriers are unfolded by control loops to reveal the detail factors.

System conditions and degradation conditions mainly talked about how the complex technical system works in normal mode and degradation mode. A control loops diagram that shows the entire conditions of signal system of Beijing subway Line No. 5 is shown in Fig. 4, including the control loops of normal system conditions and degradation conditions.

The control loops diagram of the rest four barriers are more like mission based control. As the

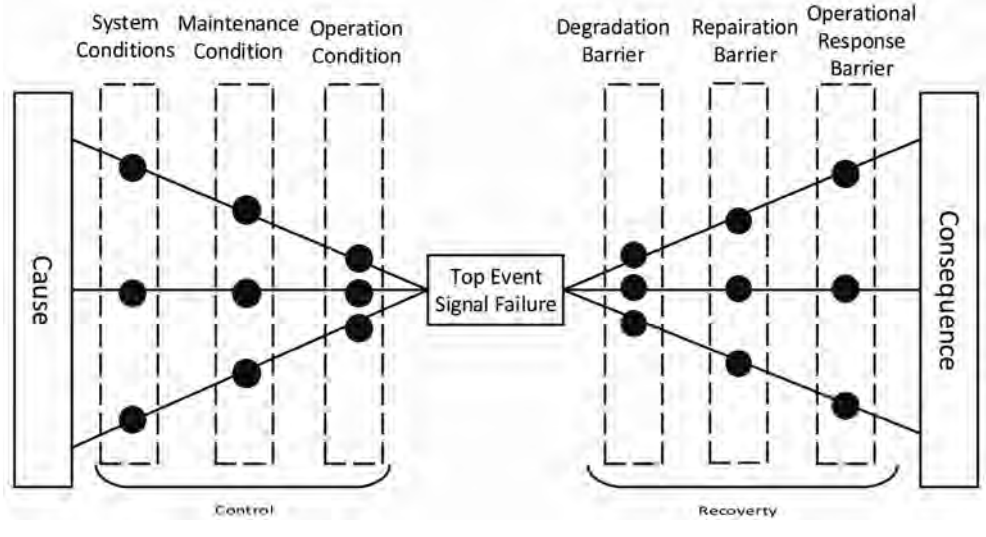

Figure 3. The bowtie part of the hybrid model.

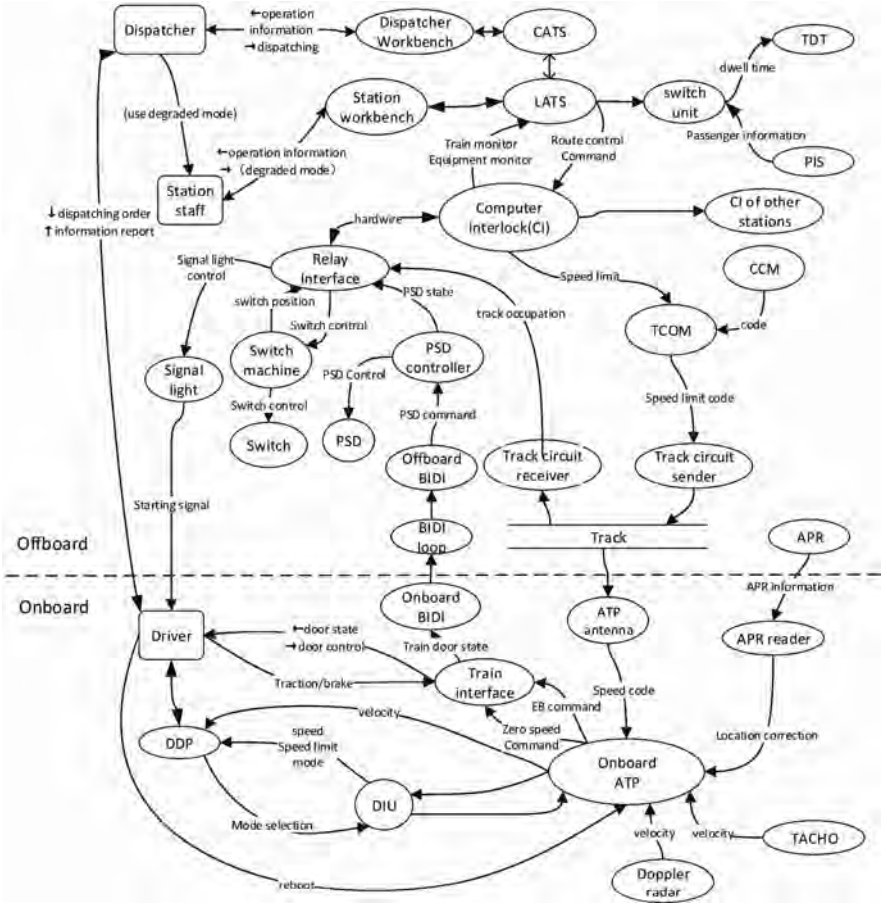

Figure 4. Control loops of system conditions.

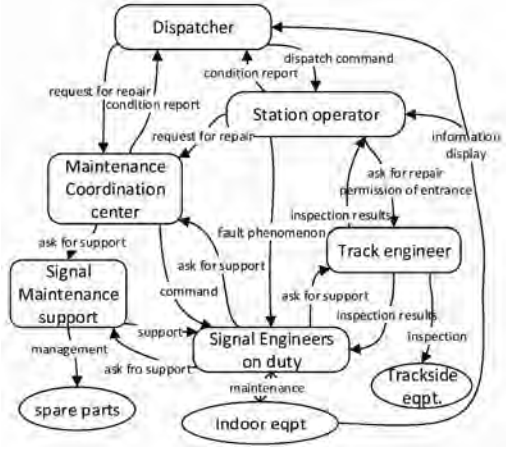

Figure 5. Control loops of EMER MAINT conditions.

control loops diagram of emergency maintenance conditions shown in Fig. 5, person, group and technical system work together to make the system operating.

Each control loop has three basic elements, which are human/equipment, interaction arrow and disturbance. Data can be obtained directly from these three elements.

4 DEMONSTRATION

4.1 *Data model*

Base on the hybrid model proposed in Section 3, a signal-related incident data model for Beijing subway Line No. 5 is built, which is shown in Fig. 6. There are 16 tables in this data model, in which the type of 4 tables are defined by the cause consequence diagram and the type of 6 tables are

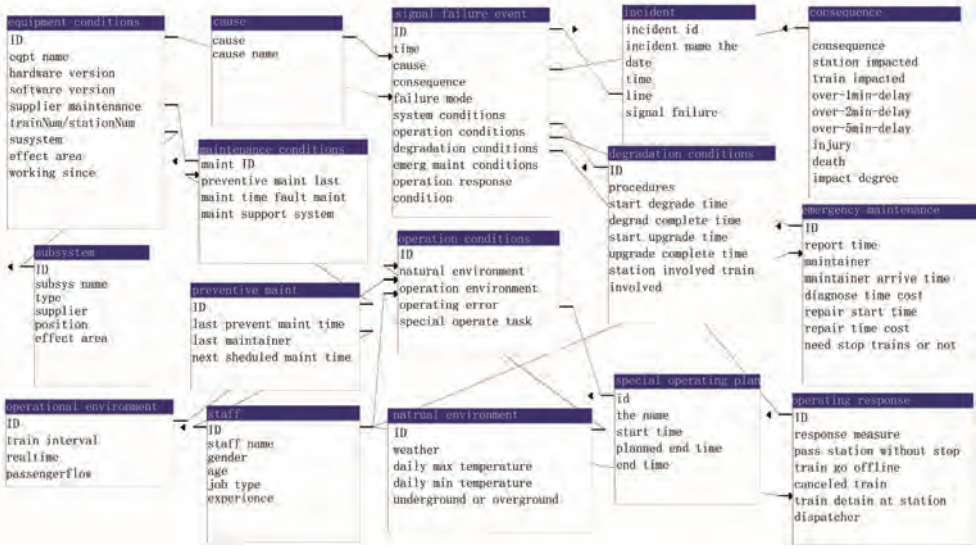

Figure 6. The data model for signal-related subway incidents.

defined by the 6 barriers categories, while the rest tables and the join between tables as well as fields in all these tables are explored in control loops. The data model can direct what kinds of data are needed for the incident data analysis.

Based on the data model, the signal-related subway incident database is built with Microsoft Access 2013.

4.2 *Data collection*

The data analysis in this paper is from the combination of varieties of existing records by Beijing subway, which includes operation accident reports, signal-related incidents records, signal system maintenance records and equipment maintenance manual. Base on the files above, a FMEA analysis is carried out and 65 usual subsystem level failure modes that affect the normal operation mode are found. The outcome is used to rebuilt the incident records, classifying the incident records firstly by the structure of system, subsystems and equipment, secondly by the subsystem failure mode, equipment failure mode and thirdly by reasons including hardware failure, software failure, human error and environment. The subsystem failure modes are defined to be the top events and the causes and consequences are also recognized.

Then files of other department are collected and attached. Dispatching control records are gathered from dispatching center so the dispatching information of every incidents are stored in the database. Then line arrangement figure is used to locate the underground and ground part of the line. Subway dispatching timetable is used to tell the train interval during the signal failure. What's more, weather data is downloaded from the website of China Meteorological Administration.

A total of 4352 incident records of Beijing subway signal related incidents from 2013 are input into the database, 69.5 percent of which have not a single 1 min delay while 0.67 percent have an effect of over-5 min-delays.

4.3 *Findings*

4.3.1 *Analysis based on RAMS*

The frequency of subsystem failure is shown in Fig. 7, in which 85 percent of subsystem failures happened in onboard system. Some factors are found with the analysis of the data.

The data analysis shows that the reliability, availability and maintainability of onboard system of Beijing subway Line No. 5 is low, for which some technical characteristics of the system should be responsible. In terms the reliability of the onboard system, the frequency of inner communication error and of APR reader failure are very high. And the structure of onboard ATP is 2 out of 2, which means no redundancy and a single failure will lead to an emergency break. In terms of availability, there is no efficient backup mode like there are in other lines. If the normal mode fails, the trains have to be operated under the instruction of signal light, which cannot deal with the train interval which is so short. In terms of maintainability, firstly there

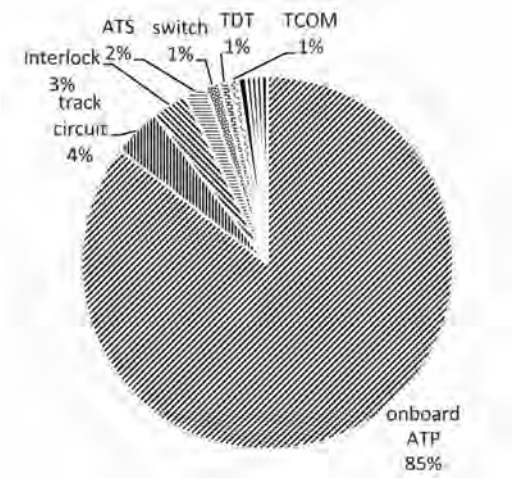

Figure 7. Frequency of incidents by subsystems.

is no assist information about what is wrong after an onboard system failure except an alarm light. So the drivers and dispatchers cannot take actions according to the specific failure and can only use the same procedure. Secondly, the signal supplier is now broken, and the reasons of many failures are too hard to figure out.

4.3.2 *Analysis on environment disturbance*

Track circuit is used in Beijing subway line No. 5 to send MA (movement authority). And MA is coded in low frequency and carrier frequency. In 2016 and the first half year of 2017, there are 64 emergency breaks that the fault code is 'LF error' or 'CF error'. So analysis is carried out to find if there are some environmental disturbances that affect this failure.

So when the LF/CF errors are compared with the location, as is shown in Fig. 8, it could be found that the frequency of these errors increased in track near Chongwenmen and Dongdan station. So the signal maintainers inspect these sections and found that the LF/CF might be disturbed by the traction return current circuit, which was maintained in early 2016.

4.3.3 *Analysis on human factors of maintainers*

Despite used for logic control for a long time, now relays are widely used in computer-based railway signal system in order to lead the system to the safety side after component failures. After the increment in the number of failures as a result of the shortening of train interval in 2014, Beijing subway increased the frequency of scheduled maintenance on the whole signal system in the late of that year.

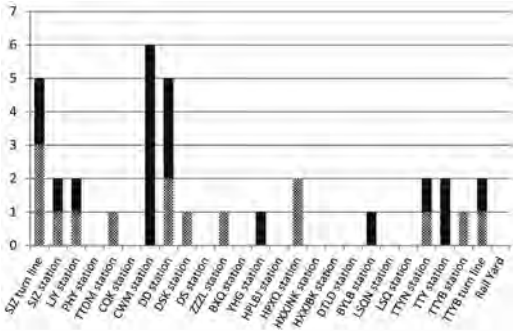

Figure 8. Track circuit code error.

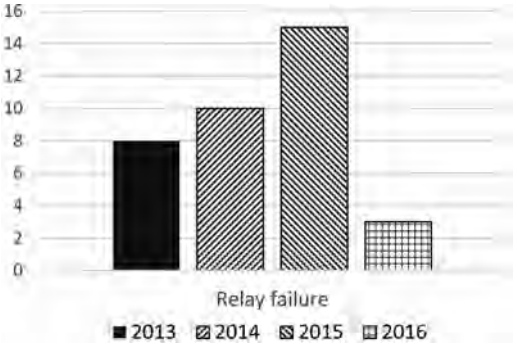

Figure 9. The trend of relay failure over years.

However, as can be seen in Fig. 9, the data shows that relay failures increased in the year 2015 and many of them were found to be or could be related to human errors. It seems that it is not a good choice to keep a high maintenance rate for every component. Relays, for example, have a large amount and every disassembling and assembling means potential of human errors. Then the maintenance frequency of relays was befittingly reduced and more importance are put on the quality of it and the failure rate reduced in 2016.

4.3.4 *Analysis on human factors of operators*

Since the reliability and maintainability of onboard signal system of Line No. 5 is not good, onboard systems often suffer from random failures and the drivers cannot read what is wrong. So there are two choices for the dispatchers to deal with the failure train before its recovery, one is to degrade the bock mode to station block, which is used as a standardized treatment but need time to the enable of signal lights, and the other is to keep the normal mode and guide the train by dispatcher themselves, which relay on dispatchers' efficiency.

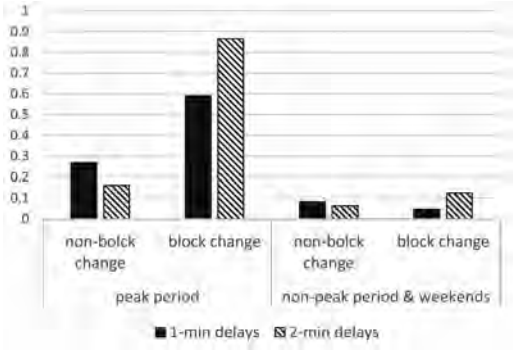

Figure 10. Average delays per onboard failure.

Both the choices are used and it often depends on the dispatchers' experience and preference.

Fig. 10 shows the average 1-min delays and 2-min delays in under different conditions. The data shows that it is related to the train interval. The signal failures with block changes have higher average delays in peak period, but the difference is not so significant during non-peak period and weekends. So it is recommended to the subway company that it is a better choice not to use block change for a single onboard failure in peak period but related regulation must be assessed to guarantee the safety.

5 DISCUSSION AND CONCLUSION

The hybrid model proposed in this paper provides a manner for maintainer and operator to gather and use data to analyze incidents and prevent operation accident that related to signal failures. The bowtie provides an overview and in a way can ensure the comprehensiveness of the categories of data. And the control loops can directly provide varieties of data in detail in a systematic way. And the two part are well bonded because control loops can describe the management of barriers in bowtie. The hybrid model is also costume to subway domains by using the concept of RAMS, which has been used as a guide in this industry for a long time. So there is no difficult for subway engineers to learn and their experience can be inherited in the structure of the database.

In this paper, the data model built from the hybrid model replaces the outdated checklist of Beijing subway and treats the signal system in the way of complex, social-technical system. The incident data analysis can help signal maintainer find the environmental disturbances of signal failure. And it can also help signal maintainer find the human factors that affect the system maintenance so as to adjust their manner of working. Operators can carry out optimistic changes to the operation manners in recovery period. The data analysis is proved to be useful for the maintenance and operation of subway signal system. What's more, the findings and changes can also be checked in future data.

The data model and data collection in this paper play four roles in helping record and collect data. Firstly, it can help subway companies to make a formal manner for signal-related incident data recording since recorders have different habit for recording incidents. Secondly, maintainers and operators record comprehensive have more comprehensive data to use that their analysis can be carried out immediately when they want to prove some measure can bring improvement the performance of signal system, but not starting from recording new data. That can improve the efficiency for them to acquaint the system. Thirdly, existing data collected by different department in a same subway company can be put together to analyze the interaction problems among them. And the environmental data recorded by other departments can be used to analyze and eliminate external disturbances. Furthermore, the model provides a way to analysis what kinds of data are valuable though they are hard to record so sensors could be bought or developed to record more system conditions data as well as advanced information system could be used to record human behaviors.

This paper proposed a hybrid model to recognize what kind of data should be recorded for maintainers and operators to improve the performance of subway signal system. Designing and establishing of this hybrid model are introduced in detailed. After that, the database is demonstrated for Beijing subway line No. 5. Based on the analysis, statistical characteristics of incidents are concluded. The trend of these factors could help companies improve the performance of subway system and the process of this analysis give them a new manner to record and learn from incident data.

In future research, an incident data analysis method could be proposed base on this hybrid model. The method may guide people or even computers to conduct data analysis.

An investigation identifying trends between the enforcement of offshore safety case regulations and the occurrence of vessel to platform collision incidents

S. Loughney, J. Wang & B. Matellini
Liverpool John Moores University, Liverpool, UK

K. Pemberton
Health and Safety Executive, Bootle, Liverpool, UK

ABSTRACT: The regulatory beginnings of the modern offshore Safety Case (SC) are demonstrated by the release of the Health and Safety at Work Act 1974, where it set up two new organisations to oversee its implementation: The Health and Safety Commission (HSC) (which was dissolved in 2008) and the Health and Safety Executive (HSE). Following the public inquiry into the Piper Alpha disaster, the responsibilities for offshore safety regulations were transferred from the Department of Energy to the HSC through the HSE as the singular regulatory body for safety in the offshore industry (Wang, 2002) (Department of Energy, 1990). In response to this the HSE launched a review of all safety legislation and subsequently implemented changes. The propositions sought to replace the legislations that were seen as prescriptive to a more "goal setting" approach. Since these events the SC regulations of 1992 have seen several amendments in both 2005 and 2015, as well as the release of further regulations, such as: The Offshore Installations Prevention of Fire and Explosion, and Emergency Response (PFEER) in 1995 and the Safety Zones around Oil & Gas Installations in Waters around the UK in 2008. However, while Safety Cases are subject to review and updating as often as is required to keep them up to date, the process of change to the Safety Case may be slow and gives a monolithic appearance to the document. Subsequently, there have been several papers suggesting that a dynamic risk assessment method should be utilised to assist with SC regulation enforcement. This has led to the investigation presented in this report where 508 vessel to platform collision incidents between 1971 and 2015 have been analysed and compared with the release of key offshore SC regulations. The incidents have been sourced from the HSE, World Offshore Accident Databank (WOAD) and the MAIB. This analysis has identified a key trend between the reporting of offshore collision incidents and the release and enforcement of offshore SC regulations.

1 INTRODUCTION

Following the public inquiry into the Piper Alpha disaster, the responsibilities for offshore safety regulations were transferred from the Department of Energy to the Health and Safety Commission (HSC) through the Health and Safety Executive (HSE) as the singular regulatory body for safety in the offshore industry (Wang, 2002) (Department of Energy, 1990). In response to this the HSE launched a review of all safety legislation and subsequently implemented changes. The propositions sought to replace the legislations that were seen as prescriptive to a more "goal setting" approach. Several regulations were produced, with the mainstay being the Health and Safety at Work Act (HSE, 1992). Under this a draft of the offshore installations safety case regulations was produced. The regulations required operational safety cases to be prepared for all offshore installations. A SC is to be submitted by the "operator" for fixed installations and by the "owner" for mobile installations. Within this all new production installations require a design safety case and for mobile installations, the duty holder is the owner (Wang, 2002).

Offshore operators must submit operational safety cases (SC) for all existing and new offshore installations to the Health and Safety Executive's (HSE) Energy Division (formerly the Offshore Safety Division) for acceptance, but not approval, yet it is an offence to operate without an approved SC (HSE, 2006a). The SC must show that it identifies the hazards with potential to produce a serious accident and that these hazards are below a tolerability limit and have been reduced to the ALARP Level (As Low As Reasonably Practicable) (Wang, 2002).

Safety and risk assessment for offshore installations is vigorous and requires demonstration

from duty holders that all hazards with potential to cause major accident are identified, all major risks have been evaluated, and measures have been or will be taken to control the major accident risks to ensure compliance with the statutory provisions (HSE, 2006b). Furthermore, it used to be a requirement stipulated in the SC Regulations that suitable and sufficient quantitative risk assessment was undertaken. However, the 2015 regulations have actually removed the requirement for this specific form of risk assessment though in practice most duty holders still use QRA extensively, it should however, only be used as an evaluation tool (HSE, 2015).

This is vitally important as accidents in the offshore industry lead to devastating consequences, such as the explosion on board the Deepwater Horizon rig in the Gulf of Mexico which was caused by the failure of a subsea blowout preventer (BOP), with some failures thought to have occurred before the blowout (Jones, 2010). This solidifies the use of quantitative risk and reliability analysis, current ideas behind these models can perform predictive analysis and diagnostic analysis (Cai, *et al*., 2013).

After many years of employing the safety case approach in the UK offshore industry, the regulations were expanded in 1996 to include verification of Safety Critical Elements (SCE). Also, the offshore installations and wells regulations were introduced to deal with various stages of the life cycle of the installation. SCEs are parts of an installation and its plant, including computer programs or any part whose failure could cause or contribute substantially to or whose purpose of which is to prevent or limit the effect of a major accident (Wang, 2002) (HSE, 1996).

Recently, however, it is felt that an expansion on Safety Cases is necessary, especially in the offshore and marine industry, as they are static documents that are produced at the inception of offshore installations, despite containing a structured argument demonstrating that the evidence contained therein is sufficient to show that the system is safe (Auld, 2013) (Eleye-Datubo, A., *et al*., 2006).

While the authors were conducting research regarding dynamic risk assessment techniques and methods for offshore installations and SCEs, more specifically data gathering regarding offshore ship to platform collisions, a periodic pattern emerged between the release of SC regulations and the number of collision incidents on the UKCS.

2 BACKGROUND

It is known that Safety Cases are subject to review and updating as often as is required to keep them up to date, the process of change to the Safety Case may be slow and gives a monolithic appearance to the document. A SC is a relatively high level document which identifies the operator/owner, describes the installation and its layout, its environmental limits, the types of operation to be undertaken and how the health and safety aspects will be managed, and the maximum number of persons expected to be on the installation at any one time. Similarly, there also needs to be a description for the arrangements for detecting toxic or flammable gas and the detection, prevention or mitigation of fires and the arrangements for protecting people from the hazards of explosion, fire, heat, smoke *etc*. usually in the form of a temporary refuge, egress routes means of evacuation and means of monitoring and control for an incident. There should also be a demonstration by suitable risk assessment that the risks have been mitigated to a level that is ALARP and a description of the verification scheme.

An attempt to identify trends with safety case regulation and incidents regarding offshore SCEs, such as gas drive turbines and generators, was conducted. However, due to possible under reporting or the availability of data, it is difficult to demonstrate the trend of some SCEs, with the updating of offshore regulations. On the other hand, it is possible to demonstrate the effect of a number of possible influences, (slow updating or enforcement of regulations, and under reporting or improper recording of incidents), and the effects they may have on incidents on-board offshore platforms. A key area that can be assessed is the issue of ship to platform collisions.

Before any data is presented, it is important to understand the timeline of key offshore regulations and incidents that have shaped the modern-day safety case regulations. The following list identifies the key timeline of incidents that have built the current safety case regulations.

- *1974 Health & Safety at Work Act (HSWA)*

The HSWA adopted a holistic approach to the health, safety and welfare of workers. The Act focuses on the concept that any situations that may give rise to harm need to be recognised and suitable measures put in place to eliminate or reduce the potential for harm. It set up two new organisations to oversee its implementation: The Health and Safety Commission (HSC) and the Health and Safety Executive (HSE). The HSE is the executive organisation that enforces the provisions of the HSWA. However, in April 2008 the HSC was dissolved and merged with the HSE. The HSC used to protect health and safety at work in the UK by conducting research, training and providing advice and information. The Commission also used to propose new regulations and approved codes of practice under the authority of the Act. This is

all now conducted by the HSE (Inge, 2007) (The Stationary Office, 1974).

- *1988 Piper alpha disaster*

Piper Alpha was an oil production platform in the North Sea off the coast of Aberdeen, Scotland. The platform began production in 1976, initially as an oil platform but was later converted to accommodate gas production. Oil & Gas fires and explosions destroyed Piper Alpha on 6 July 1988, killing 167 people, including two crewmen of a rescue vessel and 61 workers aboard survived. Thirty bodies were never recovered. The total insured loss was about £1.7 billion ($3.4 billion), making it one of the costliest manmade catastrophes ever. At the time of the disaster, the platform accounted for approximately ten per cent of North Sea oil and gas production. The Cullen Inquiry was set up in November 1988 to establish the cause of the disaster, chaired by Judge William Cullen. After 180 days of proceedings, the "Public Inquiry into the Piper Alpha Disaster" or "Cullen Report" was released in November 1990. It concluded that the initial condensate leak was the result of maintenance work being carried out simultaneously on a pump and related safety valve. The report was critical of Piper Alpha's operator, which was found guilty of having inadequate maintenance and safety procedures (Inge, 2007) (Oil & Gas UK, 2008).

- *1989 Offshore installations (safety representatives & safety committee) regulations*

The document provides information on interpretation and enforcement of the Offshore Installations (Safety Representatives and Safety Committees) Regulations 1989. These regulations were made under the Mineral Workings (Offshore Installations) Act 1971. They allow the workforce on an offshore installation to elect safety representatives from among themselves, and confers on those functions and powers in relation to the health and safety of the workforce. They also provide for time off with pay for safety representatives so they can perform these functions and undergo relevant training (The Stationery Office, 1989).

- *1990 The Cullen report*

The Cullen Inquiry was set up in November 1988 to establish the cause of the disaster, chaired by Judge William Cullen. After 180 days of proceedings, the "Public Inquiry into the Piper Alpha Disaster" or "Cullen Report" was released in November 1990. It concluded that the initial condensate leak was the result of maintenance work being carried out simultaneously on a pump and related safety valve. The report critical of Piper Alpha's operator, which was found guilty of having inadequate maintenance and safety procedures. 106 recommendations were made calling for, amongst many matters, the requirement of a SCs, the transference of the discharge of offshore regulation from the Department of Energy to a discrete division of the HSE. The responsibility of implementing the recommendations was spread across the regulators and the industry with, the HSE overseeing 57, the operators were responsible for 40, the offshore industry were given 8 to progress and the final one was for the Standby Ship Owners Association. The industry acted urgently to carry out the 48 recommendations that operators were directly responsible for. The HSE developed and implemented Lord Cullen's key recommendation: the introduction of safety regulations requiring the operator/owner of every fixed and mobile installation operating in UK waters to submit to the HSE, for their acceptance, a SC (Inge, 2007).

- *1992 Safety case regulations*

The Offshore Installations (Safety Case) Regulations came into force in 1992. By November 1993 a safety case for every installation had been submitted to the HSE and by November 1995 all had had their safety case accepted by the HSE. The Safety Case Regulations require the owner/operator/duty holder of every fixed and mobile installation operating in UK waters to submit to the HSE, for their acceptance, a safety case. The safety case must give full details of the arrangements for managing health and safety and controlling major accident hazards on the installation. It must demonstrate, for example, that the company has safety management systems in place, has identified risks and reduced them to as low as reasonably practicable, has introduced management controls, provided a temporary safe refuge on the installation and has made provisions for safe evacuation and rescue (Inge, 2007) (HSE, 2005).

- *1995 Offshore installations Prevention of Fire and Explosion, and Emergency Response (PFEER)*

PFEER deals primarily with fire and explosion events but it also deals with any event which may require emergency response and includes systems that may rely on radar on a standby vessel or responsible staff on the installation monitoring incoming vessels. The Regulations, ACOP and guidance deal with: (a) preventing fires and explosions, and protecting people from the effects of any which do occur; (b) securing effective response to emergencies affecting people on the installation or engaged in activities in connection with it, and which have the potential to require evacuation, escape and rescue (Amended in 2005 and 2015) (HSE, 2015a).

- *1996 Offshore installation (design & construction) regulations*

DCR requires the installation to possess integrity at all times, as is reasonably practicable. It requires

the design of the installation to withstand such forces that are reasonably foreseeable and in the event of foreseeable damage it will retain sufficient integrity to enable action to be taken to safeguard the health and safety of persons on or near it. The duty holder also has to record the appropriate limits within which it is to be operated. Further duties can be found in the Offshore Installations and Wells (Design and Construction, *etc*.) Regulations 1996.

- *2005 Offshore installations (safety case) regulations (April 2006)*

The Offshore Installations (Safety Case) Regulations 2005 came into force on 6 April 2006. They replace the previous 1992 Regulations. The primary aim of the Regulations is to reduce the risks from major accident hazards to the health and safety of the workforce employed on offshore installations or in connected activities. The Regulations implement the central recommendation of Lord Cullen's report on the public inquiry into the Piper Alpha disaster. This was that the operator or owner of every offshore installation should be required to prepare a safety case and submit it to HSE for acceptance (HSE, 2005). These SC regulations have been replaced by the 2015 regulations (HSE, 2015).

- *2008 Safety zones around oil & gas installations in waters around the UK (HSE)*

While this document is not a regulation, it explains the purpose and significance of safety zones around offshore oil and gas installations and their effect on marine activities, particularly relating to fishing vessels. A safety zone is an area extending 500 m from any part of offshore oil and gas installations and is established automatically around all installations which project above the sea at any state of the tide. Subsea installations may also have safety zones, created by statutory instrument, to protect them. These safety zones are a 500m radius from a central point. Vessels of all nations are required to respect them. It is an offence (under section 23 of the Petroleum Act 1987) to enter a safety zone except under the special circumstances. (HSE, 2008b)

- *2015 Offshore installations (offshore safety directive) (safety cases etc.) regulations (July 2015)*

The Offshore Installations (Offshore Safety Directive) (Safety Case *etc*.) Regulations 2015 came into force on 19 July 2015. They apply to oil and gas operations in external waters, that is, the territorial sea adjacent to Great Britain and any designated area within the United Kingdom Continental Shelf (UKCS). They replace the Offshore Installations (Safety Case) Regulations 2005 in these waters, subject to certain transitional arrangements (HSE, 2015b).

These key events from 1974 to the present day have shaped the modern SC into what it is today. After identifying these key regulations and incidents it was possible to plot these against the number of ship to platform collision incidents. This is where the data gathering and statistical analysis is conducted.

3 STATISTICAL ANALYSIS & DISCUSSION

The current database of ship to platform collisions provided by the HSE is out dated as it was last published in 2001. Similarly, the OGP (Oil & Gas Producers) produced a document in 2010 of worldwide collision statistics and Oil & Gas UK produced a document of accident statistics on the UKCS for offshore units between 1990 and 2007 (HSE, 2003) (OGP, 2010) (Oil & Gas UK, 2009). However, the OGP document provides only the frequency of collisions of incidents over key offshore and shipping areas around the world and the Oil & Gas UK document lists all accidents statistics with overall frequencies per year. These three documents are sufficient enough to demonstrate the trend between offshore collision incidents and offshore regulations. Therefore, a statistical analysis is conducted for ship to platform collisions from 1971–2015 across the UKCS.

For this study and incident has been defined as a reported impact or contact between a vessel and a fixed or mobile installation in terms of the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations (RIDDOR 2013) database, which utilizes reported incident information from the OIR/9b and F2508A forms.

The 2001 ship/platform collision incident database has been further cross-checked and extended. The complete list of incidents demonstrates a total of 508 incidents of vessels impacting or contacting both fixed and floating offshore structures. These incidents have been reported from 1st January 1971 to 31st December 2014.

The data has been recorded from a number of sources. In many cases the data is supplemented or confirmed from additional sources. Data across the whole study has been compiled from the following sources:

- RIDDOR 2013, utilizing search criteria "Collisions, or potential collisions", between "vessels and offshore installations". Information source is labelled as HSE in the database.
- World Offshore Accident Databank (WOAD) using the search criteria ("Collision", "Offshore Units" and "Europe North Sea".
- Marine Accident Investigation Branch (MAIB) using the search criteria "Offshore installations", "collision" and "contact".

- Global Integrated Shipping Information System (GISIS) using search criteria “collisions” and “North Sea”.
- World Energy Related Casualties (WREC) using search criteria “offshore installations”, “collisions” and “North Sea”.

In order to demonstrate a coherent analysis, an incident frequency and a cumulative incident frequency has been calculated based upon the approximate level of operating experience per year. Table 1 demonstrates the operating experience, the number of incidents that have been reported and

Table 1. List of all reported collision incidents on the UKCS, as well as operating experience and incident frequencies.

Year	Total experience (N)	Cumulative experience (N1)	All incidents (r)	Cumulative incidents (r1)	Frequency (λ)	Cumulative frequency (λ1)
1971		–	1	–	–	–
1972	–	–	0	–	–	–

the frequency of these incidents. It can be seen that 4 incidents were recorded from 1971 to 1974 however, they are not part of the overall frequency analysis as there is limited data regarding operating experience. Similarly, these numbers are only confirmed from WOAD as the HSE did not begin recording incidents until 1975.

Figure 1 demonstrates the number of ship to platform collision incidents from 1971–2015 as well as the key regulations and incidents as outlined previously (GL, 2017) (HSE, 2016) (MAIB, 2016).

It can be seen from Figure 1 that the number of ship to platform collision incidents from 1971 to 2015 is very turbulent, as more clearly demonstrated by the average trend-line. At a first glance, this trend seems to be rather erratic, following no logical pattern. However, when the milestones in the safety case regulation timeline are taken into consideration, patterns begin to emerge in the number of incidents each year in the UKCS.

Initially, from 1971 to 1974 the number of incidents is very low at one or two per year. A possible reason for this is that the data entries for 1971 to 1974 are from WOAD only, as the HSE began their ship to platform collision recordings from 1975. However, from 1975 onwards the number of incidents per year greatly increases until 1981 from 12 to 29 respectively. There are a number of possibilities that can cause this rapid increase. Firstly, the HSWA is enforced from 1974 hence, the recognition of dangerous incidents that can cause harm to personnel is increased. Secondly, as more and more dangerous incidents are being recognised, the need to report said incidents also increases. Therefore, it is safe to say that an increased awareness of dangerous situations coupled with the need to report these incidents gives rise to a dramatic increase in the number of collision incidents. Thirdly, according to the HSE, the approximate number of installations operating in the UKCS increases from 89 in 1975 to 121 in 1981. The increase in the number of operating platforms would statistically increase the number of collisions at that time.

From 1981, however, the number of incidents per year begins to decrease until 1987, from 29 to 6. This decrease is much greater that the increase in incidents from 1975 to 1981. It is possible that the enforcement of the HSWA had a large effect on the safety procedures on offshore platforms in the UKCS. This hypothesis would also be consistent with the approximate number of platforms operating in the UKCS which increases from 121 in 1981 to 174 in 1987. This contradicts the previous statement that the number of incidents would increase with the number of platforms in operation. However, in the 6-year period between 1981 and 1987 this is not the case. This further backs up the idea that the regulations from 1974 have been increasingly enforced and have reduced the number of incidents. However, it is also possible to state that

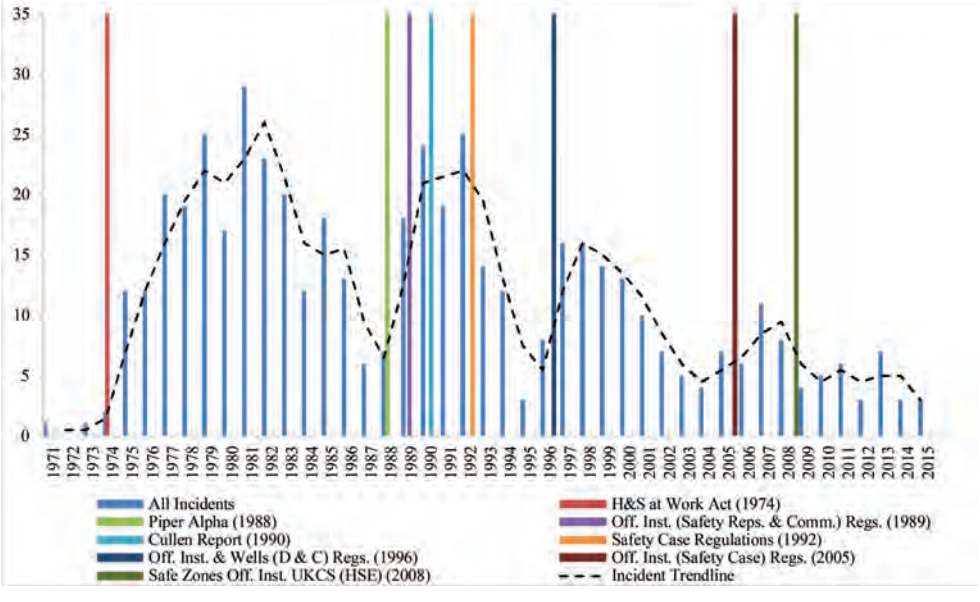

Figure 1. Graph demonstrating the number of ship to platform collision incidents per year, as well as the key regulations and events that formed the modern safety case.

the level of reporting of the collision incidents has decreased. This is a much more difficult claim to validate as there is not any possible way to determine whether an incident has happened and has not been reported. This is part of the reasoning behind an increase in research regarding offshore dynamic asset integrity modelling and autonomous systems, as the most common reason a detector or sensor will not detect and log any information is if it is faulty. On the other hand a human has the ability to choose not to carry out an action. Hence it is difficult to accurately determine the level of underreporting that would have taken place between 1981 and 1987.

Continually, the time period between 1988 and 1994, in terms of collision incidents, is very interesting. The year 1988 is well known in the offshore industry and indeed the world as the year of the Piper Alpha disaster in which 167 crew members lost their lives in the July of that year. When one examines the collision incidents that were reported in 1988, approximately 70% were reported after the loss of Piper Alpha on 6th July. This may suggest that a large-scale disaster, such as Piper Alpha, triggered an increase in the level of incident reporting. However, the number of collision incidents in 1988 alone are not enough to state this with any conviction. What is interesting however, is that the number of collision incidents increase in 1989 to 18, from 7 in 1988. This is a drastic increase in terms of the number of reported incidents in the UKCS, after a large-scale offshore disaster.

Furthermore, in 1989 the Offshore Installations (Safety Representatives & Safety Committee) Regulations were published. This stated that the workforce could elect safety representatives from amongst themselves. This may have increased the level of reporting of collision incidents in 1989. However, it appears to be too much of a drastic increase from the previous year to conclusively state that the new regulations in 1989 resulted in a considerable number of reported incidents. It seems much more likely that a combination of the Piper Alpha disaster and the release of the Offshore Installations (Safety Representatives & Safety Committee) Regulations contributed to the vast increase in reported collision incidents.

Continually, in 1990, the Cullen Report was published which was public enquiry into the Piper Alpha disaster. The report was heavily critical of the platform operators. Lord Cullen made a total of 106 recommendations within his report, all of which were accepted by industry. The responsibility of implementing them was spread across the regulators and the industry with, the HSE overseeing 57, the operators were responsible for 40, the offshore industry were given 8 to progress and the final one was for the Standby Ship Owners Association. The industry acted urgently to carry out the 48 recommendations that operators were directly responsible for. By 1993 all had been acted upon and substantially implemented. Furthermore, the HSE developed and implemented Lord Cullen's key recommendation: the introduction of safety regulations requiring the operator/owner of every fixed and mobile installation operating in UK waters to submit to the HSE, for their acceptance, a safety case. Hence, in 1992 the Offshore Installations (Safety Case) Regulations came into force. By November 1993 a safety case for every installation had been submitted to the HSE and by November 1995 all had had their safety case accepted by the HSE.

If the number of collision incidents is examined from the Cullen Report in 1990 to all installation Safety Cases being accepted in 1995, it can be seen that the number of incidents per year decreases rapidly from 24 to 3 respectively. This is again a massive fluctuation in the number of incidents following a series of key regulations being enforced. It shows that the release of new regulations prompts the level of incidents to decrease as the regulations are enforced. However, as 1995 is a number of years after the Cullen Report and the introduction of Safety Cases it is possible that an element of complacency in terms of reporting may occur. This can be seen from the number of incidents between 1995 and 2004. The number of collision incidents increases from 3 in 1995, to a peak in 1998 of 16, then to a new low of 4 in 2004. What is key is this fluctuation, actually does not exactly follow the common trend of more incidents given more operating installations. From 1995 to 1996 the approximate number of installations decreases from 289 to 262, then steadily increases to 313 in 2004. This again does not follow a pattern as the number incidents decreases after 1998 as the approximate number of installations increases. This could be attributed to a substantial level of regulation enforcement leading to a decrease in incidents, or there may be an anomaly in the approximate number of installations and incidents, given that the approximate number of installations increases steadily from 1975 to 1995, then suddenly decreases. Similarly, it is at this time that the HSE began utilising the RIDDOR regulations (from 1st April 1996).

What appears to be more likely is at the low point of 3 collisions in 1995, a new set of regulations are introduced and enforced, the Offshore Installations Prevention of Fire and Explosion, and Emergency Response (PFEER) along with the Offshore Installation (Design & Construction) Regulations in 1996. At that point, the number of incidents increases and peaks in 1998. It would be foolish to say that the introduction of new offshore

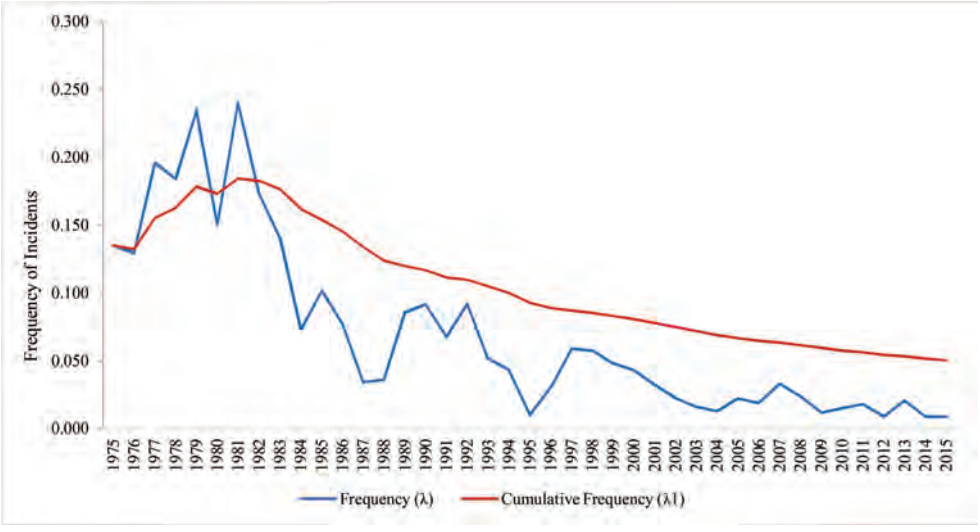

Figure 2. Incidents frequency and cumulative frequency for ship to platform collisions per year from 1975 to 2015.

regulations causes offshore incidents. What is far more likely is that the increase of new regulations prompts a more proactive response in the accuracy of incident reporting.

In addition, this trend can be seen yet again from 2004 to 2012, where the number of collision incidents per year increases from 4 in 2004 to 11 in 2007 then decreases to 3 in 2012. This could be attributed to the Offshore Installations (Safety Case) Regulations 2005 being enforced in 2006. As with the regulations in 1995 and 1996 the number of incident increases and begins to decrease. However, the number of collision incidents becomes much steadier and doesn't fluctuate as much as previous years, as the increase from 4 to 11 in 2013 is not a huge increase, and could be said to be anomalous when looking at the number of incidents in that period. However, it is an increase none the less.

Furthermore, in 2008 the Safety Zones around Oil & Gas Installations in Waters around the UK information sheet is introduced by the HSE. This specifically targets the area of offshore collisions, near misses and general safety when operating in an installations 500m zone. Therefore, it makes sense to state that this introduction has maintained a steady level of incidents between 2008, with 8, and 2015, with 3.

Furthermore, by applying the use of a calculated incident frequency and cumulative frequency, based upon the operating experience on the UKCS from 1975 to 2015, it can be seen that the number of incidents has drastically decreased over the 40 year period. This is demonstrated by Figure 2 which highlights the trend of incidents frequencies per year as well as the cumulative incidents frequency per year. What can be seen in Figure 1 and much more clearly in Figure 2 is that the average frequency of incidents has generally decreased since 1981. This clearly demonstrates that over the 40 year period from the introduction of the HSWA to the current amended Safety Case regulations, the enforced regulations have had a huge impact on installation safety in terms of collision incidents. As the general number of incidents has decreased, the approximate number of operating installations has increased.

4 CONCLUSION

From the information presented in Figures 1 and 2 as well as Table 1, it can be seen that the offshore industry can be said to be reactive in its approach to reporting incidents, especially in the area of ship to platform collisions. What is also apparent is that the fluctuation has become gradually smaller in more recent times. This shows that the effect of introducing and amending regulations over time has a positive effect on the overall trend of collision incidents. While this study identifies trends in ship to platform collisions, it would still be valid to state that the offshore industry would profit greatly from having a dynamic risk monitoring tool to aid with the continual enforcement of regulations across all areas of an offshore platform. In the near future, a widely accepted and integrated dynamic asset integrity monitoring tool could be a distinct possibility.

ACKNOWLEDGEMENTS

This research is partially supported by the HSE through a project: "Effective collision risk management for offshore installations and ship/platform collision database."

Understanding and effectively managing conservatisms in safety analysis

Steven Krahn

U.S. Department of Energy, USA

ABSTRACT: Safety analysis for nuclear facilities are performed in a conservative manner so that there is additional assurance that the nuclear facilities are safe to operate given the potential events that may impact or challenge the facilities. The degree of conservatism included in the analysis should be well know and be increased if there is a large degree of uncertainty associated with the analysis. If uncertainty is decreased, through better data or more sophisticated and/or rigorous analysis, a decrease in conservatism can be made without impacting the margin of safety of the design.

1 INTRODUCTION

1.1 *Objective*

Providing conservatism in the safety analysis of a facility results in additional assurance that the facility is safe to operate. This paper explores how the degree of conservatism and the degree of uncertainty of the safety analysis are linked in determining the margin of safety of the facility design. The objective of this research is to improve the understanding of the theoretical and technical basis for ensuring the safety of a facility design.

1.2 *Approach*

This research included the following steps.

- Reviewing definitions for conservatism
- Reviewing national and international practices regarding use of conservative inputs into safety analyses
- Evaluating conservative and best estimate analyses and a potential method for reducing conservatism while maintaining safety margins

A follow-on paper is planned that will evaluate some potential applications of the method to reduce conservatism while maintaining safety margins.

2 CONSERVATISM DEFINITION

2.1 *Definition*

A discussion of conservatism, as it relates to safety analysis, is found in the U.S. Nuclear Regulatory Commission's (NRC) NUREG-2122, *Glossary of Risk-Related Terms in Support of Risk-Informed Decision-making* (NRC 2013). NUREG-2122 takes a holistic approach in describing conservatism; it defines the term conservative in combination with "analysis," and an additional qualifying term "demonstrably"–thus implying that an analysis must be evaluated as a whole. A "demonstrably conservative analysis" is: "An analysis that uses assumptions such that the assessed outcome is meant to be less favorable than the expected outcome."

The more detailed discussion in NUREG-2122 goes on to explain that a "demonstrably conservative analysis provides a result that *may not be the worst result* of a set of outcomes, but produces a quantified estimate of a risk metric that is *significantly greater* than a risk metric estimate produced using the most realistic information available" [emphasis added]. Thus, a conservative analysis can be described as being located between a bounding analysis and a best estimate analysis—but skewed towards the bounding case and significantly away from the results of the best estimate analysis. The relationship among the terms "conservative", "bounding", and "best estimate" is discussed further below.

A guide by the United Kingdom's (UK) Office for Nuclear Regulation (ONR), Safety Assessment Principles for Nuclear Facilities (UK ONR 2014) defines conservatism as:

> *In analysis, an approach where the use of models, data and assumptions would be expected to lead to a*

result that bounds the best estimate (where known) on the safe side. The degree of conservatism should be proportionate to both the level of uncertainty and the overall significance of the estimate to the safety case.

This definition is informative, as it links the level of uncertainty to the "significance of the estimate"; i.e., the importance of the parameter being addressed; however, what is the ONR meant by "bounds the best estimate" is not clear.

3 NATIONAL AND INTERNATIONAL PERSPECTIVES ON CONSERVATIVE SAFETY ANALYSES

3.1 *U.S. Nuclear regulatory commission*

The NRC's Safety Goal Policy Statement (NRC 1986) states that, "to provide adequate protection of the public health and safety, current NRC regulations require *conservatism* in design, construction, testing, operation and maintenance of nuclear power plants" [emphasis added]. Relative to conservatism in accident analysis, NRC Regulatory Guide 1.203, *Transient and Accident Analysis Methods* (NRC 2005) states that:

... results of an analysis can be conservative due to a combination of code input and modeling assumptions…. However, conservatism in just one aspect of [a model] … cannot be used to justify conservatism in the [model] as a whole, because other aspects of the model may be non-conservative and cause the overall model to be non-conservative. The degree of conservatism in the overall model must be quantified and documented. Showing the degree of conservatism in [a model] … may be accomplished by a relatively simple uncertainty analysis….The key to simplifying the uncertainty analysis is identifying the small number of parameters and physical phenomena that are important in determining the behavior of the accident.

The issue of conservatism is also tied somewhat to the issue of probabilistic versus deterministic approaches; in probabilistic approaches, conservatism and uncertainty can be specifically evaluated, whereas in a deterministic approach there is often less information to support an understanding of the degree of conservatism. This was discussed in the NRC's NUREG/CR-7168, *Regulatory Approaches for Accessing Facility Risks* (NRC 2015). A companion issue to that of probabilistic versus deterministic approaches is whether analyses should be based on data and computational methodologies that represent the best estimate of what might really occur, with uncertainty analysis to explore the effects of incorrect data or models, or should be based on demonstrably conservative data and models. Most regulations and license applications have used a conservative, deterministic approach. The NRC has identified problems with using this approach as discussed in Appendix C of NUREG-1909, *Background, Status, and Issues Related to the Regulation of Advanced Spent Nuclear Fuel Recycle Facilities* (NRC 2008). Two of the most important problems identified were: (1) that using very conservative assumptions can mask risk-significant items, and (2) that most conservative analyses are not accompanied by an uncertainty analysis.

The NRC has also addressed the issue of conservatism in thermal hydraulic code analysis and provide guidance on how best-estimate calculations can be utilized in place of conservative models. Specifically, in Regulatory Guide 1.157, *Best-Estimate Calculations of Emergency Core Cooling System Performance* (NRC 1989), the NRC states that:

the NRC staff amended the requirements of § 50.46 and Appendix K, "ECCS Evaluation Models" (53 FR 35996), so that these regulations reflect the improved understanding of ECCS performance during reactor transients that was obtained through the extensive research performed since the promulgation of the original requirements in January 1974. Paragraph 50.46(a)(1) now permits licensees or applicants to use either Appendix K features or a realistic evaluation model. These realistic evaluation models must include sufficient supporting justification to demonstrate that the analytic techniques employed realistically describe the behavior of the reactor system during a postulated loss-of-coolant accident. Paragraph 50.46(a)(1) also requires that the uncertainty in the realistic evaluation model be quantified and considered when comparing the results of the calculations with the applicable limits in paragraph 50.46(b) so that there is a high probability that the criteria will not be exceeded.

For the purpose of the above regulatory guide, the terms "best-estimate" and "realistic" have the same meaning. Both terms are used to indicate that the techniques attempt to predict realistic reactor system thermal-hydraulic response; though best-estimate is not used in a statistical sense in this guide.

The use of conservative values has been investigated in International Atomic Energy Agency (IAEA) Safety Report 52, *Best Estimate Safety Analysis for Nuclear Power Plants: Uncertainty Evaluation*, (IAEA 2008) and IAEA Publication 1428, *Deterministic Safety Analysis for Nuclear Power Plants* (2014). These documents discuss the practices, benefits and downsides associated with use of conservative and best estimate analyses. The IAEA notes that for accident scenarios with large estimated

margins to acceptance criteria, "it is appropriate for simplicity, and therefore, economy, to use conservative analysis"; however, "for scenarios in which the margin is smaller, a best estimate is necessary.…"

The IAEA goes on to describe the need for best estimate analysis in this instance is to "to quantify the conservatism"; that is, "to show the margins to the acceptance criteria that apply in reality." However, the IAEA discussion of best estimate analysis in IAEA Safety Report 52 is always combined with a focus on evaluation of uncertainties; therefore, the IAEA discussion is of "best estimate analysis together with evaluation of uncertainties." The use of this type of methodology is qualified with the caution that "realistic input data are used only if the uncertainties or their probabilistic distributions are known." For data that do not meet this test "conservative values" should be used.

An alternate approach to conservative analysis, referred to as "best estimate plus uncertainty," is discussed in IAEA Safety Report 52. The benefits of the best estimate plus uncertainty approach are described in IAEA Safety Report 52: (1) it provides more realistic information about the physical behavior of the facility and thus assists in identifying the most relevant safety parameters, (2) the use of conservative assumptions can lead to predicting an incorrect event progression or exclude relevant physical phenomena, and (3) it provides information about safety margins which is not always obvious in conservative deterministic analyses. However, moving toward best estimate analysis with uncertainty involves several challenges. For example, it is difficult to develop a relevant, validated best estimate computational methodology for the analysis. In addition, sufficient data on critical parameters must be available so that a probabilistic distribution function can be developed that is statistically valid. IAEA Publication 1332, *Safety Margins of Operating Reactors—Analysis of Uncertainties and Implications for Decision Making,* (2003) discusses how, in safety analyses, it is customary to demonstrate that adequate margins exist between the true (but unknown) values of important, safety-related parameters of interest and the corresponding regulatory limits (requirements or physical limits) that, if exceeded, would result in adverse consequences (e.g., release of radioactivity).

Safety margins traditionally are established by relying on conservative models, conservative assumptions, and conservative interpretation of the analysis results. This approach has served the nuclear industry well; however, it can lead to employing additional safety measures and barriers that may not be strictly required, resulting in costlier and "overbuilt" designs. Also, the conservative approaches are not routinely able to identify the amount or degree of conservatism, nor do they describe the degree of confidence in the resulting conclusions and safety features.

4 TECHNICAL EVALUATION OF CONSERVATIVE AND BEST ESTIMATE ANALYSIS

4.1 *Introduction to conservative analysis and safety margins*

To illustrate the conservative approach to safety analysis, consider Figure 1 (shown at end of this paper). In the conservative approach, the results are expressed in terms of a set of deterministically calculated values for the *safety parameters of interest* (e.g., radioactive dose) that are expected to be more pessimistic than the true values of these parameters. The difference between a conservative estimate of the safety parameter of interest and the regulatory/requirement limit is called the *safety margin*. Conservatism is intended to make the calculated deterministic value more limiting than the true (but unknown) value of a safety parmeter of interst, to assure that the estimated safety margin is smaller than the *true safety margin*. The difference between the true safety margin and the estimated safety margin has been described by the IAEA (IAEA 2014) as the *overbuilt safety margin*.

As illustrated in Figure 1 (figures are shown at the end of this paper), when deterministically analyzing the safety parameter of interest the conservative safety analysis approach finds a single value of that parameter to compare to the regulatory limit/requirement (referred to as the "acceptance criterion" by the IAEA) and to determine if it is below that requirement/limit with a minimum, but undefined, amount of safety margin. In the conservative deterministic approach the degree of conservatism, and the true value of the parameter in relation to the conservative estimates, remain unknown. Generally, analysts believe that the conservative estimate provides an estimate of the safety margin smaller than the true margin, which by definition leaves some "overbuilt" margin.

As a simple example, consider the following:

Say the *Regulatory Limit* for the dose to the maximally exposed offsite individual (MOI) is 25 rem Committed Effective Dose Equivalent (CEDE).

If a *Conservative Estimate* of the dose in a given accident scenario to the MOI is calculated to be 5 rem. The *True Value* of the dose to the MOI might be 0.5 rem (if the accident scenario, accident parameters, and phenomena were exactly known).

In this case then the:

- Design Safety Margin is 20 rem
- True Safety Margin is 24.5 rem
- Overbuilt Margin is 4.5 rem

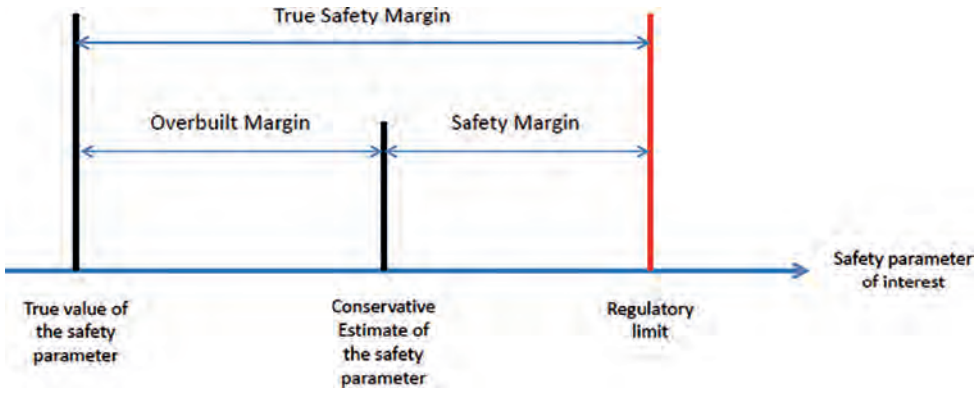

Figure 1. The concept of safety margins in conservative safety analysis.

Another way to look at the margins is the factor below the regulatory limit. In the above example, the Safety Margin is anticipated to be a factor of 5, the True Safety Margin is a factor of 50 and the Overbuilt Margin represents 90% of the True Safety Margin.

The means of assuring conservatism in deterministic safety analysis is the use of conservative models, codes, assumptions and data with the anticipation that these collectively yield pessimistic estimates of the safety parameters of interest, relative to the regulatory limit/requirements. An alternative approach to conservatism in safety analysis is the best estimate approach (as described in the NRC Regulatory Guide 1.157) to the assessment of the safety parameters of interest that includes formal quantification of associated uncertainties (or "best estimate plus uncertainty" to use the IAEA terminology).

In the best estimate plus uncertainty approach, best estimate models and computational methods, field and experimental data, and realistic assumptions are used to estimate the safety parameter of interest. Clearly, availability of such tools and data are critical to make this approach feasible. However, depending on the amount of data and information available, sometimes the best estimate approach can only provide a rough estimate of the uncertainties, which may need to be supplemented with some conservative assumptions. Conversely, when data and information are abundant, the best estimate results are frequently associated with less uncertainty. In the best estimate plus uncertainty approach, the amount of uncertainty may be expressed explicitly by obtaining the probability distribution of the safety parameter of interest and quantifying the safety margin. This concept will be discussed in more detail in the following section.

4.2 *Best estimate plus uncertainty approach to safety analysis*

In the best estimate plus uncertainty approach, the safety parameter of interest is treated as a random variable and the probability distribution within which the *true* value of the safety parameter of interest resides is estimated. Consider Figure 2, which shows a hypothetical distribution of a parameter. The true, but unknown, value of the safety parameter of interest resides somewhere within the span of this distribution. The regulatory limit/requirement of interest is shown within the range of this distribution.

Also, shown in Figure 2 is the *desired safety margin,* set to account for "unknown-unknowns." As such the safety parameter of interest should be below the regulatory limit/requirement *plus* this prescribed, desired margin.

In the best estimate plus uncertainty approach, the distribution of the safety parameter of interest, δ, is expressed by the probability density function (distribution function), $f(\delta)$, which is obtained by using realistic data, best-estimate models and codes. The best-estimate approach does not use conservative assumptions. Once developed, the distribution, $f(\delta)$, may be used to find *the probability* that the true (but unknown) value of the safety parameter of interest (expressed by the random variable, δ) is below the regulatory limit/requirement, D. In this approach it is this probability, and confidence associated with it, that forms the basis for safety decision-making. As such, in the best estimate plus uncertainty approach, the probability that the *true margin*, $(D - \delta)$, exceeds the *desired safety margin*, Δ, is expressed by:

$$Pr\left[(D-\delta) > \Delta\right] = Pr\left[\delta < (D+\Delta)\right] = \int_0^{D+\Delta} f(\delta)\, d\delta$$

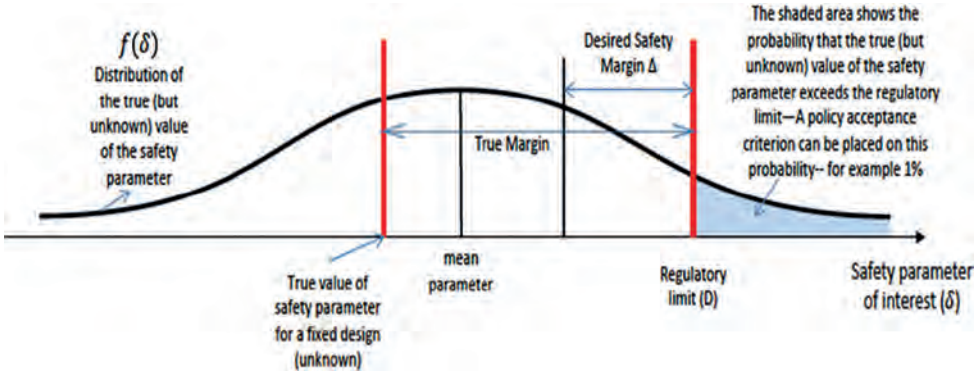

Figure 2. Conceptual depiction of the probability density function of a safety parameter.

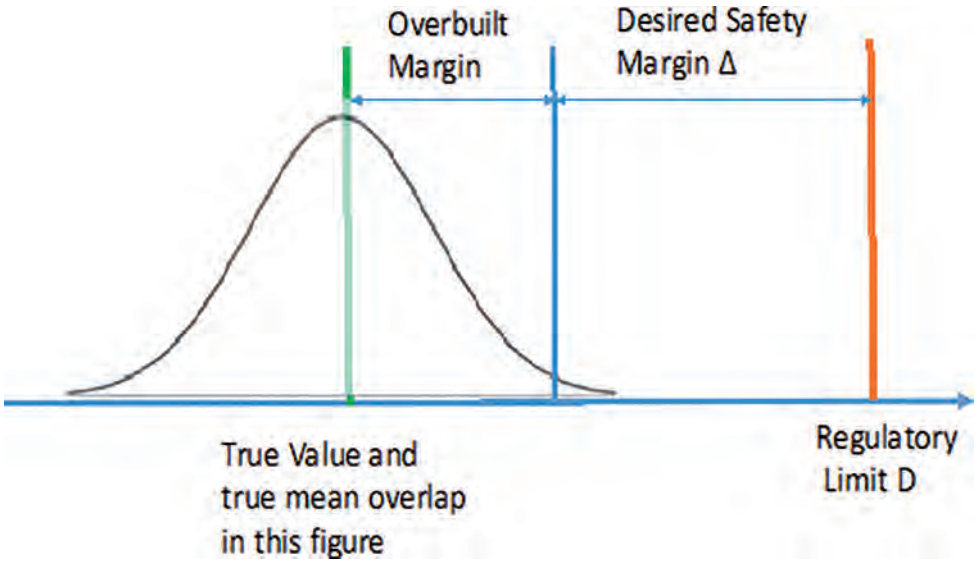

Figure 3. Potential effect of more information: True value of δ distributes narrowly.

Also, the probability that the requirement is not met would be:

$$\Pr(\delta > D) = \int_D^{\infty} f(\delta)\, d\delta$$

The benefit of the best estimate plus uncertainty method is in its characterization of the safety margin in light of the information, data and other evidence that is available. As the amount of such data increases, it is natural to expect that $f(\delta)$ becomes narrower (with smaller spread) and represents a small span within which the true value of the safety parameter of interest δ is most likely located. This concept is illustrated in Figure 3, assuming that more information about δ was available and resulting in much narrower $f(\delta)$, as compared to the probability distribution in Figure 2.

The best estimate plus uncertainty approach, as depicted in Figures 2 and 3, illustrates the cases where the true margin could become very large (for example, due to conservative initial design) by showing that $Pr\left[(D-\delta) > \Delta\right]$ could be close to unity, and highlights the presence of a large overbuilt margin. Such cases can provide a rationale to revisit the need for such large margins. This insight can only be achieved by a best estimate plus uncertainty approach, where the uncertainties associated with the margins are formally and quantitatively assessed–and confidence levels established–allowing

the overbuilt margins to be explicitly defined, explored and evaluated as to their necessity.

4.3 *Best-estimate models/codes versus conservative models*

In determining the probability distribution, $f(\delta)$, of the safety parameter of interest, one needs to have access to validated best estimate models and computational methodologies. In the conservative approach, estimates of the safety parameters of interest are obtained from conservative or bounding assumptions, and/or conservative models. To compare these two approaches, consider Figure 4. This figure shows a case where data about a safety parameter of interest are available. The conservative model (top-left branch), exemplifies an empirical (linear) model that *bounds* the data—meaning *all* the data fall below the model. As such, when the independent variable, x, takes the value x_1, the model estimates a dependent value (e.g., for a safety parameter of interest) of y_1 which is higher (more pessimistic) than all the data (evidence) that exist (note: if desired, it is possible to account for unobserved data, and draw the line above the cluster of the data with an additional margin, to cover for the unknown-unknowns).

Conversely, the best estimate approach would fit the empirical line (model) into the data using a regression analysis including the quantiles that describe the uncertainty about this model (top-right model and the bottom-right model are best estimate fits to the data). The model's upper and lower quantiles represent the model uncertainty using the residuals (expressed by the model error, ϵ). Unlike the bounding model, in the best estimate model, for a given value of a dependent variable x_1, produces a probability distribution for y_1. Similar to the conservative analysis, it may become necessary to make the best estimate model more conservative by introducing a bias to account for the unobserved data. The bottom left branch shows the same regression model of the lower right, but with an added conservative bias.

Impact of Conservatism When Multiple Parameters are Inputs to an Analysis.

When several parameters are inputs into an analysis used to determine a resulting "final" parameter or "figure of merit," which is then used to compare against regulatory limits, the amount of conservatism in the final parameter will be larger than the conservatism in each of the input parameters. This can result in large conservatisms in the resulting "final" parameter. In part, this reflects that fact that the uncertainty in the final parameter *does* increase as consequence of increases in the number of input parameters—each with its own level of uncertainty. When probability distribution

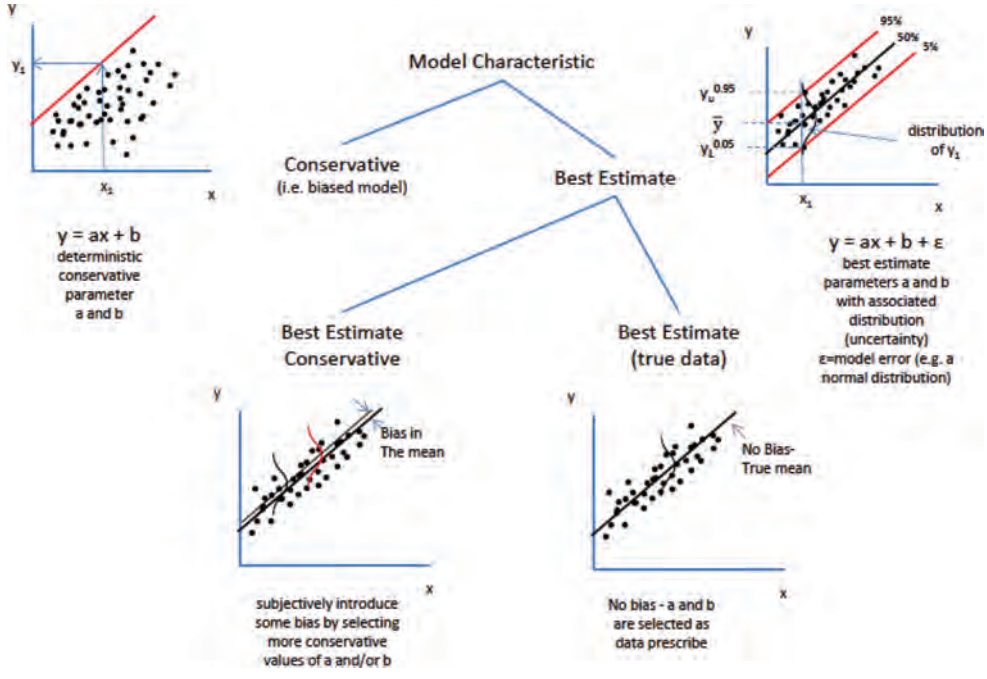

Figure 4. Comparison between best estimate and conservative models.

functions, along with associated confidence levels are not known (i.e., a "data-deficient" environment), industry standard approaches work to ensure—through conservative parametric values and/or modeling—that an appropriate level of conservatism is present in the final parameter. When this result is compared against the regulatory limit, several possibilities exist: (1) if the margin is small, more detailed analysis may be called for to more fully characterize the safety case, as discussed by the IAEA and NRC above; (2) if the margin is large and measures incorporated into system design and/or procedures are not onerous, further action may not be called for; and (3) if the margin is large and measures incorporated into system design and/or procedures are costly or result in overly complex operations, detailed analysis may be called for to assess the relative contribution of such measures to safety.

5 CONCLUSIONS

This paper first provided definitions of the term "conservative"—especially as it is applied to describe safety analyses. It then explored how the degree of conservatism and the degree of uncertainty from data supporting the safety analysis are linked in determining the margin of safety obtained in a facility design. It showed that, in theory, safety margins can be maintained with reductions in conservatism if corresponding reductions in uncertainty are made (through better data or improved analysis). This insight will help support decision-making on whether experimental or analytical resources would be best applied to making more detailed and sophisticated best-estimate analysis or by utilizing less sophisticated analysis with larger conservatisms which could lead to more resources spent on the facility design. A follow-on paper is planned to further investigate this with some example applications.

ABSTRACT: The paper deals with the level of citizen awareness in selected dangerous areas of Vysočina region and with their preparation for an emergency. In the theoretical part of the paper there was done an analysis of approaches to dealing with informing and training of inhabitants to emergencies in general as well as focusing on two selected subjects of Vysočina region. There were also discussed possibilities of training inhabitants and logistics information flows. In the practical part were created proposals for a preparation of the citizens for a potential emergency. First emergency we chose was a leakage of dangerous substances from ice skating park. There were also made a simulation of leaking of amoniak. The second emergency we focused on was a rupture of local dam. For both emergencies were made simulation to see its consequences.

1 INTRODUCTION

The article deals with the awareness of the population and their preparedness for a case of extraordinary event in 2 zones. Specifically, it focuses on emergency zones of winter stadium, where the dangerous substance, ammonia (NH_3), can escape. The second emergency zone is the flood territory of the dam Vír in the Vysočina.

According to §15 of Act No. 239/2000 Coll. "The municipal office familiarizes the population with the character of the possible threats in the region. Then the office also familiarizes them with the prepared rescue and liquidation works and the protection of the population. The office also organizes their training" (Act No. 239/2000). From the law it is clearly showen who has the task to inform, or to train the population. However there is not mentioned anywhere, how often the training should take place. This gap in the law is one of the aspects that cause the ignorance of the population. However, it is not possible to lay the blame only on the gap in the law, because the iniciation of the population is also very important nowadays. In today's world which is full of all kinds of inventions, and due to trends of travelling and learning about foreign countries, people often neglect the importance of knowledge area of their own residence. Sometimes it also happens that even when a citizen tries to get some news, it is impossible.

The paper is focused on the awareness of the population. So there was at the beginning of our work elaborated a questionnaire for the residents of vulnerable areas and for the authorities, under which the affected area belongs to. The question was if they carried out the training on possible scenarios of threats and whether the citizens know how to act in the case of an emergency or if they know where to go to get that information. The questionnaire was developed primarily to obtain an objective view on the situation and for the analysis of the current state in selected territories. The main goal of our work is to find an acceptable solution of the issue or at least to deepen the awareness and knowledge of the population in selected territories.

2 ANALYSIS OF APPROACHES TO ADDRESS THE AWARENESS AND TRAINING OF THE POPULATION

2.1 *The dam Vír*

The dam Vír is located in the Vysočina, location of the Vysočina region in the Czech Republic is shown in Figure 1, on the flow of the river Svratka. It serves as a source of drinking water for the area called Žďárské vrchy and the surrounding areas and a part of Brno. The area of flood planning for this reservoir is located along the river Svratka.

Figure 1. Location of the Vysočina region in the Czech republic.

It is reported that the possible flood wave would most likely reached up to the Brno dam, where it could cause considerable complications.

The total volume of the reservoir of the dam is 56,193 million m^3 and the size of the flooded area is 223,6 ha. The concrete gravity dam is in its crown 390 m long and 9 m wide. Harmless water drain under the dam is 55 $m^3.s^{-1}$. On the left side of the dam is located a water power plant.

According to the model of the passage of special flood caused by the breach of the dam was determined by the extent of the flood area. This model implies that the extent of the flood area lies in the stretch from the dam to the city Brno. Vulnerable place, which this work considers is the village Vír, which is located in the immediate vicinity of the dam Vír. Other endangered sites are in respectively the village Koroužné, Švařec, Štěpánov nad Svratka, Ujčov and Lower Čepí. Of course endangered sites also include other municipalities, but this work deals only with the territory of the Vysočina region.

Warning according to the operating plan for special flood is done by the owner of the dam Vír by using his own sirens and notifies the operational information centre of the fire rescue service (IRS) of the region about the dangers of specific floods. The IRS of the region then immediately notifies threatened population and also provides information about the development of the emergency (The operational plan for a special floods, 2017).

2.2 *Winter stadium*

The capacity of the winter stadium in Žďár nad Sázavou is 3500 visitors (Sportis, 2011). To the cooling of roller surface is used ammonia (NH_3). Ammonia is under normal conditions a colourless gas with a typical pungent odor; it is alkaline, irritant and caustic. Ammonia is very toxic for aquatic organisms (especially fish). Its very good solubility in water also plays an important role too. Also plants can be negatively affected if they are exposed to its higher concentrations both in air and in water. It participates in the acidification of soils (The integrated pollution register, 2017).

Due to the properties of ammonia there could occur an ecological disaster, because around the selected stadium is a river Sázava.

The ammonia has during short-term exposure of the person, irritating effect. It can burn the skin and eyes. It causes cough and difficulty breathing. In a concentration higher than 3.5 $g.m^{-3}$ is even short-term exposure the lethal. In the current environment is the concentration of ammonia so low that it does not entail almost any risk. Its advantage is an intense pungent odor, which highlights its presence in the air before it could rise to a dangerous level (The integrated pollution register, 2017).

In the cooling device of the winter stadium is the total charge of ammonia of 6000 kg (amount of ammonia is under the current emergency plan, in fact it is 1400 kg). This amount is divided into three parts—the condenser, the expansion tank and the ice-skating area (Trávník, 2016).

The zone of emergency planning for the winter stadium is about 130 m. In that zone there is a sports hall, 2 restaurants and a few family houses, which is located on the edge of the collision zone.

Due to the security and availability of hazardous substances and a large number of people at hockey games and other, may be the winter stadiums misused to commit a terrorist attack intentional discharge of a dangerous substance or destruction of the device (Zeman & Břeň & Urban, 2017).

Warning according to the emergency plan of the winter stadium in the release of ammonia is performed by the doorman of the winter stadium after the notification of the engineer. He begins to organize the measures in the premises of the winter stadium (according to existing emergency response plan). Alarms are divided into 3 groups according to the amount of leaked substance:

1. The first level of threat—a leakage of ammonia to 1 000 kg, if the spill threats only object of engineering.
2. The second level of threat—a leakage of ammonia to 2 000 kg, if the spill threats the entire object.
3. The third level of threat—a leakage of ammonia up to 3 000 kg, if the spill threats area of winter stadium and outside emergency zone in the direction of the wind (Trávník, 2016).

A liquidation of the accident in the first degree is undertaken by the staff of the ice rink with the use of a IRS of the winter stadium. Liquidation of the accident the second and third tier is governed by the emergency commission headed by the head of the winter stadium, who will call the appropriate personnel with cooperation with IRS (Trávník, 2016).

Due to the maximum range of the zone of emergency planning (130 m) it is necessary to warn about the emergency all persons who are in the zone of emergency planning by the signal general warning (Trávník, 2016).

Security protection of persons is carried out through escape routes (two kinds):

1. from the space of the winter stadium. There are two entrances in the main building and two entrances in the eastern and western bleachers. Escape routes from the machinery spaces are in addition to the main entrance to the lobby even to the back of the winter stadium (to cooling towers) and in front of the garage into the hall.
2. from the space of a vapour cloud of ammonia against the direction of the surface wind (Trávník, 2016).

Escape routes will be to the population advertised by radio device. All escape routes are properly marked and are kept passable. Movement of persons on the escape routes will be monitored by the riot service, which will guard the access to the infested area (Trávník, 2016).

To determine the state of awareness of the population in the emergency zone of the winter stadium was used questionnaire method. The residents of those zones and visitors as the winter stadium, sports hall, located next to the winter stadium, was submitted to a questionnaire of 9 questions.

3 THE RESULTS OF THE SURVEY

In the individual, above-mentioned zones of danger, it was examined, how are the residents prepared for emergency and whether they have enough information. Residents were submitted to a questionnaire of 9 questions.

3.1 *The results of the survey in the emergency zone of the dam Vír*

The number of persons surveyed in individual municipalities in the flood planning zone of the dam Vír is shown in the Table 1.

Table 1. Number of persons surveyed in the flood planning zone.

Municipality	Number of answered questionnaires
Vír	32
Koroužné	19
Štěpánov nad Svratkou	17
Ujčov	12
Total	80

On the first question, "Do you know that the place of your residence is located in flood territory?", replied to 100% of the respondents that they know about it.

On the second question, "Do you know where to get more information about the threat?" responded the majority of respondents positively. The answer "Yes, I know." checked 70% of the respondents. The remaining 30% didn't know where to get the necessary information.

The third question examined whether there is any training about what to do in case of emergencies. Approximately 57% of the respondents replied that the training is in progress, 37% did not know and the remaining 6% claimed that training is conducted. The answers of the respondents were compareted with the replies of the representatives of the municipalities in which the survey was conducted. It should be noted that municipal representatives about any training didn't know anything.

The respondents, who at the third question answered in the affirmative, they were asked about the evaluation of the appointed training. Respondents argued that the training was satisfied and beneficial. Unfortunately however, could not recall how often or when was the last time such training was held.

An important part of the questionnaire was to ascertain the opinion of citizens on their readiness for an emergency, whether they would welcome the introduction of the training and what form would this training should have. Only one fifth of the respondents had shown interest in possible training courses to attend. A total of 55% of respondents would prefer a combination of lectures and manuals, 22% only lecturing and the remaining 23% would meet the processed documents (manuals).

The fifth question examined, and vetted knowledge of the population, whether they know the manner in which they will be informed that an exceptional event has occurred. Interviewees had a choice of three options. The first option was that they hears from neighbors, the second option was that a warning signal will sound and the third, that they will start to ride the car of the IRS, especially car fire brigade and the Police of the Czech Republic. All of those interviewed, up to 8%, chose the answer that a warning signal will sound. Of those 8%, chose the answer: I learn it from the neighbors, with the argument that it learns more and earlier.

Question number 6 looked at whether the residents of the affected territory think that they are prepared on the emergency. To this question, respondents split almost in half. The first half is according to the response to emergency adequately prepared and the second on the contrary is not.

To the seventh question, answered all the questioned correctly. Had a task to choose the correct series of numbers to the IRS.

First aid can according to the eighth questions provide 92% of the respondents.

The last question examined whether the population knows what evacuation bag includes. It should be noted that in the questionnaire was the choice of just yes or no answer. However, all those who answered yes, they were verbally tested if they really know, what an evacuation bag should contain. The others were at least advised. About 52% of the respondents answered that knows what features to include evacuation bag.

3.2 *The results of the survey in the emergency zone of the winter stadium*

The number of persons surveyed in the emergency zone of the winter stadium is shown in the Table 2.

The first question was focused on whether the interviewees know about the potential dangers that winter the stadium represents. Only 30% of respondents know that it is winter stadium a source of danger.

The second question asked, whether the citizens know where to obtain more information about this risk. The answers were also alarming, only 17% knew where to get the information.

Due to the low number of informed respondents, it was almost unnecessary to ask the third question, whether they were ever trained on what to do in case of leakage of ammonia. Nevertheless, it was found that some training completed 5% of the respondents; it was for them in some way beneficial and indicated that such training is conducted about once every 2 years.

The fourth question asked respondents whether there would be interested in any training. Only 38% of the interviewed would be interested in training. They would prefer a combination of lectures and manuals or separate lectures.

To the fifth question "Do you know how you will be notified of the fact that there was an emergency?" a majority of those surveyed answered correctly. Only a small part of the chosed a different answer.

Table 2. Number of persons surveyed in the emergency zone of the winter stadium.

Place	Number of answered questionnaires
Winter stadium	56
Sports hall	44
Residential houses	3
Total	103

The sixth question dealt with the feeling of preparedness of the respondents to such emergency. A total of 83% of respondents do not feel sufficiently prepared for the emergency.

Any of the respondents do not own any protective agent for the case of leakage of ammonia.

On the contrary, everyone, as we found out in the eighth question, knows the emergency numbers.

First aid in case of contact with ammonia can provide, according to the answers to the ninth question, 26% of respondents.

From the responses it can be concluded that the awareness among the population regarding the aforementioned winter stadium is alarming and it is necessary to take care about this issue more.

From the questionnaire sent to the municipal authority, department of emergency management, in Žďár nad Sázavou, which was focused on acquiring information about ongoing or planned trainings. It was found that no training do not take place, even in the near future do not plan. The population was according to the responses informed about the issue of risk arising from the winter stadium a few years ago through the local press.

4 EVALUATION OF KNOWLEDGE OF THE POPULATION

Although education in this field at primary, secondary and higher professional schools required by law, in many cases, does not take place. Or it takes place only to a very low level.

From the results of the questionnaire survey under the dam Vír shows that the majority of the population, living in the village Vír, Koroužné, Švařec, Štěpánov nad Svratkou and Ujčov is well informed of the potential danger. However, there is the problem that there is no training due to this threat. The affirmative should be rated and that the population knows the emergency numbers and can provide first aid. But more than half of the respondents could not wrap evacuation luggage according to the investigation.

The positives

- Training is conducted in the framework of the voluntary fire brigade.
- Awareness is very good.
- People know where to get the information.
- Knowledge of emergency numbers.
- The majority of can provide first aid.

The negatives

- Official training in the scope of the village perimeters.
- Ignorance of the content of the evacuation luggage.

The results of the survey the emergency zone of winter stadium, follow that a substantial part of the population, whether living in the zone of emergency planning or visitors and sports hall, unaware of the potential danger.

The positives

- The population knows the emergency numbers.
- People know how they will be notified of the emergency event—warning signal.
- Some respondents were trained what to do in case of leakage of ammonia.
- Training sessions are carried out at least in the context of some of the schools in Žďár nad Sázavou.
- The municipality to warn population about the issue through the local press, several years ago.

The negatives

- The municipality does not perform training.
- Disinterest of a large number of citizens about the training.
- Training is not in the foreseeable future planned.
- People do not know where to get the necessary information.
- Doesn't know how to provide first aid in case of contact with ammonia.
- Insufficient readiness of the population to this extraordinary event. Obec neprovádí školení.

In determining the current state of the issue has been identified in the area of implementation of the statutory training of the population of the municipalities. This lack manifested itself especially on the ignorance of people. Surveyed population showed large gaps in knowledge of population protection, information, first aid and the total unpreparedness on the emergency.

In contrast, the population living in záplavovém territory under the dam Vír is sufficiently informed and ready for the emergence of floods. People know where to get information about the dangers, knows how to provide first aid. In this area it is necessary to arouse awareness about the content of the evacuation luggage.

After evaluation of the results, we have decided to undertake the modelling of leakage of hazardous substances from the winter stadium and, subsequently, to prepare and carry out an exercise on this to emergency.

5 APPLIED METHODS

An extraordinary event was chosen such that results from threats to the environment. To leakage of hazardous substances from refrigeration equipment occurs quite often and is still a current issue. Among other methods used for the purposes of the work are undoubtedly a literature review and questionnaire method, from which we emerged some threats.

Further there was used the method of simulation, in which were used the average values of the long-term monitoring of weather conditions in the site of the emergency and the expert estimation of the specified rate of leakage of hazardous substances. When using the method of constructive simulation is simulated entity controlled by the simulated operator. Constructive simulation is kind of simulation, when the model contains everything needed to during the simulation, replaced the original, including humans. Control of this type of simulation is implemented using the user interface. The display of the synthetic environment is similar to a topographic map. Constructive simulation is used in a variety of distinctive levels for different types of operations to deal with emergencies (Kanj & Flaus, 2015).

6 MODEL OF LEAKAGE OF HAZARDOUS SUBSTANCES FROM THE STADIUM

On the basis of the requirements for the format of the output was carried out the evaluation of the available simulation programs for the modelling of leakage of hazardous substances. There were taken into account the information about potential emergencies and the input data, which were known about the emergency. Other relevant data were long-term hydrometeorological data from the vicinity of the emergency. Due to the lack of input information was selected by the simulation program TerEX, which allows working with a minimum of input information. For more details of the evaluated programs were published in the article The Use of Simulation Programs of Leakage of Harmful Substances for Crisis management (Barta, 2015).

The main factor when entering the input data was the amount of the leaked dangerous substance. Due to the fact that the system of the winter stadium is designed so that it is divided into three independent parts with the possibility of swapping the cooling medium into any of them, it is not expected that in the event of a crash missed more than 60% of the amount that falls on 1/3 of the technology. This corresponds to approximately 280 kg of ammonia. Basic input data:

- Model: PUFF—Single release of boiled liquid with rapid cloud evaporation
- Substance: Ammonia
- Temperature: 7°C
- Total amount of escaped liquid: 280 kg
- Ground layer wind speed: 7 m/s
- Sky Overcast: 0%

- Time of incident event occurence and continuance: Night, morning or evening
- Type of atmospheric stability: D—isothermic
- Surface type in direction of substance spreading: Inhabited area

On the basis of the determined average temperature, the average values of the direction and force of the wind, was in the program TerEx performed a simulation whose result is shown in Figure 2.

For the determination of the extent of the emergency was output from the modeling program exported into the map base. As seen in the sector of Blue part in Figure 3, when the prevailing west wind was threatened residential area with several family homes. It was the basis for the processing of documents for the exercise called the leak of ammonia from the winter stadium in Žďár nad Sázavou.

For the realization of the exercise it was necessary to choose a suitable and available simulation program. In the framework of the project research we addressed this issue and then we have established the basic criteria, which has a simulation program for the implementation of practical exercises meet (Barta et al. 2016), (Urban et al. 2017), (Marana et al. 2016). Among the basic criteria belonged to the user friendliness and the variability of the simulator:

- Scene Editor;
- Implementation of External Data;

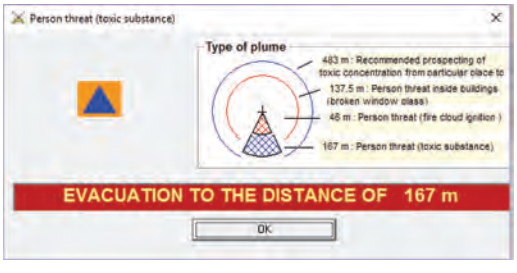

Figure 2. The output data from the program TerEx.

Figure 3. The plot of the leakage of hazardous substances into the map.

- Simulation Level (Teams or Individuals)
- Communication Possibilities;
- Continuity in Relation to the Surrounding Environment.

On the basis of comparison was evaluated as the most appropriate simulation program SIMEX, which is built on the platform of the simulator WASP (Barta & Vašková & Urbánek, 2016).

For the creation of the exercise was the best based on emergency, which become in the past. At the winter stadium in Žďár nad Sázavou there was a leakage of ammonia on 8. June 2011. On this basis, it was taken over and modified the scenario of the exercise.

6.1 *The scenario of the exercise*

8 June 2011 at 18:18 pm adopted Regional operational and information centre of the Vysočina IRS report of a leakage of ammonia from the winter stadium in the street Libušínská in Žďár nad Sázavou. To the location of the event rolls out unit of professional firefighters from the station Žďár nad Sázavou and volunteer firefighters. By carried out survey of the site firefighters found that the ammonia is leaking from a cracked pipe behind the stadium. The place was immediately marked as a danger zone. There were found two persons on the spot intervention with breathing difficulties and called an ambulance. Firefighters ordered to evacuate the population from the nearest houses downwind. They also very quickly managed to prevent further leakage of ammonia. Effluent water with a weak concentration of ammonia fell into the river, a direct threat to the environment and to the death of fish did not occur.

Before the termination of the intervention, there was carried out a final measurement with a negative result and units returned back to station.

On the basis of the scenario exercise of the ammonia leakage, it was necessary to define all entities that create, complement and comprehensively participated in the exercise. On the basis of the analysis carried out exercises with the leakage of a hazardous chemical (ammonia) to summarize each of the entities, which have been successively fed into the simulator (Oulehlová et al. 2016). The decisive step was creating lists, which contain basic clusters of entities, in particular for the area:

- Staff—as a threat to people in the winter stadium and in its vicinity, the crew of the responding units, people who are watching, etc.;
- Technical means—for example, vehicles of emergency units, auxiliary vehicle, vehicle simulating normal transport in the Žďáru nad Sázavou, etc.;
- Environment—map data of the place of leakage of hazardous substances and the terrain database with the required layers for a simulator SIMEX.

Table 3. Plan the connection of entities dealing the leakage of ammonia from the winter stadium.

Unit	Telefonne number	Work station
Regional operational and information centre	112	PS15
Fire brigade–Žďár nad Sázavou		PS02
The commander of the intervention		PS01
Units of the volunteer firefighters—Žďár nad Sázavou 2		PS03
Police of the Czech Republic	158	PS07
Emergency medical service	155	PS05
The mayor of the municipality of Žďár nad Sázavou		PS10
Management of the exercise		PS řídící
Members of the tip-off		PS13
Information line	1188	PS12
Emergency accommodation of persons		PS14
Evacuation center		PS09
Position available		
Position available		

In Table 3 are in the plan of merger provides basic entities for the resolution of an incident.

On the basis of defining the entities, there have been determined their role and activities envisaged in the framework of the scenarios dealing with emergencies (Okstad, 2016). The exercise is currently being prepared and will serve for the practical training of workers, emergency crews, and the general public to obtain information about a possible danger, its extent and consequences. In but not least, the citizens hear a lot of information how to maintain when the occurrence of an emergency with the leakage of dangerous substances.

7 CONCLUSIONS

Total awareness of the population about the risks and threats that are in their surroundings is very important. Also basic reaction and behavior of the population upon the occurrence of extraordinary events are dependent on the awareness of the population.

In the preparatory phase of the exercise had very proven freely available materials on the website of the municipality of Žďár nad Sázavou and Vysočina region. There were obtained very useful information for the preparation of exercises for informoování of the population.

This revealed that for obtaining sufficient information about the impending danger from the winter stadium (release of ammonia), inhabitants of the town of Žďár nad Sázavou have sufficient options, but these options are not used.

In the framework of the forthcoming exercises instructor received the basic information about the issue, increased knowledge about crisis management and theoretically prepared for work in the selected simulator. It was a very good basis for a workout that is focused on practice management functions, implementation of established procedures and clear communication between individual practitioners of entities.

Residents of the city may attend planned exercise, and to realize possible dangers and to obtain the necessary knowledge not only for the case of the ammonia leakage, but it will acquire a basic knowledge how to behave in emergencies, with the leakage of dangerous substances.

ABSTRACT: In the present study, the relationship between survey data regarding work conditions and safety performance is investigated. We transform a questionnaire into several factors which involve work environment, safety climate and organizational aspects, and run a series of analyses on repeated cross-sectional data in order to predict occurrences of Hydrocarbon (HC) leaks and acute spills. We apply survey data from 49 500 respondents across eight distributions from 2001 to 2015. Methodically, we conduct Analyses of Variance (ANOVA), Principal Component Analyses (PCA) with Cronbach's alpha tests, and lastly multiple logistic regressions. Our results give some support to the hypotheses—that factors of safety climate and psychosocial aspects may be predictors of safety performance. The results and inherent qualities and weaknesses of the present study are discussed, and recommendations for further research are presented. This paper is a contribution to the development of proactive lead indicators appropriate for safety management.

1 INTRODUCTION

Preventing hydrocarbon (HC) leaks and acute spills to the environment are incidents that are of great importance to the industry and society. HC leaks can in the worst-case lead to major accidents, especially due to the inherent ignition and explosion risk. Acute spills have person injury potential, however mainly they pose a concern for the environment. Acute spills from the oil and gas industry on the Norwegian Continental Shelf is subject to high focus from both regulatory authorities and the civil society. The Petroleum Safety Authority annually issues a report on the risk level for acute spills and states that there is a need for more knowledge on the conditions that lead to acute spills (PSA, 2017). In the present study, we utilize precursor survey data and technical data related to offshore installations to investigate the conditions that are associated with HC leaks and acute spills. The survey data is obtained by the standardized questionnaire called the 'Norwegian Offshore Risk and Safety Climate Inventory' (NORSCI), which is constructed to measure health and safety climate and the risk for occupational health and accidents (Tharaldsen et al. 2008). The study focuses on individual and organizational aspects measured by a survey instrument, in order to contribute to the development of valid safety indicators that may be used as "early warnings".

1.1 *Safety indicators*

Safety indicators is used in this paper to denote the independent variables used in the analysis. An indicator may be defined as a measurable variable that can be used to describe the state of a phenomenon, when the actual state of the phenomenon might be unknown (Haugen et al., 2012). Safety indicators may be seen as observable measures that should give information concerning the safety performance (Kongsvik, 2012). An indicator does not necessarily imply that there is a causality between the content of the indicators and the safety performance. A measure may be used as an indicator as long as there is a correlation with the phenomena one want to gain knowledge about. One may differentiate between lead indicators and lag indicators. Lead indicators are considered proactive performance indicators (Dyreborg, 2009). Lag indicators are conceptualized as outcome measurements, usually represented as survey items measuring the respondent evaluation of the work practice or safety level in their organization (see e.g. Kongsvik, 2012) or different types of accident statistics (see e.g. Høivik, 2007).

The question whether survey data are lag indicators or lead indicators of safety performance should be addressed as a part of the explorations of the relationship between survey data and safety performance. It seems reasonable that both directions may apply; one could believe that earlier safety records may influence the responses of a respondent in a survey, but this may also be influenced by the conditions leading to the safety records.

Kilskar et al. (2016) have conducted a review of 174 publication addressing safety indicators, in order to gain information regarding the relation between indicators and accident risk. They conclude that there is a general lack of documented valid indicators, and that there is a need for more empirical research.

The present study's analysis is a contribution towards the ambitions within the community of safety research to close this knowledge gap. An innovative aspect of this research, in relation to previous research, is the attempt to explore and develop indicators for acute spills from the oil and gas industry.

1.2 *Organizational conditions and safety performance*

Vinnem (2012) have conducted an analysis of HC leaks in the Norwegian offshore industry based on reported incident data. In his analysis of operational circumstances for the leaks, he found that 55% of the leaks where related to human interventions. Among these, 82% of the leaks could be attributed to latent errors, e.g. errors due to maintenance and modifications. These findings support the quest to explore the possible relations between measurement of human and organizational factors and HC leaks.

Several of survey instruments have been developed in order to measure conditions and phenomena that are assumed to influence safety performance. Various concepts have been used to denote these phenomena. Concepts that are relatively common in use are *safety culture*, *safety climate, and organizational and psychosocial factors.* In addition, there are different concepts and survey instruments that are designed to measure phenomena that are not directly safety-related, but where researchers have used these instruments to test possible relations with safety performance (see e.g. Høivik 2007, Bergh et al. 2014, Olsen et al. 2016).

Measuring safety culture and safety climate has been extensively debated regarding both the definition of concept and the concept validity—what are we actually measuring? In spite of the lack of consensus regarding what is actually measured, it has become a relatively common practice in some industries to conduct these measurements.

Safety climate has been conceptualized as a representation or a subset of safety culture (for example Cooper & Phillips, 2004; Zohar, 2003). Others argue that it is a reflection of the safety culture, i.e. a kind of representation of the somewhat vague and intangible safety culture (see e.g. Guldenmund, 2000; Mearns & Flin, 1999).

Safety climate has been defined as the set of perceptions that employees share regarding safety in their environment (Zohar, 1980). A safety climate questionnaire consists of a broad range of items where the respondents are asked to give responses that are assumed to reflect their perceptions of safety related topics. Common features of a safety climate construct include management/supervision, safety competence, safety systems, work pressure and risk (Flin et al., 2000).

A safety climate questionnaire often consists of items aimed to reflect the respondents' perceptions of how safety is valued in their organization (Griffin & Neal, 2000); hence these perceptions should ideally form the frame of reference for employees about the behavior that is expected, supported, and rewarded (Zohar, 2010). However, some safety climate survey instrument consist of items that measure not only perceptions of how safety is valued, but also how they describe their own work practice, and perceive and evaluate organizational conditions such as e.g. procedures, leadership, communication, competence etc.

Whereas safety climate survey tend to address how employees make sense of their work environment, their values and attitudes, psychosocial surveys instrument seems to be more oriented towards conditions that influence their cognitive and physical capacity. Simplified, one may claim that psychosocial surveys focus more on conditions that theoretically are assumed to influence human error (reflected in the use of concept denoted as e.g. "stress", burnout", "mental exhaustion", see Bergh 2014), whereas safety climate address conditions that influence violations and lack of compliance.

1.3 *The relationship between safety climate and accident statistics*

There have been several previous attempt of exploring the relations between survey data and safety performance by the use of data from the Norwegian oil and gas industry. Several of these studies are based on survey data obtained by the NORSCI instrument.

Tharaldsen et al. (2008) have investigated the association between five safety climate dimensions and accident rates. The researchers found statistically significant, but rather weak correlations between safety climate and accident rates. Similarly, Hestad and Lilleheier (2009) found correlations

between safety climate and HC leaks. Kongsvik et al. (2011) explored the leading and lagging qualities of safety climate. In line with Hestad and Lilleheier (2009), they found that safety climate could be used as both a leading and lagging indicator for HC leaks; more negative safety climate scores were associated with an increased number of HC leaks the following 12 months. HC leaks one year before measuring safety climate also correlated negatively and significantly with the safety climate indicator; more HC leaks were associated with worse safety climate scores. The correlations were medium sized. Vinnem et al. (2010) found that a safety climate measure together with barrier failure data explained 37% of the variance in HC leaks on the installation level. They also found that the safety climate measure was the strongest predictor of leaks.

Gilberg et al. (2015) found a significant relationship between safety climate, and safety performance conceptualized as HC leaks and dropped objects. In their study, which consisted of data from 2001–2013, they also found that the leading effect was stronger than the lagging.

In additions to these analysis that have combined NORSCI survey data and safety records, there have also been conducted several studies where items in the NORSCI survey data has been used as both independent and dependent variables (Kvalheim & Dahl, 2016). They found dimensions in the survey data to be a strong predictor of accident precursors such as self- reported safety compliance in the oil and gas industry; explaining roughly 27% of the variance in safety compliance over a period of 7 years.

There has also been conducted explorative studies on Norway regarding the relationship between survey data and safety performance, by the use of other survey instrument than NORSCI and with other samples of respondents. Høivik et al. (2007) have analyzed possible relationship between items in a general work environment survey and health and safety records (occupational accidents) in one oil and gas company. They found that management style and trust in the manager are important factors for predicting personal injuries. Bergh et al. (2014) have analyzed the relationship between a psychosocial risk indicator and HC leaks frequencies, with a sample from one oil and gas company. Both survey data and some technical data (variables/indicators: age, weight, number of leakage) were used as independent variables (lead indicators). They found that the survey data significantly counted for variations in HC leaks. They found no significant relation between the technical indicators and leaks.

A general work environment survey within one single company was also used in a study by Olsen et al. (2016), in order to predict HC leaks. They found that several identified dimension in the survey data, by the use of factor analysis, where significantly related to HC leaks.

Internationally, there has been conducted some meta studies regarding relationship between survey data and safety performance. Meta studies by Clarke (2009) and Christian et al. (2009) on the relationship between safety climate and accident statistics/injuries demonstrate medium size correlations between (–0.22 and –0.39 respectively). Payne, Bergman, Beus, Rodríguez, and Henning (2009) found a negative correlation between safety climate and releases/contamination and property damage one year after measuring safety climate in the process industry. A meta-analysis considering the job-demands-resources model (Nahrgang et al. 2010) found that job resources like a supportive environment were related to safety outcomes (accidents, injuries, adverse events and unsafe behavior) in several industries.

Examples of one individual studies are Swaen et al. (2004). They conducted a cohort study and found that high psychologic job demands were a risk factor for being injured in occupational accidents in a wide range of companies and organizations. Swaen et al. (2004) investigated sleep among 47 860 individuals, and found a relationship with self-reported sleep and a risk of fatal occupational accidents.

Many of these previous studies, with notable exceptions, have conducted analyses on small data sets, often because either the number of installations has been low, or that the number of incidents has been low.

1.4 *Hypotheses*

The present study adds to the current research base by including new and updated data on oil and gas installations, and a new response variable with acute spills. Acute spills have a lot of incidents and thus serves as a response variable with better inherent statistical power. In addition, we broaden the scope of survey items, not only safety climate questions, but also organizational factors and psychosocial work environment factors combined.

Based on the discourse regarding relationship between survey data and safety records, we hypothesize the following:

H1: *Negative scores on factors concerning organizational, work environment and safety climate will be significantly related to higher probability of HC leaks the year after measurement*

H2: *Negative scores on factors concerning organizational, work environment and safety climate*

will be significantly related to high probability of acute spills the year after measurement

H3: *The factors will be significantly related to HC leaks and acute spills when controlling for operator, installation type and area of operation*

2 METHOD

2.1 *Data and variables*

The PSA gather data from the companies operating on the NCS each year: this is data regarding over 20 different defined scenarios of hazard and accident (DSHA) as well as maintenance data and barrier test data. As a part of this, there is a biannually survey, using 'Norwegian Offshore Risk and Safety Climate Inventory' (NORSCI) as instrument. This study make use of the survey data, accident records regarding HC leaks and acute spills, data regarding the types of installations and the area of the operations.

We have conducted extensive data cleaning and quality assurance. This was necessary due to different ways of reporting across data sources and operators.

As a part of the preparation, we have used the concept of *installation years*. Each observation in the analysis consists of one installation year, that is, for installation X in year Y we have survey data, HC leaks and acute spills. Further we have data for the same installation every two years later. This means that each installation included in the study have a maximum of 8 observations.

The installations are coded into types; fixed, floating and mobile units (rigs). Fixed is used as a reference category in the logistic regressions.

2.2 *Survey instrument (lead indicators)*

In total, the data consists of eight distributions of a safety and work condition survey through the RNNP study, from 2001 to 2015. The data is gathered by the PSA. The survey covers safety climate factors as well as general health, psychosocial work environment factors and background questions.

For our analyses, the data from catering and cleaning crew was excluded from the present study due to their expected small impact on the causality of HC leaks and acute spills. The total number of respondents in the survey data is 69 111. After excluding responses without reported installation name, N was 57 550, and after excluding catering and cleaning crew the final N totaled 49 500.

The questions generally are answered on a scale from 1 to 5, where 1 equals a "positive" answer. However, we have recoded questions so that a high score equals a "positive" answer.

2.3 *Safety performance (lag indicators)*

We include two variables measuring safety performance, from 2001–2016; HC leaks and acute spills.

The HC variable is a dichotomous variable with number of HC leaks over 0.1 kg per second throughout the year. For the analyses using HC leaks, we excluded mobile units, such as drilling rigs, which do not have process areas for hydrocarbon in the same extent as fixed installations like oil platforms and FPSO ships. We also excluded normally unmanned installations and data related to fields rather than installations. We coded the variable so that 0 = no HC leaks, and 1 = one or more acute spills.

Similarly, we dichotomized a variable of the number of acute spills throughout the year. The acute spills were divided in three types; *chemical, raw oil,* and *other oils*. We made a binomial variable where 0 = no acute spills and 1 = one or more acute spills. As in HC leaks, we also excluded normally unmanned installations and data related to fields rather than installations.

2.4 *Research design*

The present study is a repeated cross-sectional study with several data sources. This means that temporal variations may be investigated, and that common method bias is reduced. A design using accidents and incidents as a dependent variable also allow discussion of the measures' predictive validity.

Our analysis may be divided into four steps; exploratory bivariate tests with ANOVA, dimension reduction techniques with principal component analysis, tests of reliability with Cronbach's alpha, and lastly a multiple logistic regression analysis.

The explorative *Analysis of Variance* (ANOVA) was related to H1 and H2. A central question to ask when conducting these repeated cross-sectional studies was: Does negative response to organizational factors lead to accidents, or do accidents lead to certain perceptions of the work environment and organizational factors? Which one is the strongest? It may be argued for both directions of causality, and therefore we chose to test both directions of causality in the first steps of the study.

In the ANOVA test, we ran a series of analyses where we compared the means of the survey items by the two levels of the outcome variables (0 = no incidents, and 1 = one or more incidents).

The ANOVA test is similar to a Student's t-test as $F = t^2$, with identical p-value, for analyses with two groups.

In the following analytic steps, we chose to go further with the items significantly related to HC leaks and/or acute spills, but only if they were either only significantly related to the future (leading) or better as a predictor of the future than as a product of the history (lagging).

The *Principal Component Analysis* (PCA), commonly denoted as a *factor analysis,* was conducted in order to further investigate the findings in the ANOVA analysis. This is due to that a lot of the items significantly related to our outcomes were believed to represent common latent phenomena.

We conducted four PCA's, two on each target variable. The first iteration was an exploratory factor analysis using a criterion of eigenvalue > 1 and ibspection of the scree plot to decide the number of factors. Thereafter, we conducted a confirmatory PCA with the number of factors we chose to extract based on eigenvalues and scree plot.

A *Cronbach's alpha* (a) procedure was ran on all factors in order to ensure the internal consistency of the factors. The Cronbach's alpha procedure essentially is a way of calculating all inter-correlations between items of a scale or factor (Field, 2009). A common rule of thumb is that factors should be a > 0.70 (Nunnally, 1978).

Multiple logistic regression was performed to test H3, and further H1 and H2. The factors identified in the PCA step may be confounded by other factors like differences between installation types. To control for these factors, and especially the survey factors themselves, a multiple regression method was viable.

We conducted one multiple logistic regression model for each target variable. In the first step, we included the major companies as dummy variables. The second step consisted of installation types, and the third was sea locations (the Norwegian sea or the Barents Sea).

In the final step, we included the survey factors to see a) if they could explain differences in the target variables even when controlling for these background variables, and b) to identify which survey factors that were strongest when controlling for each other.

3 RESULTS

From the ANOVA analysis—we found that a total 44 out of 144 items were significant for acute spills, and 57 for the HC leaks. As mentioned in the methods section, a lot of these were stronger as a lagging indicator than a leading indicator, that is, the survey results was more correlated with the previous year's accident statistics than the next year's. When we excluded these items, as well as some questions loading on several or none of the factors in the PCA, we had 21 items for HC leaks and 14 for acute spills.

The iterations of PCA showed four factors for acute spill items and five factors of HC leak items. The first factor of both HC leaks and acute spills was by far the most explanatory. This factor, denoted as *Framework condtitions,* consisted of items regarding e.g. competence, training, safety procedures and manning.

One of the factors of HC leak items had a Cronbach's alpha level which was not satisfactory, thus excluded from further analysis. The results are presented below in Tables 1 and 2. In sum, the ANOVA and PCA findings give support to hypothesis 1 and 2.

Descriptive statistics and ANOVA results for the factors and target variables are presented in Table 3 below.

The results from the logistic regression presented in Table 4 show that the model explained 12% of the variation in HC leaks the next year, and 21% of the Acute spills. Operator 2 has significantly lower probability of both incident types when compared to operator 1. Operator 3 and 5 also have this relationship, but only for Acute spills. For HC leak, the factor Framework conditions (see Table 5) is significantly and negatively related to HC leaks, meaning that for higher (more positive) scores on this factor, the probability of one or more HC leaks the next year is lower. The same relationship

concerns the Physical and Quantitative Work Environment and the Competence factor with regards to Acute spills (see Table 5). The factors contains questions regarding exposure to chemicals, psychosocial demands and training. Installations operating in the Norwegian Sea was significantly positively related to acute spills the next year, when compared to the North Sea.

In sum, these findings give partial support to hypothesis 3.

The items of the two strongest significantly related questionnaire factors are presented in Table 5.

Table 5. Items in the most important survey factors.

Physical and quantitative work environment (acute spills)
Are you exposed to skin contact with for example oil, drilling fluids, cleaning fluids or other chemicals?
Can you smell chemicals or clearly see dust or smoke in the air?
Do you have difficulties seeing what you should see because of lack of, weak or blinding lighting?
Is it necessary to work in a high pace? Er det nødvendig å arbeide i et høyt tempo?
Do you consider the shift arrangement as demanding?
Framework conditions (HC leaks)
I have the necessary competence to conduct my work in a safe way
The HSE procedures covers well my tasks at work
I have had sufficient training in safety
I find it easy to find things in governing documents (requirements and procedures)
Does your work demand so much attention that you perceive it as demanding?
The manning level is sufficient so that HSE is taken care of in a good way
Risky work operations are always thoroughly assessed before they start
Information about unwanted events are effectively used to prevent repetitions
Safety as the highest priority when I do my job
Competence (acute spills)
I have had sufficient training in safety
Do you get the necessary training in the use of new ICT systems?
I find it easy to find things in governing documents (requirements and procedures)

4 DISCUSSION

The aim of the present study was to investigate the predictive effect towards HC leaks and Acute spills by using a survey addressing work conditions and safety climate, offshore installation and company information.

We found that our model explained 12% of the variation in HC leaks, and 21% of the Acute spills the next year.

Our results show that these factors could be used as indicators for future safety performance, although the total explained variance is modest. The overall findings are in line with several of previous studies (e.g. Gilberg et al., 2015; Kongsvik et al., 2011, Beus et al., 2010). We also found that the set of perceptions that employees share regarding safety in their environment (Zohar, 1980; Zohar, 2003; Zohar, 2010) are somewhat related to safety performance.

In addition, we see that not only safety climate factors are related, but the fact that the Physical and quantitative work environment and Noise and sleep factors are related to safety performance (although bivariately) corresponds well with particularly the research of Nahrgrang et al., (2010) and Åkerstedt et al. (2002) on work conditions.

In the following, the hypotheses are specifically discussed.

4.1 *Hypothesis 1 – HC leaks model*

All the factors were significantly related to HC leaks, thus giving support to hypothesis 1. In the multiple regression, the Framework factor was the strongest predictor of HC leaks. This should be highly relevant from the perspective of the supervisory authority, because these are aspects that can easily be inspected by regulators. Based on our findings, targeting documentation of training, manning level analyses and the availability and quality of HSE procedures on the installations can aid in identifying installations at risk of HC leaks. The content of the Framework factor is consistent with the content of several of the safety climate dimensions such as safety system, safety competence and work pressure presented in Kvalheim & Dahl (2016) as important predictors of safety compliance.

Considering the complexity of a HC-leak, the fact that we measure the safety climate the year before, that no technical condition data is in the equation, and the inherent validity and reliability issues present with surveys as a method, we conclude that these are indeed interesting results. However, the incremental explained variance is somewhat lower than earlier studies, which may be due to new control variables (for example, installation type and area of operation), or that the inclusion of more, new and better data reduces unwanted biases in the observations.

4.2 *Hypothesis 2 – Acute spills model*

All factors but one was significantly related to acute spills the next year as shown by the ANOVA analysis. Competence was the factor that did not significantly explain any variance in the ANOVA, but, however, it was significant as a predictor in the regression analysis. In sum, this give support to hypothesis 2. The strongest predictor was the Physical and quantitative work environment factor, and the Competence factor was also related to acute spills the next year.

Interestingly, the questions and factors related to acute spills were quite different from the questions and factors related to HC leaks. Whereas the acute spills aspects were related to work environment factors, and for example the subjective experience of having a demanding work hour, the HC leaks aspects were related to framework conditions such as the competence, safety system and HSE procedures. This difference reflects the assumption that HC leaks are related to more complex work processes, which involves e.g. more coordination of different tasks and people than acute spills which may be more related to more limited task conducted within a more limited time period.

Some of the questions may be related to the baseline risk on some installations. This particularly concerns the two questions addressing whether the respondents can see or smell chemicals, or are exposed to oil. This means that a reason for the strong effect could be due to that, whatever reason, some installations have a lot of acute spills, and this influences the results on these two questions, and therefore the correlations found here are to some degree spurious. However, since we included only the questions that were more relevant as a leading indicator, some predictive explanatory effect solely by the questions is present.

4.3 *Hypothesis 3 – Multiple regression*

When looking back to hypothesis 3, we assumed that the factors related to safety performance would be significant even when controlling for variables and conditions such as operator, installation type and area of operations.

This was indeed the case for Framework conditions (in regards to HC leaks), Physical and quantitative work environment and Competence (in regards to acute spills). The other factors were not significant. This gives some support to our hypothesis.

It may be that although we find different factors using a PCA procedure, that several of the survey factors to some extent in reality measure one underlying phenomenon, a common work condition/work environment response, and that the specific aspects do not have enough explanatory effect. Indeed, the first factor of the PCA's have a larger variance explained than the others. The common method bias of a broad survey is also somewhat present, which may explain that only one and two, respectively, factors are significantly related to safety performance.

5 CONCLUSIONS AND FURTHER RESEARCH

In line with theories and findings that show the complexity of accidents and incidents, we included a broad spectrum of survey factors, including safety climate, work environment and

psychosocial factors. We found that survey factors can indeed be related to future safety performance, and to some extent even when controlling for operator, installation type and are of operation. There are inherently different causal chains which lead to HC leaks than acute spills. This was also reflected in the findings—the factors from the PCA were quite different between HC leaks and acute spills.

Further research should consider treating the variables as continuous to cover more of the data variation. Additionally, comparing results across other types of safety performance would be interesting, for example dropped objects, HC leaks below 0.1 kg/sec, or person injuries. Where data are available, such comparisons as in this study would be interesting to conduct in other industries as well. Further, some installations may vary in terms of size, operation type and activity. Installation types could be nuanced according to these aspects in further research. Efforts to find a normalization variable for the target variables should be done (e.g. HC leaks per work hour, gas produced etc.).

Lastly, considering alternative approaches to the aggregations of a single installation score could be done. Aggregating from individual to installation level is necessary a data loss, which should be investigated using different techniques than the arithmetic mean.

To sum up, this study shows that there are modest, but interesting, relationships between safety climate and work environment inquires and future safety performance. These conditions should be recognized among authorities and companies operating in the oil and gas industry, and the factors may be used as risk indicators in safety management efforts.

Reliability of power system considering replacement of conventional power plants with renewables

Marko Čepin
Faculty of Electrical Engineering, University of Ljubljana, Ljubljana, Slovenia

ABSTRACT: Power system is one of the most complex systems ever designed. Determining its reliability is therefore a demanding process, which is mostly dealt with in a way that partial problems are stated and solved. A reliability method of loss of load expectation is selected and improved and the model of conventional power system is considered as a standpoint. Reliability of the initial conventional power system is evaluated. Then, the conventional power system is changed, where one conventional power plant is abandoned and new wind power plants stand to its place. The reliability of the initial and the changed power system is calculated and compared. Discussion shows the problems of decreased reliability of the power system with increasing the percentage of wind power plants within the power system replacing conventional plants, if not enough reserve is added to the power system at the same time. The other related problems are discussed in addition, to show that the problem is very complex and one cannot only consider a limited number of influencing parameters when deciding on power system configurations.

1 INTRODUCTION

Power system is one of the most complex systems ever designed (Cepin, 2011). Determining its reliability is therefore a demanding process, which is mostly dealt with in a way that partial problems are stated regarding its reliability and then the solutions are presented. Many methods exist, which each from its viewpoint give the representative answer to the stated problem. Some of them deal with system as a static system and the term adequacy is considered as the means of power system reliability. Some of them deal with the system as a dynamic system and the term security is considered as the means of power system reliability.

Loss of load expectation is only one of the methods identified (from the static point of view to power system reliability) which has reached a number of interesting applications (Calabrese, 1947, Billinton, Allan, 1996, Elmakias, 2008, Bricman Rejc, Čepin, 2014).

The objective of the paper is to extend the static method of power system reliability assessment named loss of load expectation into an improved version of the method and present realistic examples of the method, which can represent a standpoint for discussions for selections of new power plants in the system and the amount of reserve power needed in order to keep the specified level of power system reliability.

Loss of load expectation assesses reliability of conventional power systems with constant power and constant plant availability.

Renewable power plants are different from conventional in many aspects and the variable power is one if important ones.

The objective is to improve the method is sense to allow assessment of loss of load expectation performed in several steps considering the conventional plants and considering the renewable sources, which depends largely on weather parameters (such as river flows, wind speed, sun irradiance), which drive the power of the plant. In addition to consider the power variability also the power plant availability shall be a variable and not a constant.

2 METHODS

2.1 *Loss of load expectation*

A loss of load expectation is a method, which is based on probabilistic approach for determination of required reserves in the power system or to assess its static feature how probable is state, where the loads of the power system are too high to be powered from the available power (Calabrese, 1947, Billinton, Allan, 1996). The method analyses the probabilities of simultaneous outages of power plants, which based on a model of daily load diagram, determine the number of hours per period considered, e.g. per one year, of expected power production capacity shortages.

Loss of load occurs whenever the power system load exceeds the available generating capacity of power plants. Loss of load expectation expresses value representing the number of hours or days

in a certain time period considered, when power consumption cannot be covered considering the probability of losses of generating units. This time period is usually one year.

The power system generation planners can evaluate generation system reliability and determine how much capacity is required to obtain a specified level of loss of load expectation. As demand grows over time, additional generating units are included in a way that the loss of load expectation does not exceed the required criterion.

Actually, the initial objective of the method is more to determine the required reserve power in the system than to evaluate its reliability and in this sense the application of the method is realized.

2.2 *Mathematical model*

Figure 1 shows yearly load diagram showing the terms explaining the Loss Of Load Expectation (LOLE). Mathematical model includes the following parameters:

- number of power plants that contribute to the system,
- number of steps,
- number of hours in daily load diagram (or yearly load diagram),
- generating capacity of power plant i in step j,
- availability of power plant i in step j,
- yearly or daily load diagram of the power system,
- probability of state k in step j; it includes some available and some unavailable power plant—all of them considered with their availability or unavailability, accordingly,
- time duration of loss of capacity, i.e. the time period, when the power in the yearly (or daily) diagram is larger than the sum of generating power plants in the system—and it is related to specific state; it denotes the duration of loss of capacity on Figure 1,
- installed capacity of the power system is obtained through the sum of generating capacities of all power plants contributing to the system in step j,
- unavailability of power plant i is calculated as complement of its availability,
- number of system states is calculated as the function of the number of power plants that contribute to the system (st_stanj = 2^{no_el}); each state denotes that a particular power plant is available or unavailable; thus the number of states increases with the power of number of power plants that contribute to the system; alternative recursive algorithm can be a solution for larger systems, where the number of states would reach the number, which is not possible to be evaluated with the current computers,
- time duration of not providing enough load in daily load diagram (or yearly load diagram) for system state k and step j,
- available power capacity of all the power plants, which are available.

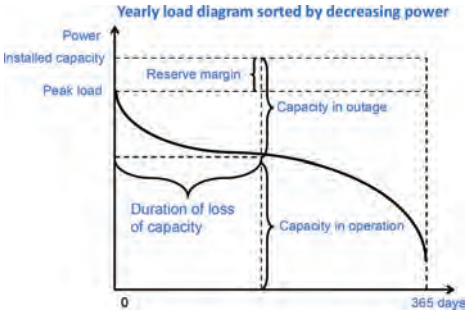

Figure 1. Yearly load diagram showing the terms explaining the loss of load expectation.

General equation for calculation of loss of load expectation is the following:

$$LOLE = \sum_{k=1}^{st\_stanj} p(k) \cdot tr\_izp\_procent(k) \qquad (1)$$

where: LOLE = loss of load expectation, p(k) = probability of state k, k = index of states, tr_izp_procent = time duration of not providing enough load in daily load diagram (or yearly load diagram), or $t(P_1 < P_2)$, where P_1 is the power capacity of power plants in specific state and P_2 is the power in the daily load diagram or yearly load diagram) or expressed on Figure 1: duration of loss of capacity.

The values of p(k) are obtained from capacity table, which needs to be prepared for evaluation.

Table 1. Example of capacity table for three power plants with powers: 40 MW, 30 MW, 10 MW and their respective unavailabilities: 0.1, 0.05, 0.04 also addressed as Forced Outage Rates (FOR).

Unit A	Unit B	Unit C	Capacity lost (MW)	Capacity in service (MW)	Probability of each capacity state
1	1	1	0	80	$0.90 \cdot 0.95 \cdot 0.96 = 0.8208$
1	1	0	10	70	$0.90 \cdot 0.95 \cdot 0.04 = 0.0342$
1	0	1	30	50	$0.90 \cdot 0.05 \cdot 0.96 = 0.0432$
0	1	1	40	40	$0.10 \cdot 0.95 \cdot 0.96 = 0.0912$
1	0	0	40	40	$0.90 \cdot 0.05 \cdot 0.04 = 0.0018$
0	1	0	50	30	$0.10 \cdot 0.95 \cdot 0.04 = 0.0038$
0	0	1	70	10	$0.10 \cdot 0.05 \cdot 0.96 = 0.0048$
0	0	0	80	0	$0.01 \cdot 0.05 \cdot 0.04 = 0.0002$

1 represents plant operable, 0 represents plant inoperable.

2.3 *Upgrade of the method*

The upgrade of the method goes in considering specifics of available power from power plants, which cannot generate the full power all the time, so their nominal power is not used in every step j, but their real power capacities are used.

Namely, the hydro power plants with not a lot of accumulation can produce the power related to the incoming flow, the wind power plants can produce the power related to the weather parameters, such as wind speed, and the solar power plants can produce the power related to the weather parameters and solar power density. Furthermore, the daily load diagram changes every day and for the more detailed model, the listed details are included.

Loss of load expectation changes through the days depending on power of power plants, depending on specific daily load diagram of the day. Its average can be calculated.

$$LOLE_{h/d} = \frac{1}{st\_cas\_k} \sum_{j=1}^{st\_cas\_k} LOLE_{h/d}(j) \qquad (2)$$

where: $LOLE_{h/d}$ = loss of load expectation (hours per day), $LOLE_{h/d}$ (j) = loss of load expectation in step j (hours per day), and st_cas_k = number of steps, j = index of steps.

At the same time LOLE expressed in hours per year can be calculated:

$$LOLE_{h/y} = \sum_{d=1}^{365} LOLE_{h/d}(d) \qquad (3)$$

where: $LOLE_{h/y}$ = loss of load expectation (hours per year), $LOLE_{h/y}$ (d) = loss of load expectation in day d (hours per day), and d = index of days.

Due to variability of power of renewable sources another dimension of power from renewable sources can be introduced to every time step of calculation, thus giving minimum and maximum of LOLE in addition to its mean value. Actually, a distribution of values instead of single value can be assessed.

2.4 *Software support*

Software for supporting calculations has been developed, which allows quick evaluation of many scenarios and which enables sensitivity studies and analyses of variations of power supply in future years with increased consumption, which calls for new production capabilities.

3 ANALYSIS AND RESULTS

3.1 *Models – base case*

Real conventional power system consists of 11 power plants: 1 nuclear, 6 thermal power plants and 4 hydro power plants and, in addition, a hydro pump storage power plant. The reliability model of selected system is developed for calculation of loss of load expectation considering the yearly load diagram as it appeared in the year 2016. This model represents the base case.

The data for the base case consists of name of the plant, nominal power (electric power delivered to the power system) and forced outage rate (or plant unavailability caused by unintentional causes). Exception is hydro pump storage power plant, which is modeled as changing directly the load diagram and its forced outage rate is not needed. When the hydro pump storage power plant operates in pumping state, its power is added to the load diagram, when it operates in generating power state, its power is reduced from the load diagram. The losses are neglected at this point, but should be considered in future.

Table 2 presents the power system data, where the hydro power plants are arranged into groups: identification, nominal power and Forced Outage Rate (FOR). The power of hydro power plants is not constant but varies significantly depending on water incoming flow. The average power of all hydro power plants through the year is around 40% of nominal power. The data is obtained from the real power system of the region.

The variants of the power system are as follows:

– Variant 1: nuclear power plant is replaced by three wind power fields, each consisting of several wind turbines. Each of wind fields has nominal power of 1154.9 MW (all three: 3470.7 MW). Their common nominal power suits the ratio of load factors for nuclear versus wind, which means that wind power plants need approximately 5 times larger nominal power than replaced nuclear power plant.

Table 2. Power system data – base case.

3.4 *Analysis and results – base case*

Loss of load expectation is calculated as 9.92 hours per year (0.027 hours per day) as the average of a number of calculations, where maximum loss of load expectation is 73.4 hours per year and minimum LOLE is 0.12 hours per year. The differences in performed calculations are due to the differences of hydro power plants, which are not assumed nominal all the time, but their power depends on incoming river flow through the year and changes respectively in the considered calculations.

If additional base load power plant of 348 MW is introduced, loss of load expectation is approximately ten times lower: 0.96 hours per year (0.0026 hours per day) as the average of a number of calculations, where maximum loss of load expectation is 8 hours per year and minimum is 0.008 hours per year.

If only the nuclear power plant is removed from the model and the rest stays as it is, the loss of load expectation increases to average of 419 hours per year (1.1 hours per day) with maximum of 2074.6 hours per year and minimum of 9.1 hours per year.

3.5 *Analysis and results – variant 1*

Nuclear power plant is replaced with three wind power plants in the model and model has been evaluated for 3 examples of wind power versus weather parameters. 3 examples of different functions of wind power as the function of time are considered, where the wind speed and other weather parameters direct the wind power.

Each of examples gives different wind power in configuration points, which can be seen also as time points and consequently the power of available power plants differs among configurations and thus loss of load expectation is different.

Figure 2 shows wind power for example 1. Figure 3 shows loss of load expectation for example 1.

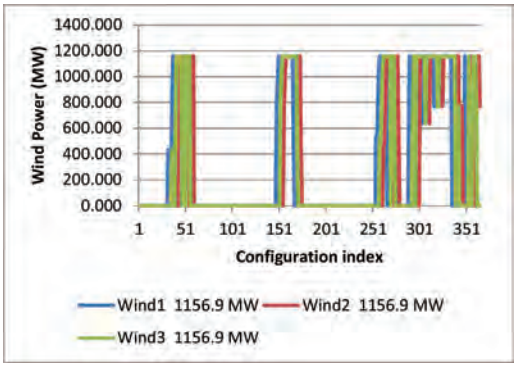

Figure 2. Wind power—variant 1 – example 1.

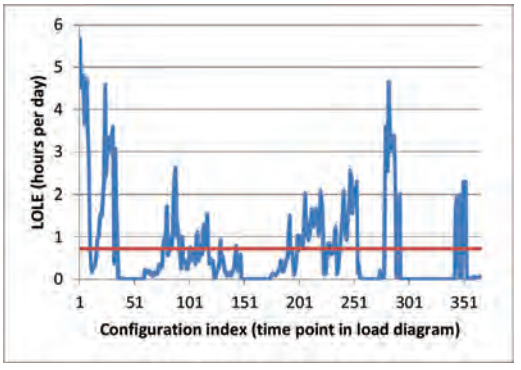

Figure 3. LOLE—variant 1 – example 1.

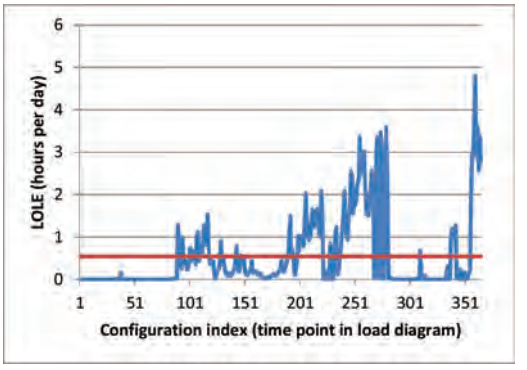

Figure 5. LOLE—variant 1 – example 2.

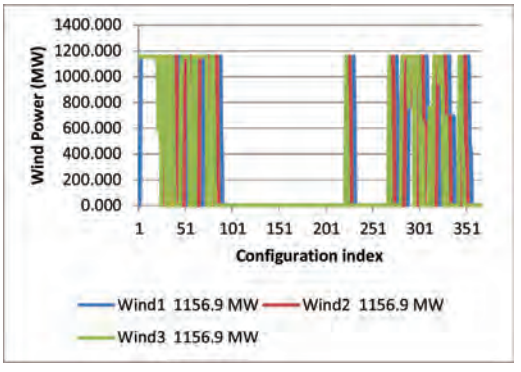

Figure 4. Wind power—variant 1 – example 2.

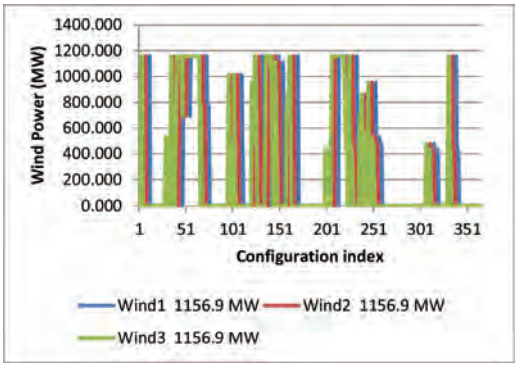

Figure 6. Wind power—variant 1 – example 3.

Loss of load expectation increased significantly with replacement wind for nuclear, which can indicate a significant decrease of power system reliability: for example 1 it is 262 hours per year (26 times increase) as the average of a number of calculations, where maximum loss of load expectation is 2075 hours per year and minimum is so low that it can be rounded to 0.

Figure 4 shows wind power for example 2. Figure 5 shows loss of load expectation for example 2.

It is 199 hours per year as the average of a number of calculations, where maximum loss of load expectation is 1755 hours per year and minimum is so low that it can be rounded to 0.

Figure 6 shows wind power for example 3. Figure 7 shows loss of load expectation for example 3.

It is 268 hours per year as the average of a number of calculations, where maximum loss of load expectation is 1755 hours per year and minimum is so low that it can be rounded to 0.

If the results of variant 1 are summarized, one can observe that the nuclear cannot be replaced by wind without significant other changes in power

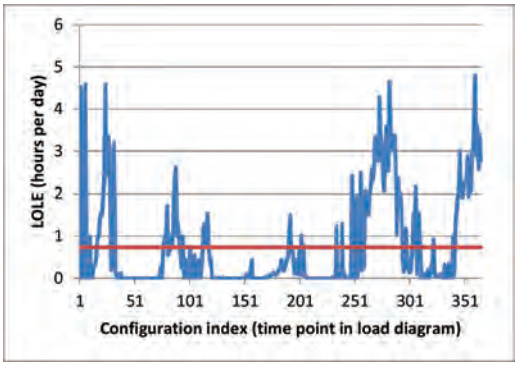

Figure 7. LOLE—variant 1 – example 3.

system such as more reserve power. In addition other factors, which are not discussed in this paper are certainly needed to be considered for such an exchange. At least some of the most important factors are listed here: frequency control of the power system, voltage control of the power system, improved rules for transmission system operation,

improved rules for distribution system, and improved rules for system operation in all aspects, which depend on intermittent power changes and the needed procedures.

3.6 *Analysis and results – variant 2*

Nuclear power plant is replaced with two wind power plants in the model and reserve power of its half power and model has been evaluated for 3 examples of wind power versus weather parameters.

Each of examples gives different wind power in configuration points, which can be seen also as time points and consequently the power of available power plants differs among configurations and thus loss of load expectation is different.

Figure 8 shows wind power for example 1. Figure 9 shows loss of load expectation for example 1.

Loss of load expectation increased notably with replacement of nuclear with wind and reserve power, which can indicate a significant decrease of power system reliability: for example 1 loss of load expectation is 47.8 hours per year (more than four times increase from base case) as the average of a number of calculations, where maximum loss of load expectation is 470 hours per year and minimum is so low that it can be rounded to 0.

Figure 10 shows wind power for example 2. Figure 11 shows loss of load expectation for example 2.

It is 46.7 hours per year as the average of a number of calculations, where maximum loss of load expectation is 376 hours per year and minimum is so low that it can be rounded to 0.

Figure 12 shows wind power for example 3. Figure 13 shows loss of load expectation for example 3.

It is 46.5 hours per year as the average of a number of calculations, where maximum loss of load expectation is 470 hours per year and minimum is so low that it can be rounded to 0.

If the reserve power is increased to 620 MW instead to 348 MW, the loss of load expectation is at approximate similar level as at the base case (with 696 MW of nuclear power).

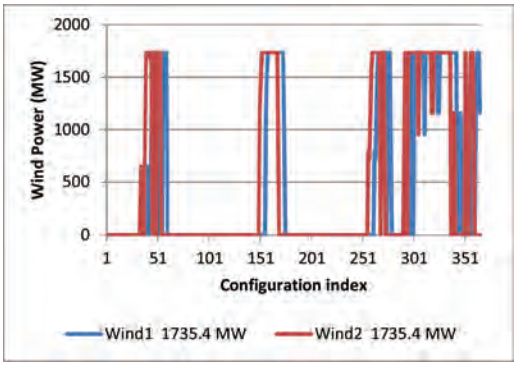

Figure 8. Wind power—variant 2 – example 1.

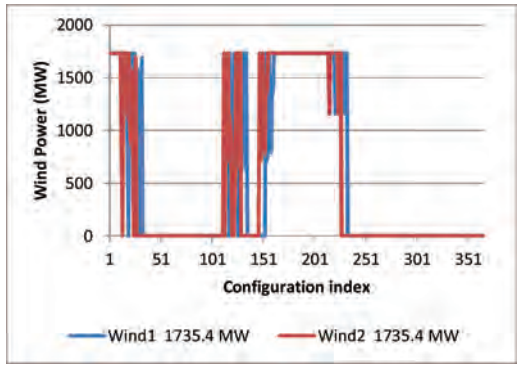

Figure 10. Wind power—variant 2 – example 2.

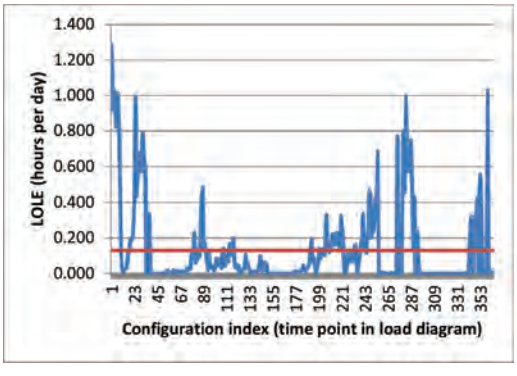

Figure 9. LOLE—variant 2 – example 1.

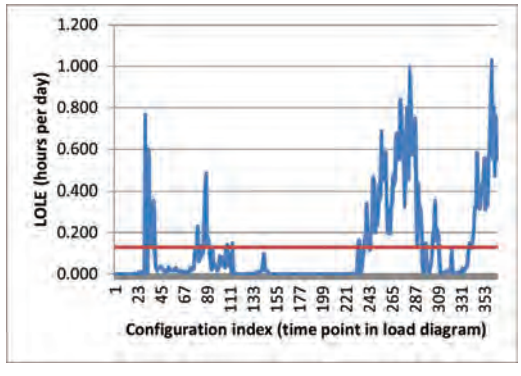

Figure 11. LOLE—variant 2 – example 2.

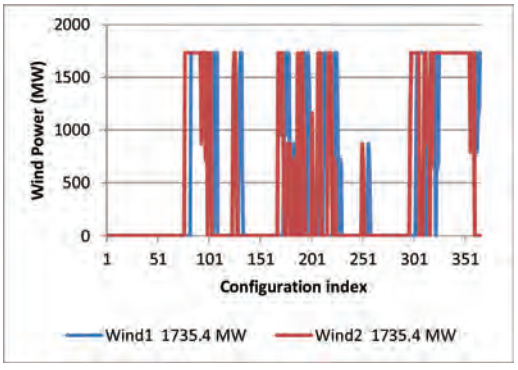

Figure 12. Wind power—variant 2 – example 3.

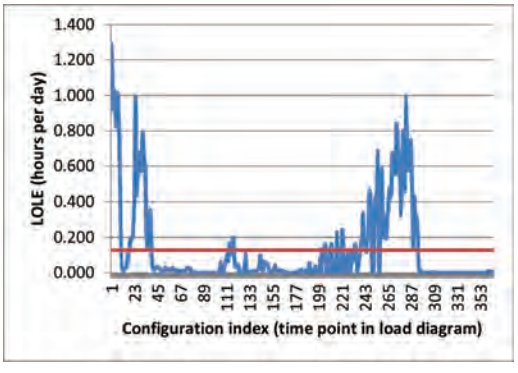

Figure 13. LOLE—variant 2 – example 3.

If the results of variant 2 are summarized, one can observe that the nuclear cannot be replaced by wind and half of its power with reserve power without significant reduction of power system reliability. In addition, other changes in the power system need to be performed (see the comments on that in the previous section).

4 CONCLUSIONS

The objective of the paper was to present realistic examples of the improved method for calculation of loss of load expectation to foster discussions about the amount of reserve power needed in the power system with increasing portions of renewable sources replacing conventional power plants.

The method was presented and improved. The computer code for the application on real examples was developed. The realistic cases have been analysed and the results were obtained.

The results show significant decrease of power reliability or in other words: a significant increase of loss of load expectation, in the case that nuclear power plant is replaced with the wind power plants of approximately five times larger joined nominal power.

The results show less significant increase of loss of load expectation, if replaced wind power goes along with additional reserve power, e.g. gas power plant of half of nominal power of nuclear power plant. But still several times of increase of loss of load expectation is present.

If the nuclear power plant is replaced with five times larger nominal wind power and with additional reserve (around of 90% of replaced nuclear power), the loss of load expectation shows that the power system reliability from the static point of view is not decreased. More sensitivity studies are needed for justifying this statement in more details.

If the number of wind power plants is larger, the variability of wind power may be smaller than shown at these examples (variant 1 and variant 2) and less reserve power may be needed (than indicated 90%). If the power system consists of several hydro power plants with large accumulations, which by themselves introduce the reserve accumulation in the power system, the problem can be solved with less additional power.

The probabilistic methods to calculate contribution of renewable sources in the power system may be used in this sense.

Future work can be oriented to consideration of probability distributions of renewable power to assess probability distributions of loss of load expectation.

Losing containment at high temperature and pressure—an experimental study with water-steam circuit

F. Heymes, P. Lauret & C. Lopez
LGEI, IMT Mines Ales, University of Montpellier, Ales, France

P. Hoorelbeke
Total SA

ABSTRACT: The design of pressure vessels aiming to contain water under high pressure and temperature conditions considers steady state behavior of the fluid. But if pressure decreases suddenly thanks to a leak or a rupture, water can get into a supercritical state. Supercritical state is a high energy and metastable state that could lead to a catastrophic accident such as explosion. The phase change of the superheated fluid is expected to entail a violent repressurization of the vessel, and may blow up the vessel. Little data can be found in literature about that repressurization process. The aim of this work was there to measure the repressurization dynamics of superheated water following a loss of containment. Experiments were performed at high temperature and pressure (up to 315°C, 100 bar) in order to understand the phenomenon. The pressure drop in the tank was fast and well below the saturation pressure at the given temperature. Then, a repressurization peak occurred, depending on the pressure drop history. The set of results is discussed and compared to literature data.

1 INTRODUCTION

Steam is widely used in industry to carry heat. After condensation, hot water flows usually back to a furnace to be reheated and vaporized. Steam is produced and used at different temperatures and pressure. Typically, steam below 3.5 barg is termed as low pressure steam. Steam above 3.5 barg but below 17.5 barg is termed as medium pressure steam and steam above 17.5 barg is termed as high pressure steam. Some users define their steam above 40 barg as ultra-high pressure steam.

A water-steam circuit will comprise sections of piping where water flows at high pressure and high temperature. In case of a leak the hot water will undergo a rapid transformation into steam due to violent boiling or flashing. This phenomenon is called a steam explosion. The higher the degree of superheat (i.e. the difference between the temperature of the water and the atmospheric boiling temperature of the water) the more violent will be the explosion. The water vaporizes from liquid to vapor with extreme speed, increasing dramatically in volume. A steam explosion sprays steam and boiling-hot water and the hot medium that heated it in all directions, creating a danger of burning. Some steam explosions appear to be special kinds of Boiling Liquid Expanding Vapor Explosion (BLEVE), and rely on the release of stored superheat.

This presentation presents (i) thermodynamics considerations about the superheated state of water, (ii) the experimental setup, (iii) results about the depressurization dynamics in the vessel and the conclusions that can be driven for the collected data.

2 THERMODYNAMIC CONSIDERATIONS

2.1 *Phase diagram (P-T)*

Water thermodynamic properties were widely investigated previously. Phase change lines, triple point and critical point are given on Figure 1. Experimental data about triple point and critical point are given in Table 1.

A specific state of water is called the superheated state. This state (sometimes referred to as boiling retardation or boiling delay) is usually described as the phenomenon in which a liquid is heated to a temperature higher than its boiling point, without boiling. Superheating is achieved by heating a homogeneous substance in a clean container, free of nucleation sites, while taking care not to disturb the liquid.

More generally, a liquid is said to be superheated when its temperature exceeds its saturation temperature of its pressure or when its pressure decreases below its saturation pressure of its temperature

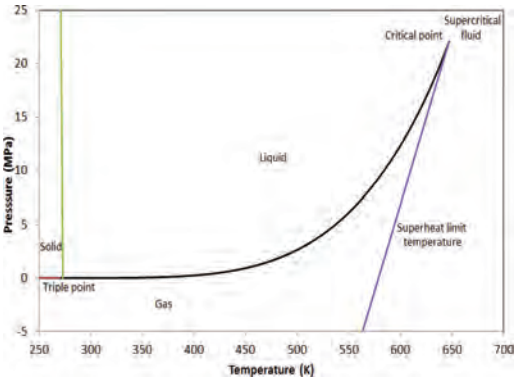

Figure 1. Phase change diagram of water in (T,P) coordinates.

Table 1. Specific thermodynamic points of water (Abbasi & Abbasi 2007).

	Temperature		Pressure	
	K	°C	Pa	atm
Triple point	273.15	0.01	661.73	0.00653
Critical point	647.37	374	22 120	218

while the liquid is still not boiling: $T_L > T_{sat}(P_L)$ or $P_L < P(T_L)$. Superheating may happen at any pressure below the critical point. Superheat domain is usually delimited by a line defined between the critical point and the superheat limit temperature at atmospheric pressure.

2.2 *The superheat state*

The superheat state may be described on the usual P-V diagram as following (Figure 2). C is the critical point. [BCB'] is the saturation curve or the binodal. The isotherm at temperature T = 580 K (306.85°C) is [ABEFB'D]. B and B′ are equilibrium states on the binodal. P_{sat} is the equilibrium pressure at T.

When the liquid state is between A and B, it is called the subcooled liquid. The liquid at point B is called the saturated liquid. When the liquid state is between B and E, it is called the superheated liquid because its temperature has been higher than the saturation temperature of its pressure or its pressure has been lower than the saturation pressure of its temperature.

When the liquid becomes superheated, it also becomes metastable which means its stability can be easily broken by external perturbations. If so, it can no longer maintain its liquid state and phase transition must occur. When the metastability of the liquid becomes larger (the liquid is approaching point E), the minimum perturbation required to break the stability of the liquid becomes smaller and finally at point E, the thermodynamic stability limit has been reached, which means phase transition will spontaneously occur without any external perturbations or without any suitable nucleation site. The stability of the liquid can be broken by the density fluctuations of the liquid itself.

2.2.1 *Kinetic Superheat Temperature (KSL)*

In experiments on superheating measurements of a liquid, bubble nucleation (generation of small bubbles) will start when point K on the isotherm in Figure 2 is reached. Point K is called the Kinetic Superheat Limit (KSL). The KSL can be measured experimentally provided early bubble generation by impurities of wall effects is prevented (no heterogeneous nucleation). Avedisian (1985) did a comprehensive work about the KSL measurement and reported values of KSL from the literature. A large discrepancy was observed due to different operating data.

2.2.2 *Thermodynamic Superheat Limit (TSL)*

Point E is called the Thermodynamic Superheat Limit (TSL) of the liquid and [CE] is called the superheated liquid spinodal. The phase separation occurring at the TSL is called spinodal decomposition. On Figure 2, [CE], [CF] and [BEFB'] curves are not experimental but only illustrative, since experimentally the spinodal decomposition has only been observed by light scattering techniques at a temperature very close to the critical point in binary mixture systems and the process is too fast to allow transient measurement of thermodynamic properties.

The thermodynamic superheat limit (TSL) curve is defined by the spinodal curve, given by the equation:

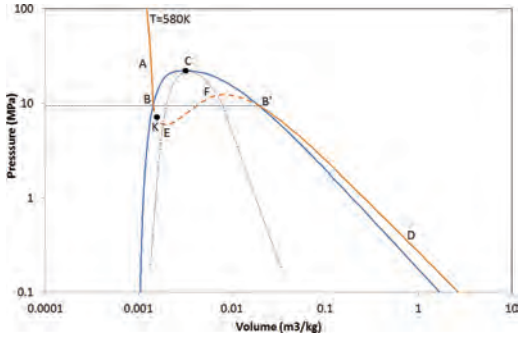

Figure 2. Coexistence line (BCB'), isotherm at equilibrium (ABB'D), liquid spinodal (CE) and vapor spinodal (CF) in case of water.

$$\left(\frac{\partial P}{\partial V}\right)_T = 0 \tag{1}$$

This equation is a condition of thermodynamic stability. It separates two regions on the PT diagram (Figure 1) separated by the superheat limit curve, defined by the value of the pressure gradient:

If $\left(\frac{\partial P}{\partial V}\right)_T < 0$ the system is stable

If $\left(\frac{\partial P}{\partial V}\right)_T > 0$ the system is unstable

TSL can be predicted by use of equations of state (EOS). There are several equations of state, depending on the considered pressure and temperature range and the molecular structure of the compound. (Reid 1979) used the Redlich Kwong EOS to predict the thermodynamic superheat limit temperature. (Kim-E 1981) proposed to use the Peng Robinson equation (PR EOS):

$$P = \frac{RT}{V-b} - \frac{a}{V(V+b)+b(V+b)} \tag{2}$$

By deriving this equation, the following relation has to be solved:

$$V^4 + \left(4b - \frac{2a}{RT}\right)V^3 + 2b\left(b + \frac{a}{RT}\right)V^2 + 2b^2\left(\frac{a}{RT} - 2a\right)V + b^4 - \frac{2ab^3}{RT} = 0 \tag{3}$$

where V is the molar volume, a and b are constants depending on which specie is being analyzed. The constants can be calculated from the critical point data of the gas. For a temperature below the critical one, the previous equation will yield four real roots. One will be less than the saturated liquid volume and another will be greater than the saturated vapor volume; these are disregarded. The two remaining roots are between the liquid and vapor saturation curves; the smallest root corresponds to the liquid spinodal curve and the largest to the vapor spinodal curve. The TSL can therefore be calculated at atmospheric pressure by solving this equation.

Other equations of state can be used. (Abbasi & Abbasi 2007) used 9 models to calculated TSL in case of water (Table 2): Van der Waals (VDW), Soave Redlich Kwong (SRK), Peng Robinson (PR), Twu-Redlich-Kwong (TRK) or Peng-Robinson-Mathias-Copeman (PRMC), Berthelot (B). According to the authors calculations, the TSL varied in the range [546.6–604.5] K, that is a range of ΔT = 58 K depending on the considered EOS.

2.2.3 *Superheat limit curve*

Where does the superheat limit curve drawn on Figure 2 locate? Reid (1979) claimed that the thermodynamic superheat limit TSL predicted by the Redlich-Kwong equation of state is reasonably in agreement with experimental data, but he doubted those results because "...no satisfactory correlation now exists to relate p, v and T in the superheated liquid region...". An equation of state is obtained by correlating experimental data outsides the saturation dome. Using an equation of state for metastable states inside the saturation dome (Figure 2) is equivalent to extrapolation of those experimental data. For slightly superheated liquid, the extrapolation is still reliable (Mengmeng 2013), but for highly superheated liquid states, Reid's worry is inevitable. The accuracy of an equation of state to predict the TSL cannot be demonstrated by such comparisons unless the measured KSL has been proven to be very close to the real TSL, which has not been done in any experiment yet. If the validity of an equation of state in predicting the thermodynamic superheat limit has not been proven, the close agreement of its predictions with the measured superheat limit cannot be interpreted as matching.

In case of water, Abbasi compared TSL calculations to experimental KSL at the atmospheric pressure and calculated absolute deviations. For water, the VDW-EOS gives the minimum average absolute deviation of 1.20% from the experimental value; The Twu-Redlich-Kwong equation of state (TRK-EOS), gives 5.90%; The PR-EOS and its modified version, the Peng-Robinson-Mathias-Copeman equation of state (PRMC-EOS) give the deviations of 7.90% and 8.02% respectively; The Berthelot equation of state (Berthelot-EOS) gives 7.53%; The RK-EOS gives 4.76% and the Soave-Redlich-Kwong equation of state (SRK-EOS) gives 9.27%. For more information refer to the study of Abbasi & Abbasi (2007) or Salla et al. (2006).

According to these considerations, it appears that the superheat limit temperature of water is still not well defined. The KSL seems more reliable since it can be measured experimentally, keeping in mind that the value depends strongly on the surface state of the apparatus.

Two values of KSL at atmospheric pressure were found in the literature: Avedisian et al proposed a KSL of 575.1 K (301.95°C) whereas Abbasi et al proposed a KSL for water at atmospheric pressure of 553.2 K (280.05°C).

2.3 *Phase change of superheated liquid*

The key point of this work is the violent phase change of the superheated liquid. Therefore a focus has to be done on the phase change

dynamics. Two kinds of phase change have to be considered: homogeneous and heterogeneous nucleation. When a liquid becomes superheated, vapor embryos can be formed because the excess energy of the superheating can be used to cover energy needed for phase change and to maintain surface tension. This process called bubble nucleation, has two forms, depending on the locations where vapor embryos form:

- Homogeneous nucleation, as the name indicates, occurs in the middle of the fluid where no phase boundaries are present;
- Heterogeneous nucleation occurs on phase boundaries such as rough walls or suspending solid impurities.

To form a vapor embryo with the same volume, heterogeneous nucleation requires less energy than homogeneous nucleation because the presence of the phase boundaries allows a lower interface area of the vapor embryo. Generally speaking, heterogeneous nucleation occurs at a lower degree of superheat than homogeneous nucleation.

Distinction has to be made between nucleation and bubble growth in the metastable state but still far away from the KSL and nucleation and vaporization close to the KSL. In conditions away from the KSL, homogeneous nucleation is much less probable than heterogeneous nucleation and the question how fast the nucleation is, also involves questions on availability and properties of surfaces for nucleation. Avedisian et al (1985) suggested that the nucleation rate J (nuclei/cm^3.s) depends on the superheat level ΔT (Figure 3). J_0 defines the minimum nucleation rate below which homogeneous nucleation is unlikely. The superheat ΔT_1 and ΔT_2 correspond to rates J_1 and J_2 respectively. The superheat at J_{max} is shown corresponding to the thermodynamic limit ΔT_t.

When a liquid is superheated but is still far away from the superheat limit, vaporization will start first on locations most favorable for the formation of initial small bubbles which is on solid surfaces or on dust or other solid particles in the fluid. Once bubbles are formed they grow according growth laws which have been well studied in the literature.

Approaching to the superheat limit state, the process generating smaller bubbles (nuclei) is different than away from the superheat limit state because the small 'vapor' nuclei originate homogeneously in the fluid and at a much faster rate. The smallest stable bubbles close to the KSL are much smaller than away from the KSL. Classical homogeneous nucleation theory has been developed to describe this case. It turns out that its predictions of nucleation rate are extremely dependent on details.

The growth of bubbles at the superheat limit also proceeds in a different manner than away from the superheat limit. The rapid growth of bubbles

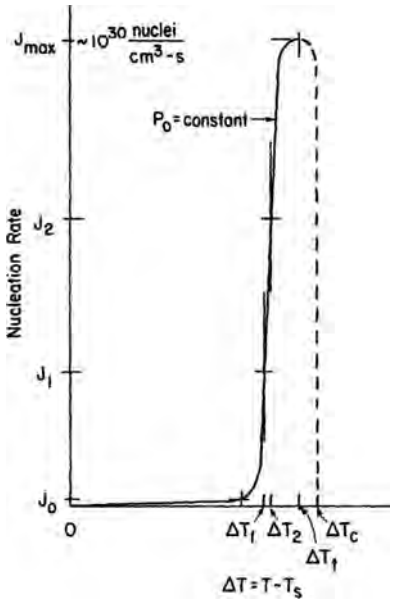

Figure 3. Schematic variation of nucleation rate with temperature at a given ambient pressure (Avedisian 1985).

may create a rise in pressure which counterbalances the initial pressure drop, and keeps the liquid away from the superheat limit. This phenomenon must be taken into account in the evaluation of the effects of rapid depressurization or rapid heating.

Moreover, during a depressurization of a superheated liquid, the decrease in pressure is not felt instantaneously all over the liquid but spreads in the form of a wave. The local temperature at different locations in the liquid may be different, depending on the features of the accident causing the vessel and the amount of heat used for vaporization.

The starting points at different locations in the liquid may be at different locations on the saturation curve. The decrease in pressure due to opening of the vessel will be felt at different locations at different moments in time and once vaporization starts the decreases in pressure can be stopped by the expansion of the mixture due to vapor generation. The rate of depressurization is also controlled by the time needed for vessel rupture.

This has been taken into account in a refinement of the superheat limit theory proposed by (Mcdevitt 1990). As summarized in the review proposed by Leslie & Birk (1991), the homogeneous boiling only occurs at the rupture location where the liquid sucked out of the breach first reaches atmospheric pressure. Their study focused on the liquid behavior inside the vessel (liquid hammer, pressure recovery etc.), before a possible total disintegration of the vessel. A vaporization front can have very complex shape and wildly fluctuating properties.

The break-up of existing bubbles in smaller bubbles in a wildly fluctuating vaporization front creates extra area and also new nuclei for heterogeneous vaporization. This can enhance the vaporization rate and the front propagation rate enormously. The question arises whether the vaporization in a propagating front can generate a sufficiently strong volume source for significant blast propagation.

These considerations indicate that apart from experiments and thermodynamic models to determine the superheat limit curve for various substances, also experiments and fluid dynamic models are needed to determine the propagation speed of vaporization fronts.

3 THE BOILING LIQUID EXPANDING VAPOUR EXPLOSION (BLEVE)

A superheated liquid is in a high energy state and a metastable equilibrium. Therefore it can release a large amount of energy in explosive behavior. A superheated liquid explosion requires that a large part of the liquid vaporizes in very short time. Different behaviors were described in literature. Two main categories can be made, according to the way the liquid becomes superheated:

- By sudden pressure loss, such as observed in boiling liquid expanding vapor explosion (BLEVE)
- By sudden temperature increase, such as observed in rapid phase transition (RPT)

BLEVE is the most common phenomena which resulted in many studies. The standard theory of BLEVE was originally proposed by (Reid 1979). The essential idea is illustrated Figure 4. Under normal conditions the content of the vessel containing a liquid and its vapor is in thermodynamic equilibrium and the pressure and temperature combination lies at the saturation curve (points A or C). In the case of vessel rupture the pressure suddenly decreases resulting in superheated liquid. There is a limit to the degree in which a liquid can get superheated. At constant pressure, the superheat limit temperature is the highest temperature that a liquid can sustain without undergoing phase transition and at constant temperature; the superheat limit pressure is the lowest pressure for a liquid to maintain its liquid state. According to Reid's theory, when the pressure of the liquid decreases from point C to D, the liquid reaches the superheat limit curve and a BLEVE will occur while in the process of A to B, the liquid does not reach the superheat limit curve, no BLEVE will occur. Based on previous part, the superheat limit referred in Reid's theory should be the kinetic superheat limit (KSL).

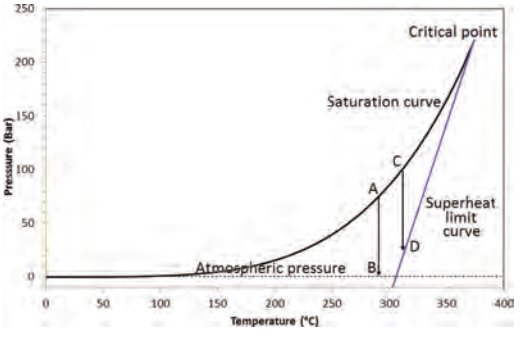

Figure 4. Schematic explanation of Reid's superheat limit theory for BLEVE in depressurization processes.

As explained previously, the situation in a real incident will be much more complicated than the simple trajectories from A to B or from C to D on Figure 4. In Reid's superheat limit theory (Reid 1976), the severity of the hazard of a BLEVE is attributed to the fact that the KSL has been reached, not the TSL. Throughout a study on BLEVE one should bear in mind the difference between the two superheat limits definitions and the difference between an experimentally observed phenomenon (KSL) and a theoretical thermodynamic property (TSL).

Direct correspondence between a BLEVE and the spinodal decomposition has never been proven by experimental data. Recently Birk (Birk et al. 2007) after an analysis of a number of medium scale BLEVE tests have come to the conclusion that in the case of rupture of high pressure vessels only partially filled with liquid propane (fill level in the range 13 to 61%) the shock waves observed in the far field seem rather produced by expansion of the vapor and not by the vaporization of the liquid, which is said to be a too slow process for generating a strong blast. In (Birk et al. 2007) it is mentioned however that the rapid vaporization process can produce significant dynamic pressure effects in a near field. These effects are of particular importance in case of a BLEVE in a confined space such as a tunnel. Their demonstration does not involve superheat limit theory but uses a thermodynamic estimate of the available energy. Such estimates can assume isentropic expansion (Prugh 1991) or, more realistic, adiabatic irreversible expansion (Planas-Cuchi et al. 2004). The second estimate is about half of the first (Abbasi & Abbasi 2007).

4 MATERIALS AND METHODS

The apparatus was designed to heat water at high temperature and pressure and to release pressure thanks to a ½″ fast ball valve. The specifications

of the vessel are given in Table 2. A sketch and a picture of the setup are given on Figure 5.

Eight K type thermocouples were set on a vertical axis in the vessel. A stirrer was put at the symmetry axis of the vessel, so the thermocouple axis was shifted 5 cm on the side of the stirrer axis. Location data are reported in Table 3.

The power of the heater was 8000 W, with a maximum wall temperature of 450°C, so one hour was necessary to reach the target temperature (300°C). The apparatus was be completely insulated to minimize heat losses.

Two water cooled dynamic pressure sensors (Kistler 601C) were put on the vessel to measure the transient pressure in the vessel. Data acquisition rate was 200 kHz. Two static pressure sensors were put at a distance from the vessel (250 bar) and remained cold during the tests. A half inch fast discharge pneumatic valve was put at the top of the vessel and controlled remotely.

Table 2. Experimental vessel specifications.

Pressure vessel standard	CODAP 2005
Volume	5 L
Steel	X2CrNiMo17-12
Maximum allowable working pressure	142 bar
Working temperature	0°C to 300°C
Design pressure	190 bar
Design temperature	300°C
Test pressure	305 bar
Safety valve pressure	183 bar
Internal diameter	125 mm
Internal height	395 mm
Wall thickness	11.5 mm
Vessel volume	5000 mL
Total volume (incl. pipes)	5090 mL

5 RESULTS AND DISCUSSION

A series of 8 experiments was performed. Operating conditions of the tests are given in Table 4.

5.1 *Test description*

The experimental vessel was filled with an accurate quantity of high purity water (milliQ grade). The gas space remained filled with air at atmospheric pressure. The heater was switched on. In order to purge the air, the relief valve remained open until vapor was observed at the exit of the valve, typically during 2–3 minutes. Then the valve was closed. Very little water was lost during the air purge. During this purge dissolved gases were also removed.

Figure 6 shows the water temperature evolution on a vertical axis during the test. T1 was located at the lowest level whereas T8 was located at the uppermost level in the tank. Temperature stratification occurred during the ten first minutes. Then, boiling at the wall created bubbles and turbulence that are clearly observable on the temperature curves. When the boiling was sufficient to provoke a complete mixing of the liquid, all temperature records converged to a single temperature curve. The internal pressure increased according to the vapor-liquid equilibrium law (Figure 7).

A perfect fit is observed with the literature data on the (T,P) diagram of water (Figure 8). When the temperature target was reached, the fast discharge valve was opened. A powerful and noisy steam jet was created. A noise recording was performed at the operator bunker and indicated a level of 102 dB. The temperature and pressure dropped very rapidly.

These data were recorded at an acquisition rate of 20 Hz. In order to record perfectly the fast pressure dynamics in the tank, two dynamic pressure gauges and a high speed recording equipment enabled to get data at a 200 kHz recording rate.

After a strong depressurization, a small repressurization occurred and was measured with both

Table 4. Summary of experiments.

Experiment	Water quantity (g)	Water temperature at relief time	Pressure at relief time P_R	Volume fraction at T_R
	g	°C	bar	%
1	3995	202	17	91%

pressure transducers. This repressurization was very short in time; quickly the depressurization overcame the repressurization phenomena and the

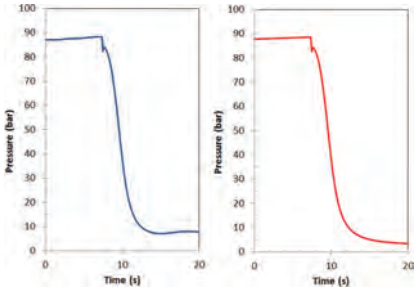

Figure 9. Dynamic pressure in the tank (200 kHz, test #6).

pressure restarted to decrease. In the considered case, a depressurization of 4.7 bar occured during 110 ms and was followed during 140 ms by a 1.8 bar pressure increase. Then, the pressure restarted to decrease to reach the atmospheric pressure. The data of both dynamic pressure transducers are reported on Figure 9. The data on the left corresponds to pressure sensor located at the bottom of the vessel, the data on the right corresponds to pressure sensor located at the top of the vessel. Both data match perfectly.

5.2 *Influence of superheating temperature*

According to the theory, nucleation and repressurization rate are expected to depend on the superheat level. Therefore five experiments were performed at different temperatures: 236°C, 267°C, 281°C, 290°C and 300°C.

The transient pressure data are given on Figure 10. In these tests, a repressurization peak was observed. The peak is more visible at higher temperatures (281°C, 290°C and 300°C), but a slight peak is also noticeable at 267°C and some oscillation can me observed at 236°C.

5.3 *Discussion*

Experimental data about kinetic superheat limit are reminded in Table 5.

Tests performed at 281, 290 and 300°C tests (Figure 10) were above the KSL and indicated a repressurization peak which seems to corroborate the proposal of (Avedisian 1985). Indeed, the pressure drop due to venting was countered by the nucleation rate in the vessel. It is not possible to check if nucleation was homogenous of heterogeneous.

The data was computed in order to get the numerical value of the pressure drop and the consequent repressurization pressure peaks (Table 6). According to the theory of (Avedisian 1985), the difference between superheated temperature of water before release and the standard boiling temperature ΔT was calculated and reported on Figure 11. This figure has to be compared with Figure 3, with a dif-

	Temperature	Target pressure	Pressure drop	Pressure peak
Test	°C	bar	bar	bar
3	26	53	11.68	0.42
4	28	65	6.28	1.97
5	290	76	7.72	2.62
6	300	88	5.89	1.64

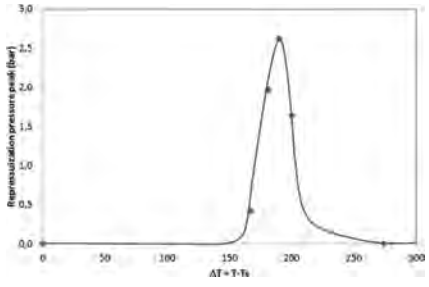

Figure 11. Repressurization peak as a function of superheated level.

ference that the nucleation rate was unknown and replaced by the repressurization peak on the y-axis. Both values are linked by non-linear relations that were not investigated in this work.

A similar trend was observed, but further work will be required to investigated more accurately the nucleation rate for comparison with the work of (Avedisian 1985).

In the frame of pressure vessels safety, results indicate that the pressure peaks remained small (< 3 bar) in comparison with the pressure in the tank at relief time. Therefore, if an industrial vessel or pipe containing superheated water is depressurized by a little hole due to corrosion of mechanical failure, no significant pressure peak able to break the vessel should be feared for the conditions studied in this article.

ACKNOWLEDGMENTS

The authors are grateful to TOTAL SA for proposing and supporting this study.

An investigation and statistical analysis into the incidents and failures associated with dynamic positioning systems

O. Olubitan, S. Loughney & J. Wang
Liverpool John Moores University, Liverpool, UK

R. Bell
Engineering Safety Consultants Ltd., UK

ABSTRACT: This investigation highlights the safety of DP (Dynamic Positioning) systems by briefly discussing the existing risk assessment methods and risk control measures provided by the International Maritime Organization (IMO). Following a study regarding DP systems and the loss of position incidents reported to the International Marine Contractors Association (IMCA) and contained in the World Offshore Accident Databank (WOAD), the relevant hazards are identified and collated. The primary causes of loss of position incidents were found to be: the positional reference system failures and thruster failures, with both contributing to 20.6% each of the total incidents from 2000 to 2016. Similarly the time period of the analysis is the 17 years between 2000 and 2016. Given the two stated primary causes, the positional reference system failures and thruster failures, the thruster failures are analysed further. This is due to thruster failures occurring at an increased rate within DP incidents from 2011 to 2016. Hence, this trend, between 2011 and 2016, is analysed further. Three undesired events for loss of position due to thruster failures were identified, these are as follows: "drive off", "drift off" and "time loss". Further investigation of incidents in more recent years, in this case, 2012 to 2016, identified that the DP control system accounted for 33.7% of the initiating incidents that led to thruster failures. Furthermore, the undesired event "time loss" accounted for 71.2% of total incidents caused by thruster failures.

1 INTRODUCTION

Many marine vessels are now equipped with Dynamic Positioning (DP) systems. These vessels have different functions and come in different sizes. Some vessels are used for Simultaneous Operations (SIMOPS) and Combined Operations (COMOPS), bringing them in close proximity with other vessels and/or offshore installations. Some are used to conduct diving operations, with a huge number of vessels also used for drilling operations. The functions of these DP vessels are very numerous, challenging and distinct. To cater for these functions, their level of safety was required to be increased and classified. Through time, with support from different organizational bodies and from lessons learnt from past DP failures, the safety of DP systems and vessels has been increased. These DP systems now utilize a redundancy scheme to ensure that a single failure would not lead to an accident. In this research the term safety is derived from the definition of functional safety outlined by Bell (2010). This states that "*functional safety is a part of the overall safety that depends on a system or equipment operating correctly in response to its inputs. In essence, this means the achievement of safety through application of control systems. This requires identifying what has to be done and how well it should be done*" (Bell, 2010).

DP has evolved over the years, from use as a tool for mobile offshore drilling units, for maintaining position over offshore wells, to being employed for a wide range of position keeping operations. We see DP systems being fitted on an increasingly large number of new and diverse vessels, from offshore units to shuttle tankers to passenger vessels (IMO 1994).

The increase in the number of diverse applications results in an increase to the estimated risks involved with dynamic positioning vessels, further requiring an increased level of safety. To this end there has been a growth in the development of the dynamic positioning systems. There are now several classes from DP0 to DP3 (DNV 2012), each class with a different level of safety.

The rationale behind this topic is to identify, investigate and analyse the loss of position incidents due to DP system failure. These incidents are analysed

according to the seasons in which they occurred, types of vessels, main causes and initiating causes.

2 BACKGROUND

2.1 *Dynamic positioning*

DP can be defined as "a means of holding a vessel in a relatively fixed position with respect to the ocean floor, without using anchors, accomplished by two or more propulsive devices, controlled by inputs from sonic instruments on the sea bottom and on the vessel, by gyrocompass, by satellite navigation or by other means" (Holvik 1998).

The launch of the Global Positioning System Satellite network brought new ideas and new technology to be integrated into the DP vessels for more efficient performance. In 1981, the Nautical Institute began working on certification process for DP operators. This was done to reduce accidents and failures caused by human error. In 1983, the Department of Energy and the Norwegian Petroleum Directorate produced guidelines for diving from DP vessels. Howard Shatto in 1983 further improved on the DP systems, allowing greater water depths of 7,500 m and even rougher seas to be achievable. From his knowledge of satellite positioning and through his participation in the first use of Failure Mode and Effects Analysis (FMEA) for DP systems in 1983, the Mean Time Between Failures (MTBF) for DP systems was improved six-fold (DPC-MTS 1996).

By 1985, the number of DP capable vessels had increased to over 150. At this time, the vessel types equipped with DP systems had also increased. The following are some of the types of DP vessels that were available by 1985 based on their functions: Drillships, Mobile Offshore Drilling Units (MODU), Diving Semi-Submersibles, Diving and Emergency Response Vessels, Remote Operated Vessels, Diving Support Vessels, Shuttle Tankers and Accommodation Vessels (Flotels).

The following years saw an increase in the use of DP systems various functions and vessel types. In 1990, the first DP Floating Production Storage and Offloading (FPSO) vessel, Seillean, was launched by British Petroleum. The Dynamic Positioning Vessel Owners Association (DPVOA) was formed in the same year. In 1994, IMO provided guidelines for DP systems, MSC/Circ.645, the same year, the American Bureau of Shipping (ABS), introduced their first DP rules. The following year, 1995, the International Marine Contractors Association (IMCA) was formed through the merger of the Association of Offshore Diving Contractors and the DPVOA. In a bid to encourage exchange of information, foster improvement of DP reliability, develop guidelines, train and educate, and address any other issues pertinent to DP that encourage an incident free operation of DP systems. The DP committee was founded in 1996 as a Professional Committee of the Marine Technology Society (Sean 2009).

DP systems have been improved considerably since the installation of the first DP drill ship, Eureka. Vessels used for a variety functions are now equipped with DP systems. Some functions have been stated previously.

2.2 *Classification of the DP systems*

The different classes in the IMO and the ABS regulations are examined. The only difference between the two is that there is not a Class 0 for IMO regulations. ABS uses DPO to refer to vessels without DP systems. IMO does not put this as a class of DP vessels. IMO classes start from Class 1.

1. Class 0: DPS-0
   "For vessels, which are fitted with centralized manual position control and automatic heading control system to maintain the position and heading under the specified maximum environmental conditions" (ABS, 2013). Class 0 does not exist on the IMO classification.
2. Class 1: DPS-1
   "For vessels, which are fitted with a dynamic positioning system, which is capable of automatically maintaining the position and heading of the vessel under specified maximum environmental conditions having a manual position control system" (ABS, 2013).
3. Class 2: DPS-2
   "For vessels, which are fitted with a dynamic positioning system, which is capable of automatically maintaining the position and heading of the vessel within a specified operating envelope under specified maximum environmental conditions during and following any single fault, excluding a loss of compartment or compartments" (ABS, 2013).
4. Class 3: DPS-3
   "For vessels, which are fitted with a dynamic positioning system, which is capable of automatically maintaining the position and heading of the vessel within a specified operating envelope under specified maximum environmental conditions during and following any single fault, including complete loss of a compartment due to fire or flood" (ABS, 2013).

DPS-1, DPS-2 and DPS-3 classification notations stated by ABS (2013) are structured to conform to IMO (2017). Therefore, the classifications DPS-1, DPS-2 and DPS-3 relate to IMO's equipment classifications 1, 2 and 3 (ABS, 2013).

3 STATISTIC ANALYSIS

For the purpose of hazard identification, incident data has been gathered from two sources: the World Offshore Accident Database (WOAD) and the IMCA. The data from IMCA has been utilised for the majority of the analysis as it is consistent and covers a substantial time period.

3.1 *Terms used by IMCA*

The incidents and events listed in the various reports have been categorized by IMCA into three areas, where PL stands for Position Loss. These categories are:

1. *DP Incident (PL 1): This is the loss of automatic DP control, loss of position or any other incident which has resulted in or should have resulted in a RED Alert status* (IMCA 2017). In other words, these are incidents of a serious nature.
2. *DP Undesired Event (PL 2): Loss of position, loss of stability, or another event which is unexpected or uncontrolled and has resulted in or should have resulted in a Yellow Alert status* (IMCA 2017). As such, they are incidents of a less serious nature.
3. *DP Downtime: Position keeping problem or loss of redundancy which would not warrant either a 'Red' or 'Yellow' alert, but where loss of confidence in the DP has resulted in a stand-down from operational status for investigation, rectification, trials, etc*. (IMCA 2017). From an operational point of view, a loss of time or downtime can be seen as an undesired event which should be avoided at all cost, so as to save money.

For the purpose of this research, further analysis focuses on the prior two incidents; DP Incidents (PL 1) and Undesired Incidents (PL 2).

There are two common types of position loss, these are as follows:

1. Drive Off: This is characterised by the thrusters going to high unwanted thrust usually because the DP control system believes the position is wrong (Jenman 1998).
2. Drift Off: This is caused by the lack of sufficient power or thrust. For example, a total blackout on a ship on high seas, combined with strong currents. This would lead to a drift off (Jenman 1998).

There was a debate as to how one would differentiate a "drift off" and a "drive off" of vessels that were quickly recovered and returned to their original position as opposed to vessels which travelled far from their original position and could not be easily recovered (Jenman 1998). These arguments led to the addition of the third type of position loss, Large Excursion.

3. Large Excursion: This is an excursion that takes the DP vessel beyond its normal excursion characterised by its footprint. The footprint is the outline of the vessels movement in a particular sea state (Jenman 1998).

3.2 *IMCA reporting*

Vessels from all over the world, report DP related incidents to IMCA, who ensure that the vessel reporting is kept anonymous, thereby ensuring safety and keeping company integrity. Also, there are a range of export regulations and restrictions which affect business and trade with many countries of the world. These include restrictions on dual-goods and technology as well as the various sanctions regimes (UN, US and EU) targeting individual states including, regulation (EU) No. 833/2014 which is directed at Russia.

The data used in this research is available on the IMCA website, to IMCA members only. However, there are exceptions so that the information can be released to other interested parties who are not IMCA members. IMCA requires both its members and non-members to confirm that they will not use any IMCA document in breach of the Restrictions.

The data provided spanned over 17 years (2000–2016). From the reporting styles over the years, some improvements in reporting are visible, thereby creating differences in the data provided.

From Table 1, a total of 1,163 incidents were analysed and documented by IMCA between the 17-year periods. From Table 1, it is possible that the incident reporting by vessel owners is not consistent. It declined from 2000 to 2004 then picked back up, to peak in 2008 and fall again in 2010. Then there was a steady increase throughout the remaining years.

More emphases should be placed on incident reporting, including potential near misses.

Table 1. Incident data analysed from 2000 to 2016.

Incidents reported			
2000	110	2008	102
2001	98	2009	75
2002	64	2010	56
2003	51	2011	54
2004	34	2012	64
2005	36	2013	64
2006	59	2014	71
2007	67	2015	80
2008	102	2016	78

From the 1,163 incidents analysed, 633 of those incidents indicated the month in which they occurred. This was from the year 2007 to 2015. Based on these IMCA reports, Table 2 was developed.

It can be seen from Table 2 that in the spring and summer of the 9 years, recorded the highest amount of incidents reported. Taking a closer look at the individual years and months, it is evident that even though spring has the highest number of incidents reported over the 9 years, there were more years when summer had more incidents reported than spring. From this, one can state that the majority of the incidents reported occur during summer and spring time.

Looking at the seasons of the year and looking at the months where natural disasters are prominent, this falls within the same seasons as the one stated above. According to AccuWeather Inc., an American media company that provides commercial weather forecasting services worldwide, hurricanes occurs at different times of the year for different regions in the world. For the Atlantic Ocean, hurricane season runs from June to November. In the Eastern Pacific Ocean, it occurs in the months of May through to November. The hurricane season for the Western Pacific Ocean runs from July to November, while in the South Pacific Ocean, it runs from October through to May, reaching a peak in late February or early March. The Indian Pacific Ocean's hurricane season runs from April to December in the Northern Indian Ocean and October to May in the Southern region (Mummey 2010).

Research conducted by the University of Manchester, showed that tornado season in the UK occurs within the months of May to October (Mulder & Schultz 2015). Mother Nature Network on tornado season in America stated that it occurs between March and Early June in the Southern regions. They also state that in the Gulf Coast, tornadoes occur during the spring, while peaking in June and July in the Northern regions. Some states are also mentioned to experience a later tornado season from October to December (Sarah 2011).

From the analyses above, it is evident that most of the adverse weather conditions occur during the spring to autumn seasons. It is safe to attribute this to the reason why there is a higher frequency of incidents reported within the spring to autumn seasons.

Furthermore, the IMO does not state at which time of the day these incidents have occurred. Similarly, it should be noted that these incidents are provided from all around the globe, not one specific region.

For legal, trade and restriction reasons, the number of incidents occurring in different areas of the world has been withheld.

3.3 *Incidents according to vessel type*

Several DP vessels with different functions report incidents to IMCA. Inconsistency in reporting and change of reporting style can be seen in this area. The years stated in this report are the years that were clearly documented by IMCA. The following types of vessels that reported incidents over the aforementioned years are as follows:

1. Remote Operated Vehicles (ROVs)
2. DP Diving Support Vessels (DSV)
3. Drilling Vessels
4. Pipe/Cable Lay Vessels
5. Offshore Loading Vessels
6. Standby Vessels
7. Well Operations Vessels
8. Seismic Vessels
9. Multi Service Vessels (MSV)
10. Shuttle Tanker

Table 2. Incident data analysed from 2000–2016.

	2007	2008	2009	2010	2011	2012	2013	2014	2015	Total	Season

11. Flotels
12. Construction Vessels
13. FPSO
14. Rock Dumping Vessels
15. Crane Vessels
16. Supply Vessels

Since there are different types of vessels of different functions and not all these vessels reported incidents every year, Table 3 shows a list of the vessels that reported incidents consistently through the stated time period.

Table 3 shows that DSVs have reported the most incidents in the 10 years stated above. From 2008 to 2014, the reporting style changed and the various vessels that had experienced incidents were not reported.

Table 3. Types of vessels reported 2000–2016.

	DP DSVs	Drilling	Pipe/Cable Lay
2000	21	22	4
2001	35	5	15
2002	11	5	12
2003	15	10	4
2004	4	13	2
2005	9	15	2

2007	16	15	11
2015	10	20	9
2016	18	2	19
Total	152	116	88

3.4 *Incident main causes*

In the IMCA reports, they go further by indicating the primary cause of each incident, making the statistical analysis very easy for the user. Table 4 shows the incident causes over the past few years

As shown in Table 4, the amount of incidents caused by the various DP elements are visible. On further study of Table 4, the elements that cause the most incidents per year can be identified. These elements have been highlighted in bold in Table 4. Judging from this, it is evident that the major main causes of the DP incidents that have been reported are caused by either Reference element or the Thruster Element. It should be noted that the reference element mentioned in Table 4 includes the sensors while the thruster element mentioned includes the propulsion system.

It has been found that in the years prior to 2010, reference system failures were the main cause of incidents. However, from 2011 to 2016, it can been seen that thruster failures have consistently been identified as the main cause of DP incidents. In 2000, there was a drastic drop in incidents related to reference systems. The number of reference related incidents then peaks again in 2008 falls drastically again up to 2016 and the reasons for this has not been identified here. It may be assumed that multiple DP regulations were adopted and enforced across the 17-year period which led to the decrease in reference related incidents.

Looking at the whole 17-year period, Table 4 sums up the total incidents caused by the different

Table 4. Incident main causes from 2000–2016.

Main causes	Computer	Environment	Power gen.	Operator	Reference	Thruster	Electrical	Other	Total

systems and elements, showing their various percentages as they relate to each other.

3.5 *Thruster statistics analysis*

From the analysis of Table 4, it is evident that the thruster system in recent times (2012–2016) has been the major cause of incidents. Looking further into this, it is possible to define initiating causes of undesired events relating to thruster failures. For this, a more specific analysis of incidents caused by thruster failures, that occurred within the years of 2012–2016, was conducted. It can be seen that for the period in question, a total of 357 incidents occurred, of which, 114 incidents were thruster-caused (31.9%), which is extremely high compared to other elements. Of the 114 incidents, 105 were categorized into the different undesired events; "drift off", "drive off" and "time loss" events. Table 5 shows the undesired incidents that occurred and their initiating events.

From Table 5, it is clear that the majority of thruster related incidents begin with a fault in the DP control system, followed by the electrical system and the mechanical system. It is worth noting here that some minor failures have been grouped together to make up the failures mentioned above. For control system, there are failures such as, feedback error, loss of control, wrong DP operator input, *etc.* These are the failures that are rectified when the DP control system is restarted. Software errors can also fall under DP control system errors. Under electrical errors, there are occurrences such as: loose wiring, fibre optic fault, low/high voltage supply, loose fuse, field circuit failure and DC motor failure. In this case, when the loose wire has been fixed or the electrical problem fixed, operation continues.

In the case of mechanical initiating failures, there are faults such as, low oil pressure, hydraulic pump failure, faulty valve, engine failure, oil pipe leakage, cooling motor failure, brake failure, *etc*. In any of these mechanical event scenarios, a redundant system will have to be used or the system will be taken off DP control and returned to port for fixing. For the category of human error, there are a number human failures, such as: wrong procedures, lack of maintenance, inexperience and late response. Some human errors fall under the DP control system, because there has to be an interface between the control system and the human. Here, depending on the fault, the vessel is regained as soon as possible to avoid a worse undesired event. For the reference system, there are errors such as; wind sensor errors, tachometer errors, DGPS errors, *etc*. These errors coupled with some hidden errors can cause the thruster to fail at an odd angle (pitch). Finally, there are failures relating to the power generators. These failures are explanatory on their own and can cause more than the thrusters to fail. They also include the failure of the Uninterrupted Power Supply system (UPS). When these fail, they can cause an immediate failure of the thruster, which can be fixed by a redundant power generation system.

Table 5. Undesired incidents identified from thruster failures and their initiating causes from 2012 to 2016.

Undesired events	Drive off	Drift off	Time loss	Total
Reference	0	0	2	2
Electrical	5	3	21	29
Mechanical	2	2	21	25
Generator	0	0	1	1
Control system	7	6	22	35
Human error	3	2	7	12
Total	17	13	74	104

4 CONCLUSION

From the statistical analysis presented in this study, it was possible to determine the number of incidents that occurred in the different seasons of the year, over a 9-year period. From the results obtained, it was observed that there was an increase in the incidents in the spring and summer seasons. From research it was discovered that this could be as a result of the harsh natural weather conditions that occur during those seasons of the year, such as, tornadoes, hurricanes, *etc*. The tides that occur during the spring, resulting in high tide were also mentioned as a factor for increased incidents during these seasons.

The vessel types with the most incidents were also analysed. It was found that of all the vessels recorded, the three types; DSV, Pipelay and Drilling Vessels had the most incidents recorded. The DSV had the most recorded incidents, with 152 consistently recorded (see Table 3). The reason for this was not fully identified, however it can be argued that pipelay vessels are not used as frequently the DSVs or Drilling vessels. Hence, this has resulted in large difference in the number of reported incidents relating to these vessel types.

Following this, the main causes were analysed and separated into several categories. It was found that the two categories with the highest number of incidents in the 17 year period (2000–2016) were the reference and thruster systems. On further investigation of the data, it was found that within

the years 2000 to 2002 there was a drastic drop in reference caused incidents. Although not found, it is suspected that a regulation was brought into force during that time that either checked incident occurrence or made the operators not to be able to report incidents.

Failure of thruster systems were further analysed because in previous years (2012–2016), they were the major cause of DP incidents. The analysis led to the discovery of the initiating events of the thruster failures and their final consequences (Drift-Off, Drive-Off and Time Loss). This helped to identify the hazards and establish the basic events that would cause the release of such hazards and provided a base to conduct a risk assessment.

Although there were changes in the style of reporting, which led to the inconsistency of some information, the data sourced from IMCA was sufficient in identifying the hazards relating to DP operations.

Finally, from the hazard analysis, reference failures and thruster failures were identified as the major causes of DP incidents, with control failure being the most frequent initiating event leading to thruster failures.

ABSTRACT: We present a method based on heterogeneous ensemble learning for the prediction of the Remaining Useful Life (RUL) of cutting tools (knives) used in the packaging industry. Ensemble diversity is achieved by training multiple prognostic models using different learning algorithms. The combination of the outcomes of the models in the ensemble is based on a weighted averaging strategy, which assigns weights proportional to the individual model performances on patterns of a validation set. The proposed heterogeneous ensemble has been applied to real condition monitoring knife data. It has provided more accurate RUL predictions compared to those of each individual base model.

1 INTRODUCTION

As the digital, physical and human worlds continue to integrate, the 4th industrial revolution, the internet of things and big data, the industrial internet, are changing the way we design, manufacture, deliver products and services. In this fast-pace changing environment, the attributes related to the reliability of components and systems continue to play a fundamental role for industry. On the other hand, the advancements in knowledge, methods and techniques, the increase in information sharing and data availability, offer new opportunities of analysis and assessment for reliability engineering. Based on this increased knowledge, information and data available, we can improve our reliability prediction capability. Particularly, the increased availability of data coming from monitoring the relevant components and systems parameters and the grown ability of treating these data by intelligent algorithms capable of mining out information relevant to the assessment and prediction of their state, has open wide the doors for Prognostics and Health Management (PHM) and predictive maintenance in many industrial sectors, for improved operation and maintenance (Zio, 2016). Approaches for RUL estimation can be generally categorized into model-based and data-driven (Baraldi et al., 2015a). Model-based approaches use physics-based models to describe the degradation behavior of the equipment (Baraldi et al., 2015a). On the other side, data-driven methods are of interest when an explicit model of the degradation process is not available, as they rely on the availability of field data collected during the operation of one or more similar components. Among data-driven methods one can distinguish between (i) degradation-based approaches, modeling the future equipment degradation evolution and (ii) direct RUL prediction approaches, directly predicting the RUL.

Degradation-based approaches are based on statistical models that learn the equipment degradation time evolution from time series of the observed degradation (Baraldi et al., 2017). The predicted degradation state is, then, compared with a failure criterion, such as the value of degradation beyond which the equipment fails performing its function (failure threshold). Examples of modeling techniques used in degradation-based approaches are Auto-Regressive models (Gorjian et al., 2009), Relevance Vector Machines (Di Maio et al., 2012) and Semi-Markov Models (Cannarile et al., 2017a) (Cannarile et al., 2018).

Direct RUL predictions approaches, instead, typically resort to machine learning techniques

that directly map the relation between the observable parameters and the equipment RUL, without the need of predicting the equipment degradation state evolution towards a failure threshold (Schwabacher et al., 2007). Techniques used in direct RUL prediction approaches are, for example, Artifical Neural Networks (Wang & Vachtsenavos, 2001), Extreme Learning Machines (ELM) (Yang et al., 2017), Gaussian Processes (GP) (Baraldi et al., 2015b), etc.

When few run-to-failure degradation trajectories are available, direct RUL approaches may overfit, i.e., these algorithms customize themselves too much to learn the relationship between the observable parameters and the corresponding RUL in the training set. Therefore, these methods tend to lose their generalization power, which leads to poor performance on new data. To overcome this, ensemble approaches, based on the aggregation of multiple model outcomes, have been introduced (Baraldi et al., 2013a). The basic idea is that the diverse models in the ensemble complement each other by leveraging their strengths and overcoming their drawbacks.

Thus, the combination of the outcomes of the individual models in the ensemble improves the accuracy of the predictions compared to the performance of a single model (Brown et al., 2005) (Baraldi et al., 2013a). Different methods, such as ANN (Baraldi et al., 2013b), Support Vector Machine (SVM) (Liu et al., 2006) and kernel learning (Liu et al., 2015), have been used with success to build the individual models. For example, an ensemble of feedforward Artificial Neural Networks (ANN) has been embedded into a Particle Filter (PF) for the prediction of crack length evolution (Baraldi et al., 2013b) and an ensemble of data-driven regression models has been exploited for the RUL prediction of lithium-ion batteries (Xing et al., 2013). In (Rigamonti et al., 2017) a local ensemble of Echo State Networks (ESN) has been proposed to improve the RUL prediction accuracy of turbofan engines.

The objective of this work is to predict the RUL of knives installed on Tetra Pak® A3/Flex filling machines used to cut package material. The prognostic task is complicated by the fact that few run-to-failure degradation trajectories are available, and a failure threshold is not available. To cope with these issues, this work proposes an ensemble formed by multiple data-driven direct RUL prediction models, capable of aggregating the RUL predictions for good performance throughout the entire degradation trajectory of a knife. Ensemble diversity is achieved by *heterogeneous* ensemble generation, i.e., by training the models using different prognostics algorithms. Aggregation is obtained by averaging the output of the individual base models with weights proportional to the inverse of their Empirical Generalization Error (EGE) on retrieved patterns in a validation set. The application of the proposed heterogeneous ensemble method to real condition monitoring knife data has shown to provide more accurate RUL prediction compared to that of each individual base learner in the ensemble.

The paper is organized as follows: in Section 2, the objectives of this work and the assumptions are discussed; in Section 3, ensemble learning main concepts for data-driven direct RUL prediction are illustrated; in Section 4, performance metrics to compare different prognostic models are discussed. The application of the methodology to Tetra Pak® A3/Flex filling data is described in Section 5, whereas Section 6 draws the work conclusions.

2 ASSUMPTIONS AND OBJECTIVES

We assume to have available run-to-failure degradation trajectories of N pieces of equipment similar to the one currently monitored (test equipment). Let $\boldsymbol{x}_i(\tau_i) \in \mathbb{R}^m, i = 1,..,N; \tau = 1,...,n_i$ be the vector of m features extracted from signal measurements performed at time τ_i on the ith i^{th} equipment, with ni indicating the total number of data acquisitions performed on the ith equipment before its failure. The ground truth RUL of the ith piece pf equipment at time τ_i will be referred to as $y_i(\tau_i), i = 1,\ldots,N; \tau_i = 1,\ldots,n_i$. We consider a case in which the failure thresholds for the extracted features are not known. In this setting, fault prognostics is framed as a regression problem: given the historical dataset U formed by N realizations (degradation trajectories) $\{\boldsymbol{x}_i(\tau_i), y_i(\tau_i), \tau_i = 1,\ldots,n_i\}, i = 1,\ldots,N$, of a stochastic process $(\boldsymbol{X}(\tau), Y(\tau)) \in \mathbb{R}^m \, x(0,+\infty)$, our task is to find a function $\tilde{f}: \mathbb{R}^m \to (0,+\infty)$ such that it associates to a test pattern $x_{test}(\tau_{test}) \in \mathbb{R}^m$, the corresponding output $y_{test}(\tau_{test})$. In what follows, we refer to $\tilde{f}$ as base model or base learner (Zhou, 2012).

3 ENSEMBLE LEARNING FOR FAULT PROGNOSTICS

In contrast to ordinary learning approaches which try to construct one base learner from training data, ensemble methods try to construct a set of learners $\widetilde{f_1},\ldots,\widetilde{f_H}$ and combine them to obtain an ensemble learner $\widetilde{f_{ens}}$. In this work, we consider combination of base learners based on weighted averaging (Zhou, 2012), i.e., the combined output $\widetilde{f_{ens}}$ is obtained by averaging the output of the individual learners with different weights α_h,

which implies that the different learners have different importance

$$\widetilde{f_{ens}}\left(\boldsymbol{x}(\tau)\right) = \sum_{h=1}^{H} \alpha_h \widetilde{f}_h\left(\boldsymbol{x}(\tau)\right) \quad (1)$$

where

$$\sum_{h=1}^{H} \alpha_h = 1; \quad \alpha_h \geq 0; \; h = 1,\ldots,H \quad (2)$$

3.1 *Error ambiguity decomposition*

In this Subsection, we motivate the use of ensemble learning to enhance RUL predictions of a test equipment. Referring to the ensemble generalization error as $GE\left(\widetilde{f_{ens}}\right)$, one can show that the following error-ambiguity decomposition holds (for more details, see the Appendix):

$$GE\left(\widetilde{f_{ens}}\right) = \overline{GE}(h) - \overline{ambi}(h) \quad (3)$$

where $\overline{GE}(h) = \sum_{h=1}^{H} \alpha_h GE\left(\widetilde{f}_h\right)$ is the weighted average of the hth individual base learner generalization error $GE\left(\widetilde{f}_h\right)$; and $\overline{ambi}(h) = \sum_{h=1}^{H} \alpha_h ambi\left(\widetilde{f}_h\right)$ is the weighted average of the hth individual base learner ambiguity $ambi\left(\widetilde{f}_h\right)$ defined in Appendix. The quantity $ambi\left(\widetilde{f}_h\right)$ quantifies how much the hth base learner predictions, $\widetilde{f}_h$, differ from the ensemble predictions. On the right-hand of Eq. (3), the first term $\overline{GE}(h)$ represents the individual learner average error, which depends on the generalization ability of individual base learners whereas the second term $\overline{ambi}(h)$ represents the ambiguity, which depends on the ensemble diversity. Since the second term is always positive, and it is subtracted from the first term, it is clear that the error of the ensemble will never be larger than the average error of the individual base learners. Further, Eq. (11) shows that the more accurate and the more diverse the individual learners, the better the ensemble.

3.2 *Ensemble generation*

According to the error-ambiguity decomposition discussed in Subsection 3.1, ensemble diversity, i.e., the difference among the individual base learners is a fundamental issue in ensemble learning. Therefore, since complementarity is more important than pure accuracy (Zhou, 2012), an ensemble formed by only very accurate learners can provide worse performances than one formed by also some relatively weak learners. Two approaches are typically used to generate diverse base learners:

- *Homogeneous ensemble generation*: different base learners are generated using the same prognostic algorithm and diversity is achieved by manipulating data in different ways: subsampling from the training set (e.g., bagging ((Zhou, 2012))) or using different subsets of features.
- *Heterogeneous ensemble generation*: different base models are generated using different prognostic algorithms.

In this work, we have resorted to heterogeneous ensemble generation since it has been shown able to provide better performance than homogenous ensemble methods in cases of few low-dimensional data (Rathore & Kumal, 2017).

3.3 *Setting the ensemble base model weights α_h*

The data extracted from the available N run-to-failure degradation trajectories of similar components are divided into training, validation and test subsets, formed by P_{train}, P_{valid} and P_{test} instances, respectively. The training subset is used to build the H individual base models, the validation subset to assign them weights to be used for the aggregation of the individual model outcomes (Eq. (1)) and the test subset to verify the final ensemble performance. The weight α_h associate to the hth base learner is calculated based on its performance in predicting the RUL of the validation set patterns. Performance is measured resorting to the Empirical Generalization Error (EGE), which for the hth base learner is defined as the mean squared error on validation set patterns:

$$\widehat{GE}\left(\widetilde{f}_h\right) = \frac{1}{P_{valid}} \sum_{p=1}^{P_{valid}} \frac{1}{n_p} \sum_{\tau_p=1}^{n_p} \left(y_p(\tau_p) - \widetilde{f}_h\left(\boldsymbol{x}_p(\tau_p)\right)\right)^2 \quad (4)$$

In this work, we have considered weights proportional to the inverse of the EGE, i.e.,

$$\alpha_h = \frac{\dfrac{1}{\widehat{GE}\left(\widetilde{f}_h\right)}}{\displaystyle\sum_{l=1}^{H} \frac{1}{\widehat{GE}\left(\widetilde{f}_l\right)}} \quad h = 1,\ldots,H \quad (5)$$

4 PROGNOSTIC PERFORMANCE METRICS

In addition to EGE, we have considered other performance metrics, which are typically considered (Rigamonti et al., 2017) for quantitatively assessing and comparing the point prediction performance of different prognostic algorithms (Saxena et al., 2009). A brief description of the implemented metrics is

given hereafter considering a generic test trajectory $\left(\boldsymbol{x}(\tau), y(\tau)\right), \tau = 1, \quad, n$ and a general base learner $\tilde{f}$.

- *Relative Accuracy (RA)*:

$$R\left(\tilde{f}\right) = \sum_{\tau}^{n} \exp\left(-\frac{\left|\tilde{f}(x(\tau) - y(\tau)\right|}{y(\tau)}\right) \tag{6}$$

Notice that $R\left(\tilde{f}\right)$ is in the range $[0,1]$ and the larger the relative accuracy the more accurate is the model.

- *Precision*:

$$P = \sqrt{\frac{\sum_{\tau=1}^{n}\left(e(\tau) - \bar{e}\right)^2}{n}} \tag{7}$$

$$e(\tau) = \tilde{f}\left(x(\tau)\right) - y(\tau) \tag{8}$$

$$\bar{e} = \frac{1}{n}\sum_{\tau=1}^{n} e(\tau) \tag{9}$$

This measure quantifies the dispersion (stability) of the prediction error around its mean. Closer to zero is the precision, more stable is the model.

5 CASE STUDY

This Section presents the results of the application of the proposed method to Tetra Pak® A3/Flex filling knife condition monitoring data.

We have available run-to failure-degradation trajectories from N = 10 different knives. For each knife, we have available m = 2 health indicators which have been extracted using the procedure presented in (Cannarile et al., 2017b).

In this work, a heterogeneous ensemble generation has been developed considering H = 4 prognostic algorithms:

- Gaussian Process Regression with Squared Exponential (GPRSE) covariance function;
- GRP with Matern 3/2 (GRPM) covariance function;
- Support Vector Regression with Gaussian Kernel (SVRGK);
- SVR with Quadratic Polynomial Kernel (SVRQPK).

These algorithms have been selected, since they have proved to be effective also when few training data with no clear patterns of regularity are available for training (Domingos, 2012). To properly compare the performance of the ensemble model with that of each base model, we have resorted to a twice nested Leave-One-Out-Cross-Validation (LOOCV) approach. The outer loop is to assess the performance of the ensemble and the single base learners, whereas the inner loop allows setting the weights $\alpha_h, h = 1,..,4$. In practice, the weights associates to the base learners are computed on each outer-validation set (using the inner LOOCV loop) and the final performance is measured on the corresponding outer-testing set (see Figure 1).

Table 1 compares the performances of the developed ensemble model with that of the GRPM model, which has resulted to be the best performing individual model.

Notice that the ensemble model performs better than GRPM in all the considered metrics. In particular, the average EGE is 11.14% lower (more satisfactory) than that of GRPM, the relative accuracy of the ensemble is 3.34% larger (more satisfactory) than that of GRPM, whereas, the two methods are comparable from the point of view of the precision. Finally, Figs. 2 and 3 show the RUL predicted by the ensemble and GRPM for two representative test trajectories.

The most satisfactory ensemble predictions tend to be at the begininning of the life of the test knife. This is reflected by the great improvement of the EGE metric, which is more sensible to errors at the beginning of the run to failure trajectory than the relative accuracy.

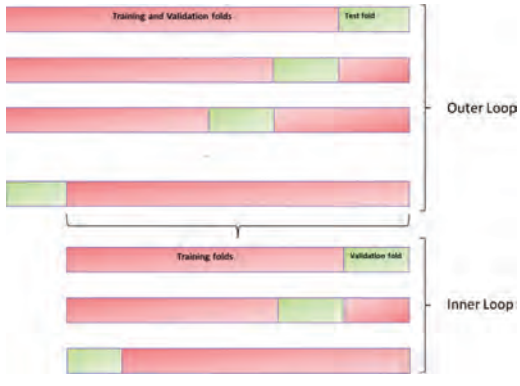

Figure 1. Twice nested LOOCV.

Table 1. Comparison between the ensemble and the GRPM performances.

	Ensemble	GRPM
Empirical Generalization Error (EGE) (best value 0)	3.2991	3.7127
Relative Accuracy (RA) (best value 1)	0.8149	0.7804
Precision (best value 0)	0.0569	0.0633

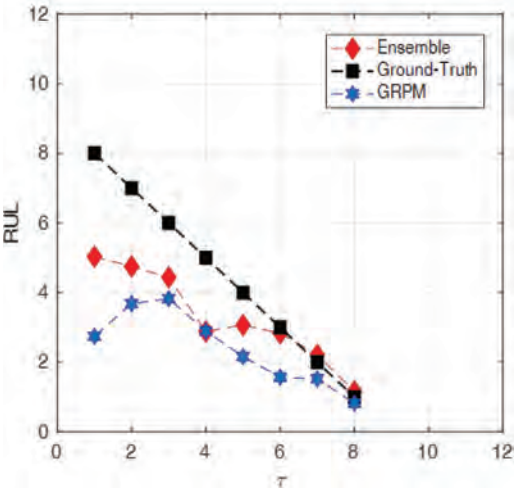

Figure 2. Predicted RUL by the ensemble (diamonds) and GRPM (exagon) for a test trajectory.

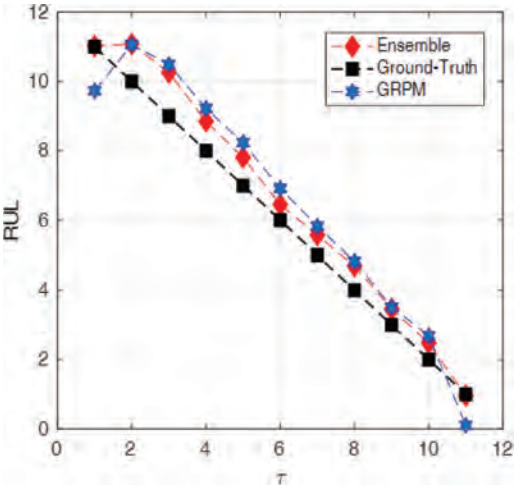

Figure 3. Predicted RUL by the ensemble (diamonds) and GRPM (exagon) for a test trajectory.

6 CONCLUSIONS

In this work, we have developed a heterogeneous ensemble model for enhancing the accuracy of the RUL prediction of knives used in the packaging industry. Thanks to the diversity of the base learner algorithms, the proposed approach has been shown capable of reducing the generalization error and providing more accurate RUL predictions compared to that of each individual base learner in the ensemble.

APPENDIX

Given an instance $\boldsymbol{x} = \boldsymbol{x}(\tau)$, the ambiguity of the individual base learner $\widetilde{f}_h$ is defined as

$$ambi\left(\widetilde{f}_h|\boldsymbol{x}\right) = \left(\widetilde{f}_h(\boldsymbol{x}) - \widetilde{f_{ens}}(\boldsymbol{x})\right)^2 \quad h = 1,\ldots,H \quad (10)$$

and the ambiguity of the ensemble is

$$\overline{ambi}\left(\widetilde{f_{ens}}|\boldsymbol{x}\right) = \sum_{h=1}^{H} \alpha_h ambi\left(\widetilde{f}_h|\boldsymbol{x}\right) = \sum_{h=1}^{H} \alpha_h \left(\widetilde{f}_h(\boldsymbol{x}) - \widetilde{f_{ens}}(\boldsymbol{x})\right)^2 \quad (11)$$

The ambiguity term measures the disagreement among the individual base learners on instance $\boldsymbol{x}$. If we use the Squared Error (SE) to measure the performance, then, the error of the individual base learner $\widetilde{f}_h$ and the ensemble $\widetilde{f_{ens}}$ are, respectively,

$$SE\left(\widetilde{f}_h|\boldsymbol{x}\right) = \left(\widetilde{f}_h(\boldsymbol{x}) - f(\boldsymbol{x})\right)^2 \quad h = 1,\ldots,H \quad (12)$$

$$SE\left(\widetilde{f_{ens}}|\boldsymbol{x}\right) = \left(\widetilde{f_{ens}}(\boldsymbol{x}) - f(\boldsymbol{x})\right)^2 \quad (13)$$

Then, one can show that (Zhou, 2012)

$$\overline{ambi}\left(\widetilde{f_{ens}}|\boldsymbol{x}\right) = \overline{SE}\left(\tilde{h}|\boldsymbol{x}\right) - SE\left(\widetilde{f_{ens}}|\boldsymbol{x}\right) \quad (14)$$

where $\overline{SE}\left(\tilde{h}|\boldsymbol{x}\right) = \sum_{h=1}^{H} \alpha_h SE\left(\widetilde{f}_h|\boldsymbol{x}\right)$ is the weighted average of the individual base learner errors. Since Eq. (14), holds for every instance $\boldsymbol{x}$, after averaging over the input distribution $p(\boldsymbol{x})$ from which the instances are sampled, it still holds that.

$$\sum_{h=1}^{H} \alpha_h \int ambi\left(\widetilde{f}_h|\boldsymbol{x}\right) p(\boldsymbol{x})\, d\boldsymbol{x} = \sum_{h=1}^{H} \alpha_h \int SE\left(\widetilde{f}_h|\boldsymbol{x}\right) p(\boldsymbol{x})\, d\boldsymbol{x} - \int SE\left(\widetilde{f_{ens}}|\boldsymbol{x}\right) p(\boldsymbol{x})\, d\boldsymbol{x} \quad (15)$$

The generalization error and the ambiguity of the individual base learner $\widetilde{f}_h$, can be written as, respectively,

$$GE\left(\widetilde{f}_h\right) = \int SE\left(\widetilde{f}_h|\boldsymbol{x}\right) p(\boldsymbol{x})\, d\boldsymbol{x} \quad h = 1,\ldots,H \quad (16)$$

$$ambi\left(\widetilde{f}_h\right) = \int ambi\left(\widetilde{f}_h|\boldsymbol{x}\right) p(\boldsymbol{x})\, d\boldsymbol{x} \quad h = 1,\ldots,H \quad (17)$$

Similarly, the generalization error of the ensemble reads

$$GE\left(\widetilde{f_{ens}}\right) = \int SE\left(\widetilde{f_{ens}}\,|\,\boldsymbol{x}\right) p(\boldsymbol{x})\, d\boldsymbol{x} \quad h = 1,\ldots,H \quad (18)$$

Based on the notation just introduced and Eq. (14), we obtain the error-ambiguity decomposition (Zhou, 2012):

$$GE\left(\widetilde{f_{ens}}\right) = \overline{GE}(h) - \overline{ambi}(h) \quad (19)$$

ABSTRACT: Risk Informed Decision Making (RIDM) is based on risk metrics obtained from a Probabilistic Risk Assessment (PRA). For plants exposed to multiple hazards, Multi-Hazards Risk Aggregation (MHRA) is necessary to inform decisions. In practice, this is often done by a simple arithmetic summation over the different risk contributors, without taking into account that the state of knowledge of the risk models of the different hazards can be quite different. In this paper, we provide a hierarchical framework to assess the strength of knowledge that PRA models are based upon. The framework is organized in three attributes characterizing the knowledge which a PRA model is based upon (assumptions, data, phenomenological understanding). These attributes are further broken down into sub-attributes and, finally, "leaf" attributes that can be evaluated. The PRA models of two hazards groups for Nuclear Power Plants (NPPs) are considered and the strength of knowledge behind each model is assessed using the developed framework.

1 INTRODUCTION

In risk assessment, quantities are calculated to describe the magnitude and likelihood of the consequences from accidents that may develop from known hazards [1]. The confidence on the calculated risk indexes depends on the knowledge available to support the risk assessment [3–5]. For example, in the risk assessment of Nuclear Power Plants (NPPs), there is more experience and knowledge on internal events than other hazard groups like external flooding [1]. Evaluating the strength of knowledge of a risk assessment, is, then, important to evaluate how much confidence we can put on the risk outcomes, that are, then, used to inform decision making [2].

Research efforts have been conducted, recently, for linking knowledge, knowledge evaluation and knowledge management to Risk-Informed Decision-Making (RIDM) [4–7]. For example, in the nuclear industry, knowledge management has been identified as a key factor in sustaining nuclear power programs and maintaining their safety and security [3]. However, most of the existing works are qualitative in nature. A semi-quantitative method for evaluating the strength of knowledge has been proposed by Flage and Aven [4], where the strength of knowledge is evaluated in terms of four attributes: (i) phenomenological understanding and availability of trustable predicting models; (ii) reasonability and realism of assumptions; (iii) availability of reliable and relevant data, and information; (iv) agreement/disagreement among peers. The four attributes were assessed in three levels (minor, moderate and significant) and aggregated for strength of knowledge assessment [4]. Although the knowledge attributes proposed are plausible and reasonably complete, their definitions remain ambiguous. In addition, the evaluation of these attributes is somewhat intangible in practice, since it is done by simple scoring based on a plain description of the attributes. To overcome this problem, we expand the work in [5] and introduce a hierarchical tree-based framework for evaluating the state of knowledge.

The rest of the paper is organized as follows. In Sect. 2, we present the developed framework for strength of knowledge assessment. Section 3

applies it on a case study of two hazard groups considered in NPPs risk assessment. Finally, in Sect 4, the paper is concluded with a discussion on potential future developments.

2 ASSESSMENT FRAMEWORK

We consider the strength of knowledge assessment of event tree models which are widely applied in PRA of NPPs. The events probabilities in the event tree model might are typically calculated by fault tree models. The risk index associated to a given consequence (e.g. the probability of core damage) is calculated by summing the values of the risk index from several risk models:

$$R = \sum_{i=1}^{n_O} \sum_{j=1}^{n_{S,i}} R_{i,j} \quad (1)$$

where n_O is the number of operation states (O), $n_{S,i}$ is the number of accident sequences (scenarios, S) that in operation state i can lead to the given consequence. Each $R_{i,j}$ in (1) quantifies the specific risk index under scenario j (e.g., medium flood level) in operation state i (e.g., emergency shutdown).

The risk models used to calculate the risk index $R_{i,j}$ values are characterized by Initial Events (IEs), Basic Events (BEs) and the combinations of the latter into Minimal Cut Sets (MCSs). In practice, it can often be assumed that the MCSs are mutually exclusive; then, $R_{i,j}$ can be calculated by [5]:

$$R_{i,j} = \sum_{k=1}^{n_{MCS,i,j}} \prod_{q=1}^{n_{BE,k}} P_{BE,q} \quad (2)$$

where $n_{MCS,i,j}$ is the number of minimal cut sets in the risk model for operation state i and scenario j, $n_{BE,k}$ is the number of basic events in the kth minimal cut set, and $P_{BE,q}$ is the probability of having the qth basic event. The five elements, S, O, IE, BE and MCS, fully define a PRA model, as shown in Figure 1. In this paper, we refer to these five elements as "atomic elements".

To assess the strength of knowledge of a PRA model, all the five atomic elements need to be considered. In practice, however, PRA models are very complex and contain many scenarios and operation states combined in large and complex fault trees and event trees, that consist of thousands of BEs and MCSs [6]. For such a complex risk assessment model, it is not practical to consider all atomic elements for evaluating the strength of knowledge. To address this problem, in this work, we first develop a reduced-order model for (1), in order to limit the number of atomic elements that need to be analyzed.

A flowchart of the developed knowledge assessment method is given in Figure 2. The first step

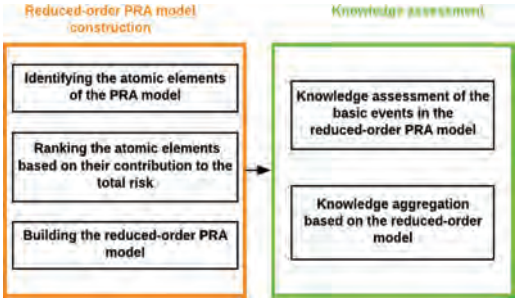

Figure 1. Steps of PRA model knowledge assessment.

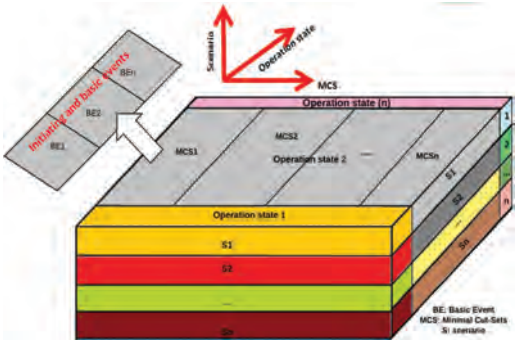

Figure 2. Atomic elements of a PRA model.

involves developing a reduced-order model for the original risk assessment model. A detailed discussion on how to construct the reduced-order model is given in Sect. 2.1. Then, the strength of knowledge supporting each atomic element in the reduced-order model is assessed by an Analytical Hierarchy Process (AHP), as illustrated in Sect. 2.2. Finally, the strength of knowledge of each element is aggregated to evaluate the strength of knowledge of the entire PRA model. A detailed discussion is given in Sect. 2.3.

2.1 *Reduced-order PRA model construction*

It is often observed in PRA models that most of the contribution to the total risk is due to a small number of elements of the problem (known as "*Pareto principle*") [7]. We can, then, reduce the PRA model into a reduced-ordered model, which consists of only the most important "*elements*".

The procedure for constructing the reduced-order model comprises of three steps. Firstly, the number of operation states n_O is reduced to $n_{O,Red}$, as follows:

- Calculate the risk R_{O_i} for each operation state:

$$R_{O_i} = \sum_{j=1}^{n_{S,i}} R_{i,j}, \quad 1 \le i \le n_O \tag{3}$$

where $R_{i,j}$ is calculated by (2).

- Rank R_{O_i} in descending order.
- Find the minimal $n_{O,Red}$, so that

$$\frac{\sum_{i=1}^{n_{O,Red}} R_{O_i}}{R} \ge \alpha \tag{4}$$

where α is the fraction of total risk that can be reproduced by the operation states in the reduced-order model (in the case study in Sect. 3.2.1, we assume that $\alpha = 0.8$).

- Keep only operation states for $i = 1,\cdots,n_{O,Red}$; operation states with $i > n_{O,Red}$ are eliminated.

The second step is to define the reduced number of scenarios $n_{S,Red,i}$ for each operating state i in the reduced-order model, where $i = 1,\cdots,n_{O,Red}$:

- For $i = 1,\cdots,n_{O,Red}$, calculate the risk $R_{i,j}$, $1 \le j \le n_{S,i}$ by (2).
- Rank $R_{i,j}$ in descending order.
- Find the minimal $n_{S,Red,i}$ so that,

$$\frac{\sum_{j=1}^{n_{S,Red,i}} R_{i,j}}{R_{O,i}} \ge \beta \tag{5}$$

where R_{O_j} is calculated by (3) and β is the fraction of total risk that can be reproduced by the scenarios in the reduced-order model (in the case study in Sect. 3.2.1, we assume that $\beta = 0.8$).

- Keep only scenarios for $j = 1,\cdots,n_{S,Red,i}$; scenarios with $j > n_{S,Red,i}$ are eliminated.

Finally, the number of minimal cut sets $n_{MCS,i,j}$ is tailored to $n_{MCS,Red,i,j}$, $i = 1,...,n_{O,Red}, j = 1,...,n_{S,Red,i}$:

- Calculate $R_{i,j,k}$ by:

$$R_{i,j,k} = \prod_{q \in MCS_{i,j,k}} P_{BE,q}, \begin{matrix} 1 \le i \le n_{O,Red} \\ 1 \le j \le n_{S,Red,i} \\ 1 \le k \le n_{MCS,i,j} \end{matrix} \tag{6}$$

- Rank $R_{i,j,k}$ in descending order.
- Find the minimal $n_{MCS,Red,i,j}$ so that,

$$\frac{\sum_{k=1}^{n_{MCS,Red,i,j}} R_{i,j,k}}{R_{i,j}} \ge \gamma \tag{7}$$

where $R_{i,j,k}$ is calculated by (6) and γ is the fraction of total risk that can be reproduced by the minimal cut sets in the reduced-order model (in the case study in Sect. 3.2.1, we assume that $\gamma = 0.8$).

- Keep only minimal cut sets for $k = 1,\cdots,n_{MCS,Red,i,j}$; minimal cut sets with $k > n_{MCS,Red,i,j}$ are eliminated.

Assuming that the MCSs are mutually exclusive, the total risk of the reduced-order PRA model can be calculated by:

$$R_{Red} = \sum_{i=1}^{n_{O,Red}} \sum_{j=1}^{n_{S,Red,i}} \sum_{k=1}^{n_{MCS,Red,i,j}} \prod_{q \in MCS_{i,j,k}} P_{BE,q} \tag{8}$$

Note that from (4), (5) and (7), the reduced order risk R_{Rec} can reconstruct $\alpha \cdot \beta \cdot \gamma$ of the total risk R. Only the events that are contained in the reduced-order model (8) are used for assessing the strength of knowledge of the PSA.

2.2 *Knowledge assessment for the risk elements*

Once the reduced-order model is constructed, the strength of knowledge of each atomic element in such model is evaluated. In Section 2.2.1, we present a tree-based hierarchical framework for knowledge assessment. Then, in Section 2.2.2, we show how to proceed with the evaluation using the Analytical Hierarchy Process (AHP) method.

2.2.1 *Knowledge assessment framework*

A tree-based hierarchical framework is here developed for knowledge assessment, as shown in Figure 3. The strength of knowledge, represented by K (Level 1), represents the solidity of knowledge that supports a PRA model. A higher value of strength of knowledge indicates that the PRA model is supported by trustable evidence and reliable knowledge, and, therefore, its results can be taken with confidence.

As in Flage and Aven [4], we evaluate the strength of knowledge in terms of three attributes: assumptions (K_1), data (K_2) and phenomenological understanding (K_3) The attribute K_1 represents the adequacy, solidity and plausibility of the assumptions upon which the model is based; K_2 represents the amount and quality of the available data that are used to estimate the parameters of the model; K_3 represents the knowledge behind the phenomenon described in the model.

For their evaluation, the three attributes are further decomposed into sub-attributes. In particular, assumptions (K_1) is evaluated in terms of quality of assumptions (K_{11}), value ladenness (K_{12}) and impact (K_{13}); data (K_2) is evaluated in terms of the amount of data (K_{21}) and the reliability and consistency of data (K_{22}); phenomenological understanding (K_3) is evaluated in terms of years of experience of the experts involved in the model development (K_{31}), number of experts involved (K_{32}), academic evidence (K_{33}) and industrial evidence (K_{34}). Value ladenness and reliability and consistency of data are further decomposed into "leaf" sub-attributes in level 4 for their evaluation, as shown in Figure 3.

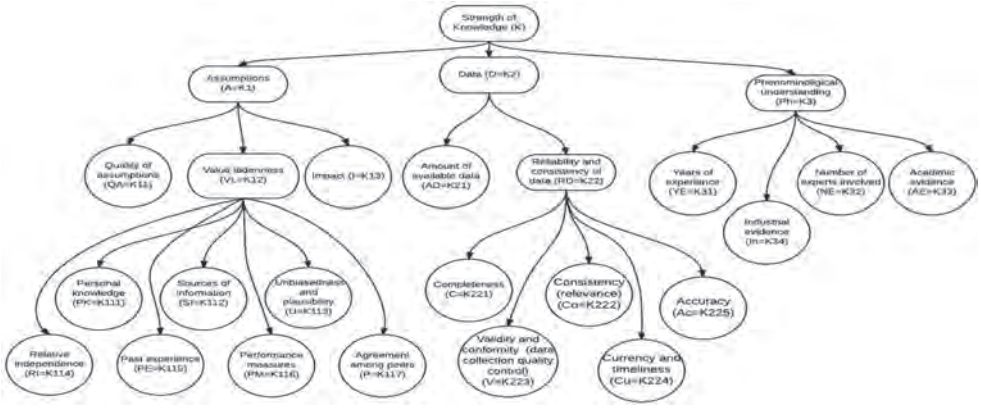

Figure 3. A hierarchical tree-based framework for knowledge assessment.

Table 1. References that justify the model in Figure 3.

Attributes	References
Strength of knowledge is evaluated by K_1, K_2 and K_3.	[4]
Realism and plausibility of assumptions (K_1) is evaluated by the quality of assumptions (K_{11}), the value ladenness and subjectivity of the experts (K_{12}) and sensitivity analysis on the assumptions (K_{13}).	[9]; [10]; [11]
Value ladenness (K_2) is defined by K_{111}–K_{117}.	[10]; [9]; [12]; [13]; [14]
Data (K_2) is evaluated in terms of amount of available data (K_{21}) and reliability of data (K_{22}).	[4]
Reliability of data is defined by: (i) completeness; (ii) consistency; (iii) accuracy; (iv) validity; (v) timeliness.	[15]; [16]; [17]

The tree structure in Figure 3 is constructed based on a thorough literature review related to trustworthiness and validity assessment of PRA/QRA. References related to the construction of the tree model are given in Table 1. It should be noted that for phenomenological understanding, few references directly consider its assessment. A comprehensive understanding of phenomena requires its explanation [8], which depends on the capability of the experts involved in the risk modeling and analyses. Then, four sub-attributes are proposed for the assessment of phenomenological understanding: (i) industrial evidence; (ii) academic evidence; (iii) number of experts involved; (iv) number of years of experience in the domain).

2.2.2 *Evaluation using AHP*

Given the hierarchical tree in Figure 3, the assessment of the strength of knowledge is carried out within a Multi-Criteria Decision Analysis (MCDA) framework. AHP is adopted [18], as it is fit for both quantitative and qualitative evaluation of attributes and factors [19] and for group decision making [20].

A first step in applying AHP is to evaluate the "leaf" attributes (the non-decomposable attributes in Figure 3). A score between 1 and 5 is used to represent the strength of knowledge with respect to each "leaf" attribute, where 1 represents the lowest knowledge level and 5 represents the highest knowledge level. The score is evaluated based on some predefined evaluation criteria. Due to page limits, we only present the evaluation criteria for K_{11} as an example (See Table 2).

Then, the inter-level priorities (weights) are determined for each attribute, sub-attribute and "leaf" attribute, denoted by $W(K_i), W(K_{ij})$ and $W(K_{ijk})$, respectively. Based on [14] and [20], a scale of 1–9 is used for evaluating the importance of each of these attributes relative to each other, with reference to their contribution to the parent attribute: a value of 1 is assigned when two attributes of the same level of the hierarchy are equally important and 9 is assigned when one attribute is significantly more important than the other.

The strength of knowledge of the ith atomic element, denoted by K_i, is, then, calculated as a weighted average of all the scores of the "leaf" attributes. The value of K_i is between 1 and 5 and a high value indicates that we have stronger knowledge on that atomic element.

Table 2. Quality of assumptions scoring guidelines.

Attribute \ Score	1	3	5
Quality of assumptions	The assumptions are based aon weak knowledge and not realistic (conservative assumptions or over-optimistic)	The assumptions are acceptable based on moderate knowledge, simple model and extrapolated data	The assumptions are based on strong knowledge and established theory, verified by peer review and very plausible

2.3 *Knowledge aggregation*

From (8), the risk index of the reduced-order PRA model is the sum of $n_l = \sum_{i=1}^{n_{O,Red}} n_{S,Red,i}$ risk index values $R_{Red,l}$ from the corresponding elementary risk model, where each elementary risk model is further composed of MCS and BEs, as shown in (2):

$$R_{Red,l} = \sum_{k=1}^{n_{MCS,Red,l}} \prod_{q \in MCS_{l,k}} P_{BE,q} \tag{9}$$

In (9), $R_{Red,l}$ is the risk index of the l-th reduced elementary risk model, where $l = 1,2,\cdots,n_l$ and $n_{MCS,Red,l}$ is the number of MCS in the l-th reduced elementary risk model.

Let $K_{BE,l,q}$ denote the strength of knowledge of the q-th BE in the reduced elementary risk, where $K_{BE,l,q} \in [1,5]$ and a large value of $K_{BE,l,q}$ indicates strong knowledge of BE. The $K_{BE,l,q}$s are assessed using the procedures described in Sect. 2.2.

The next step is to aggregate the $K_{BE,l,q}$s to assess the strength of knowledge of the whole risk assessment model. The aggregation should consider the difference in each atomic element's contribution to the total risk.

Different importance measures can be used to evaluate the contribution of the atomic elements with respect to the total risk. Since the elementary reduced-ordered risk model is constructed by the BEs through MCSs, the weights of the BEs are calculated based on Fussell-Vesely importance measures:

$$W_{BE,l,q} = \frac{I_{BE,l,q}}{\sum_{q=1}^{n_{BE,l}} I_{BE,l,q}} \tag{10}$$

where $I_{BE,ij}$ is the Fussell-Vesely importance measure of the corresponding BE in the elementary risk model l.

The strength of knowledge for the l-th elementary reduced order risk model, denoted by K_l, is calculated by:

$$K_l = \sum_{q=1}^{n_{BE,l}} W_{BE,l,q} \cdot K_{BE,l,q} \tag{11}$$

The importance of the elementary reduced-order model is evaluated by its contribution to the total risk:

$$W_l = \frac{R_{Red,l}}{\sum_{l=1}^{n_l} R_{Red,l}} \tag{12}$$

where $R_{Red,l}$ is the risk index value of the l-th elementary reduced order model and is calculated by (9).

To calculate the total strength of knowledge K_{Red} of the reduced-order risk model, the knowledge indexes K_ls of the reduced-order elementary risk models are further aggregated by considering their contributions:

$$K_{Red} = \sum_{l=1}^{n_l} W_l K_l \tag{13}$$

The index K_{Red} is, then, used to represent the strength of knowledge of the entire PRA. Its value is between 1 and 5, and a high value indicates that we have strong knowledge in support of the PRA model and its risk outcomes.

3 CASE STUDY

3.1 *Problem description*

In this section, we apply the developed method to assess the strength of knowledge of NPPs PRAs. Two hazard groups, i.e., external hazards and internal events are considered in this case study.

External hazards refer to the undesired events originating from sources outside the NPPs such as: external flooding, external fires, seismic hazards, etc., [21]. In particular, external flooding is a naturally induced hazard that might be caused due to different reasons such as: tides, tsunamis, dam failures, snow melts, storm surges and etc., (see [22] for more examples). The choice of these initiating events to be a part of the external flooding risk assessment models is site-specific and some guidance should be provided for this purpose [23]. In general, for external flooding, the state of PRA practice is considered less mature than for internal events [24]. For

example, the flood frequencies are obtained using statistical models and by extrapolating design basis flood levels to the fitted historical data (usually limited), which results in a very high uncertainty [24]. Moreover, for extreme floods, the probability of occurrence is very low but, on the other hand, the potential consequences can be catastrophic [22]. The low probability and the consequent lack of data experience introduces large uncertainties in the risk analysis of this type of events [22].

Internal events refer to the undesired events that originate within the NPPs itself, which cause initiating events that might lead to loss of important systems and might eventually result in core meltdown [1]. The internal events are mainly [25]: (i) different types of components, systems and structures failures, missiles and fires; (ii) safety systems operation and maintenance errors. These types of internal events can cause other initiating events such as turbine trip or Loss of Coolant Accidents (LOCAs). The risk assessment of internal events has been significantly developed and considered to have lower uncertainty compared to other hazard groups [1].

3.2 *Evaluation of hazard group strength of knowledge*

In this case study, we consider the risk analysis models of two hazard groups developed by Electricité de France (EDF) using Risk Spectrum Professional software [26]; [27]. The knowledge assessment framework developed in Section 2 is applied to evaluate the strength of knowledge of the risk models for both internal and external events. Technical reports were provided to the experts to support the knowledge assessment with the needed data and information. For simplification, we only present the case of the external events (specifically flooding). For internal events, we only show the results of the application.

3.2.1 *Reduced-order model construction*

Based on Eq. (4) with $\alpha = 0.8$, we found that only one out of six operating states (NS/SG-normal shutdown with cooling using steam generator-NS/SG) is needed for the reduced-order model, which contributes to 86% of the total risk index. Similarly, based on Eq. (5) with $\beta = 0.8$, only one out of ten scenarios (water levels) is needed for the reduced-order model, whose risk contribution is 98.7% Based on Eq. (7) with $\gamma = 0.8$, the number of MCSs needed for the reduced-order model is 5 out of 3102, and the risk contribution is 80.1%. Therefore, a reduced-order model is constructed based on the atomic elements in Table 3, as shown in Figure 4.

3.2.2 *Strength of knowledge assessment*

After constructing the reduced-order model, the knowledge assessment framework in Section 2.2 has been applied on each of the atomic elements and, then, AHP is used to compare the overall model strength of knowledge. The strength of knowledge for external flooding turns out to be $K_{EF} = 2.78$. The results of the knowledge assessment for both hazard groups are graphically illustrated in Figure 5. It can be seen from the Figure that the strength of knowledge on the internal events is higher than that on external flooding. In fact, these results confirm our expectations. In addition, most of the risk assigned to the external flooding is due to two basic events (failure to close the isolating valve in the auxiliary feedwater system and failure of the containment spray system), whose strength of knowledge is very weak.

Table 3. Reduced-order model constituents.

Operating state	Scenarios	Number of MCS	Number of basic events BE	Total risk contribution
NS/SG	Water level A	5	10	$0.86 \times 0.987 \times 0.801 = 0.6799$

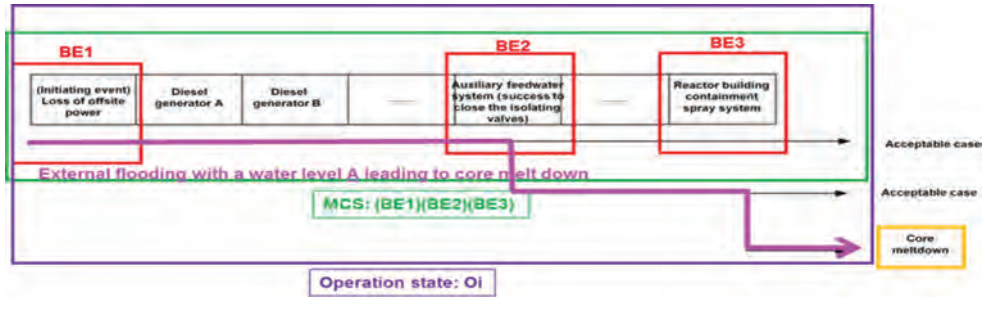

Figure 4. An illustration of the reduced-order model.

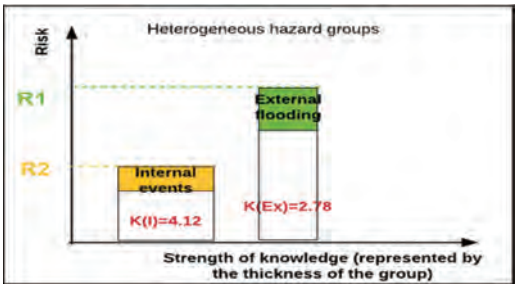

Figure 5. Representation of hazard groups levels of risk and strength of knowledge.

4 CONCLUSION

An analytical hierarchy process-based framework has been proposed for assessing the strength of knowledge of PRA models. The framework is based on three main attributes (assumptions, data, and phenomenological understanding), which are further decomposed into sub-attributes and "leaf" attributes. A reduced-order PRA model is constructed, that reduces the number of atomic elements to be analyzed. The framework has been applied on two hazard groups in NPPs.

In the future, model uncertainty in the PRA model will be considered for a more comprehensive knowledge assessment. In addition, in the current framework, the weights of the attributes in the AHP were subjectively evaluated. Future investigations will be devoted on how to more objectively evaluate the weights.

Formalization of RAM contracts for advanced consistency and completeness checking

A. Joanni & D. Ratiu
Siemens AG, Corporate Technology

ABSTRACT: Non-compliance with contractual terms concerning Reliability, Availability and Maintainability (RAM) can have significant financial impact on the profitability of technical projects due to e.g. penalties or warranty costs. Often, these terms are stipulated in complex (multi-party) contractual agreements. In practice, these contracts are captured as natural language prose and this can lead to ambiguities, inconsistencies or incompleteness. In this paper, we present the benefits obtained when RAM contracts have a precise formal description expressed in a semantically rich language. Examples of benefits are advanced validation and consistency checks such as overlap of time periods, gaps in warranties between parties, transfer of risks to other parties, even before a numerical evaluation is performed. We present a brief theoretical background of the approach, an illustration by means of exemplary contractual warranty terms, and give an outlook on further possibilities and advantages.

1 INTRODUCTION

Non-compliance with contractual terms concerning reliability, availability and maintainability (RAM) characteristics can significantly impact the profitability of technical projects. Complex projects involve contractual agreements between different par-ties working in different stages of the supply chain. These contracts must be perfectly synchronized and orchestrated to avoid unnecessary non-conformance costs for the contractor, for instance due to failures of the integrated components.

Common practice today is that contracts are written in plain natural language and thereby are often ambiguous and incomplete. Furthermore, natural language contracts are not amenable to automatic analyses.

A typical example of complex RAM contracts is related to warranties. Servicing of warranty cases involves additional (non-conformance) costs to the contractor and these costs depend on product reliability and contractual warranty terms between the contractor and the customer. Furthermore, these costs can be (fully or partially) covered by warranty contracts between the contractor and the individual suppliers. As extensively discussed in literature, see e.g. Murthy & Jack (2003), there is a wide variety of warranties policies determined by different warranties periods and associated costs. Examples of different periods are simple periods, extended warranties, life-time warranties, physical life, technological life; examples of different forms of penalties are product renewal, repairing and looping of warranty. Taking informed decisions about liability due to warranties requires transparent assessment of contractual requirements between all stakeholders (customer, contractor, suppliers). Other examples of complex RAM contracts are related to performance guarantees of technical systems.

Furthermore, automatic analysis of "what if" questions like "what additional costs would occur if the contractor offered extended warranty to customers" or "what is the longest warranty a contractor can offer such that the risk budget is under a certain threshold with a given confidence" require precise modeling and analysis of contracts.

In this paper we present our work in progress on using domain specific languages to model contracts in a precise and unambiguous manner. Once semantically rich contract models are available, they represent a basis for further analyses for consistency and completeness. As an example we model warranty clauses of multi-party contracts.

2 MODELING OF RAM CONTRACTS

2.1 *Previous work*

Formalization of (business) contracts using formal models and languages with precise semantics has been subject of research for about two decades; see e.g. Peyton Jones et al. (2000), Hvitved (2011) or Farmer & Hu (2016). In particular, these approaches have been adopted early on by the financial industry for pricing of contracts that

were traded e.g. in the financial derivative markets. It was realized that formalization of contracts not only gives a precise way to describe complex contracts, which may immediately reveal ambiguities of contracts expressed in a natural language. Moreover, the formal semantics provides the basis for analyzing and integrating formal methods into contracts, as well as for automated contract management. Last but not least, it provides a means to valuate contracts over time. All of this is, naturally, compositional and comes with a high degree of reusability, modularity and abstraction.

Modeling and valuation of contractual RAM requirements has been demonstrated in a previous paper by Joanni & Ratiu (2018), based on the pioneering work by Peyton Jones et al. (2000). Namely, a compact library of so-called contract primitives is used to perform compositional analysis of contractual RAM requirements expressed in the library, and based on this it is shown how to perform valuation of a broad range of contractual requirements. The contract primitives are supplemented by the concept of so-called observables, which determine how the meaning (and value) of a contract evolves over time. Observables, for instance, define when certain conditions become true that entail a certain payment at that time, or what the precise amount of a payment is. In the context of contractual RAM requirements: whether a given component has failed or not may constitute an observable; another example of an observable is the average availability of a module of a process plant over a given time period. In essence, observables are concepts that glue together the formal contract model and the model of the technical system.

2.2 *Modeling of technical and contractual RAM aspects*

This section briefly exemplifies and reiterates how contractual RAM requirements are expressed in terms of contract primitives and observables as demonstrated by Joanni & Ratiu (2018), in order to set the stage for advanced consistency and completeness checking of RAM contracts which is the focus of this paper.

For the purpose of contractual RAM requirements, the modeling of technical RAM aspects is one source of observables that determine how the meaning (and value) of a contract evolves over time. For instance, suppose that the warranty risks for component failures arising from a contract for a major technical project are to be analyzed, and the event of a control system failure of a given subsystem, say system 2, constitutes an observable whose value becomes true as soon as a control system failure occurred. Let this observable be denoted by *system2:controlFailure* in the following.

Some of the contract primitives are introduced next, in order to show how contractual RAM requirements can be composed in terms of these generic contract primitives and linked to observables. First, the contract *(one EUR)* represents a contract where, once acquired, the holder immediately receives one unit of the currency Euro. The contract *(give c)* is a contract where all rights and obligations arising from contract *c* are reversed. If the contract *(or c1 c2)* is acquired, then the holder must immediately choose whether to acquire *c1* or *c2*, where the choice will be such that the benefit is greatest. Finally, once the contract *(and c1 c2)* is acquired, both of the contracts *c1* and *c2* are immediately acquired. As an example, if the contract.

(give (and (one EUR) (one EUR)))

is acquired, then holder is obligated to immediately pay two Euros. Consequently, in order to be willing to acquire the contract above, one would expect to receive two Euros in return as a fair price. Generally, we consider only a fair price when we talk about contract valuation, and the usual profit margin would have to be added afterwards.

Up to now, the contract primitives did not refer to any observables, and all rights and obligations took effect immediately. These limitations will be overcome with the following contract primitives. If the contract *(scale o c)* is acquired, then the contract *c* is immediately acquired where all payments arising from the contract *c* are multiplied by the value of observable *o* at the moment of acquisition. The contract *(when o c)* implies that, once acquired, the holder must acquire the contract *c* as soon as the observable *o* becomes true.

It should be noted that, while both observables introduced in the previous paragraph are in fact stochastic processes, the first one can be seen as a numerical value, whereas the second one is a stochastic process that assumed the values true or false. Other examples of the latter kind are observables like *(at date d)*, which becomes true at a certain date *d*, or *(between d1 and d2)*, which assumes the value true between the dates *d1* and *d2* (and false otherwise).

Using the contract primitives introduced so far, we will now give examples how these can be linked with observables, and how contractual RAM requirements of practical relevance can be expressed by exploiting the compositional aspects. For instance, the contract.

(when (at date 2017-01-31) (scale 100 (one EUR)))

pays the holder of the contract the amount of 100 Euros on January 31, 2017. In order to determine a fair price for the contract at the time of acquisi-

tion, one would have to calculate the discounted present value at the time of acquisition depending on interest rates (and possibly currency exchange rates). Certainly, the value of the contract is zero if acquired after January 31, 2017. Similarly, we can define a contract.

(when system2:controlFailure (give (scale 100 (one EUR))))

which implies that the holder of the contract is obligated to pay 100 Euros on occurrence of the event *system2:controlFailure* (see beginning of the section). This already constitutes a simple contractual RAM requirement which could potentially be found in a real contract. The value of this contract at the time of acquisition, i.e., the fair amount of money the contractor would receive once it has entered into the contract, depends here on the number of occurrences within the contract duration, and on the time instants the event occurs (in case of discounting).

Next, consider a typical warranty clause from a technical contract that requires that a certain amount be paid to the customer on occurrence of failures of respective components (or, equivalently, the components must be replaced at the contractor's expense). This only applies within a given warranty period, and the total amount is limited by a cap of 20,000 Euros. Expressed in terms of contract primitives, this could take the following form.

(or (scale 20000 (give (one EUR))) (and (when (system2:controlFailure && between startOfProject and November 03, 2021) (give (scale 800 (one EUR)))) (when (system3:valveFailure && between startOfProject and November 03, 2021) (give (scale 130 (one EUR)))) …))

where a Boolean expression is used in the condition, and the date *startOfProject* is a variable that was defined elsewhere in the model.

It is noted here that the possibility to compose more complex contractual RAM requirements from contract primitives is a key point and adds great value to our approach. Without it, it would be hardly practicable to capture and analyze the various types of contractual requirements that may be encountered in realistic contracts.

It is also important to note that, since our approach targets persons in charge of technical, contractual and commercial aspects who are domain specialists and do not necessarily have any programming background, the expressions in terms of contract primitives can be just as well automatically generated from higher-level expressions of contractual requirements, which are closer to natural language formulations. The reader is referred to Joanni & Ratiu (2018) for details.

3 ADVANCED CONSISTENCY AND COMPLETENESS CHECKING

3.1 *Formalization of the contract model*

What has been presented in Section 2 is essentially a model-based form of a contract. This can be expressed in form of a domain specific language with constructs which directly represent concepts from the domain of contracts. Individual contracts can thereby expressed as models written using the domain specific language. The model can be represented as a tree (see Figure 1 above for the example from the previous section). The value of the contract at a certain point in time is determined by a precisely defined, so-called *valuation semantics*; see Peyton Jones et al. (2000). Moreover, prior to numerical evaluation, it may be useful to apply certain transformation rules in order to obtain the contract in an optimized form (ibid.).

Typically, a project involves contractual obligations that are not restricted to one party, but are stipulated in several contracts with multiple parties. Several contracts can be merged in a single one where the individual contracts are subsumed by an *and* contract. Care must be taken, though, to correctly express the rights and obligations arising from the individual contracts from the point of view of the party of interest (e.g. the main contractor). An observable such as a failure of a specific component then usually affects more than one contract, if the event gives rise to contractual rights or obligations for more than one of the parties involved.

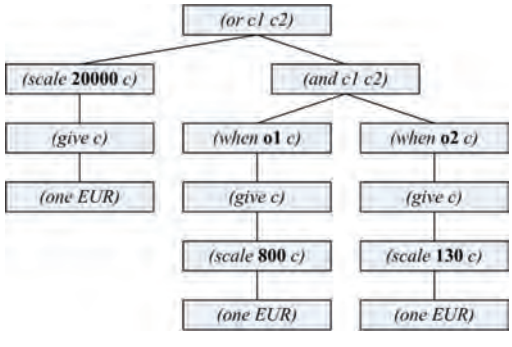

Figure 1. Tree representation of a contract. Observables are shown in bold face (the observables related to failure events are replaced by **o1**, **o2**).

3.2 *Enriching the contract model with additional semantics*

Generic contracts can be enriched with additional semantics, such as whether a given branch in the tree represents the contract with a specific party, for instance the customer and the various suppliers. One possible way to implement this is by annotating certain branches of the tree with information on the respective contractual party. Moreover, certain parts of the tree can be annotated with information on the specific type of payments arising from this part of the contract, for instance contractual penalties or warranty payments. In this way, information on the type of payment and the contractual parties involved can be retained and recorded during the numerical evaluation, e.g. through stochastic simulation.

Once contracts have a precise formal description expressed in a semantically rich language, it is possible to implement advanced validation and consistency checks such as overlap of time periods, gaps in warranties between parties, transfer of certain risks to other parties etc., even before a numerical evaluation is performed. Some more concrete examples are given in the following:

- In the context of warranty costs, a formal check can reveal if warranty payments owed to the customer in case of component failures is always (fully or partially) balanced by warranty payments received from the respective suppliers (back-to-back coverage). This is not always obvious for complex systems with many components, where warranty periods may be even be subject to looping conditional on certain events.
- In case of random events which entail payments and/or liabilities from different parties, a formal analysis can help determine bounds on the overall financial impact. This is extremely useful particularly if the frequency of occurrence is based on uncertain estimates, but determining bounds may not be an easy task to do manually if certain payments or liabilities are subject to further conditions.

This list is certainly not exhaustive and depends on the specific technical system and contractual aspects under consideration.

4 TOOLING AND IMPLEMENTATION

In our implementation of the approach, the financial and technical aspects of RAM contracts are expressed with the help of domain specific languages (DSLs). A DSL provides a formal syntax (meta-model) for representing the domain concepts and relations between them. Once appropriate constructs are available, simple consistency checks which define the set of well-formed contracts can be implemented easily. In addition, advanced consistency and completeness checks can be implemented as described in this paper.

The technical basis for our implementation is language engineering technologies as provided by the Jetbrains MPS language workbench (www.jetbrains.com/mps). MPS allows creation and composition of different modular DSLs, which enables domain experts to directly and explicitly express concerns from their business domain. We created DSLs to describe both the technical and commercial aspects of contractual RAM requirements, so they are available as models. Compared with previous work on (business) contract formalization, which was e.g. implemented in Haskell and requires know-how about functional programming, our approach targets persons in charge of technical, contractual and commercial aspects who are domain specialists, and it does not require any programming background.

Moreover, our implementation gives confidence in evaluation by validation of input and advanced consistency checks; the models are "correct by construction" and allow time saving due to efficient specification of the technical, contractual and commercial aspects of contractual RAM requirements.

5 EXAMPLE

In order to demonstrate the modeling and advanced checking of contractual RAM requirements, a simple example in the context of product warranty is given in the following. For a comprehensive review of warranty policies see e.g. Murthy & Jack (2003) or Rahman & Chattopadhyay (2006). In this paper, we restrict ourselves to the case of so-called *Free Replacement Warranty* without renewal, where a certain amount is to be paid to the customer on occurrence of failures of certain components within a fixed time interval. This amount may comprise the costs for replacement of the failed components as well as additional servicing costs. The corresponding model of the customer contract is shown in the top pane of Figure 2, which repeats the exemplary warranty clause from Section 2.2. The model is annotated by a label "CustomerWarranty" in order to indicate that, within this branch of the tree, any observables related to component failures incur a liability towards the customer. The specific amount to be paid, the warranty periods and the fact that a cap was agreed are not considered here, but will certainly influence the value of the contract. The intention here is to check whether warranty costs due to component

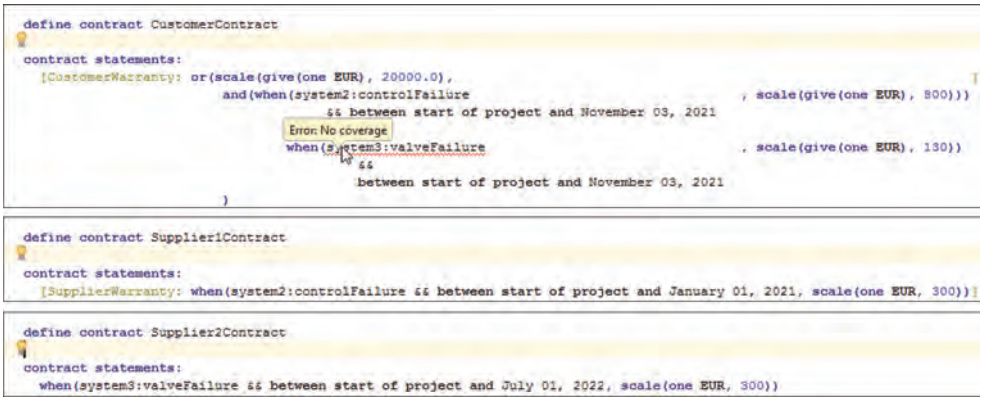

Figure 2. Exemplary customer contract (top pane) where the warranty clause indicates an incomplete coverage by an error message. This is because only the contract with supplier 1 (middle pane) is annotated as a supplier warranty, but the contract with supplier 2 (bottom pane) is not.

failures can, in principle, be balanced by warranty payments received from the respective suppliers, based on the contracts entered.

Similarly, the middle pane of Figure 2 shows a model for a supplier contract that states that failure of the component *system2:controlFailure* incurs a payment received from the supplier of this component. Here, the corresponding model is annotated by a label "SupplierWarranty" in order to indicate that, within this branch of the tree, any observables related to component failures imply that a claim can be made towards the supplier. The bottom pane of Figure 2 shows a model for another supplier contract for payments received from the supplier on occurrence of failures of component *system3:valveFailure*. Here, however, the model was not annotated by a label "SupplierWarranty", which will be revealed by the checking rule as shown below.

An advanced checking rule was implemented in order to identify component failures that only incur a liability towards the customer but no corresponding claims towards the supplier, based on all contracts entered. This was done by traversing the tree of the contract model and searching for observables related to component failures that are annotated with the label "CustomerWarranty", but not "SupplierWarranty". Consequently, an error message is shown in the model of the customer contract that points out the respective components which failures are not covered by a warranty clause in any of the supplier contracts. In this example, the obvious remedy would be to annotate the contract with the second supplier with the label "SupplierWarranty". However, it may well be the case for complex projects that it has been overlooked to agree on a warranty clause for one or more components. In this case, the error message suggests that it would be advisable to renegotiate appropriate warranty agreements with the suppliers of the respective components.

6 DISCUSSION AND OUTLOOK

Based on our approach to express contractual RAM requirements by means of a precise formal description with a semantically rich language, we have explained the principles of performing advanced validation and consistency checks of certain contractual characteristics of interest (in addition to providing a way to efficiently evaluate the contractual requirements as demonstrated in Joanni & Ratiu (2018).) The example presented in this paper demonstrates the implementation for a rather simple example of warranty costs. However, the contract model can, in principle, also be transformed into other mathematical models that allow for more sophisticated checking algorithms that cover various aspects such as completeness of conditions. This is the subject of our ongoing research.

In our opinion, formalization of contractual RAM requirements is not only of theoretical interest, but is of practical applicability and provides significant benefits such as efficient assessment and potential reduction of non-conformance costs, in addition to increased transparency particularly when dealing with complex contractual agreements for projects where multiple parties are involved.

Cost-benefit analysis for non-structural flood risk mitigation measures: Insights and lessons learnt from a real case study

G. Pesaro, M.T. Mendoza, G. Minucci & S. Menoni
Politecnico di Milano, Milan, Italy

ABSTRACT: Cost-Benefit Analysis (CBA) in flood risk management is becoming increasingly popular as a tool that makes the relationship between investments in mitigation measures and the related effects more comprehensible. Even if the application of CBA in flood risk management is nothing new, there is still limited evidence on its use conditions and possible limits when applied in real. The essay first suggests a new classification of Flood Mitigation Measures (FMM), towards a new taxonomy that goes beyond the distinction between structural and non-structural. This distinguishing between risk and damage reduction measures, public and private decision-making processes, mandatory and voluntary actions and allocating more importance to the value of the avoided damages related to the commons (i.e. cultural heritage) and other non-renewable, non-reproducible or non-restorable territorial resources. Second, the contribution of CBA as an ex-ante decision-making tool in flood risk reduction is discussed. Moreover, the essay offers a methodological insight and operational elements as results of a case study developed in the European research project IDEA, where a CBA for a non-structural mitigation measure was performed using the data and information available after the 2012 and 2013 flood events in the Umbria Region (Italy). Here, dams built to produce hydroelectric power have been used for laminating the floods, as a non-structural risk mitigation measure. The experimental application of the CBA to this measure, including the combination of real damage data collected after the floods and damage modeling for the alternative scenario, provided methodological and operational evidence of its capability to reduce/avoid a part of the damage. Finally, the essay presents the lessons learnt, the open problems and future developments required for an effective CBA, in reference to the technical and scientific perspective and to the difficulties in the understanding and interpretation of the whole of the cause-effect chains and externalities.

1 INTRODUCTION

In recent years, Cost Benefit Analysis (CBA) has been increasingly proposed as a key tool to support decision-making processes for flood risk prevention and mitigation, including in the European Floods Directive 2007/60/EC. It serves the purpose of comparing the costs of mitigation measures with the potential benefits interpreted as reduction of potential Damage and Losses (D&L). However, there are a number of limitations implied by most common C&B analyses regarding a variety of issues (Ale et al. 2015). There are difficulties in assessing the entirety of costs, for example indirect ones, questionable values are attached to both costs and benefits without adequate empirical supporting evidence; ethical and equity concerns arise, for example, when intangibles are assessed in monetary terms. In order to address some of those limitations, we have proposed some innovative procedures while carrying out C&B analyses according to a more rigorous economic thinking. At first, a better classification of Flood Mitigation Measures (FMM) with respect to most C&B applications, is proposed, as the variety of the possible solutions and the related results when implemented is very high. This because both costs and benefits can be better assessed if mitigation measures are better identified and distinguishable one from the other.

In fact, a better classification of FMM has a twofold purpose. On the one hand, if exhaustive enough, it offers planners a wider variety of options which to choose from (Yevjievich 1994). On the other hand, diverse FMM typologies have different costs and therefore require different degree of investment. A better classification of FMM may also help in highlighting for each combination of measures the different mix of direct and indirect costs that are associated.

Bouwer et al. (2014) underline the fact that there is often a solid base of information on the direct cost in hard mitigation measures, whereas there are few cost assessment methodologies for non-structural measures. Moreover, Mechler's review (2016) on available studies on CBA for DRR measures shows that mostly structural measures are considered.

In this context, we first propose a new classification framing the different types of FMM. Then a focus is made on the analysis of a non-structural measure, namely the use of dams for electric hydropower production to retain potential overflow due to heavy rains. This case-study introduces a second level of novelty in the arena of most widely applied C&B methodologies, in that it uses real damage and costs experienced after events that have actually occurred as a starting point for establishing monetary values of benefits intended as avoided damage. This in line with the methodological approach taken by the European funded project, IDEA (Improving Damage assessments to Enhance cost-benefit Analysis).

2 FLOOD MITIGATION MEASURES (FMM)

2.1 *Scientific background: FMM classification*

Yevjievich et al. (1994) classify FMM on the basis of a geographic approach according to (i) adjustment to natural hazards (ii) typology of flood damage prevention; (iii) typology of flood damage reduction; (iv) typology of flood policymaking and (v) basic categories of individual measures.

The Australian Bureau of Transport and Regional Economics in 2002 proposed to classify FMM from an economic perspective according to (i) flood modification, (ii) property modification and (iii) response modification. On the basis of the latter, Hawley et al. (2012) categorize FMM by (i) structural and non-structural flood control, (ii) exposure and property modification and (iii) behavioral response modification. Considering the time scale before the damaging event, Mechler (2005) differentiates between FMM that reduce risk (mitigation/prevention and preparedness) or transfer and spread it on a larger basis (risk financing).

The FLOOD-ERA Joint Report (Schanze et al. 2008) enlarges the economic perspective by considering both ex-ante and ex-post evaluation of structural and non-structural flood mitigation measures.

A multi-sectoral perspective on FMM ex-post evaluation is provided in the FLOOD*site* project (Klijn et al. 2009), which takes into account not only the economic efficiency but also the effectiveness, robustness, and flexibility of selected measures. Accordingly, measures (i.e. physically tangible interventions) are differentiated from instruments (i.e. interventions that cause effects indirectly).

2.2 *Towards a new taxonomy*

On the base of the literature review, a preliminary list of a large selection of possible flood mitigation measures and a new FMM classification have been developed (Table 1). These measures have been classified according to the following criteria: (i) typology, i.e. structural or non-structural measures, (ii) purpose, i.e. "risk" or "damage" mitigation, (iii) who takes the decision, (iv) typology of action. The definition for structural and non-structural measures adopted in this work is the one by the UNISDR (see Terminology on DRR, 2017).

Regarding non-structural measures, we propose as sub-categories: riverine environment-based (e.g. river management), built environment based (e.g. building regulations), social involvement-based (e.g. education programs) and economic-based (e.g. risk transfer through insurance).

Concerning risk mitigation, investments are directed to the reduction of flood exposure, no matter how vulnerable the exposed subjects and objects are. As for D&L, reduction may mean the capability: (i) to reduce exposure, (ii) to recognize and intervene on the vulnerability of a great variety of individual situations, and (iii) identify the potential loss of territorial resources/values that are either unreplaceable or uneasily restored/rebuilt.

Moreover, flood mitigation measures involve, in different ways, public and private actions, decision-making and investments. It is therefore important to address attention not only to risk or damage mitigation measures or to structural and non-structural interventions, but also to the main decision-makers involved in their implementation. These were categorized as "public", "public-private", "economic subject" (private firms) and "private individuals". Regarding the typology of action, three sub-categories were defined: "regulated" (when regulation exists with defined procedural aspects), "mandatory by law" (binding action by law) and "voluntary" action. Of course, particularly in this last category, there might be substantially different results for different territorial areas and countries, according to the different regulation and institutional systems.

Table 1. The proposed new FMM classification.

	Mitigation measures	Mitigation type		Main decision-maker				Action typology		
Typology	Description	Risk	Damage	Public	Public-Private	Private firms economic subject	Private-Individual	Regulated	Mandatory by law	Voluntary
Structural	Levees	X		X				X		
	Dams	X		X	X	X		X		X
	Diversions and channel improvements	X		X				X		
	Flood walls	X		X				X		
	Detention Basins	X		X				X		
	Urban Drainage and pumping	X		X				X

3 CBA FOR FMM

3.1 *Economic thinking and CBA in flood risk management*

The assessment methods and tools to quantify some of the damage categories are central elements when referring to the economic approach to disaster risk reduction. The debate developed during the last two decades converge to that damages suffered by populations and the built environment are nowadays better understood than in the past. In the contrary, less evidence is available on damage suffered by economic sectors and by the entirety of territorial resources, encompassing cultural heritage, the natural environment, and shaping communities' identity and social models (some of these elements are discussed in Mechler 2016). This is mainly due to the incidence of indirect and systemic damage (Cochrane 2004a,b), that are instead often underestimated (Shreve & Kelman 2014) but also to the difficulties in assessing the monetary value of intangibles, such as public resources, cultural and historical heritage (Pesaro 2005).

Looking at the whole of the resources a territorial area can rely on to sustain its production and consumption models, qualitative and quantitative growth, the economic perspective suggests to account not only direct quantitative damage, using money as the measure unit, but also indirect and systemic D&L even if not easily quantifiable and measurable. Monetization models have been developed in the field of environmental economy, first, and in risk and damage matters afterward, for instance, for cultural heritage and natural environment, but still, monetary evaluation remains very controversial (see, among others, Meyers et al. 2013).

Cost-Benefit Analysis (CBA) for the evaluation of flood mitigation measures is an important and widely used tool for decision makers to rely on, even though sometimes the incidence of non-monetizable values limits its potential. In a decision-making framework, the main question is how to choose among different possible action/intervention alternatives using an economic-based toolbox, whose strength also lies in the use of quantitative measure units, able to offer clear-to-read results to support and address a selection process. Moreover, it enables to look at the results envisaged for different mitigation measures not only concerning the technical and operational performance but also in terms of investments effectiveness.

CBA can be assessed following an economic approach, which is preferred and adopted in the preset article, and a purely financial one. According to the economic approach, costs and benefits associated with a policy or a project ensure a more exhaustive assessment of damage and effects, including those to third parties. Whereas the financial approach to CBA is mainly based (if not exclusively) on a cash flow analysis. Consequently, economic CBA aims at highlighting the whole range of values and externalities implied by a certain mitigation measure.

Several studies are available introducing cost-benefit analysis as a tool to assess the economic feasibility of flood management strategies (Botzen et al. 2017). Brouwer & van Ek (2004), for instance, justify changes in land use and floodplain restoration in the Netherlands based on both cost-benefit and multi-criteria analyses when ecological, social and economic benefits in the long term are considered. Jonkman et al. (2004) investigate the application of CBA in decision-making on flood protection measures in the Netherlands as well. Joseph et al. (2014) apply conceptually the cost-benefit analytical framework to flood risk adaptation measures taken at the property level in the UK and show the involved costs and benefits. Moreover, the EU Floods Directive (2007/60/EC) requires CBA for supporting public decision making to tackle flood risk in all member states of the European Union.

The use of CBA to enhance the implementation of disaster mitigation measures relies on the concept of intervention profitability, which, in its turn, refers to the capability of investments in mitigation measures to obtain the expected outcomes in terms of risk prevention and/or damage mitigation. It is a method to compare the whole range of direct costs associated with each typology of mitigation measure and their relative outcomes, measured as the total value of the avoided damage and losses plus the benefits coming from an increase in safety and territorial quality.

In this conceptual framework, CBA is seen as an ex-ante decision-making tool, which calls for the capability to develop the assessment process in an ex-ante perspective. In this case, mitigation measures in flood risk allow the system to act on both risk and damage mitigation and reduction.

The results of a CBA might be effective also in the light of a common problem decision-makers encounter very often, that is the perception of direct and quantifiable costs related to mitigation measures implementation. Quantified costs, even when related to damage prevention, are much more evident and easy to perceive than the possibility of a reduction of potential D&L in an uncertain and or known future. The clearer today's mitigation costs but not directly comparable to future damage decrease, the more difficult is to obtain consensus on expenditure (both public and private) in time of peace.

In this respect, CBA should be regarded as an effective tool as it is able at least to elicit relevant knowledge and information to support policy-makers in choosing among different alternative

measures and interventions to reduce damage and risk, even when some elements cannot be directly assessed in monetary terms. In this context, the question is how to recognize the "list" of costs and benefits suitable for describing the risk in a given area and how to evaluate and monetize them. The high variety of local conditions in terms of exposure and vulnerability, which influences the impacts of events on territorial subjects and objects (even when considering just floods) makes this task challenging.

3.2 *The costs side*

An effective synthesis focused on the comparison among the costs of different available mitigation measures assessed by way of different methodologies is offered in Hawley et al. (2012). Likewise, Bouwer et al. (2014) use a cost classification that distinguishes between direct and indirect costs, tangible and intangible.

Besides the direct costs of FMM, such as construction costs of physical infrastructure or evacuation costs, negative externalities or "co-costs" (Rose 2016) can be generated, e.g. interferences with the natural environment and landscape amenities. The externalities that are usually included in economic CBA are the costs or benefits resulting from a project that influences third parties without monetary compensation (European Commission 2014). Negative externalities, or external costs, are considered in social analyses because they impact on the social welfare, causing market failure when not included (Pesaro et al. 2016).

3.3 *The benefits side*

In CBA, benefits are evaluated as the "positive impacts obtained because of the reduced or avoided D&L" due to the different mitigation measures to be implemented. Flood damage assessments are then crucial to measure avoided damages, which may include primarily health problems and loss of lives, physical damage to buildings, infrastructures and lifelines, environmental assets, cultural heritage, and business interruption. Such assessment, along with the costs side mentioned in the above paragraph, can be developed both ex-ante and ex-post the flood occurrence.

Concerning avoided damage, economic subjects and businesses are still less considered than households or public infrastructures, even though economic activities are core elements for the functioning and development of a territory. The problem is the great variety characterizing the economic sector, production activities and assets which make them differently prone to damage and losses.

As for positive externalities or "co-benefits" of disaster mitigation investments, such as, among others, environmental conservation, improved social cohesion and increased agricultural productivity, they may materialize even in the absence of a disaster (Tanner et al. 2015). Discussions developed during the IDEA Project revealed that civil protection representatives, for instance, carefully consider as positive externalities the positive reputational effect resulting from the enhancement of prevention and mitigation measures.

It is finally important to highlight also the "system benefits" arising from stakeholders' perception of safety, which have to be better integrated into the "benefit scenarios". If safety were perceived as a strength/value of a place to live or to locate economic activities, a "safer" place might become more attractive. This, of course, would produce an increase in the demand for safer space and properties, which, in its turn, not only would generate a rise in the real estate values but also a more dynamic environment for households and businesses in such safer zones. However, over time, as a drawback, exposure to residual flood risk would increase as well. Therefore, also other system benefits should be acknowledged, like for example improved knowledge and information dissemination, leading to changes in households and economic subjects' behavior in case of flood. An increased awareness of flood risk would make communities better able to respond rapidly to any event, reducing damages, losses and psychologic distress.

4 THE DAM COST-BENEFIT ANALYSIS FOR FLOOD EVENTS IN THE UMBRIA REGION

4.1 *Case study background*

After a national directive on national and regional warning system for hydro-geologic risk for civil protection purposes was issued in Italy in 2004, the National Department of Civil Protection established a technical panel on this topic focusing on the Tiber river basin. As a first result of this activity, an "informal agreement" on the use of dams to retain water in case of heavy rains was signed among different authorities (Tiber river Authority, Dam Operators, etc.) in 2005. On the base of this, dams were emptied according to early warning and could reduce the river flow during flood events in Umbria in 2005, 2008, 2010, 2012 and 2013. Furthermore, the Umbria and Lazio Regions adopted a framework agreement and a flood management plan in June 2016.

4.2 *The "dam exercise": data collection, maps design, data processing and CBA assessment*

During both the 2012 and 2013 events, three dams (Montedoglio, Valfabbrica/Casanuova, and

Corbara) were used to retain water and consequently reduce the river flow. The approach proposed in this paper for the development of CBA is the economic one, as in Brouwer & van Ek (2004), while avoided damage has been derived from the real damage and costs as evaluated by the Civil Protection of the Umbria Region, that is by a public actor.

In order to understand the net benefits thanks to the application of the dams as non-structural measures 5 main steps were followed: (i) identification of the "avoided event" and its associated damages; (ii) identification of damages of the "occurred event"; (iii) calculation of "avoided damages", (iv) identification of costs; (v) identification of the net benefits.

As "avoided event", we mean the flooding that had not occurred thanks to the water retained by dam reservoirs. The "avoided event" was assessed by analysing the rainfall data and the water depth measured upstream of the dams from the reports done by the Civil Protection of Umbria Region, for the 2012 and 2013 flood events.

The damage that the "avoided event" could have provoked were estimated with the Flood-IMPAT procedure (see Molinari et al. 2016), which performs a damage assessment at the meso-scale level by depth-damage curves in a GIS environment. Flood-IMPAT allowed estimating direct damages to the residential, industrial/commercial and agricultural sectors, and consequently, only these typologies were considered for the analysis (Table 2a).

The damages due to the "occurred event" (Table 2b) were assessed by using the real flood damage values collected by the Civil Protection through the damage declarations filled in by households and economic subjects (see Menoni et al. 2016). The avoided damages due to the operation of the dams during the flood event result from the difference between the estimated damages of the "avoided event" and the damages of the "occurred event" (Table 2c).

The assessment of the costs associated with the use of the dams for flood lamination was based on the hypothesis that the dams of Montedoglio and Casanuova were used exclusively for energy generation. These costs (Table 3a) were estimated based on the loss of revenue due to the unsold energy as a consequence of the lack of whirl of the dams during the whole operation (considering also the days before the flood when the dams were emptied).

Finally, the net benefits associated with the flood lamination (Table 3b) for each event were calculated with the difference between avoided damages (benefits) and the loss of revenue (costs). As a further step, it has been computed the absolute net benefits in order to understand the relevance of the net benefits in relation to the damages of the avoided event. The absolute net benefit for the 2012 and 2013 flood events is respectively 32% and 73%,

Table 2a. Estimate of the total damage of the "avoided" events in 2012 and 2013.

	Damages without dam management (Flood-IMPAT) [M€]			
Event	All sectors	Residential	Agriculture	Industry/ Commercial
2012	55.5	5.5	19	30.5
2013	12.5	1.5	6.5	5

Table 2b. Occurred total damage per sector for the 2012 and 2013 events.

	Occurred Damages [M€]			
Event	All sectors	Residential	Agriculture	Industry/ Commercial
2012	36	2.5	12	21
2013	2	1.5	0	0.5

Table 2c. Total avoided damages due to the use of the dams in the 2012 and 2013 events.

	Avoided damages with the use of dams [M€]			
Event	All sectors	Residential	Agriculture	Industry/ Commercial
2012	19.5	3	7	9.5
2013	10.5	0	6.5	4.5

Table 3a. Costs beard by the energy operator (operators' calculations).

Event	Dam	Laminated volume [m^3]	Loss of revenue [€]
2012	Corbara	70 M	2
	Montedoglio	25 M	0.7
	Casanuova	20 M	0.5
2013	Montedoglio	25 M	0.7
	Casanuova	21 M	0.6

Table 3b. Net benefit from the CBA assessment.

Event	Benefits [M€]	Costs [M€]	Net benefits [M€]
2012	19.5	1.2	18.3
2013	10.5	1.3	9.2

which means that the use of the dams in both cases clearly allowed reducing damages, up to such a high performance as in the second case. Such a significant result is obtained because a risk mitigation and not just a damage mitigation measure has been applied, reducing the severity hazardous event at the origin. A damage reduction degree even higher if the indirect and systemic effects of the avoided direct losses had been evaluated.

4.3 *Lessons learnt*

The economic advantages obtainable by means of dam management as a non-structural risk mitigation measure proved to produce high savings in terms of avoided damage. The case study allowed to identify a variety of factors related to the use of the CBA methodology and to the uncertainties linked to the processing of technical and scientific elements.

Adopting the economic approach perspective, problems arise from the difficulties in assessing the cause-effect chains and externalities. This is mainly due to the presence of indirect and systemic damage, suffered by the territorial elements and subjects, from the one side, and by the private owners of the dam on the other side. This means a potential lack of damage information from both the benefits side, in terms of avoided damage, and in terms of costs, due to the losses produced because of the implementation of the measure. In this particular case, the production of electrical hydropower is concerned, which means that the accounting for costs depends on the energy costs, the tariffs profiles, the customers typology, the variable demand for power during different periods of the day and the related energy production functions. On the other hand, negative externalities could occur because of the interruption of energy production, depending on the overall power production sources, and the amount of the power demand covered by the dam production.

From a technical and scientific perspective, flood damage estimation by means of real damage assessment presents a set of shortcomings similar to those implied by fully modelled damage, depending on the availability of context-based functions and local specific characteristics that hamper the possibility to transfer results in space and time (see Merz et al. 2010).

In addition, the case study shows that there is a huge space for non-structural measures negotiated among territorial actors, both ex-ante and ex-post events, whose costs are difficult to be assessed but whose benefits might be important. Although not directly considered in the case study, the use of the dam was possible through the negotiation process and collaboration between private and public subjects. Therefore, negotiation costs should be better taken into consideration, together with the different negotiation models and related power degree. In the dam example, for instance, the private subjects, that is the private dam managers, have been obliged to accept the demand for intervention under the specific regulation mentioned above, the Umbria Region's *Piani di laminazione* (flood retaining plans). In principle, private subjects should be compensated for the costs undertaken for public interest purposes, however their right has to be balanced against the fact that they are beneficiaries of a license arrangements to use water for energy production (Pesaro 2007).

5 OPEN PROBLEMS AND FUTURE DEVELOPMENTS

The proposed FMM classification shows that, even if traditionally less utilized (WMO 2009), non-structural measures are more numerous and variate than structural ones. A discussion about Flood Mitigation Measures (FMM) is central to better understand the potentials of CBA and improve it. Furthermore, structural measures are usually less cost-effective (Kelman 2013). Non-structural measures should then be considered avoiding professional biases or limitation in the appraisal process (Mechler 2016). Furthermore, the use of CBA as proposed here has been based on the comparison between "near to real" costs and benefits, derived from damage evaluated by the Regional Civil Protection and not on theoretical monetization methods. The aim of the exercise was to prove the evidence of the potential effectiveness of non-structural measures to reduce damages, whose dimensions have been calculated based on the real damage data collected on the ground after the described event. Moreover, disaster risk reduction being the main goal, attention was driven toward costs in terms of interventions able to reduce the territorial impacts of floods and on non-structural measures as investments able to reduce implementation costs and related territorial and landscape impacts.

Following the proposed example of CBA applied to the use of dam reservoir to store part of the peak volume, further efforts are required to estimate the economic efficiency of this type of measures, as well as to identify and assess their related systems of costs.

Concerning future developments from the "benefits side", avoided damages should also consider the high potential weight of the indirect and systemic damage to economic activities. In fact, more attention should be devoted as well to show how non-structural measures entail larger positive systemic effects on economy, by taking into consideration local and over-local links and interactions.

Investments in FMM might produce a system of other positive externalities, which should be better taken into consideration in decision-making processes about the selection of the FMM. Such additional side effects might therefore maximize the effectiveness of the investments from a system's perspective, producing win-win effects. This, for instance, when, even in absence of flood events, territorial and natural environment management and conservation are considered and, where, therefore, consensus can be achieved more easily.

From the "costs side", the presence of often neglected negative externalities from flood mitigation interventions, mainly the structural ones, should be included in the analysis (monetary or not) because they may make other measures more desirable at the system level. A reason why, finally, there is the need for a more interdisciplinary perspective to better integrate the economic thinking when assessing the impacts of mitigation.

Behavioural modelling of attackers' choices

S. Panda, I. Oliver & S. Holtmanns
Cybersecurity Group, Nokia Bell Labs, Finland

ABSTRACT: This paper examines a cyber environment involving attackers and telecommunications operators from attackers' perspective. We incorporate a behavioural approach to understanding attackers' behaviour during the attack process. Traditionally, security games have been analysed assuming the attackers to be of strictly bounded rationality or strategy-less. Furthermore, studies consider attackers do aim to maximise their expected gain which contradicts the assumption of bounded rationality of attackers. We have analysed security interactions considering attackers as rational entities with attack strategies. To understand the thought process and behavioural decision-making choices of attackers, we utilise a decision analysis model capturing the attack process. Based on our analysis, we propose a framework providing a way to enhance attack strategies against cooperating and non-cooperating (competing) operators. This study is intended to capture essential characteristics of an attacker to comprehensively understand and predict their expected behaviour assisting cybersecurity.

1 INTRODUCTION

The major concerns in cybersecurity are to measure the security risks and to determine the effectiveness of one's security investments against perceived threats. As in cybersecurity, security is defined by not only on an individual's security-related investments but also by others' security investments (Anderson and Moore 2006, Laszka et al. 2015). This security interdependence adds additional complexities in quantifying the security risks and crafting appropriate measures against it.

Game theory, being a mathematical modelling tool, has been widely used to study varied aspects of security (Roy et al. 2010, Merrick et al. 2016, Altman et al. 2006, Liang and Xiao 2013) and privacy (Manshaei et al. 2013). Most of the work focused on studying defenders' behaviour and have proposed strategic recommendations which include stochastic approaches, frameworks, cognitive and behavioural models strengthening defenders' chances of successfully defending against attempted attacks. Studies have often assumed strategy-less behaviour of adversaries with a prescribed set of actions consistent with the threat models. However, alongside defenders, attackers are also intelligent entities and this assumption is not ideal in real-world situations which consists human adversaries (Camerer 2011).

In cybersecurity, attackers' behaviour has been less explored due to lack of reliable data on their intentions and interactions limiting our understanding of their characteristics and behaviours. (Veksler & Buchler 2016) and (Anderson 2009) have indicated that cognitive approaches can aid in predicting attackers' behaviour addressing real-world security problems.

In addition, over the past years, adversaries have become more financial oriented (Gordon 1994, Gordon 2000, Franklin et al. 2007) making them highly unpredictable. Some intentions behind these malicious activities are instigated by curiosity, or for peer recognition, and are often undecided in terms of ethical legitimacy (Gordon 1994, Gordon 2000). The possibilities of using illegal methods provoke new classes and strategies of attacks creating a need in studying and analysing attackers' behaviour to understand their intentions and decision making criteria.

We performed a game-theoretic investigation on attackers' strategies in the context of cybersecurity. The examined scenarios illustrate security games between attackers (cybercriminals, hackers) and telecommunications operators (defenders). An attacker is an external entity with malicious objectives attempting to break through the security of the targeted entity/system with an intention to hamper the existing state of the target.

A behavioural approach is utilised to anticipate decision-making behaviour of attackers. We intend to determine attack strategies optimising attackers' effort in performing an attack and improving their perceived utility. A viewpoint this paper aims to highlight is when attack strategies are taken into consideration, what can the choice of not attacking signify?

This study is a step towards understanding the mentality of attackers and their decision-making

behaviour from a cybersecurity perspective. Lack of decisive information on adversaries along with the available security information being highly asymmetric—favouring the attackers; results from this study can be used by defenders in assessing their conditions and perceiving the most expected attack strategies.

The rest of the paper is organised as follows. Section 2 covers the relevant literature and highlights the relationship of our work with existing research. Section 3 discusses the behavioural aspects of attackers and presents an attack framework disintegrating the efforts required in an attack process. An analysis of how attack strategies can be optimised using the attack framework is explained in Section 4. Section 5 discusses our findings and concludes this paper.

2 RELATED STUDIES

Even though this paper is confined towards understanding attackers, the complementarity of attackers' behaviour on operators' state is such that modelling them without an underlying operators' state is complex and unrealistic. An operator's state is defined by his security-related investments and relationships with other operators—cooperation (Laszka et al. 2015, Kunreuther and Heal 2003, Varian 2004, Hota and Sundaram 2015) and competition (Jiang et al. 2008, Sun et al. 2008, Khouzani et al. 2014, Panaousis et al. 2014), which induces additional security dependencies.

Attackers, alike operators (defenders), have strategic incentives and work towards maximising their expected utility (Laszka et al. 2015, Hausken 2006). The expected utility is a critical influencer in any decision-making process. For example, an operator invests in a particular security technology only after acknowledging that the investment will attain the expected returns (Hausken 2006). Similarly, the expected utility moderates attackers' strategic choices, especially the motivation (Hausken 2006, Herley 2010), behind attacks. The strategic choices of attackers are also influenced by available resources (Hausken 2006), the context of the interaction and the targeted operator's state which shapes the expected utility.

From an economic perspective, Herley (Herley 2010) pointed out that an attack strategy should be defined by the economics of attacks. He proposed attack strategies distinguishing attacks into scalable attacks and targeted attacks. In scalable attacks, the effort is independent of the number of users attacked. While in targeted attacks, the effort depends on per-user attacked suggesting targeted attacks must be on users with higher than average expected value. A profitable attack strategy involves accurately distinguishing viable from nonviable targets and deciding which viable target to attack based on the expected value (Herley 2012).

Grossklags et al. (Grossklags et al. 2008) analysed the Nash equilibria and social optima for different classes of attacks and defences in weakest-link, best-sort, and sum-of-effort security games. They introduced a weakest-target game "where the attacker will always be able to compromise the entity (or entities) with the lowest protection level but will leave other entities unharmed." Florencio et al. (Florêncio and Herley 2013) refined this criterion by incorporating the concept of free-riding (discussed by (Varian 2004)) to the lowest protected entity (or entities) stating that even though there exist economically profitable targets, many attacks are extremely difficult to turn into profitable ones grounding it to the economics of attacks.

From an extensive literature review, Hausken and Levitin (Hausken and Levitin 2012) categorised attack tactics on plausible types of attacks such as attacking a single element, attacks against multiple elements, consecutive attacks, random attacks, attacks involving a combination of intentional and unintentional impacts, attacks with incomplete information, and attacks with variable resources. However, a critical difficulty in modelling opponents in general, specifically in the security domain, is due to lack of decisive information regarding potential adversaries and attackers-defenders interactions being highly complex and extensive (Pita et al. 2012).

To understand the behavioural aspects of participants in cybersecurity, (Kusumastuti et al. 2015) and (Ryutov et al. 2015) have studied not only technical aspects but also psychosocial aspects through a three-player cybersecurity game. Kusumastuti et al. (Kusumastuti et al. 2015) used mini-max solution to identify game parameters and their influence on a player's behaviour. Ryutov et al. (Ryutov et al. 2015) aimed at understanding and modelling roles, motivations and conflicting objectives of players. In addition, (Anderson 2009), (Tambe et al. 2014) and (Veksler and Buchler 2016) have demonstrated improvement in the predictability of attackers' behaviour by using behavioural/cognitive modelling in a repeated security game environment.

To address adversary's bounded rationality, researchers have been pursuing alternative approaches. One approach includes robust optimisation techniques *avoiding adversary modelling* (Yang et al. 2011, Pita et al. 2012, Pita et al. 2010), while the other approach incorporates human decision-making models for computing *defend strategies* (Nguyen et al. 2013). Our work utilises the later approach and differs from the existing research by focusing on modelling adversaries

rather than defenders. Firstly, instead of strictly bounded rationality of attackers, we consider attackers with strategic incentives working towards maximising their expected utility. More precisely, we pose a decision model with an intention to understand the mentality of attackers and their decision-making behaviour. We also introduce a generalised attack framework distinguishing the effort required during an attack process. The attack framework is used to evaluate and refine attack strategies. In addition, this framework also facilitates a way of addressing the abstract states of the decision model, which we believe applies to a whole class of security scenarios.

3 BEHAVIOURAL ANALYSIS AND FRAMEWORK CHARACTERISATION

We define the attackers-operators interaction as a game-theoretic model that captures essential characteristics of strategic decision making. The essence of game theory is to study factors influencing behaviour by reasoning what players think other players will do. However, in reality, having complete and perfect information regarding your opponents is never feasible. This applies particularly in the context of security, where the threat is almost always unknown and effectiveness of security investments are very hard to quantify (Laszka et al. 2015). So, every interaction is considered to involve certain degrees of uncertainty in committing to decisions. For example, attackers might have knowledge regarding an operator's investment in security but have no decisive information related to the extent an operator has invested or on what kinds of secure technologies has the operator invested in.

Attackers, alike defenders, being a deficit in resources (Florêncio and Herley 2013) have to act strategically maximising their expected gain and optimising their investment of resources. Aiming this, we analyse the attackers assuming their end goal is to successfully attain the expected results while minimising their effort in the attack process. First, this assumption alleviates the strictly bounded rationality of attackers and facilitate them with diverse attack strategies in contrast to the only choices of attacking or not attacking in traditional game-theoretic modelling approaches. In addition, it supports analysing interaction environments under conditions when attackers do not react—ignore or watch the target; diverging from the traditional approach where attackers follow a prescribed path of invariably attacking.

Introduction of strategic attackers expands the possibilities where an action can bear latent objectives and motives raising concerns regarding the admissibility of proposed defence strategies. To take a concrete example, consider a case of distributed denial-of-service (DDoS) attack, where an attacker attempts to prevent an operator from delivering information or services. With a strategy-less attacker, the resultant action for the operator would be to invest resources in countering the attack with full capacity to minimise the damage. The attacker being strategy-less an attack would precisely be an attempt to harm the existing state of the operator. However, for a strategic attacker, the DDoS attack might merely be a probing attack to assess the strength of the operator or it can be a diversion ahead a powerful targeted attack.

Figure 1 presents a glimpse of an extended action set for strategic attackers. However, further characterisation of attacks based on the severity of attacks and dependencies between attacks are beyond the scope of this paper. Additionally, we consider investment in security as discrete (Grossklags et al. 2008, Kunreuther and Heal 2003, Lelarge and Bolot 2008), providing insulation towards all forms and degrees of attack, with no further distinctions in their capabilities to defend specific attacks.

Extracting the intent and decisions made to achieve the intended results from an instance of a highly restricted interaction scenario achieved through classical game theory is challenging. Indeed, it is the very problem in decisively predicting the behaviour of human players administring strictly bounded rationality (Camerer et al. 2004), especially while addressing human adversaries (Camerer 2011) where there is no evidence on generated forms of motivation and intention behind attacks. One approach to tackle this problem is by understanding the context of interaction, as

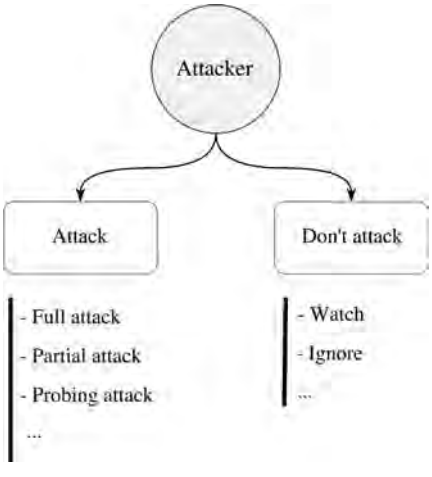

Figure 1. Attacker's decision space.

a decision must be made within a specific context and can be best represented through a hierarchy of decision states (Lewis 2013). Figure 2 is a hierarchical decision analysis tree capturing the mentality of attackers. The lowest level of the hierarchy represents concrete actions or choices of an attacker. As we ascend the hierarchy, states become increasing abstract and can be further fragmented into transitional stages precisely representing and supplementing an interaction scenario.

The hierarchical decision analysis tree is a highly simplified decision model representing cognitive workflow of attackers, initiating from the thought of an attack and terminating on a definitive decision on attacking or not attack, replicating an attack process. The thought of an attack is supported by deciding on whether to search for vulnerabilities or the type of attack to perform within the attacker's capabilities. Based on the context of interaction there could be numerous other decision paths to choose from for attackers. These intermediate choice of paths are latently, or innately, or precisely influenced by factors backing the intended goal. The subsequent steps down the hierarchy include designing attack strategies and then deciding whether to commit to an attack. The low-level decisions which demonstrate certain behaviour are being modelled using game theory. Game theory being a mathematical modelling tool supplements in determining and quantifying elements influencing decisions and assist in predicting behaviour (Burke 1999). The low-level behaviour can be used to infer higher-order objectives that are likely driving such behaviour augmenting our understanding of the intention behind attacks. An improved understanding of intention and motivation will support rigid estimations of attackers' behaviour. However, understanding the abstract states—top levels of the hierarchy demands a multi-disciplinary approach with effective application of concepts from behavioural psychology and cognitive science.

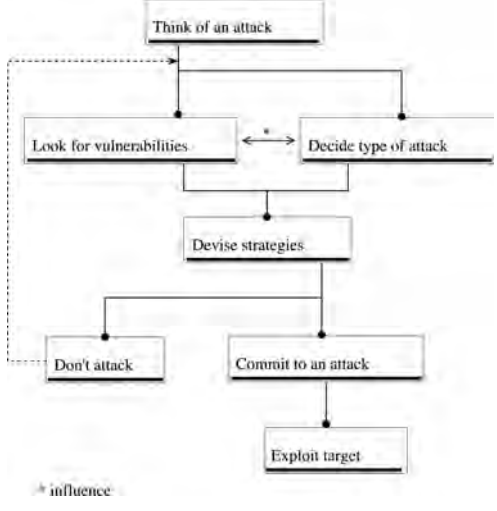

Figure 2. Attacker's decision analysis.

Figure 3. Attack framework.

We have characterised the attack process into different efforts required in performing an attack, acknowledging attackers to be rational entities. Figure 3, presents the attack framework demonstrating the efforts required in the attack process. The overall effort required can be broadly divided into *searching effort* and *breaking-in effort*. The searching effort includes efforts required in searching victims (targets), gathering information and searching vulnerabilities to exploit. Breaking-in effort represents the efforts required to compromise a system after choosing a target and a vulnerability to exploit. Based on the total effort required to compromise the target, an expected value can be derived. The expected value is one of the crucial factors moderating an attacker's decision (Herley 2010, Laszka et al. 2015).

The conversion of attackers' decision model into efforts required in the attack process disintegrates the top abstract levels of the decision model into modellable units. These modellable units can be used to quantify the expected utilities revealing the incentives behind attacks offering a better understanding of attackers' decision-making behaviour. Additionally, the attack framework assists in evaluating and enhancing attack strategies by effectively regulating the efforts strengthening the efficacy of attacks and ensuring better profits.

4 OPTIMISING ATTACK STRATEGIES

Lack of complete and perfect information against target induces uncertainty in attackers' decisions. The attack process eventually converges to a point of choice where an attacker has to decide on whether to attack or not to attack. The fate of an attempted attack depends on the target's capabilities to defend against attacks which further

depends on the extent of security investments. Figure 4, represents the expected payoffs of an attack against a targeted operator. We consider the investment in security as discrete—successfully preventing all forms and degrees of attacks. In the Figure 4, secure represents a system capable to successfully defend an attack and insecure represents the alternate.

In reality, defenders outnumber attackers. A critical problem attackers face is identifying targets such that a committed attack would yield something. For example, let's say the telecommunications domain has a total of N operators with N_c cooperating operators sharing security dependencies and N_n non-cooperating operators competing against security. It is an extremely expensive task for attackers to choose a viable target from such an intertwined mesh of operators. Here, the number of systems under each operator is ignored as considering it magnifies the complexity by many folds. Possible tactics attackers might adopt addressing this situation are

1. To randomly choose an operator and try breaching through the operator's defences. This approach would involve a heavy searching effort and a heavy breaking-in effort. This approach adds additional uncertainty as the attacker is unsure regarding his capabilities in successfully compromising the target.
2. To search for a certain type of vulnerability and then trying breaching it. This approach would involve heavy searching effort but a small breaking-in effort. Even though this approach involves high searching effort, chances of successfully compromising the chosen operator are very high.

The expected Utility (U) represents the probable payoff an attacker will receive on attacking the chosen operator. Based on the attack framework in Figure 3, the expected Utility for an attack can be determined as

$$U = cost\,(Information\_searching + Target\_searching + Vulnerability\_searching + Breaking\_in) - expected\ Value$$

where from (Herley 2010),

$$cost\,(Information\_searching) < cost\,(Target\_searching)$$

and any other forms of relationships cannot be defined from the existing literature.

Gathering and sharing of security-related information is a key factor heightening cybersecurity in both cooperating (Hausken 2017) and non-cooperating (Khouzani et al. 2014) environments. However, it is a known fact that the proposed information by defenders supports attackers in strategic decision-making. The following analysis illustrates how commonly available knowledge on operators can be used to reduce the cost of an attack. The use of available information reduces the information-searching effort to a static cost, represented as C_i, rather than a variable cost. In addition, attackers must bear the vulnerability-searching costs, represented as C_v, as a common cost irrelevant to any choice of target. t represents the choice of a target from the set of operators.

In a cooperating environment, the state of an operator is not only influenced by his decision but also by other cooperating operators' decisions. An attacker knowing that a set of operators (N_c) are cooperating refines the target-searching scope from N operators to N_c operators, where, $N_c < N$, reducing the effort to an extent. The expected Utility (U_c) for attacking cooperating operators can be defined as

$$U_c = C_i + cost\,(Breaking\_in) + C_v \sum cost\,(Target\_searching)\, N_{c(t,-t)} - expected\ Value$$

Whereas, in a non-cooperating environment, an operator's security investment might encourage competing operators to invest in better security measures. On the other hand, it might also increase the likelihood of attacks on competing operators as the attacker will prefer a victim will lower resistance. Knowing operators are competing reduces the victim-searching effort considerably, as it is economically beneficial to attack the losing operator. Reduced victim-searching effort can facilitate in allocating additional resources for vulnerability-searching and for breaking into the operator's defences. The expected Utility (U_n) for attacking competing operators can be defined as

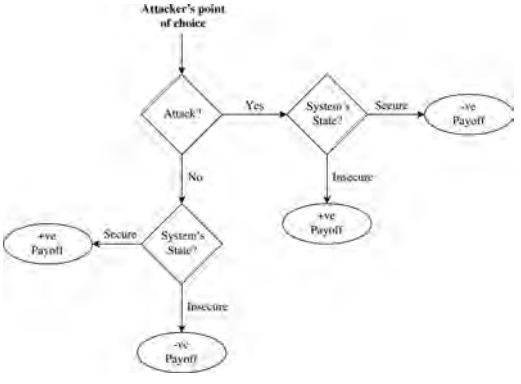

Figure 4. Attacker's expected payoff.

$$U_n = C_i + cost\,(Breaking\_in) + C_v \sum cost\,(Target\_searching)\, N_{n(t,-t)} - expected\ Value$$

Desired Gain represents the amount of gain the attacking wants from an attack. From an economic perspective, an attacker would prefer the attack that maximises his desired Gain. That is, from the available range of attacks which would successfully compromise the found vulnerability, he chooses the attack which max(U – expected Gain). This indicates co-existence of several classes of attacks on a point of attack. The expected payoff and the desired gain from an attack would moderate the decisions of the attacker. As

$$\text{decision} = \begin{cases} Attack, & \text{if } U \geq \text{expected Gain} \\ Do\ not\ attack, & \text{if } U < \text{expected Gain} \end{cases}$$

5 CONCLUSION AND FUTURE WORK

We investigated cybersecurity environment from attackers' perspective. Our results show that taking into consideration and admitting that attackers have strategies, incentives etc, implies that defenders (telecoms operators in our studies) need to change how they perceive, defend and react to attackers. The implications given the rise of targeted/coordinated attacks versus uncoordinated attacks (eg: DDoS) mean that operators must significantly reassess their investment in security technologies towards the former, despite the latter having better 'security theater'[1].

Traditionally, security games have been analysed **assuming the attackers to be of bounded rationality with limited set of prescribed choices**. Furthermore, studies consider attackers do aim to maximise their expected gain and this consideration contradicts the assumption of bounded rationality of the attacker. We study the attackers considering they **share similar characteristics as defenders** with attack strategies maximising their expected gain.

In particular, we model security interactions with an extended set of actions available to the attackers. This expands the possibilities where an action can bear latent objectives and motives raising concerns regarding the admissibility of proposed defence strategies. We present a hierarchical decision tree capturing the mental model of attackers during the attack process. The decision model is supported by a generalised framework representing the attack process in terms of efforts required by the attackers addressing the abstract levels of the decision model. Using this framework attack strategies against cooperating and competing operators are derived optimising attackers' effort resulting in a better gain. Furthermore, it facilitates a way of understanding the strategic decision-making abilities of attackers.

Not all attacks are intended towards achieving economic targets. A novice attacker might not aim to maximise his economic payoff rather aim in gaining experience, or reputation and the interaction might end on an attempted attack. However, it might be a completely different picture for an experienced attacker. When such personality traits of the attackers are considered, specifically the strategic option of not attacking, it unsettles the traditional security modelling approach, particularly the Stackelberg approach (Kar et al. 2017), where the game proceeds with the assumption that the attacker acts (invariably attacks). This raises a number of research questions challenging the traditional approach used in modelling cybersecurity. For example

- Is every interaction between an attacker and defender a repetitive process or is it a single-point interaction which ends on an attempted attack?
- Is using Stackelberg Security Games to model security interactions an appropriate choice?

Considering the economics of scalable and targeted attacks discussed by (Herley 2010), would it be an effective strategy to launch a small scalable attack to determine the strength of the target and then launch a specific attack incapacitating the target?

In (Kusumastuti et al. 2015), attackers are facilitated with an option to not attack and invest in enhancing their capabilities enabling in launching stronger attacks in the future. This consideration would reduce the breaking-in effort and vulnerability searching effort. From a psychological perspective, Rogers (Rogers 2000) classified hackers depending on their expertise (from novice to experienced), areas of interests (software, hardware, etc.) and behavioural patterns.

Modelling players to be able to predict expected behaviour in a more realistic way requires a profound understanding of their incentives, motives and the context of the interaction. Behavioural modelling of the attacker will not only assist in understanding the expected intentions and behaviour of attackers but will also assist in devising comprehensive defences against such characteristics of attacks.

However, each instance of an interaction is unique, with a unique set of parameters characterising and moderating it. Modelling these unique

1. Bruce Schneier—Beyond Security Theater: https://www.schneier.com/essays/archives/2009/11/beyond_security_thea.html.

interactions under common grounds is highly ineffective. They demand to be modelled based on the context of the interaction and using only game-theoretic concepts restricts the context and the interaction environment to a larger extent through biases, heuristics, and convenience.

This preliminary exploration will guide our future studies in aptly modelling behavioural aspects of attackers and in refining the attack strategies and characteristics of attackers by incorporating proposed concepts from the existing research work. This would further aid in comprehensively modelling the behavioural aspects of the participants in the context of information-cyber security.

Asset replacement decisions: A Markowitz efficient frontier approach to evaluate the trade-off between total costs and system availability

A.M. Teodoro-Filho, G.A. da Costa-Lima & L.A.N. Costa
Aremas, Campinas, Brazil

F.C. Marinho & A. Prestes
Brookfield Renewable, Rio de Janeiro, Brazil

ABSTRACT: In this work, an approach to estimate the optimal strategy to replace groups of assets is discussed. The model includes parameters such as cost of economic depreciation, cost of decommissioning and probabilistic distributions to represent random variables (for instance, time between failures) and uncertainty in cost of failures. This simulation model helps to understand the trade-off relationship between cost and availability according to the possible replacement strategies available. We present and discuss how Markowitz effective frontier can be created based on the simulated values for different replacement strategies. This work can fill a gap in the literature concerning the problem of asset group replacement, which are not well explored, but is important for decision-makers dealing with real world problems. The approach presented also helps the asset replacement strategy, which is part of the operational strategy, to be more flexible to support the high level business strategy.

1 INTRODUCTION

One of the main tasks of a plant and maintenance engineer is related to the replacement of existing assets, which are especially important in industries such as mining, petroleum, power generation, etc. The problem faced by companies, though, is not only related to finding the economic life of each asset individually, but it is also related to assessing the impact of different asset replacement strategy in the system performance by techniques such as RAM (Reliability Availability and Maintainability) modeling. In this paper, we employ the Reliability Block Diagram (RBD) and Monte Carlo simulation to evaluate the impacts of asset replacement strategies in system performance variables such as total cost—which include OPEX (Operational Expenditure) and CAPEX (Capital Expenditures) – and downtime. These are conflicting objectives. In this context, the main objective is to understand the trade-off between cost and availability according to the possible replacement strategies available. A numerical example of a generation unit system of a power generation company in Brazil is used to define the Markowitz effective frontier.

In order to fulfill the goals of the paper, the modeling technique is Reliability Block Diagram (RBD) employed together with the tool Monte Carlo simulation as discussed in section 2. Section 3 contains the results (simulated and calculated). Section 4 presents finals comments.

2 ASSET REPLACEMENT

Authors like Eilton et al. (1966) Bazargan & Hartman (2012) and Al-Chalabi et al. (2015) use analytical models to find the asset replacement age in order to minimize the Total Cost of Ownership (TCO). Also, others like Shi & Min (2014) and Adkins & Paxson (2017) use Brownian geometric motion to simulate the costs of an asset to be applied to asset replacement management models.

The weakness of this approach to minimize the TOC is that its focus is on asset level and does not take into account the importance of performance index like availability and reliability at system level, which is the real problem. In this matter, Leung & Tanchoco (1990) mention that if multiple assets are employed in an integrated system, then the replacement decision for each equipment of the system must be analyzed simultaneously.

In spite of the idea of this integrated analysis has been a not so recent concernment, there is still a lack models studying real problems in the asset management literature.

As discussed, the isolated analysis sometimes is not enough to give the decision maker the correct insight about the reality, because it does not consider the complex configuration of a production system found in real world. In this isolated analysis, it does not matter if the equipment is in series, active parallel or in standby in the system by the reliability point of view. This is the reason

why RBD was employed in the current paper. Simulation is employed to allow more flexibility in this problem with conflicting objectives. The final model may contribute to feel part of the gap of models to solve real replacement problems in asset management.

3 MARKOWITZ EFFICIENT FRONTIER

There are N strategies in asset replacement with different and conflicting relation between availability and cost. Then, there is efficient frontier for management decision making.

In financial world, the objective of a portfolio of stocks is (a) maximize the average return and (b) minimize risk. There is a conflict between these two variables—the higher the return, the higher the risk. As explained by Powel & Baker (2009), both objectives cannot be met simultaneously, but optimization techniques can be used to exploit the trade-offs.

For financial analysis, Markowitz (1952; 1959) developed an approach to examine the trade-off between risk and return of a portfolio where the random variable is rate of return over time. The optimization consists in the selection of stocks in order to give the highest expected return (measure by average) for a given risk (measured by the variance of return).

In the present work of replacement strategy, the attention is not in the trade-off between risk and return, but in the one between cost and availability for a system composed of a number of assets that suffer degradation over time with use.

The managerial flexibility is the replacement decision of each individual equipment. Each managerial flexibility give different cost and availability at system level. Then, by simulation a number of managerial alternatives it is possible to construct a Markowitz efficient frontier with solutions that are not overcome by others. From this information, managers will be able to choose de replacement strategy according to the companies risk profile.

4 MODELING

This paper considers the Markowitz efficient frontier of a Power Generation Unit. Its Reliability Block Diagram is in Figure 1.

In Figure 1, equipment is in series, that is, each one asset can turn the system unavailable. This type of system demands less initial capital investment, but has more risk of failure.

In discussing modeling by reliability block diagrams, Zhang et al. (2012) mentions that there are two approaches: (1) Top-down when the stochastic behavior modeling of the failure time of an system does not consider its components individually and (2) Down-top, when the simulation of the moment of occurrence of failure of an system considers the premise that the statistical modeling of the time until the failure of the individual components of this equipment is known.

In an RBD analysis, the choice of the Top-down or Down-top approach is influenced by the availability of historical data. Thus, for some equipment the amount of data available allows for a more detailed representation of the time until the individual components fail, but for other cases this is not possible.

Model presented in Figure 1 follows the approach Top-down. Noteworthy that the RAM analysis based on the flexibility of Monte Carlo simulation gives flexibility enough to become the model as complex as the judgment of the analyst requires. Table 1 summarizes the code, description and current age of each asset.

According to Table 1, Auxiliary Service Transformer, for example, is indicated by the asset code AST and its current age is 10 years of operation (87.600 hours).

The current age of each asset affects directly its failure rate and consequentially its availability and maintenance cost. Table 2 shows the probability distribution of time-to-failure of assets of Power Generation System.

As shown in Table 2, for example, the lifetime of Auxiliary Service Transformer is modeled using Weibull distribution with scale parameter (eta) equal to 56.940 hours and shape parameter (beta) equal to 1,8. It is interesting to note that all assets

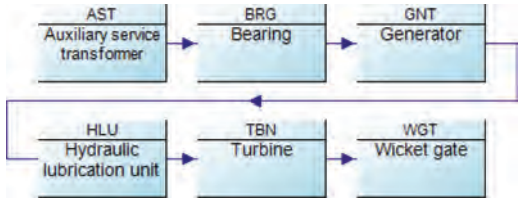

Figure 1. Reliability block generation unit system.

Table 1. Assets characterization for RDB modeling.

Asset		
Code	Description	Current age (hours)
AST	Auxiliary service transformer	87,600
BRG	Bearing	87,600
GNT	Generator	131,400
HLU	Hydraulic lubrication unit	87,600
TBN	Turbine	131,400
WGT	Wicket gate	43,800

Table 2. Probabilistic modeling of time-to-failure of each asset.

Asset code	Weibull distribution parameters	
	Eta (hours)	Beta
AST	56,940	1,8
BRG	30,660	4,2
GNT	61,320	3,8
HLU	78,840	3,2
TBN	70,080	3,6
WGT	43,800	1,4

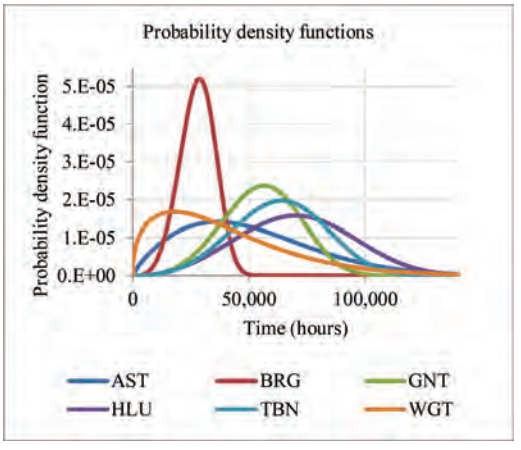

Figure 2. Probability density functions.

have an increasing failure rate, giving rise to expect find degradation as the main failure rate.

The probability density functions based on the parametes of Table 2 can be observed in Figure 2.

Each curve in Figure 2 represent the probability density function of the first failure of each asset.

After the failure of each asset, management applies corrective maintenance. An important assumption is that after maintenance, the probability density function of second failure due is not the same of the first one. Table 3 contains the characteristic of the corrective maintenance task of each asset.

Considering again the Auxiliary Service Transformer (ASF), the task duration of the corrective maintenance is 120 hours, the cost of this task is $ 66,000 and the age reduction factor is equal to 5%. To understand the concept of age reduction, consider that after a maintenance task, the asset can return to a condition as good as new, as good as old or intermediate. To quantify this intermediate condition the following model can be used (Malik, 1979):

$$I_d = I_a * (1 - ARF) \quad (1)$$

where I_d is the age of the equipment after maintenance, I_a is the age before maintenance and ARF is the age reduction factor. The as good as new condition is represented by ARF = 100% and the as good as old condition is represented by ARF = 0%. The condition after the maintenance depends on the complexity of the asset, among others things.

The modeling of the asset failure rate per hour appears in Figure 3 according to just one simulation.

In the simulation presented in Figure 3, one failure occurred after 67,991.3 operations hours, then a corrective maintenance was performed and the failure rate was affected by the age reduction factor. Other failures occurred after 82,065.8 and 93,971.2 hours and again it is possible to see the impact on failure rate. The asset replacement was performed in 96,360 hours, when the failure rate returned to as-good-as-new condition. The last simulation of failure occurrence was around 158,454.5 hours.

The problem of finding the right ARF is complex and requires additional data for modeling. In this context, the present work does not have make inferences about the unknown parameters of an

Table 3. Maintenance corrective characteristics.

Asset code	Corrective maintenance		
	Task duration (hours)	Cost ($)	Age reduction factor
AST	120	66,000	5%
BRG	72	21,000	85%
GNT	144	72,000	5%
HLU	96	60,000	5%
TBN	168	114,000	5%
WGT	120	90,000	5%

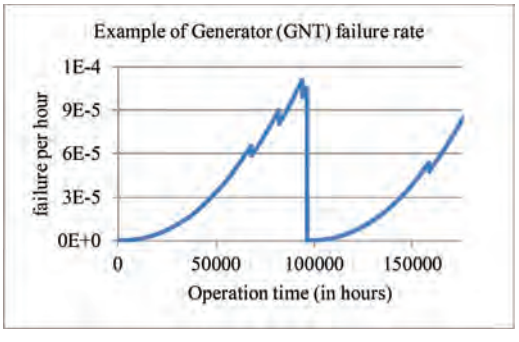

Figure 3. Profile of failure rate per hour using simulation.

Table 4. Task and cost used in asset replacement.

Asset code	Asset replacement	
	Task duration (hours)	Cost ($)
AST	24	300,000
BRG	48	90,000
GNT	240	750,000
HLU	120	270,000
TBN	480	630,000
WGT	240	255,000

imperfect repair model as in Melchor-Hernández et al. (2014) and Toledo et al. (2015).

The activity of asset replacement implies in a replacement duration (downtime) and Capital Expenditure (CAPEX). In Table 4 there are some data of tasks duration and cost of equipment of Figure 1.

In Table 4, the replacement of the Auxiliary Service Transformer has task duration equal to 24 hours and investment cost equal to $ 300.000. Data for other assets are also in Table 4.

5 RESULTS

Based on parameters discussed in section 2, excluding current age and asset replacement characteristic, Figure 4 contains the maintenance cost profile simulated of each asset for a period of 20 years.

Each profile is the result of the simulated mean maintenance cost after 10,000 simulations using the software Isograph Availability Workbench (AvSim®) considering that each equipment is new in year zero.

From Figure 4, it is easy to notice that different assets have different corrective maintenance cost profile over time. For example, considering only the year 20, the Turbine (TBN) has the highest simulated mean maintenance cost. Then, it is expected that the optimal replacement strategy is not equal for all assets.

The model of economic life of an asset based on cost minimization depends strongly on maintenance cost profile and other economic variables. In this case, consider that the opportunity cost of capital equal to 12% per year, fiscal depreciation equal to 10% per year, income tax rate equal to 25% a year and economic depreciation of asset value of 10% per year.

Figure 5 shows the relationship between Total Cost Ownership and time of replacement from Costa Lima & Teodoro- Filho2013) for different assets.

Figure 5 highlights that each asset has its own economic life. Turbine (TBN) and Generator

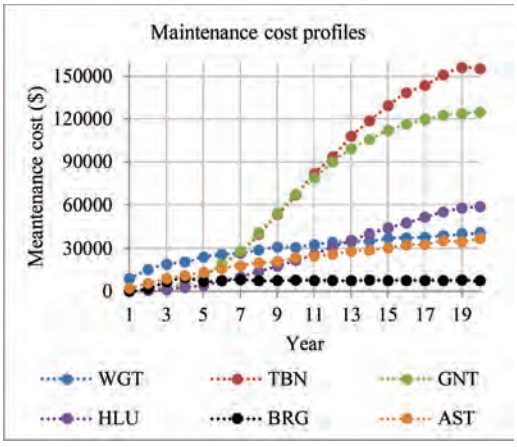

Figure 4. Simulated mean cost of maintenance of different asset.

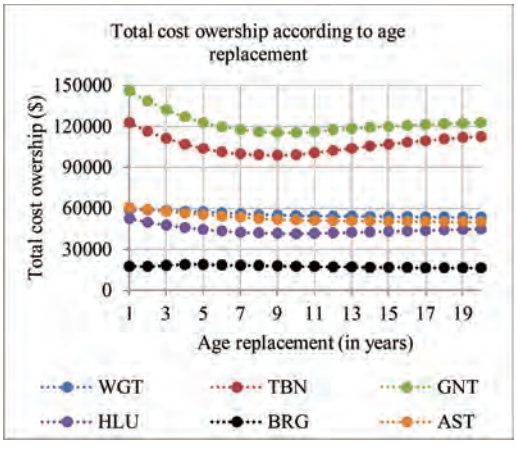

Figure 5. Total cost ownership according to age replacement.

(GNT), for example, have economic life of 9 and 10 years, respectively. By other hand, for the Auxiliary Service Transformer (AST), its economic life is at least for a period of 20 years.

In reality, the problem faced by the companies is related not only about finding the economic life of each asset, but about assessing the impact of different sets of asset replacement (strategies) in system performance. In order to illustrate the question, consider the model discussed in section 2 simulated for 3 years. In case of no replacement at the beginning of the period, the simulated present value of mean total cost is equal to $ 1,389,415 (considering opportunity cost of capital equal to 12% per year) and mean system downtime equal to 2,749 hours as shown in Table 5.

Table 5. Results of simulation present values of cost and downtime—Part 1.

Replacement decision	Mean total OPEX ($)*	Mean total cost ($)*	Mean system downtime
Replace all	61,874	1,692,042	611.00
No replacement	1,389,415	1,389,415	2,749
AST	1,330,456	1,525,853	2,658
BRG	1,354,562	1,413,181	2,688
GNT	834,091	1,429,673	1,775
HLU	1,304,659	1,480,516	2,723
TBN	823,115	1,323,404	2,319
WGT	1,352,345	1,456,770	2,935

*Present value.

In Table 5, replacing all assets at the beginning of the period results in a mean total cost equal to $ 1,692,042 and mean system downtime equal to 2,749 hours. Replacing only the Auxiliary Service Transformer (AST) at the beginning of the period results in a mean total cost equal to $ 1,525,835 and mean system downtime equal to 2,658 hours.

In short, Table 5 presents the results of the following replacement strategies: (a) replacing all assets at the beginning of operation, (b) no replacement at beginning and (c) replacement of only a specific asset and the others not. The mean total cost in present value is calculated based on the mean OPEX (represented by the corrective maintenance cost) plus the investment cost in new assets less the resale value of the assets replaced. Both result is generated based on the simulation. In this model the resale value is calculated considering an economic depreciation of 10% in relation to the last year.

In contrast, in Table 6 contains all 15 combinations of two assets replacement.

Considering the replacements of two assets, to replace GNT and TBN results in the lowest mean system downtime. To replace BRG and TBN results in the lowest mean total cost in present value.

In Table 7 the results of all possible 3 assets replacement are presented.

To replace GNT, HLU and TBN results in mean system downtime equal to 900 hours, which is even lower the replacing only GNT and TBN. None of 3 asset replacement strategy results in lower mean total cost than replacing only BRG and TBN or replacing only TBN.

All 4 assets replacement simulated performance is presented in Table 8.

Replacing AST, GNT, HLU and TBN results in mean total downtime is 780 hours, but has a mean total cost in present value equal to $ 1,595,473. Again, no option is the best in both criteria simultaneously.

benefits the other criteria, but some strategies can be discarded for being surpassed by at least one other strategy in both criteria.

All 64 assets replacement combination was simulated, but the plot of Figure 5 highlights only 26 solutions. These solutions were chosen to the plot for being between the 14 best solutions to minimize cost or unavailability. In Figure 6 the plot indicates the mean total down time and mean total cost in present value to each strategy.

It is clear that some strategies are overcome by at least one other strategy and others are not. The strategy of replacing BRG and GNT (green circle), for example, is surpassed by replacing BRG, GNT and TBN not only in terms of cost, but in terms of availability too.

The unsurpassed strategies form the efficient frontier as in Table 10.

The strategy of replacing only the Turbine in the beginning of the period results in the minimum

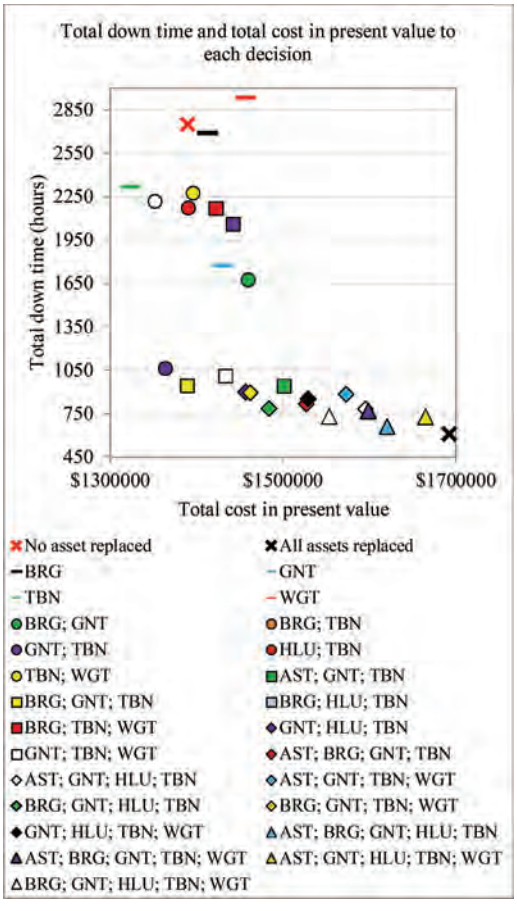

Figure 6. Mean total down time and mean total cost in present value to each decision.

Table 10. Markowitz effective frontier.

Replacement decision	Mean total cost ($)*	Mean system downtime
All assets replaced	1,692,042	611
TBN	1,323,404	2,319

BRG; GNT; HLU; TBN; WGT	1,553,340	732

*Present value.

total cost in present value, but results in an high unavailability. The choice for one strategy must rely on budget to maintain the system and availability

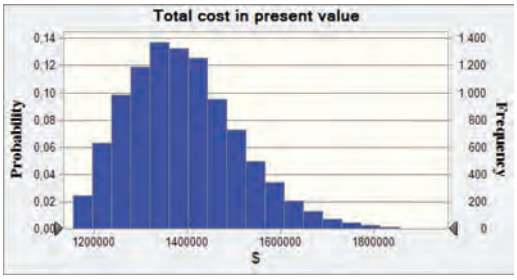

Figure 7. BRG, GNT, TBN replaced.

targets. So, if the companies do not tolerate total down time in hours to 3 years surpassing 650 hours, the strategy of replacing all assets can be a good option.

As the value discussed so far considers only the averages, we can also consider the uncertainty in costs. So the mean failure frequency is used to simulate the number of failure based on a Poisson distribution and considering each corrective maintenance cost as a uncertain variable which can assume a value between 80% and 120% of the value presented in Table 3.

In Figure 7 the histogram of the total cost in present value simulated considering replacement of Bearing, Generator and Turbine is presented.

Mean total cost in present value is equal to $ 1,389,261 similarly to the value presented in Table 10. The advantage of this simulation is to show the dispersion of the total cost represented by a standard deviation equal to $ 119,971, 10th percentile equal to $1,246,437, 90th percentile equal to $ 1,549,009, minimum value equal to $ 1,154,489 and maximum value equal to $ 1,937,684. So, the manager even making a decision based on the mean values can investigate the dispersion of each variable to have a better understanding about the risks.

6 CONCLUSIONS

Different strategies have different impacts in total cost and in total down time. Considering the existence of trade-offs between the two variables, an effective frontier can be created based on the simulated values for different replacement strategy, similarly to Markowitz (1952).

A big system contains a lot of asset, which results in a lot of combinations of replacement (strategies). This problem easily falls in the curse of the dimensionality, so, to big systems, the modelers must consider optimization algorithms in order to find a good solution or the efficiency frontier.

Considerations related to insurance of cruise traffic in the arctic waters

K. Trantzas, O.T. Gudmestad & E.B. Abrahamsen
University of Stavanger, Norway

ABSTRACT: The wish of humans to explore new areas, environmental changes and growing worldwide demand have led to the Arctic region's increasing popularity in recent years. The cruise industry is continuously evolving in this area, creating an important need for more research into the risk of operating in the Arctic Ocean. However, most insurance firms do not yet have standard procedures for evaluating risk and policies to build insurance premiums for the Arctic cruise ship industry. The paper refers to our participation in a survival exercise in Arctic waters during May 2017, where the objectives were to assess the capability of rescue means in cold regions. Using our experience of the exercise as a basis, in this paper we are presenting the limitations related to cruise voyages in the Arctic. We suggest an insurance process that should be followed and finally discuss on some key factors that drive an insurance premium's cost for the cruise ship industry in the Arctic.

1 INTRODUCTION

In recent years, the Arctic has gained more and more popularity due to the extraordinary environmental and developmental changes that have taken place in this region. Meanwhile, climate change has led to extensive thinning of sea ice, making marine access in the Arctic Ocean much easier. It is obvious that this ice reduction extends to all seasons of the year, giving the maritime industry the opportunity for extended seasons of navigation and access to new areas that were previously difficult to reach. (Guy, 2006, Lasserre, 2011, Østreng et al., 2012, Sarrabezoles et al., 2014, Lasserre and Pelletier, 2011). At the same time, global marine tourism is rising and a place of extraordinary beauty like the Arctic could not stay unaffected by this trend. The potential impacts of these new marine uses—social, environmental and economic—are unknown but will be significant. Thus, there is great interest from both cruise ship owners and insurance companies regarding these trips. Safety is the main challenge that should be addressed by the owners of cruise ships operating in a remote and isolated area, with harsh weather conditions and poor infrastructure and communications. When a company needs to manage the negative consequences of an accident, it can: a) take all the consequences if/when an accidental event occurs, b) reduce the probability of an accident and/or its consequences by safety measures or c) transfer the consequences of the occurrence to parties better able to carry them (i.e. buying insurance) (Abrahamsen and Asche, 2011). As during any other operation, when planning a cruise, especially in an in-hospitable environment like the Arctic, both the ship owners and the passengers must be insured. Thus, marine and travel insurance companies are keen to increase their involvement in Arctic cruising, and this paper aims to give some considerations, in relation to insurance policies, that should be followed in the Arctic region. The limitations that the insurance companies should place on the ship owners, in order to offer insurance for their vessels, are discussed. In addition, this paper presents a standardized procedure that the insurance companies should follow before putting a value on the insurance contract. Finally, we debate which are the cost drivers and how could they affect the price of an insurance premium.

2 CRUISE INSURANCE

Cruise insurance is not considered marine insurance (Burke, 2000) but is better described as the sum of two categories: marine insurance and travel insurance.

With the term 'marine insurance', we mean the contract offered by an insurance company to the ship owner. With this contract, the insurer undertakes to indemnify the assured, in manner and to the extent thereby agreed, against marine losses, that is to say, the losses incident to marine adventure (Marine Insurance Act, 1906). There are specific marine insurance types and policies, which the cruise ship-owners are obliged to have, according to the international law and the national regulations of each country, depending on the specifications and the details of the upcoming voyage of their vessel.

Figure 1. Cruise insurance.

On the other hand, travel insurance is considered as the insurance product designed to cover the costs and losses of the passengers and to reduce the risk associated with unexpected events that someone might incur while traveling. Here again, there are different types that cover the specific needs of travelers.

In this subchapter, we discuss the policies of Arctic cruise insurance. The limitations that the insurance companies should place on the ship owners in order to offer insurance for their vessels, are presented. Finally, we debate which are the cost drivers and how could they affect the price of an insurance premium.

3 LIMITATIONS

The insurance companies decide whether they should offer insurance to a shipowner, according to their policies. Whether they offer an insurance premium to a cruise vessel owner depends on the risk appetite, meaning that it depends on the 'amount' and type of risk that a company is willing to take in order to meet their strategic objectives. An insurance company can be defined as: a) risk-averse when the company dislikes risk and will stay away from adding high risk investments to their portfolio, b) risk-seeking when the company prefers to take some high-risk investments and c) risk-neutral when the company seeks high-risk investments but at an average level.

Insurance is considered an alternative to investing in safety measures offered in order to transfer risk to a third party (insurance company) (Abrahamsen and Asche, 2011). However, the Arctic is a very hostile environment, about which we lack sufficient knowledge. Although there are no specific limitations stated by the regulatory framework in the Arctic, in order for a ship-owner to obtain insurance, we strongly believe that there should be some minimum requirements that should be covered by the cruise ship owners prior to an Arctic expedition.

Quite often ship-owners try to save from the costs of investing in safety measures by buying insurance. To make Arctic expeditions safer, there should be some limitations regarding their ability to obtain insurance. The main requirement that they must meet is to have an adequate polar- or ice-class-certified vessel for traveling in the Arctic. A vessel should not be allowed to operate in the Arctic area unless it is certified as eligible for the area. In August 2006, the International Association of Classification Societies (IACS) released a document, titled the "Unified Requirements for Polar Ships", which standardized global ice classification specifications for vessels (Table 1).

Another limitation should be the shipping firm's competence in Arctic shipping. There should be a strict investigation of the firm's past behavior in relation to safety policies. For example, if a shipping firm has neglected safety issues in previous trips and put passengers' lives at risk, then it should not qualify for an insurance contract.

Furthermore, before a ship-owner is given the right to insure his vessel for an Arctic voyage, there should be a thorough inspection of the vessel and the extent to which the ship owner has covered the requirements for survival equipment. An insurance company must deny insurance to a ship that does not have sufficient lifeboats and life rafts for all the passengers, modified to suit the Arctic needs (i.e. winterized). Another example could be the lack of adequate insulated survival suits, as well as Personal Survival Kits (PSKs) and General Survival Kits (GSKs). An insurance company could protect itself against wrongdoing or neglect on safety issues by the shipping firm, by stating specific terms in the insurance premium that place the blame on the ship-owner in the case of an accidental event which occurred due to the shipowner's negligence.

But then an important question arise: Should those limitations regarding the shipping firm

Table 1. Polar Class descriptions (International Association of Classification Societies, 2016).

Polar class	Ice descriptions (based on WMO Sea Ice Nomenclature)
PC 1	Year-round operation in all polar waters
PC 2	Year-round operation in moderate multi-year ice conditions
PC 3	Year-round operation in second-year ice which may include multiyear ice inclusions
PC 4	Year-round operation in thick first-year ice which may include old ice inclusions
PC 5	Year-round operation in medium first-year ice which may include old ice inclusions
PC 6	Summer/autumn operation in medium first-year ice which may include old ice inclusions
PC 7	Summer/autumn operation in thin first-year ice which may include old ice inclusions

depend only on the insurance company's interpretation? As already stated, certain insurance companies are considered to be risk seeking, meaning that they are willing to take high risks in order to gain profits. Thus, it is of great importance that these limitations be included in a legally binding agreement. There must be a regulatory framework between the Arctic countries and the ship owners interested in operating in Arctic waters that states specific limitations for the vessels, in terms not only of operating in the Arctic but also of obtaining insurance coverage. This way, the ship owner can be made responsible in the case of an accidental event that involves neglect or wrongdoing on the shipping firm's side.

4 INSURANCE PREMIUMS IN THE ARCTIC

The lack of data and standardized methods regarding the assessment and the modeling of the risks, as well as the poor background knowledge, create a big challenge for insurance companies in the Arctic. This leads the underwriters to work on a case-by-case basis that vastly increases the cost of the insurance premium. Thus, the sustainability of Arctic expeditions is strictly dependent on the cost of marine insurance, and the industry is calling for more standardized procedures. Here, a standardized procedure for the insurance companies is suggested (Figure 2).

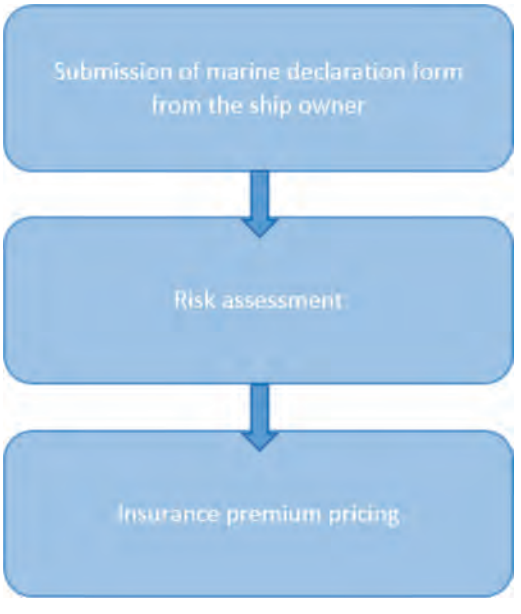

Figure 2. Phases of suggested insurance premium procedure.

Initially, and after receiving all the relevant information regarding the vessel and the trip to be insured, from the ship owner through the marine declaration form, an insurance company should check whether the shipping firm covers the limitations regarding obtaining insurance (polar/ice class, life-saving equipment, etc.). If those limitations are covered, then a risk assessment should follow, with focus on the consequences and the associated probabilities. The risk assessment starts with a qualitative risk analysis, in which the hazard identification and their categorization take place. After identifying the possible hazards and their related consequences, a quantitative risk analysis should follow, in which, according to the data for the region of the trip concerned and the background knowledge of previous incidents, a probability number will be assigned to each accidental event. Then, by using the specific information obtained from the shipping firm regarding the vessel and the trip (e.g. ship design information, winterization of the ship, quality and quantity of survival equipment, etc.), adjustments should be made to the probabilities linked with the specifications of the shipping firm. Special attention must be given to the strength of knowledge and the uncertainties, as these may lead to a higher insurance premium. In general, the insurance premium is to a large extent equal to the expected costs. Then, the insurance premium is considered fair. If an insurance company does not offer fair insurance another company can attract their customers. Thus, high uncertainties or poor background knowledge can result in higher insurance premiums. For example, one important finding of our participation in the survival exercise in the Arctic was the influence of an integrated heating system in the lifeboats on the survivability rate of the passengers (Gudmestad et al., 2017). A vessel that does carry lifeboats with an integrated heating system will be assigned a higher probability for the risk of people getting cold due to low temperatures than a vessel equipped with lifeboats with a heating system. Thus, the insurance premium will be lower for the second vessel, as the passengers have a higher probability of surviving and the insurance company is taking a lower risk.

After finishing the risk assessment, the pricing of the insurance premium follows. In this phase we identify two main steps. During the first step, the expected costs are calculated by using information from the risk assessment. The expected cost for each accidental event, $E[C|A_i]$, is multiplied by the associated probability $P(A_i)$. This is done for all the accidental events, and then summarized to give an initial price at the insurance premium. During the second step, the insurance premiums calculated on the previous step based on the expected costs, are

adjusted in order to take the strength of knowledge and uncertainties into consideration. Finally, the administration costs and a percentage of the profit that the company wants to make should be added to the price of the premium decided by the insurance company on the first step. As already mentioned, an insurance premium is considered fair when it is to a large extent equal to the expected costs. As a result, the added profit that an insurance company wishes to obtain should not be too high. It is also recommended that this later adjustments of the second step should be made through a broad managerial review. It is also of great importance that the insurance company executes a self-assessment of the vessel, sending its own surveyors to check the design and the equipment of the cruise ship.

A cruise ship operator is concerned with lowering the costs to increase the profits and will, most likely, only want to fulfill the minimum requirements stated by the legal framework. However, if the requirements are very strict and conservative, it might make the vessel owners stop their Arctic cruise business. Having first-class survival equipment that could fit every passenger on a cruise ship of more than 2000–3000 passengers could be quite expensive. Thus, there must be a conscious effort by the legislators to secure top levels of safety in Arctic cruise traffic, while, at the same time, not acting conservatively and overestimating the presence of extra safety measures.

5 ARTIC REGION COST DRIVERS OF MARINE INSURANCE

After presenting the limitations that should apply to Arctic voyages, and our suggestion for a standardized procedure that should be implemented on determining an insurance premium in the Arctic, we will now discuss the influence of specific factors on the insurance premium.

The most important criterion that influences the cost of the insurance premium is the ice class of the vessel. As previously mentioned, insurance companies should not offer insurance contracts to firms whose ships are not designed for navigation in potentially iced waters. However, there are different polar and ice class categories and, thus, the higher the polar and/or ice class of a vessel is, the lower the price of the insurance premium offered by the insurance company. This is reasonable, as the higher the ice class of a vessel, the higher the capacity of the vessel to withstand harsh weather conditions and avoid any accidental events.

Another factor that could influence the cost of an insurance premium in the Arctic is the winterization of the vessels. Winterization is a process, which enables vessels to operate in extreme sub-zero temperatures without suffering loss of equipment operability, vessel stability and power, and personnel habitability, and which permits crew operations to be performed safely (Ghosh and Rubly, 2015). Class regulations require equipment and systems to be winterized. Some of those winterizations procedures are presented by Hasholt (2011). Sheltered pathways, under-deck heating, heated mooring equipment, low temperature emergency generators, ice navigation radar, ice searchlights, etc. are all elements that could drive the cost of an insurance premium down. The more of the aforementioned elements a cruise ship has, the more 'winterized' it is and the less is the price of the premium. Each element has specific importance for operating in the Arctic and together they constitute the winterization of the vessel. For example, if a vessel is considered 40% winterized then there could be an agreement with the insurance company to lower the insurance premium price by 5%–10%.

Communication systems and stability play an important role in the Arctic region. The remoteness of the area highlights the need for survival equipment able to help the passengers to survive for the period of five days stated in the regulatory framework for ships operating in the Arctic, The Polar Code (IMO, 2016). The presence of enhanced communication systems and adequate survival equipment could dramatically lower the overall price of an insurance premium. During harsh weather, improved communication systems could prevent loss of communication, which could be vital for the cruise ship. Being equipped with sufficient lifeboats, life rafts, survival suits, PSKs and GSKs is one of the previously stated limitations. However, during our survival exercise in Arctic waters, it was noted that further improving the survival suits, by adding integrated woolen underwear, and providing sizes for all the passengers could lead to an insurance company's decision to lower their offer, as the severity of the consequences in case of an unexpected event are reduced (Gudmestad et al., 2017, Solberg et al., 2016).

The time of the year and the route that the cruise ship is planning to take can also influence the insurance premium. For instance, a trip planned during August would have a lower insurance premium than one trip planned during the beginning of the Arctic cruise season in May. This is because the probable ice concentration and ice movement during August would be lower than the corresponding ice concentration and ice movement during May (Lasserre, 2014).

One of the most important criteria for an area like the Arctic, where we lack sufficient knowledge, is the experience of the captain and crew members'. According to Sarrabezoles et al. (2014), after inter-

viewing several companies that offer marine insurance for the Arctic, they found most firms said that trust in the shipping company is important and that they therefore might be reluctant to insure firms that do not have experience in Arctic shipping. Some of them stated that they would examine every submission but evaluate the preparedness of the shipping firm, the crew's experience, charts' accuracy and contingency planning in case of problems. However, for the majority of firms, it is clear there is a strict inspection of the shipping firm's past behavior and safety-related policy. This means that the insurance company expects to see proof that the shipping firm is able to perform well in Arctic waters.

Finally, each traveler should have private travel insurance. However, most private travel insurance companies require travelers to have separate search and rescue cover. This can raise the price for the traveler by two or sometimes three times, compared to the initial travel insurance cost. Furthermore, it is not unusual for those third-party companies that offer search and rescue cover, to put extra limitations on travelers, such as age or the area in which they provide cover. Thus, it is of significant importance that the ship-owners should acquire such search and rescue cover for all their passengers. This would decrease, the insurance premium provided by the insurance company, as there would be higher chances of survival in the case of an accidental event and, thus, lower severity of consequences. The private travel insurance premium of the travelers would also decrease. However, the ship owners will have to undertake extra cost for the search and rescue cover.

6 CONCLUSIONS

Although Arctic cruises are gaining in popularity, the Arctic region remains a hostile environment, where we lack sufficient background knowledge and data to determine insurance premiums. There are many hazards related to cruise traffic in the Arctic, and even more challenges arise in the case of an accidental event during the voyage.

Through a legislative framework, specific limitations must be implemented that, unless met by the ship owners, forbid the signing of insurance cover. Ice and/or polar class certification, thorough background check, inspection of the vessel and adequacy of survival equipment must all be included as mandatory limitations before insuring a cruise vessel for an Arctic voyage.

A standardized procedure should be followed by underwriters to determine insurance premiums in the Arctic. Thus, the creation of a platform, where Arctic data would be gathered and easily accessed is of high importance.

Different factors can influence the cost of an insurance premium between a shipping firm and an insurance company, the most important being the level of winterization of the cruise vessel, the level of training of the shipmaster and the crew members and the coverage of the search and rescue procedure for the passengers in case of emergency.

The impact of personal liability concerns on incident reporting in engineered systems

Jan Hayes, Janice Wong & Christina Scott-Young
School of Property, Construction and Project Management, RMIT University, Melbourne, Australia

Sarah Maslen
School of Government and Policy, University of Canberra, Canberra, Australia

ABSTRACT: Previous research on aviation and health sectors has found that individual blame for small failures discourages incident reporting and so adversely impacts disaster prevention. This finding has widely influenced practice in organizations relying on engineers. Based on a survey of Australian engineers (n = 275) this paper examines how personal legal liability considerations impact on hazard reporting and other forms of knowledge sharing. We found that 48% of engineers are more likely to report hazards despite changes in societal expectations and the tendency to blame. Only 5% indicated that they were less likely to report hazards as a result of their liability concerns. We suggest that these findings are due to the nature of engineering work, where decision-making is distributed across time, place and people. In this environment, blame and responsibility are less attributable to individual actors. Equally, reporting a hazard may act to transfer responsibility and so limit one's personal liability.

1 INTRODUCTION

Excellence in organizational safety performance requires that all personnel are willing to learn from small faults and failures (Hopkins, 2009) and also from past accidents (Snook, 2000) in order to prevent recurrence. This leads to a range of strategies for collecting and sharing information ranging from formal incident reporting to informal sharing of stories within professional groups (Hayes and Maslen, 2015, Maslen and Hayes, 2016).

When it comes to formal incident reporting systems, a key challenge is encouraging people to report what they know so that systemic problems can be identified and addressed. A culture that encourages reporting is thought to be a just culture—one in which people can report genuine mistakes without fear of retribution (Dekker, 2007, Reason, 1997). Much of the research that led to these conclusions was originally grounded in the health and aviation sectors although the findings have been assumed to generalize into any complex socio-technical system including those where work is largely carried out by engineers. Our study challenges this paradigm within the engineering context.

We have studied the impact of personal legal liability concerns on high stakes decision making by engineers. The results of our survey show that personal legal liability supports good decision-making when legal responsibility aligns with issues over which engineers have control (Hayes et al., 2017). Where these are not in alignment, there is evidence that 'defensive engineering' practices can develop analogous to 'defensive medicine'—a set of practices that have grown up in the health sector in response to increased liability concerns (Catino, 2009).

In this article we focus specifically on those aspects of the survey related to the impact of personal liability concerns on reporting and knowledge sharing. Knowledge sharing practices include incident reporting, the sharing of stories about past incidents and the release of findings from high quality accident investigations that support learning. First, we engage with the literature on safety culture and responsibility in engineering. We then describe our survey method and the survey results as they apply to learning from accidents and incidents. The paper concludes with a discussion of the implications of our findings and key conclusions.

We argue that the nature of engineering work means that knowledge sharing behaviors (reporting, storytelling) are less impacted by personal liability concerns in engineering-based industries than in healthcare and aviation. Rather than inhibiting reporting, concerns about blame may encourage reporting. There is some evidence of impacts of personal liability concerns on storytelling among our respondents' colleagues, though this is not as pronounced as in healthcare and aviation. The implications of this result warrants further inquiry.

2 JUST CULTURE AND ENGINEERING RESPONSIBILITY

Much organizational learning uses a strategy of trial and error, but learning in order to prevent disasters requires more sophistication. Reason's (1997) famous Swiss cheese model of accident causation encourages us to seek out those holes in the cheese not only so they can be fixed, but because they provide important information about organizational weaknesses. Similarly, high reliability theorists tell us that high performing organizations are preoccupied with finding small errors and faults, again for the insights they provide on underlying organizational issues that have the potential to result in more serious failures (Weick and Sutcliffe, 2001).

Such learning strategies rely critically on professionals throughout organizations being prepared to report small errors and faults but this is an inherently difficult undertaking when, at least in some circumstances, people are effectively being asked to report themselves. As Reason (1997, pg. 196) says, 'human reactions to making mistakes take various forms, but frank confession does not usually come high on the list'.

In response to this problem, a significant research literature and safety practice has developed around what is known as 'just culture' which attempts to balance accountability for current problems with learning in order to prevent more problems in the future (Dekker, 2007). Enacting a just culture within an organization is seen as the ultimate goal in fostering open reporting of small faults, failures and errors and so maximizing opportunities for learning (Aveling et al., 2016, Gerede, 2015, Khatri et al., 2009). These ideas have been taken up with gusto, particularly in the health sector. A Scopus search for 'just culture' returns 175 items of which 71% are health sector publications and 12% are air traffic management-related. Only six articles are based in engineering-related industries and all of these focus on application of the just culture concept.

Despite this lack of specific evidence, the proposition that a just culture increases reporting is assumed to apply in engineering-based industries, too. In particular, it has become common for safety culture survey tools to include questions based on just culture principles (see for example Kines et al., 2011, Shirali et al., 2013).

In addition to formal reporting systems, informal practices including sharing stories are also important for learning and accident prevention. Engineering professionals share stories among their professional group with the explicit purpose of fostering expertise (Hayes and Maslen, 2015, Vastveit et al., 2015). This also provides a mechanism for learning from past failures, be they small faults or major disasters. Through stories, workers come to understand the potential consequences of their decisions (Maslen, 2014, Maslen and Hayes, 2016, Størseth and Tinmannsvik, 2012). They support the development of a 'safety imagination'—an ability to link one's actions to the potential consequences (Pidgeon and O'Leary, 2000). When then faced with potentially minor operating anomalies, engineers are able to draw connections to past major events and so dig deeper into the state of the system (Macrae, 2009).

Professionals taking responsibility for their own expertise and learning to ensure the best decision making is an example of what the engineering ethics literature calls forward-looking responsibility: 'a virtue or a moral obligation to see to it that a certain state-of-affairs applies' (Doorn and van de Poel, 2012, pg. 10), in this case accident-free operations. Some authors have called for an increased focus on this aspect of engineering responsibility pointing out that the discourse on engineering ethics and responsibility tends to be dominated by a framework of responsibility as blameworthiness (Coeckelbergh, 2012, Doorn, 2012, Kermisch, 2012). Questions of engineering responsibility therefore link directly to the issue of learning from incidents and accidents as past errors can be interpreted either as deserving of punishment or as key lessons to prevent recurrence (Fahlquist, 2006).

We find these issues occupying the attention of survey respondents, but in ways that may not be expected based on the body of published research.

3 METHOD

To assess the prevalence and impacts of liability concerns among engineers in Australia, we developed and administered a survey with a mixture of closed- and open-ended questions. It was designed for self-completion via an internet browser on a computer, tablet or smartphone and was programmed and administered using Qualtrics software.

The questionnaire addresses six main issues:

- Risks and benefits of considering personal liability.
- Impact of serious incidents on personal liability concerns.
- Impact of others' individual experiences on personal liability concerns.
- Impact of personal liability concerns on reporting and knowledge sharing.
- Impact of personal liability concerns on professional board registration.
- Impact of personal liability concerns on career.

Survey participants were recruited from two sources. Email invitations to participate in the survey were sent to Australian Pipeline and Gas Association Research and Standards Committee members

and to Engineers Australia's Brisbane area members. A total of 275 Australian engineers participated in the survey during the period July to September 2016. Due to the way in which Australian engineers were recruited for this survey (i.e. a snowballing approach was used whereby one group of targeted respondents was asked to circulate the survey throughout their organisation in addition to participating themselves), it is not possible to accurately identify the total number of Australian engineers invited to participate. Therefore, it is not possible to accurately calculate the survey response rate nor to comment quantitatively on the extent to which the results might be indicative of engineers in Australia overall.

This work has been approved by the relevant university human ethics committees. The survey data were processed using the IBM SPSS-23 statistical software package and both IBM SPSS-23 and Microsoft Excel were used to produce percentages. Graphical representations of the data were produced in Microsoft Excel.

The percentage results presented against each survey question have been calculated using the total number of valid responses received for that question. The number of valid responses (as shown in each figure) varies due to individuals (either intentionally or unintentionally) not providing a response to a question and/or individuals not being eligible to complete a question given their previous responses in the questionnaire.

4 IMPACT OF PERSONAL LIABILITY CONCERNS ON REPORTING AND KNOWLEDGE SHARING

The extent to which respondents are concerned about personal legal liability provides important context for these results. Thirty-two per cent of respondents indicated that they think about personal liability to a great extent when making decisions at work. Further, 89% of respondents indicated that they consider personal liability at least to some extent. These findings show that personal liability is an important issue for respondents.

To investigate the impact of liability concerns on formal hazard reporting and informal practices for sharing knowledge about things that have gone wrong, we asked a series of questions regarding hazard reporting practices and other practices about learning from past failures.

Over four fifths of respondents (83%) said their organization provided a formal system for employees to report hazards. Among these respondents, close to all (93%) of those who had encountered a hazard in their organization said they reported it into the organization's formal system. Only 12 of the respondents (out of a possible 107) who had encountered a hazard in their organization had not formally reported it.

Members of this small group were then prompted to explain why, giving the following reasons for not making a formal report:

- The incident was too small to report. This was the most frequently noted reason ('I felt the hazard was minor'; 'it was isolated…it was personal factors, not systemic'; 'trivial problems—can't cotton ball everything and everyone').
- Time to report the incident ('no time'; 'not worth the time to report').
- The incident was already known. One respondent observed '[I] didn't want to create a fuss over something that was already known'.
- The incident was immediately fixed ('the people involved investigated and steps [were] taken to redress the problem immediately'; 'I was able to do something about it rather than just report it for someone else to deal with').

In the context of the survey, it is noteworthy that no-one indicated that they had failed to report a hazard as a result of concerns about liability and blame.

Building on this, Figure 1 shows responses regarding whether personal liability concerns impact on whether a respondent is likely to report hazards into their organization's formal system. Forty-seven per cent of respondents indicated that personal liability concerns would have no impact. Only 5% of respondents indicated that they were less likely to report hazards as a result of liability concerns. In contrast, 48% of respondents indicated that they were more likely to report hazards including 21% who said they were much more likely to report hazards. In other words, personal liability concerns promote rather than hinder likelihood to report. This is a critical finding because it is contrary to what we would anticipate based on previous research that emphasizes the importance of a just culture in fostering hazard reporting.

Another way in which learning about problems occurs is via informal sharing of stories. Figure 2 shows responses regarding whether personal liability concerns impact on the likelihood that a respondent will share stories of things that have gone wrong with colleagues so that lessons can be learned. Forty-two per cent of respondents indicated that personal liability concerns would have no impact. Sixteen per cent of respondents indicated that they were less likely to share stories as a result of liability concerns. While this is more than the 5% who indicated they were less likely to report hazards as a result of liability concerns it is still a low figure. Again, contrary to what might be expected from the broader literature on organizational learning and

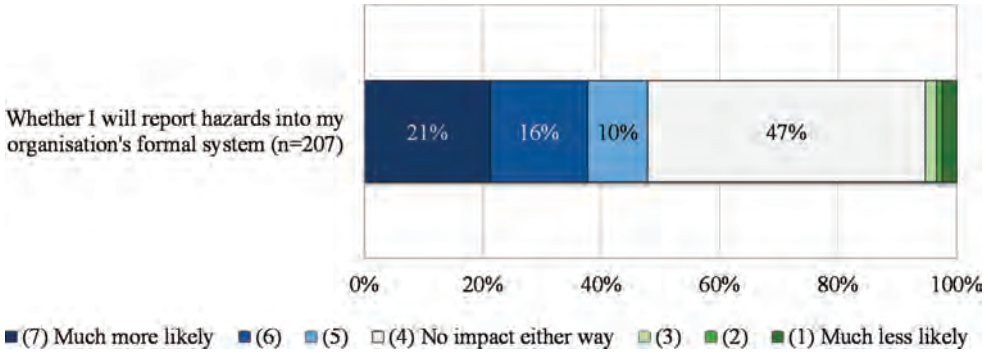

Figure 1. Does the risk of your personal liability make it more or less likely that you will report hazards into your organisation's formal system?

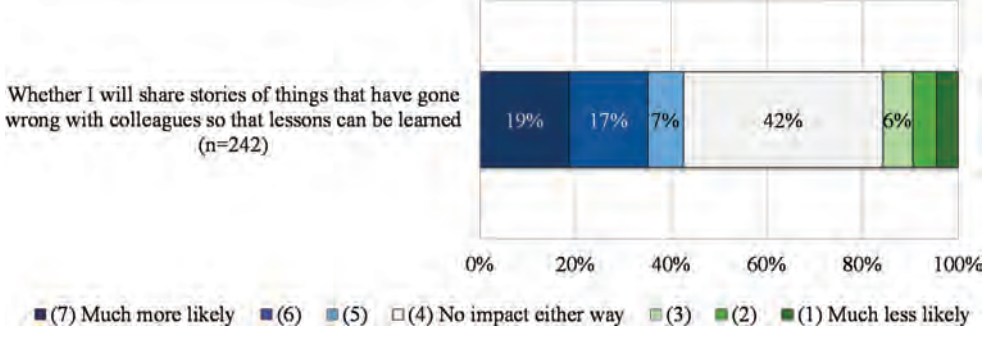

Figure 2. Does the risk of your personal liability make it more or less likely that you will share stories of things that have gone wrong with colleagues so that lessons can be learned?

blame, 43% of respondents indicated that having personal liability concerns made them more likely to share stories, including 19% who said the concerns made them much more likely to share stories.

While personal liability concerns appear to have only a minor impact on willingness to share stories, it is important to note that these figures were higher when engineers reflected on sharing of stories by others. Figure 3 indicates that almost one third of respondents (31%) were aware of other engineers being unwilling to share stories of things going wrong due to concerns about personal liability.

Those aware of such cases were asked to provide more details. Thirty seven respondents chose to do so.

Key reasons cited that influenced people's perceived willingness to share stories of things going wrong are:

- Contractual relationships and concerns about blame and financial liability;
- Failures being indicative of incompetence and so those involved being unwilling to admit what has occurred;

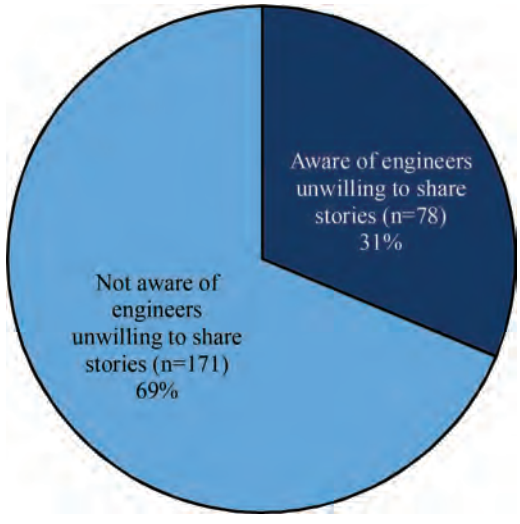

Figure 3. Are you aware of any engineers (other than yourself) who were unwilling to share stories of things going wrong due to their concerns about their personal liability?

- Fear of blame linked to job security; and
- Fear of blame linked to legal processes.

We would expect unwillingness to share stories on these grounds based on the just culture research. The reasons that engineers feel that their peers may be less likely to share stories than themselves warrants further inquiry.

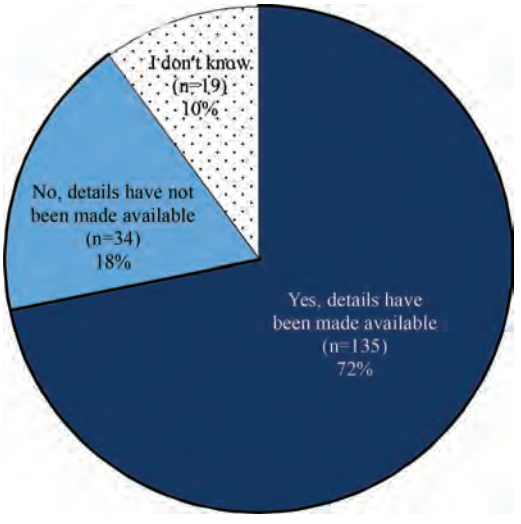

Figure 4. [Regarding the serious accidents that occurred in your sector, either in Australia or overseas] Have details of those serious accidents been made available in a way that allows lessons to be learned?

Other sources that may be drawn upon to learn about disaster prevention include investigations into the causes of serious accidents. As shown in Figure 4, 72% of respondents reported that details of serious accidents in their particular sector have been made available in a way that allows lessons to be learned. While this is positive, it also shows room for improvement. Twenty-eight per cent of respondents indicated either that information had not been made available or they were not aware whether it had been made available. In either case, respondents were not able to learn from serious accidents. Opportunities to learn lessons from major failures are mercifully rare. However, this makes it all the more important that lessons are maximized when accidents occur to prevent future occurrences. In this context, it is problematic that almost a third of respondents had observed information not being made available post-disaster.

Looking into this issue further, respondents were asked if they knew why information had not been made available for learning. As shown in Figure 5, in more than two thirds of cases (68%), respondents reported that lessons had not been generated and/or not released. In only 12% of cases, was the issue one of timing in that lessons would be released in the future. In 21% of cases respondents were not aware why lessons had not been released.

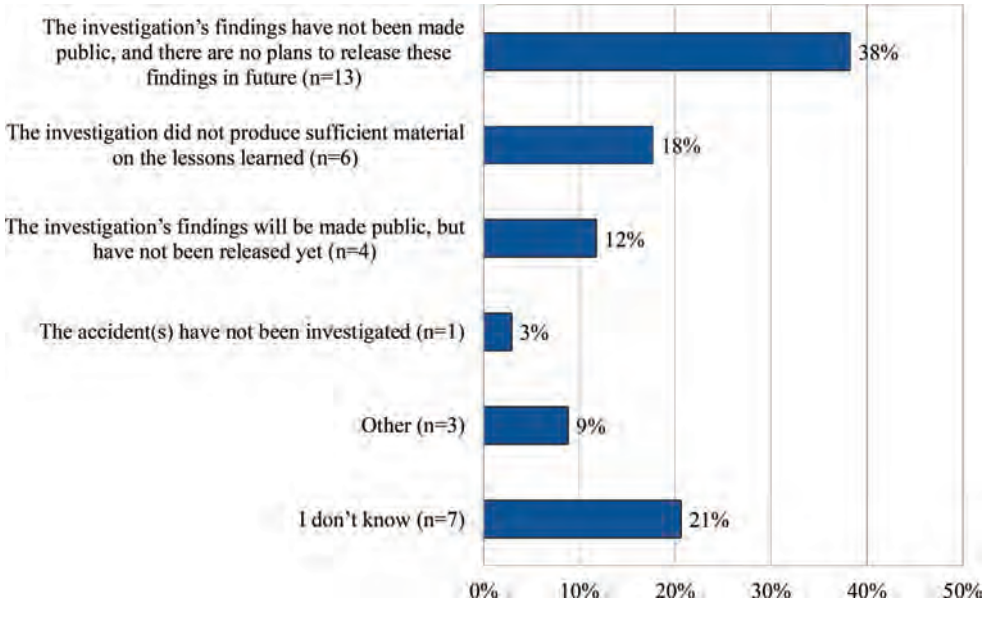

Figure 5. Do you know why the details [of the serious accidents] are not available?

5 DISCUSSION

Based on the small survey population it appears that most engineering organizations have in place a system for reporting hazards and that engineers use such systems with very few exceptions. Despite the expectations of the just culture literature that concerns about blame would inhibit reporting, this does not seem to be the case for these small and relatively common workplace problems. This surprising result is also borne out by our previous work in incident reporting in a nuclear power station which exhibited over 2000 reports per annum with the primary advantage to those making reports being seen as quick action to remediate issues raised (Hayes, 2009).

When asked specifically about legal liability and hazard reporting, many respondents saw liability as a reason to increase, rather than decrease, reporting. Respondents reported similar behavior when it came to more informal professional learning practices regarding sharing stories with colleagues. This raises the question as to why liability is of less concern in the engineering sector than in health. Doorn and van de Poel (2012) have highlighted the extent to which responsibility is a key issue in engineering ethics (in contrast to medical ethics, for example). They maintain that this is in response to the collective nature of engineering activity and also the uncertainty and indirect causality of major engineering failures. As Coeckelbergh describes, '… between the actions of an engineer and the eventual consequences of her actions lies a world of relationships, people, things, time and space (2012, pg. 37).

It is possible that this goes some way to explain our surprising results on this issue. In an environment where work is both distributed and collective, responsibility for small problems is also distributed. Perhaps reporting small problems could be seen as 'insurance' against blame beyond one's sphere of direct control in the event that something goes wrong. Reporting possible warning signs may provide something to point to as a defense against blame when collective endeavors fail to give the required outcomes. This explanation is somewhat speculative, but it is consistent with evidence to date.

Overall, the positive link between liability and reporting appears to be good news. Concerns about legal liability are perhaps raising awareness of the need to learn and so increasing forward-looking responsibility. At its best, forward-looking responsibility is conceptualized by ethics scholars as going beyond simply doing one's duty. Duty implies rule-following, whereas responsibility is more concerned with getting the best outcome. As Goodin (1986, pg. 50) explains, '[d]uties dictate actions. Responsibilities dictate results.' Other safety researchers have warned of the dangers of decision making grounded only in compliance where obeying rules becomes an end in itself, rather than a means to safe operations (Bieder and Bourrier, 2013). It seems at least possible that a link between learning and responsibility mediated by an increased focus on liability may support the development of forward-looking or virtue responsibility, rather than simply a desire to avoid blame.

The potentially positive impact of liability concerns on learning is tempered by the results obtained when questioning moves from self-reported behavior to observations about the behavior of professional colleagues. Almost one third of respondents reported seeing colleagues who are unwilling to share stories of things going wrong for reasons linked to liability. Possibly in these cases the potential storyteller has a more personal link to the problem at hand and so feels more acutely a sense of backward-looking responsibility as blameworthiness outweighing a sense of forward-looking responsibility and virtue in efforts to prevent accidents.

This could also be a reflection of the reflexivity of respondents and their discomfort confessing their own perceived shortcomings. They are uncomfortable talking about their own shortcomings, but are much more talkative about the shortcomings of their colleagues. In another study, in which we examined decision making in the oil and gas sector, we found that respondents claimed that their decision making was not influenced by financial incentives such as bonus payments awarded by their employer (Maslen and Hopkins, 2014). Incentives would have a negative impact on the quality of decisions from a safety perspective, in the same way that failing to share stories due to personal liability concerns has the potential to negatively impact disaster prevention. In contrast, many felt that their colleagues' decisions could be influenced by incentives. In an interview context, as opposed to a survey, the interviewer has an opportunity to explore the reasons for this inconsistency. Is it perhaps that liability concerns (like incentives) do influence behavior in a way that is not readily acknowledged? This is a critical question that warrants attention using qualitative methods such as interviewing and observation.

The final issue of interest is learning from significant disasters that have been the subject of formal inquiries. The survey results indicate that there is room for improvement in this area. Respondents reported a significant proportion of cases in which lessons are not made available for learning. Dekker (2015) describes four psychological purposes of accident investigations: epistemological (establishing what happened), preventative

(identifying pathways to avoidance), moral (tracing the transgressions that were committed and reinforcing moral and regulatory boundaries) and existential (finding an explanation for the suffering that occurred). These different orientations to an investigation result in different findings as shown by Gephart (1993) in his detailed analysis of a Canadian pipeline failure. As our survey respondents indicate, not all orientations result in effective lessons to prevent recurrence.

6 CONCLUSIONS

Much published research focuses on the adverse impact of personal liability and blame on learning from accidents and incidents. The conventional wisdom is certainly that blame inhibits learning. Our study in the engineering profession reveals a more complex relationship. It seems that, at least for our respondents, a focus on personal legal liability may act to increase practices related to learning as a result of an increased sense of virtue responsibility.

This finding is tempered however by reports that a significant minority of engineers are unwilling to share stories as a result of liability concerns. Legal constraints may also be responsible for a reluctance to share lessons for major accident investigations in some cases.

It appears that liability is a double-edged sword with both positive and negative effects on learning which are surely worthy of further investigation, particularly in this engineering context where such issues are little studied by comparison with the health sector.

It must be emphasized that this is effectively a pilot study with a relatively small cohort of respondents. As such, we make no specific claims that these findings are representative of the engineering profession in Australia or globally. Nevertheless, the findings are surprising and deserve further investigation in the context of organizational learning for accident prevention.

ACKNOWLEDGEMENTS

This work was funded by the Energy Pipelines CRC, supported through the Australian Government's Cooperative Research Centres Program. The cash and in-kind support from the APGA RSC is gratefully acknowledged.

We acknowledge the support of Engineers Australia Queensland Division in distributing the survey and the interest they have expressed in the results.

We also acknowledge the survey participants who contributed to this study. Many of the respondents expressed a desire to contribute to the future of their profession and they saw our survey as a vehicle to do so. They deserve our sincere thanks.

ABSTRACT: Following the implementation of international and national regulations and standards pertaining the control of risks in different industrial and civil domains, a general increase of the safety knowledge was noticed and recognized in literature (e.g. Lee & Harrison, 2000). Indeed, different campaigns to rise the awareness of the general public were developed and implemented. However, even if numerous studies and researches measured the safety culture in occupational domains (Choudhry et al., 2007), a measurement of the safety culture in the civil society is far to be defined. The present paper shows an attempt of measuring the public safety knowledge: a simple methodology based on gaming (safety quiz related to darts playing) was developed to collect data on the safety knowledge in the population, both for children and for adults. Different sets of questions were established for children (aged from 4 to 15) and adults. The quiz was proposed during the European Researchers' Night in 2015, 2016 in Turin (Italy), collecting about 250 replies. The present paper presents the analysis of the data collected, together with some observations both on the diffusion of the safety culture in the general public and on the possible improvement of the data collection approach.

1 INTRODUCTION

Today, the occupational incidents are an economical and social problem (Hamalainen et al., 2006). I.e., in 2004 the cost of the occupational accidents in the European Union was around 35,000,000,000 €, with 3.2% of workers involved (Battaglia et al., 2014). For this reason, since 1989, UE promoted policies to reduce the occupational accidents, as the Council Directive 89/391/EEC (1989).

Between 1994 and the 2012, ESAW data (European Statistics on Accidents at Work) showed a decrease trend in the occupational accidents, however in 2013 (Eurostat, 2013) registered 3647 fatal accidents and 3,100,000 non-fatal accidents, which cannot be considered negligible values. Lehtola et al. (2008) explained the decreasing trend as the product of multiple factors, such as the regulation change, the demographical change (Morse et al., 2009) or the deindustrialization process (Loomis et al., 2004).

The data collected in Italy confirm the European trend (Figure 1). In Italy, the decrease trend started around 50 years ago, and accidents occurring demonstrated to be strictly correlated with the socio-economical evolution in Italy (Comberti et al. 2017).

The numbers of domestic and non-work related accidents are more difficult to be defined; however,

Figure 1. Non-fatal occupation accidents in Italy 1951–2005.

INAIL – Italian institution for insurance against accidents at work evaluate the Italian domestic accidents in around 3,000,000 (Ferrante et al. 2012), with a stable trend in the decade 1998–2008 (Figure 2). This value highlights the socio-economic importance of domestic accidents, most of all considering that they can involve also children.

Different accidents, both occupational and domestic, are caused by the lack of knowledge on the basic safety rules. For the occupational safety, the Italian Legislative Decree 81/08 required the

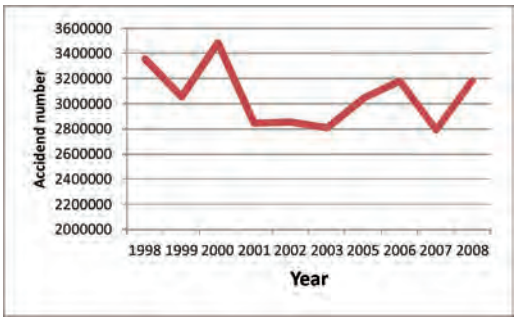

Figure 2. Domestic accident in Italy.

employers to develop mandatory safety training sections for the workers. At the end of each safety training, the workers' acquired knowledge is tested. However, since the test is not repeated after a while, it is not possible to verify if the workers maintain, apply and consolidate the lessons learned.

Literature provides several studies on the safety knowledge (Choudhry et al., 2007) in specific working sectors such as: Australian manufacturing and mining sector (Griffin & Neal, 2000); Iranian meat processing (Ansari-Lari et al., 2010); medical sector (Kolade 2002); nuclear power plant (Lee & Harrison, 2000), etc. However, scarce studies are available on the safety knowledge among the population: i.e., Kennedy et al. (2005) analyzed safety knowledge of the customers about food management.

In order to increase the safety knowledge and safety culture of the population, it is fundamental to start teaching the basis of the safety rules to children. For this reason, some tools were promoted and developed by EU and the member states, such as "Napo for teachers" (napofilm.net, 2017), or in Italy, the projects "Scuola e sicurezza – School and safety" (Dettoni, 2011), applied in Piedmont region, and "A scuola di sicurezza! – At safety school!" (Bove et al., 2002), applied in Lombardy region. Testing the safety knowledge acquired by the children can provide interesting information on the proper functioning of these programs.

This paper presents the data on the safety knowledge of a sample of Turin population: both adults and children, were tested through the participation to a simple game, in order to verify the continuity and solidity of the safety information acquired at school, at work, or through the media.

The data were collected during the "European Researchers' Night" in Turin, in 2015 and 2016; 100 stands and more than 1000 researchers were present (CLOSER, 2016). This choice allowed to attract and test a large number of people, representing a wide range of age, gender and work conditions. In the end, 115 adults (between 10 to 73 years old) and 132 children (between 5 to 15 years old) participated to the safety game, providing meaningful indications on the safety knowledge levels of the civil society.

2 MATERIAL AND METHODS

The data collection was carried out through a game, developed and then applied by the researchers of the SAFER team of Politecnico di Torino (Centro Studi su Sicurezza Affidabilità e Rischi), led by prof. Micaela Demichela. The game was part of an entire stand dedicated to safety, aimed at disseminating safety rules and showing the result of research in the safety field. For attract more participant at the data collection was used a gaming approach. During the game at the participant are proposed 3 questions on the safety. The questions proposed at each participant are chosen in the random way. And the answers are used for test the safety knowledge in the population.

2.1 *Gaming*

The data collection was structured like a game with the aim of attracting more participants, stimulating their competitiveness and their willingness to get involved. The game consisted in a simple darts-playing; depending on the score made on the dartboard, the participant is subjected to questions related to safety, with an increasing level of difficulty.

The 120 questions, with 5 different categories of difficulty, were prepared by the research team, but only 3 questions were asked to each participant, chosen in a random way. The participants could play alone or proceed with a sort of "race", verifying who could provide more right answers.

The questions tested the knowledge of the participants; the collected answers constituted a useful sample of data on the diffusion and level of safety awareness of the population. In particular, the number of correct and incorrect answers was analyzed. The safety game and the related data collection also gave the possibility to the researchers to carry out a disseminating activity about safety, in particular in case of incorrect answers.

2.2 *Questions*

The questions allow a multiple-choice: 3 possible choices are provided, only one is correct. 2 groups of questions were prepared on the basis of the age of the participants:

- Junior (less than 15 years old);
- Senior (over 10 years old).

The 2 categories present a common age range, between 10 to 15 years old. This is due to the fact that the questions in the category "Junior" were designed for younger children, centered in the primary school age, while the questions of the "Senior" category were more work-oriented (even

if not only regarding safety in the workplace). Therefore, the participants between 10 to 15 years old could find the "Junior" questions too easy, and the "Senior" questions too difficult. In the end, it was decided to let the children choose, before starting the game, if answer to "Senior" or "Junior" questions. Many children decided to answer "Senior" questions, demonstrating to have in any case an adequate knowledge to correctly deal with them.

For each participant, were collected:

- General data for statistical purposes (gender, age);
- ID code of the question proposed;
- Answer obtained.

The data were collected in a dedicated form in anonymous way.

2.2.1 *Senior questions*

Around 70 questions were developed for the "Senior" categories, covering different safety fields, such as:

- Safety rules in the workspace;
- Personal Protective Equipment and its use;
- Properties of chemical substances and their classification;
- Safety signals and symbols;
- Other safety fields.

An example of "Senior" question is:
"When you work on computer, how far from you is the monitor?

A. 35–50 cm;
B. 25–40 cm;
C. 50–70 cm."

2.2.2 *Junior questions*

Around 40 questions were developed for "Junior" category, to verify the awareness of the children in relation to:

- Safety rules in the school;
- Road safety;
- Safety during free time (sport, game, …);
- Rudiments of emergency management (emergency number, behavior in case of earthquake, …);
- Other safety fields.

The questions present simple scenarios and the children have to choose a possible solution. An example is: "You are at a friend's house and you are playing together. Since you are thirsty, you go in the kitchen and you find a bottle without labels. What are you going to do?

A. Drink;
B. Open the bottle, sniff and then drink;
C. Drink from the tap."

3 RESULTS

247 people from 4 years old to 73 years old were involved in the data collection between 2015 and 2016; 115 people were tested in the "Senior" category; while 132 children were tested in the "Junior" one.

The following tables and figures represent gender and age distributions for the "Senior" category (Table 1 and Figure 3) and "Junior" category (Table 2 and Table 3); for adults, it resulted that the majority of participants was younger than 25 years old and 55% was male. For the children, the gender of the participants was equally distributed, and the majority was between 7 and 12 years old.

3.1.1 *"Senior" category results*

The 61.3% of the people involved in the "Senior" category provided corrected answers. The global

Table 1. Gender distribution in "Senior" category.

	Participants		
	Total	Male	Female
2015	40	22	18
2016	75	41	34
Total	115	63	52

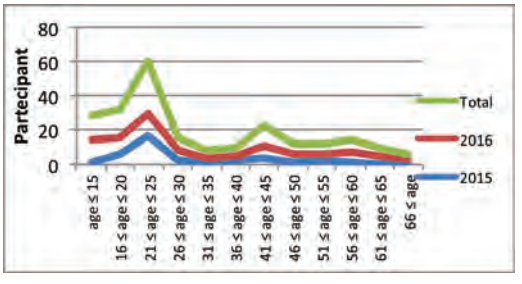

Figure 3. Age distribution in the "Senior" category.

Table 2. Gender distribution in "Junior" category.

	Participants		
	Total	Male	Female
2015	74	36	38
2016	58	30	28
Total	132	66	66

Table 3. Age distribution in "Junior" category.

	Participants			
	age ≤ 6	7 ≤ age ≤ 9	10 ≤ age ≤ 12	13 ≤ age ≤ 15
2015	8	24	40	2
2016	5	20	26	7
Total	13	44	66	9

value of correct answers was almost constant in 2015 (61.9%) and 2016 (61.2%) and apparently there is no difference between male and female, as shown by the last bars of Figure 4. However, in 2015 women gave more correct answers than men, while in 2016 the opposite trend occurred. Figure 5 shows the percentage of correct answers on the basis of the age of the participants: the fraction of correct answers is higher (around or over 60%) for participant younger than 45 years old. A negative peak is registered after 45 years old, and then the correct answers increase again. For some age groups, the uncertainty boundary is higher: give the small number of participants, wrong answers assume a high impact on the results. On the contrary, when the number of participants is high for both the years analyzed, the uncertainty is lower.

3.1.2 *"Junior" category results*

The 70.3% of the children provided correct answers, but the percentage of correct answer was higher in 2015 (72.9%) than in 2016 (67.1%).

About the gender difference, in the "Junior" category, girls gave more correct answers than boys, a trend particularly evident in 2015 (Figure 6).

Concerning the correlation with the age distribution, Figure 7 shows that the correct answer trend grows with the age of the participants.

Figure 4. Correct answer in the "Senior" category divided for gender.

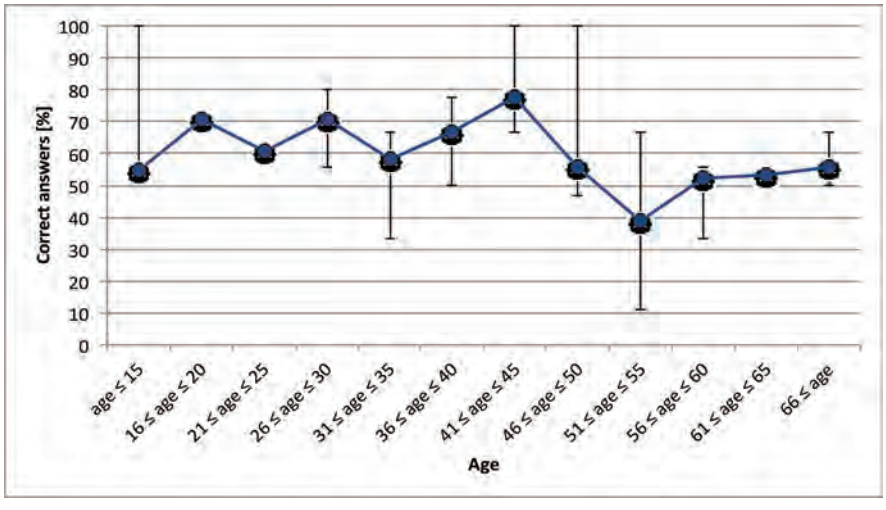

Figure 5. Trend of correct answer by age of participants, in the "Senior" category.

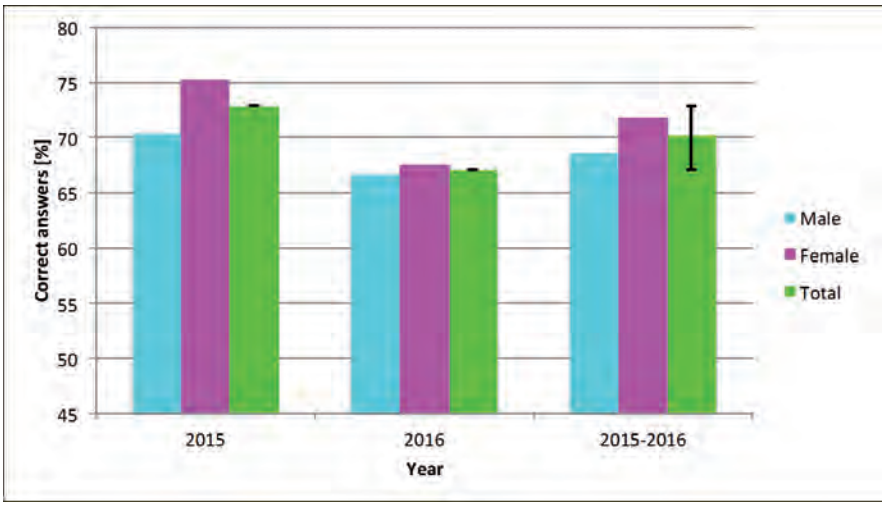

Figure 6. Correct answer in the "Junior" category divided for gender.

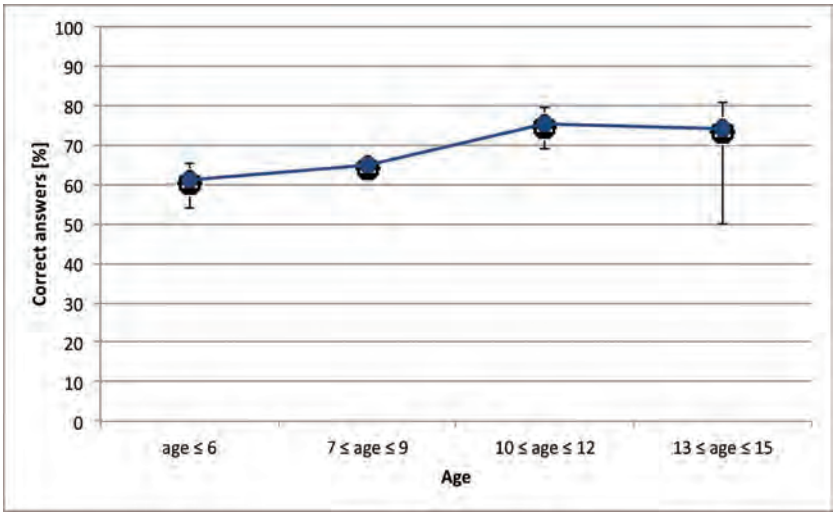

Figure 7. Trend of correct answer by age of participants, in the "Junior" category.

4 DISCUSSION

On the basis of the data collected and presented in the previously paragraphs, some consideration can be done.

For the adults, the mean values obtained from the test underline that the population know the basis of safety knowledge; but the level needs to be increased to reach a sufficient quality and diffusion of knowledge.

The data show no gender gap in the safety knowledge, while the age trend gives some encouraging signal for the future. In fact, the younger participants in the "senior" category gave more correct answers than the older ones. This result probably evidences the importance of the several activities of sensitization about safety conducted in the last 20 years during the school period (primary, secondary and high school). On the contrary, the worse results for the older participants mark the resistance in learning and adapting to safety rules, a behvaoiur that is still quite common in the Italian culture.

In the "Junior" category, the mean value of safety knowledge is higher than for "Senior", reaching values in line with those of the younger "Senior" participants. This good result probably underlines the effect of the safety sensitization campaign done during school age; it represents an

encouraging signal of a possible radical change in the culture of workers and citizens, but this trend has obviously to be monitored in the future. At the moment, the answers given by the younger "Senior" participants seem to confirm this increased sensitivity of the younger generations to the themes of the safety culture.

Finally, the last interesting date emerged from the analysis is related to gender: "Junior" females showed a more in-depth safety knowledge than males. Further investigations should be executed to strengthen the definition of this trend, but in case of confirmation this could be the basis for a multidisciplinary investigation on possible cultural differences in learning mechanisms.

5 CONCLUSION

In this paper, a method for data collection on safety knowledge of the population is presented. A gaming approach was settled to attract and involve more participants: series of multiple—choice questions were developed and exposed to the users as a quiz. The game was applied during the "European Researchers' Night" in Turin in 2015 and 2016, with different questions for adults and children.

The data collected showed that the adults have a discrete level of safety knowledge, and that younger participants have an in-depth safety knowledge than the older ones. Children demonstrated to have a good safety knowledge level.

The data collected prove that the safety-related projects applied in schools are producing good results on the population, but it is fundamental to continue with the activity of training both for young and older people. In particular for the latter, it should be essential to recover the gap in knowledge for people between 50 and 60 years old; in fact, these persons could be in influent positions inside their companies and jobs, therefore their awareness and knowledge in relation to safety themes has a wider influence than the foreseen.

ACKNOWLEDGEMENT

Special thanks to the organization of the "European Researchers' Night" in Turin for the fundamental and excellent job that allowed the data collection; and most of all, to all the participants for their collaboration.

Safety climate and compliance in the Norwegian aquaculture industry—employees' perceptions at different company levels

T.Ø. Kongsvik
Department of Industrial Economics and Technology Management, NTNU, Norway

SINTEF Ocean, Norway

K.V. Størkersen
NTNU Social Research, Norway

ABSTRACT: The aquaculture industry is economically important in Norway, and the production is expected to increase in the future. Employees at the fish farms face a high risk of accidents compared to employees in other industries and the focus on safety from both industry and researchers has increased during the last decade. Adding to the knowledge on safety in aquaculture, the objective of this paper is to study employees' perception of safety climate, and whether aspects related to safety climate may predict employees' compliance. Findings from two surveys aimed at managers and employees in different companies are analysed. The first is a telephone survey targeting employees and managers at the fish farms. The second is a web-based survey involving the onshore management level. The results show that employees at all levels have a positive perception of the safety climate, but they also illustrate challenges related to work pressure, maintenance and employee participation. Furthermore, the analysis shows that work pressure affects compliance negatively while participation and competence have positive associations with compliance. These results give input to some practical measures for safety management in the industry.

1 INTRODUCTION

Norway is the second largest exporter of fish worldwide, and the largest producer of finfish (FAO, 2016). Since the 1970's aquaculture, and fish farming in particular, has become a significant contributor to the national value creation. In 2016, the total production in the aquaculture industry was 1,3 mill metric tons, equal to a value of 65 billion NOK (Norwegian Directorate of Fisheries, 2017). 93% of this was Atlantic salmon.

There are both large and small companies in the industry, and the structure of management levels depends on the size. Smaller companies may have personnel that serve different roles, combining the responsibility for safety with other areas such as quality management. Larger companies may have dedicated management working solely with health and safety. The lowest management level is the operational managers, who are responsible for biological production and personnel at one or two fish farms, typically manned by three to six employees (fish farmers).

There are typically six to 12 circular plastic collar net cages in one fish farm (Jensen et al., 2010, Holen et al., 2017a). The fish farm also has a feeding barge for equipment and feed storage, the feeding system, as well as manager offices, meeting rooms and accommodation for shift workers.

Fish farmers are decreed to perform daily inspections to assess fish welfare and document that the net cages are in order. Fish farmers often use boats and cranes in their work, but increasingly rely on specialized service vessel crews to perform tasks such as mooring operations and delousing. The safety for fish, material assets and personnel is regulated by an extensive set of statutory requirements (Holmen et al., 2017b), which are audited by five different regulatory authorities (Holmen et al., 2017c).

The aquaculture production has the potential to increase in the future (Olafsen et al., 2012). Technology innovations aim to enable production at areas more exposed with respect to climate, wind and currents. This raises new challenges when it comes to fish welfare and operational safety (Bjelland et al., 2015).

The attention to occupational and operational safety in the aquaculture industry has increased during the last decade. Recent studies indicate that safety and risk management systems need to

be improved to maintain a sustainable food production and ensure a safe work environment at harsher locations (Størkersen, 2012, Holmen et al., 2017b, Holmen et al., 2017c).

Being a fish farmer is the 2nd most risk exposed occupation in Norway after being a fisherman, according to the rate of fatal accidents (McGuinness et al., 2013, Holen et al., 2017b). Fall, blow by object, entanglement/crush and cuts are the most common modes of injuries in the Norwegian aquaculture industry (Holen et al., 2017a). In a recent study among aquaculture workers, three out of four respondents reported to have knowledge of near accidents (Thorvaldsen et al., 2017). Organisational aspects and safety indicators have been the topic in several studies (Fenstad et al., 2009, Størkersen, 2012, Thorvaldsen et al., 2015, Holmen et al., 2017b). Looking back, Allred et al. (2005) found that many companies had implemented some systematic HSE work, although production often was given priority.

In this article we will explore the following problems: 1. How do fish farmers, operational managers and onshore management/staff perceive the safety climate? 2. To what extent can safety climate predict safety compliance?

1.1 *Safety climate*

Safety culture has been a defined area of research since the late 1970s, and there is still much research activity related to the issue. Up until 2015, 1789 research publications related to safety culture has been published (van Nunen et al., 2017). In the beginning it was applied as a construct related to causal analyses of major accidents, with Barry Turner's (1978) contribution as an important starting point. Later, the research interests spread over different topics, and involved different disciplines, including anthropology, psychology, sociology and the engineering sciences. Today it is considered a multi-dimensional and cross-disciplinary field of research (van Nunen et al., 2017)

The contributions from psychology is in particular related to *safety climate*, a construct which is in many instances used as synonymous to safety culture and defined in similar ways (Guldenmund, 2007). A much used definition of safety climate is provided by Zohar (2003), who sees it as shared perceptions about safety policies, procedures and practices in a work community. Questionnaire surveys are commonly used to measure safety climate in a work community, involving assessments of topics such as the safety system, work pressure, the safety competence and leadership/supervision (Flin et al., 2000).

Much research on safety climate has been related to identifying causal links between safety climate as an independent variable and different safety outcomes, summed up in review studies (Clarke, 2006, Christian et al., 2009). This includes exploration of safety climate as an indicator (Kongsvik et al., 2010). The review studies also point to many studies that find a positive relationship between safety climate and safety compliance (adherence to safety instructions, rules, and procedures).

A general finding in the research is that the safety climate in a work community is associated with the work practices in the same community; a positive safety climate is related to compliance and participation in safety-promoting activities, and also mindful safety practices (Dahl and Kongsvik, 2018).

2 METHOD

2.1 *The surveys*

The results are based on two different surveys, that were later combined. The first included fish farmers, operational managers and service vessel crew members as well as some employees in other positions. Representatives at the management level in a selection of 40 companies were informed about the aim of the survey, and invited to share employees' phone numbers. A professional polling company conducted the survey, and a total of 447 out of 735 employees participated. Here, answers from 258 fish farmers and 110 operational managers are used.

The second survey included onshore management and staff. Companies were contacted and asked to provide e-mail addresses to their employees who then got an e-mail linking to the digital survey. Some companies distributed the link to their employees themselves, so the response rate cannot be estimated. A total of 135 persons responded. Here, the net sample includes 92 onshore managers or staff.

The questionnaires were developed on basis of earlier surveys, but were tailor made to the aquaculture industry. In both surveys, the respondents were asked to state their agreement to different statements related to safety climate, on a 5-point Likert scale, ranging from totally disagree to totally agree.

2.2 *Analyses*

Answers from both surveys were extracted and combined in one data file. Some items had divergent wording, mirroring their position.

The items common for the two samples were thematically sorted into four categories: Work pressure, Participation, Competence and resources and Compliance. The first three categories are directly related to the safety climate construct, while Compliance is related to safety practices and whether employees live up to requirements given by the companies.

The statistical analysis aimed at comparing the perceptions of three groups, involving comparing means related to the responses. One-way ANOVA was applied for comparing the means. The limit for statistical significance (P-value) was set to 1%.

We performed a multiple regression analysis to explore if compliance could be predicted by the safety climate factors. The analysis was restricted to the fish farmers (n = 258) to ensure homogeneity in the work situation for those included. A *Compliance scale* was constructed by combining three items: 1. I use the required protective equipment 2. If I see dangerous situations at work, I report them. 3. Safety has first priority when I do my job. The Cronbach's alpha for the scale was .71. The *Work pressure scale* consisted of three items: 1. Sometimes I feel a pressure to continue working, although safety can be compromised 2. In practice, consideration to production is prioritized at the expense of safety 3. Inadequate maintenance has reduced the safety level. The Cronbach's alpha for the scale was .67. The *Participation scale* also included three items: 1.I participate in making new procedures 2. I get involved when new procedures are to be introduced 3. My manager appreciates that the employees take up safety issues. The Cronbach's alpha for the scale was .70. The *Competence scale* included two items: 1. I have the necessary competence to handle my work tasks safely. 2. I have received the necessary training for handling critical or dangerous situations. The Cronbach's alpha for the scale was .60.

The independent variables in the regression analysis were introduced by forced entry. Missing values were excluded list wise. The variance inflation factor (VIF) varied between 1.141 and 1.276, and tolerance values varied between 0.783 and 0.876. This gives no indications of multicollinearity. To check the assumption of independent errors, the Durbin–Watson test was performed. This test shows there was no concern regarding autocorrelation, with a test statistic of 2.063 (Field, 2005).

3 RESULTS

Here, the mean values reported by the respondents of the surveys are compared. Results are presented by the three following groups: onshore management (M), operational managers (OM) and fish farmers (F).

3.1 *Perceived safety climate*

The safety climate can be expressed by the survey results about work pressure; competence and resources; and compliance.

3.1.1 *Work pressure*

Table 1 reports the results from three items considering work pressure.

The first item is phrased differently for operational and onshore personnel. Yet, all groups somewhat disagree that production pressure makes operational personnel break safety rules and continue unsafe work. Onshore management agree more than operational personnel that employees will compromise on safety because of production pressure.

On the next item, this controversy is partly reversed. On average, fish farmers neither agree nor disagree that production is prioritized over safety, while both types of managers disagree more. Still, analysis show that 22.9% of the fish farmers and 13.6% of the operational managers agree or totally agree that consideration to production is prioritized at the expense of safety.

All three groups' mean values show they somewhat disagree that inadequate maintenance has reduced the safety level. 19.8% of the fish farmers and 18.2% of the operational managers agree or totally agree that safety has been reduced due to inadequate maintenance.

3.1.2 *Participation*

Table 2 includes three items about employee participation.

All groups agree that managers appreciate employees' safety engagement. Onshore management appreciate that employees take up safety issues more than considered by the employees.

Table 1. Perceptions of Work pressure – means on a scale from 1 (totally disagree) to 5 (totally agree).

Items	Groups	Mean	P-value
F/OM: Sometimes I feel a pressure to continue working, although safety can be compromised	Fish farmers	2.02	0.000
	Operational managers	2.16	
	Onshore management		
M: Owing to the company's production demands, the employees sometimes have to break the safety rules		2.63	
In practice, consideration to production is prioritized at the expense of safety	Fish farmers	2.56	0.001
	Operational management	2.09	
	Onshore management	2.19	
Inadequate maintenance has reduced the safety level	Fish farmers	2.40	0.609
	Operational managers	2.30	(NS)
	Onshore management	2.47	

Table 2. Perceptions of Participation – means on a scale from 1 (totally disagree) to 5 (totally agree).

		Mean	P-value
F/OM: My manager appreciates that the employees take up safety issues	Fish farmers	4.20	0.000
	Operational managers	4.32	
M: As manager, I appreciate that the employees take up safety issues	Onshore management	4.92	
F/OM: I participate in making new procedures	Fish farmers	2.77	0.000
	Operational managers	3.54	
M: The employees participate in making new procedures	On shore management	3.61	
F/OM: I get involved when new procedures are to be introduced	Fish farmers	3.35	0.006
	Operational managers	3.73	
M: The employees get involved when new procedures are to be introduced	On shore management	3.76	

The mean results about employees' participation in development of new procedures lies around neither/nor. Fish farmers lean towards disagreement, while both management groups agree somewhat that employees (including the operational managers themselves) participate in making procedures.

Management agree that employees get involved in introduction of procedures, Analysis shows that 24.4% of the fish farmers disagree or totally disagree that they are involved when new procedures are introduced, compared to 19.1% of the operational managers.

3.1.3 *Competence and resources*

The three items considering Competence and resources are presented in Table 3.

All groups agree that the operational personnel have the competence to work safely and that manning is sufficient for safe work. It is 12.4% of the fish farmers and 12.7% of the operational managers that disagree or totally disagree that manning was sufficient.

There are larger differences regarding learning from unwanted events. Fish farmers and operational managers agree that information regarding unwanted events is utilized to prevent recurrence, while onshore management state neither/nor.

3.1.4 *Compliance*

All respondent groups' in average *agree* regarding the three items about compliance, but there are some differences (Table 4).

Table 3. Perceptions of Competence and resources – means on a scale from 1 (totally disagree) to 5 (totally agree).

		Mean	P-value
F/OM: I have the necessary competence to handle my work tasks safely	Fish farmers	4.49	0.578 (NS)
	Operational managers	4.56	
M: Our employees have the necessary competence to handle their work tasks safely.	Onshore management	4.47	
The manning is sufficient to maintain the safety	Fish farmers	3.70	0.235 (NS)
	Operational managers	3.62	
	Onshore management/ staff	3.87	
F/OM: Information regarding unwanted events is utilized adequately to prevent recurrence	Fish farmers	4.11	0.000
	Operational managers	4.13	
M: We utilize the information from reported unwanted events sufficiently in the preventive work	Onshore management	2.91	

The analysis displays no significant differences regarding perceptions of reporting of dangerous situations. However, 31.4% of the fish farmers answered that they agreed or totally agreed with the statement: *I think it is uncomfortable to point out lack of compliance to safety rules and procedures*. 16.4% of the operational managers said the same. Onshore management were not asked about this aspect, as it relates to the operational context and the everyday interaction between workers at the fish farms.

Regarding use of protective equipment operational personnel totally agree that they use it, while onshore staff only agree.

Operational personnel agree (4.30), while onshore management almost totally agree (4.71) that safety has the first priority.

3.2 *Safety climate's relation to compliance*

A linear regression analysis restricted to the fish farmers in the sample was performed. Work pressure, Participation and Competence were used to predict Compliance.

Work pressure, Participation and Competence explained 30.4% of the variance in Compliance ($p < 0.000$). Each of the predictor variables had a significant contribution to the model.

Table 4. Perceptions of Compliance – means on a scale from 1 (totally disagree) to 5 (totally agree).

		Mean	P-value
F/OM: If I see dangerous situations at work, I report them.	Fish farmers	4.38	0.209 (NS)
	Operational managers	4.54	
M: The employees use the reporting system adequately when it comes to personal injuries and other serious events.	Onshore management/ staff	4.32	
F/OM: I use the required protective equipment	Fish farmers	4.55	0.000
	Operational managers	4.72	
M: Our employees always use the required protective equipment	Onshore management	4.20	
Safety has first priority when I do my job	Fish farmers	4.30	0.000
	Operational managers	4.30	
	Onshore management	4.71	

Table 5. Linear regression analysis predicting 'Compliance': Beta-values (B), standard errors (SE B), standardised betas (β) and explained variance (Adjusted R^2) (N = 253).

	B	SE B	B	Adjusted R^2
Constant	2,086	0.301		0.304
Work pressure	–0.150	0.044	–0.197	
Participation	0.112	0.043	0.156	
Competence	0.366	0.054	0.381	

Work pressure had a negative association with Compliance, while Participation and Competence had a positive association. High perceived work pressure was thus associated with lower Compliance, while higher degrees of participation and Competence, was associated with higher Compliance.

4 DISCUSSION

Considering the results, variations in perceptions of safety climate related to the three different groups and company levels are discussed.

4.1 *Regarding work pressure*

All groups recognize some pressure to continue unsafe operations or violate rules and prioritize production over safety (two first items, Table 1). Almost ¼ of the fish farmers agree that production sometimes trumps safety. Unsurprisingly, managers disagree more as they often have a more positive (Fenstad et al., 2009) or less realistic view of operations (Hale and Borys, 2013b, Hollnagel, 2011). When considering if *production pressure will make employees compromise on safety,* managers agree more than operational personnel do. One explanation may be that management have HSE as their area of expertise, and might have learned, in practice and theoretically, that operational personnel will feel pressured to work efficient and not thorough (Hollnagel, 2009) or prioritize production over protection (Reason, 1997) with a drift towards unsafe performance (Dekker, 2011, Vaughan, 1997, Rasmussen, 1997).

This resonates with earlier findings in Norwegian aquaculture. In Allred et al. (2005), 21% agreed that they were pressured to work in a way that could threaten safety. In addition, 27% agreed that the operational manager did not have the time to sufficiently manage employees' HSE – meaning that they focused on production to make the ends meet (ibid). Priority of the biological product, the fish, is also qualitatively described (Fenstad et al., 2009, Størkersen, 2012).

A more recent study found that work pressure may be caused by poor planning of operations, insufficient staffing, time pressure and working long hours (Thorvaldsen et al. 2015). And even though their personal safety may be threatened, employees are very conscious about following up on their work responsibilities.

An increased efficiency pressure coincides with the statements about maintenance (Table 1). 1/5 of the fish farmers and operational managers think that inadequate maintenance has reduced the safety level. Maintenance on existing equipment might be postponed to times with less activity and potential earnings. It is shown that coastal vessels running for the prosperous aquaculture industry have tighter schedules and more stress than vessels operating in slower markets (Størkersen, 2017).

Economic priorities are relevant here, as it may affect maintenance of existing equipment at a given fish farm or vessel, but also limit investments in new technology (Thorvaldsen et al. 2015). A previous study also found that fish farmers experienced increased profit as more important than workers' safety (Fenstad et al. 2009).

4.2 *Regarding participation*

Personnel on all levels agree that managers appreciate employees' safety engagement. However, mangers seem to appreciate employees taking up safety issues more than fish farmers think. The interaction between company levels as well as differences between formal and informal communica-

tion may be reflected here. Fish farmers may take up safety issues with the operational managers, who then decides whether and how to address a specific issue. In larger companies, formal reporting systems are also used. As operational managers give a higher score than fish farmers, fish farmers may think about day-to-day interaction when they disagree with the perception of the operational managers, or they may be thinking about the (lack of) response they get when they address safety issues through formal reporting systems.

Allred et al. (2005) found that 81% agreed that employees could influence the HSE conditions to a large degree. Still, a third of the respondents said they did not have the chance to participate in HSE strategies.

When it comes to new procedures, and employees' participation in developing them, the answers gave a neither/nor result. Fish farmers disagree more than the managers. Here, a likely explanation will be that the onshore managers involve the operational mangers and some of the fish farmers when procedures are made. Even though not all fish farmers are involved in such processes the onshore managers do involve some of the employees.

The situation seems to be somewhat similar when it comes to new procedures. Almost 25% of the fish farmers and 19% of the operational managers disagree. As procedures are often sent to employees via computer-based systems, this answer may indicate that this is not seen as involvement, but rather as information.

4.3 *Regarding competence and resources*

Over all, the participants agree that operational personnel at the fish farms have the competence to work safely. Several companies also provide external safety courses for employees, and companies use internal procedures to document how operations should be performed. Experience is also highly valued at the fish farms (Holmen et al., 2017a, Thorvaldsen et al., 2015).

In 2005, 68% stated that employees got adequate safety training, but 41–44% wanted more training in sickness and injury preventing work and safety routines (Allred et al., 2005).

When it comes to staffing, about 12% of both fish farmers and operational mangers disagree that manning is sufficient. Safety issues when workload is increased without additional personnel has been discussed in previous studies in aquaculture (Thorvaldsen et al. 2015) and maritime industries (Hetherington et al., 2006, Österman and Hult, 2016).

Fish farmers and operational managers agree that they use information from previous events for prevention, but onshore staff answers neither/nor. It may be that onshore management see more potential for learning and prevention both on their part and from the operational personnel. Onshore management must follow up on non-compliance reports from many fish farms, and may lack time and resources do to this optimally. The operational personnel on the other hand, may answer more positively based on activities and measures on their specific fish farm, and not what comes from the onshore management. With more formalized systems for reporting, one might think that this was an area that had improved a lot during the last decade. Looking back, however, 72% of the participants in 2005 (Allred et al.) answered that information about accidents and unwanted events was actively used by the companies.

4.4 *Regarding compliance*

All groups agree they report dangerous situations (the first item, Table 5), but a third of the fish farmers also are uncomfortable pointing out non-compliance. Not every company meets deviance from rules with an understanding that most personnel follow rules, but that some rules can be difficult to follow because they are contradictory to other rules, the context, or resources (March, 1994). It may even be necessary to break a rule to get the job done (Reason, 1990). Thus, the safety literature has emphasized that safety is not attained by blind rule-following (Hollnagel et al., 2006, Hale and Borys, 2013b). Still, compliance might be the safest option if the rules can be followed. A literature review of quantitative studies indicates "a positive linear relationship between safety compliance and safety. That is, the more compliance the better for the state of safety" (Dahl, 2014: 31). In the study of Allred et al. (2005), the findings were at least as positive as in the current study: 65% stated that employees always reported safety issues and dangerous conditions, and ¾ meant operational manager encouraged employees to report such conditions.

Both the current and previous studies (Allred et al., 2005) find that protective equipment mostly is used.

All groups prioritize safety in most situations, the management respondents are most certain. This is related to the statement that the production is prioritized over safety in some operations, although management disagree that production is prioritized over safety (Table 1). Management is commonly looser coupled to the negotiations in the operations. A relevant point here, is that our survey has targeted management respondents with health and safety as their responsibility. Furthermore, as Allred et al. (2005) also discuss, we do not know if it is only the most positive representatives working in the most HSE focused companies who have answered the surveys (Hollnagel et al., 2006, Hale and Borys, 2013).

4.5 *Safety climate and compliance*

The regression analysis revealed that safety compliant behaviour was predicted by safety climate

measures among fish farmers. In our context, compliant behaviour involves adherence to safety rules, and procedures, such as the use of the required protective equipment, reporting of dangerous situations if they are observed, and prioritizing safety when they do their job.

Among the three safety climate factors, Competence was the most important predictor, followed by Work pressure and Participation. Competence and Participation were positively related to Compliance, while Work pressure was negatively related to Compliance.

Several studies have shown similar results, adding up to a quite robust relationship between safety climate and safety behaviour (Clarke, 2006, Christian et al., 2009). In general, this research show that those who perceive safety as valued and prioritized in their work community, display a more positive safety behaviour, including compliant behaviour, than those who perceive safety as less valued (Dahl and Kongsvik, 2018).

This relationship has not been studied in the aquaculture industry previously. The results indicate that the relationship can be valid also in this context. This gives input to some practical measures for safety management in the industry. The competence scale included items on training, including training for emergencies. Providing such training might increase compliance through increased knowledge of the procedures. Further, avoiding work pressure that goes at the expense of safety might also increase compliance and reduce exhaustion for the individual employees. This may be a challenge, as there are some very labour-intensive periods related to delousing operations etc. Still, organizing these periods as to avoid long hours and heavy workloads might have a positive influence on compliance and safety climate. Lastly, involving employees in the construction of procedures, and having an 'open door' policy regarding safety issues can also have a positive influence on ownership, feeling of involvement and compliance.

Although safety compliance is one important aspect, it is also true that procedures and rules tend to be underspecified and cannot cover all eventualities in complex systems (Hollnagel, 2009). On the one hand, the work at fish farms include many routine tasks, where the applicability of clear procedures is evident. On the other hand, flexibility, situational awareness, practical experience, and problem-solving skills are also vital qualities in this context (Thorvaldsen et al. 2015). Consequently, rules and procedures should be dynamic, and involve sharp-end workers in formulating and evaluating them (Hale and Borys, 2013 a). So even if compliance in many instances is a basic foundation for many work operations in high-risk industries, performance variability is also a valuable asset that might increase the resilience in a sociotechnical system (Hollnagel, 2009, Haavik et al., 2017).

The results give grounds for further exploring the relationship between safety climate and safety compliance in the aquaculture industry. Future research could include onshore personnel, and suitable measures for safety climate and safety behaviour. This could broaden the view on how accidents can be prevented in the industry. Also, the cause and effect relationship between climate and safety outcomes can be explored. Other studies indicate that this relationship might be reciprocal (Kongsvik et al., 2011).

5 CONCLUSION

This article explores perceptions of safety climate at different company levels based on two surveys amongst employees in the aquaculture industry. Over all, perceptions of the safety climate are positive at all levels. This may reflect an increased focus on workers' health and safety during the last decade. Still, there are challenges related to work pressure, maintenance and employee participation. While aspects related to compliance such as reporting, wearing protective equipment and prioritizing safety get a high score, many fish farmers are uncomfortable with pointing out colleagues' lack of compliance.

The analyses further reveal that fish farmers' compliance to safety requirements is predicted by safety climate, and in particular by competence. Training, including emergency exercises, will be valuable for increased safety. The same goes for reduced work pressure. Work pressure relates negatively to compliance, and almost one quarter of the fish farmers agree that production is prioritized over safety.

Differences between company levels reflect different points of view and responsibilities within the companies. It is important that fish farmers are involved when their work procedures are created and introduced. Fish farmers and operational managers who work at the sharp end are physically closest to the occupational hazards, and rely on the onshore management to get the necessary means to mitigate the risks.

Societal threat landscapes of petroleum industry activity in the high north

E. Okstad, T.O. Grøtan & A. Øren
SINTEF Technology and Society, Safety and Mobility Research, Trondheim, Norway

ABSTRACT: Today, industrial and societal systems interact and become more complex than ever, and hidden, dynamic and emerging threats and vulnerabilities evolve. By observing the petroleum activity in the north (west Barents Sea) along with other developments and societal trends in the region, it is possible to sketch out a threat landscape of the high north. A threat landscape is formed from interconnected 'pictures' of threats and actors, given some external conditions. These conditions are 'on the move', and requires that the risk pictures as well as the landscapes must be maintained and revised. Examples of such are effects of declining oil prices, or a changing climate. It is important to assess the validity of any picture contributing to the landscape. Threats may lead to 'spillover effects' and unexpected events if pictures become saturated. Scenarios applicable for stress-tests may be derived from such threat landscapes. The severity and urgency of a scenario is strengthened by events occurring simultaneously, or as combined events. Risk mitigation should thus be handled more in collaborating teams of interconnected actors instead of by single entities themselves. Actors involved in the 'oil in high north' threat landscape either take part in, support, or are affected by the petroleum activity in some way. Each party should consider their situation and role in view of the evolving threat landscape, and look for alternative handling of emerging risks. As part of a case work in the New Strains of Society project, key actors have been interviewed. In addition to the interviews, associated workshops have been held. This paper summarizes the foundations of a preliminary threat landscape based on these interviews and workshops, with recommendations for further elaboration by researchers as well as practitioners. Main challenges associated with the aforementioned threat landscape are outlined. The concepts of robust organizations and resilience are reflected upon as alternatives to the prevalent failure-oriented safety approaches. Knowledge from the current study serve as input to the final New Strains of Society framework.

1 INTRODUCTION

A threat could be explained as a possible danger that might exploit vulnerability of a system and cause possible harm. Threat landscapes then cover threats and vulnerabilities of a thematic area that involve a network of agents and stakeholders, interacting normally or more randomly (Grøtan & Antonsen, 2016). The landscape metaphor involves an aggregate of the more prevalent notion 'threat pictures'. A 'threat picture' is confined and focused on a narrowed set of topics, either thematic-centric (e.g., oil spill) or actor-centric. A picture comprises a frame or a border that represents a clear demarcation of the relevant vs. non-relevant issues belonging to the threat, including the relevant vulnerability and presumptions on operational conditions. Such presumptions can, however, be turned the other way around. They can be recognized both as demarcation lines for the validity of a picture in relation to hidden, dynamic and emergent effects, but also as a key to understanding when a picture will become saturated with unaccounted or unprecedented conditions. The overall idea is that as threat pictures mature, scenarios for stress testing can be built.

The finalized project New Strains of Society (New Strains) dealt with these matters. Empirical studies of societal threats and vulnerabilities were focused on gradual developments of threat landscapes for thematic areas like the petroleum activity in the high north. Information was gathered from documentation reviews, followed up with guided interviews and workshops. By utilizing a joint interview guideline, the representatives from involved actors were incited to elaborate on threat pictures and scenarios that normally fall outside their normal belief of system behavior. Okstad et al. (2017) described a basis for the design of empirical case studies of which the results should support to the New Strains framework.

1.1 *Objective*

The main objective of this paper is to summarize generic findings gathered from interviews and workshops with involved actors concerning threat

landscapes arising from the thematic area 'oil in high north', and to organize the finding into a rudimentary threat landscape that can be subject for elaboration and extension at a later stage, involving more actors.

2 INFORMATION GATHERED

2.1 *Description of case studies*

The case 'oil in high north' is about possible implications of the offshore petroleum business in the high north (Barents Sea). In addition to this case, there are two other cases covered in the New Strains project; the 'Pandemic' and 'ICT infrastructure'. The latter is much about cyber safety, security and resilience and is as such, integrated in the other two thematic areas. In fact, it deals with vulnerability and risk handling of critical ICT infrastructures, of most importance in maintaining any societal function.

The 'oil in high north' case defines threat landscapes much as societal impact of the petroleum activity and its presence in the region. Examples are environmental concerns, access to limited services in emergencies (e.g., SAR), like public hospitals and air-borne ambulance, as well as the dependability of shared infrastructures. The latter could be communication infrastructure, energy supply, transportation systems for goods and/or services to offshore installations as well as to local communities.

'Pandemic' is about dealing with a global epidemy that crosses national borders, affecting the public widely and thus, indirectly threatening important societal functions and infrastructures, herein questioning the deliberations of saturation points and interdependencies of the preliminary threat landscape presented in this paper.

2.2 *General aspects; method and interview guide*

In this paper, we try to delineate a preliminary threat landscape, based on tentative threat pictures, interviews and available public information. The key activity is to encircle and 'carve out' possible 'pictures' and their saturation characteristics. What external events could 'shake' or interrupt them? Possible spillover effects are here those effects that carry the potential to influence other (external or overlapping) pictures, and ultimately the whole 'landscape'. The strategy for doing this is based on the landscape representation of Grøtan and Antonsen (2016). Separate interviews were carried out and pragmatically used for this purpose, providing crucial grounds for the New Strains framework development aiming for stress-testing as the ultimate objective. Each interview was aligned to contribute in an optimal matter to the framework, and based on a joint interview guide (Grøtan and Antonsen 2016). Key players were interviewed at both a general level, and on specific topics related to their presumed or self-declared 'picture'. The initial aim was to identify the interviewees' home ground with respect to risk pictures and the risk management been implemented. What kind of events were covered by the risk analysis normally, and what have been the criteria for establishing emergency- and contingency plans?

By going through past events and how the organization responded, characteristics of how they were surprised are revealed, in addition to information about situation handling. By going through these experiences, one should touch upon the outer edge of what (situations) are possible to handle by the organization. This could be explained as the thickness of the threat pictures' frame. Next, the aim was to challenge actors to look for the bigger picture given the situations experienced, how could the situations possible escalate? What may have happened if the initial event occurred slightly different, or conditions were some otherwise for the scenario? At this stage, it was expected that actors used their imagination and took the opportunity to respond actively on both thinkable, and less thinkable scenario escalations. Important questions in this phase were:

- What has been done after the incident to be better prepared (learned by experience)?
- What kind of effects in sense of improved interaction between actors are seen?
- What kind of overlap with other threats are seen in the hypothetical crisis?
- How could such kinds of interactions and overlap be handled in practice?

Threat landscapes for 'oil in high north' have been formulated on basis of adapted interviews and meetings. The strategy was to pursue initiating events further and challenge operators and actors with respect to possible ways of escalations. By exerting pressure on a given threat landscape, one or more threat pictures were approaching a saturated state which triggered thinkable events. These events escalated from some defined 'overlaps' between the set of threat pictures and/or actors in the landscape.

One possible escalation relates to the production installation's dependence of electric power supply from shore in normal operation. A scenario, with overlapping threat pictures, e.g. challenging weather, or vulnerable power supply, could initiate from a winter storm caused by a polar low pressure. The storm knocks out the power supply to the offshore production facility, while at the same time hampers evacuation of personnel from installation by helicopter.

Then, we ask what could be done to avoid similar experiences, or to be better prepared. The risk management should be updated accordingly. Finally, taking as a premise that surprises anyhow might occur in the future—what could be done, or should happen to successfully deal with these surprises? Here, we identify some resilience capabilities. The interviews were structured according to the predefined sequence of issues starting with the interviewee's home ground, i.e. a description of the risk management- and emergency preparedness system in service.

2.3 *Actors involved in 'oil in high north'*

A list of potential interviewees was established based on a predefined actor landscape, shown in Figure 1.

These actors, or organizational units, were assumed to play active roles in the threat landscape. Hence, they will also be prime candidates for being actors in a future 'resilience landscape' (Grøtan & Antonsen 2016). Founded on the New Strains principles of building such landscapes (Grøtan & Bergström, 2016), Grøtan (2018) utilizes a New Strains discursive-support structure that enables such a polycentric resilience landscape to evolve over time. Based on this, a preliminary threat landscape may be elaborated and evolving further.

2.4 *Interviews and workshops accomplished*

During the project work, we managed to get in touch with an oil company, the council of county emergency preparedness in Finnmark, the regional health company and a local health company. We also planned to interview representatives from the police, the national electric power net agency, telecommunication companies and the local electric power company. This turned out to be difficult, inter alia because we easily run into asking for classified information that we cannot receive. There have been three workshops held in 2016–2017 on the topic cyber safety, security and resilience of critical infrastructure. Information from these workshops is elaborated on in the discussion part of the paper.

In addition to the obstacles of classified information, we also come into or derive information and knowledge that is obviously sensitive (but unclassified), and therefore is omitted.

However, it is emphasized here that the conception of 'sensitive' is based own judgements.

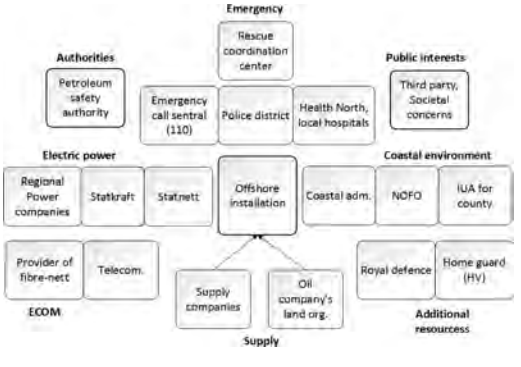

Figure 1. Actor landscape: 'Oil in High North'.

2.5 *Findings from narrative-structured interviews*

The 'narrative structure' is based on Grøtan and Antonsen (2016).

2.5.1 *General issues*

General characteristics of the high north involving the petroleum industry activity and maritime traffic in the area were i.a. as follows:

- A situation with limited 'resources' in the high north put constraints on crisis mitigation.
- Actors have experienced limited information provided by externals in early phases of situations, combined with bad communication.
- The region is known for rough weather conditions and large distances between parties and service providers in reaching the necessary resources.
- There are still conflicting interests between nations in the Barents region.
- Societal events, and/or global changes to society seem to have effect on business as usual.
- Cyber-security, hidden, dynamic and emerging (h/d/e) risks are evolving. These issues are incorporated in emergency exercises, initiated by the county administration, that involve actors and stakeholders starting to learn by collaboration.

2.5.2 *Actors 'state of the art' in risk management*

Oil companies give lower priority to security issues than pure (physical) safety. The petroleum business in Norway is not defined as a CI and thus, not subject to the Security Act like other critical infrastructures.

Misleading, cyber-related actions, or events with purposes others than what seems to be the case at first place are challenging tasks for the industry. It is generally difficult to improvise on such ICT-problems when lacking overview or knowledge to problem origin in the early phases of a scenario/event. Achieving a delayed overview of the situation, or late awareness of the main purpose of an attack is normal, not exceptional. Generally, there are limited roles, or dedicated activities in strengthening the security field in the petroleum business. Measures are prescribed for physical protection mainly, e.g.

like to secure persons from becoming violent offshore, implement 100% check of personal luggage before offshore flights, etc. However, the industry is aware of cyber threats like the 'denial of service'.

From the authority's point of view, cyber security is part of the overall emergency preparedness in society. Finnmark county has included these issues in their emergency-preparedness plans, and constitute an important part of their training program.

Geographical coverage of the health emergency-preparedness is defined in dialogue with national authorities. Focus is on robust systems for alerting, assessing and managing unexpected situations. The regional health company (Finnmark) is set for handling of major accidents with many injuries. It incorporates plans for the critical infrastructures. Emergency plans, that includes infrastructures, are aligned with the relevant actors, like oil companies, hospitals, police, coast guard, national defense, etc. The ambulance services are also crossing national borders to Russia and Finland.

2.5.3 *Experiences from h/d/e events in own business*

The following draws an overview of some threat pictures that are relevant for the 'oil in high north'. These pictures mainly are derived from the interviews.

Offshore installations may become vulnerable to electrical-power shut down from shore, given the new Norwegian policy that requires electrical power supply from shore. The tense political climate, with environmental activists and Russian collaboration makes operations challenging to a certain extent. The public society in the northern part of Norway, including the petroleum industry, have been surprised by several big events lately. Three examples were:

- The refugee situation in 2015 with large groups of people crossing Norwegian border at Storskog.
- The big avalanche at Svalbard in 2016 came as a surprise and challenged the health company's preparedness, including transportation of personnel.
- The ash cloud came from the Iceland volcano in 2010 led to major ambulance-flight restrictions.

Oil companies typically expect only minor, or none surprising events from own business. As mentioned, cyber security of critical infrastructures and lack of overview/delayed knowledge about emerging problems are general issues given implementation of new/innovated technology in society.

Finnmark as a large county with resources geographically spread is also a challenge. There is limited capacity of the local hospitals to handle big events with lots of injuries. Anyway, unforeseen events happen all the time in the north, often related to the challenging weather conditions and long distances. The time factor in an acute situation often become critical, and the required resources in an emergency may be far away, and take 2–3 hours to mobilize. An example of such is the fire-fighting service.

There are periods of the year with less access to back-up health personnel, e.g. during the Easter with people spending their holiday time out in the terrain. Personnel resources to solve ICT-problems may also be scarce locally, and it becomes a critical aspect if communication gets down during handling of a crisis.

Finally, the electric power situation depends on a power distribution grid crossing borders to both Finland and Russia, which makes it even more vulnerable. The electrical power net covering the northern parts of Norway is operated by 7 companies. Although, Norway, Russia and Finland have agreed on training the emergency preparedness against events (including power supply) that involve all three countries, the handling of crises near the borders to each country with utilization of the common resources is a critical issue.

2.5.4 *Pandemic as a threat*

The national preparedness plan for pandemic flu describes how to prevent and reduce the spread of infection, morbidity and death, and to provide good treatment and care for people affected by the flu pandemic. Municipalities in Norway are obligated through the Civil Protection Act, to actively work with emergency preparedness, such as e.g. to have a plan for how to handle possible pandemics. Some of our project group members were allowed to observe and challenge participants in the crisis response team during one specific manoeuvre, 'exercise Virus', in one municipality during the autumn 2017. The type of virus was in this case a seasonal influenza virus. In this exercise, all municipal offices were involved.

A pandemic is a complicated situation to handle for a municipality. It involves the administrative and operative management, and several different professionals such as general practitioners, hospitals, nursing homes, transportation, schools, day-care, groceries, to mention some. Moreover, a pandemic flu situation is highly different than an emergency event as e.g. a major explosion, that leaves an unexpected complex situation with a high degree of uncertainty. While many emergencies occur suddenly, a pandemic flu spreads and escalates in a slower manner. It is possible, to a certain degree, to be prepared and prevent the severity of the outbreak. However, it should be mentioned that the lethality of a flu pandemic could be abnormally high, in which could leave the situation even more complex and difficult to solve. Ebola pandemic, with the high degree of lethality, is another example of complex pandemic.

During the 'exercise Virus' it was observed that the organisation involved in handling the crisis is complex, the distance between the members in the

crisis management, the crisis response team, the administrative and operative management, as well as the many other actors involved, could lead to a non-optimal communication dialogue between professional institutions, external actors and decision makers. At some offices, the person of contact could have changed, without notifying in the emergency preparedness plan or in the digital crisis management tool, in which led to further communication problems. Misunderstandings could easily take place; degree of severity, underestimation of time consumption, and which resources are available. Moreover, since also neighbouring municipalities are affected in case of a pandemic, competition for the same resources as e.g. beds for a temporary emergency room/hospital, could occur. Other important issues are the complex logistics for handling sick persons, to continue with safe operation of critical societal functions and to have enough qualified personnel to run daily operations.

On the positive hand, since the pandemic situation often escalates in a slow matter, the management can reallocate human resources. E.g., personnel working at the municipal cultural school could be reallocated to work at vaccination posts or nursing homes, as there most likely would be shortage of health personnel in a pandemic situation. Still, because of the high numbers of persons involved in a pandemic, even a pandemic with low lethality could have the potential to paralyse—to a certain degree, a whole society.

From this, we hypothesize that a pandemic component in 'The High North', could affect the capability and function of persons directly involved at offshore installations as well as the support network on-shore from the Finnmark county. This could again threaten the safety for the work and the environment in 'The High North'. Although we presume that 'pandemic' aspects already have been considered by the 'Oil in High North' actors, we find reason to issue a warning that the 'crippling' effect of a pandemic is likely to jeopardize any assessment of saturation effects related to almost any risk picture. This is probably even more relevant for scarcely populated areas, where competent people probably have several roles, related to e.g., authorities, companies, NGOs and the civic society. The latter is especially important for reliance on community resilience, despite the assumption that the population is more robust compared to rural areas (see later discussion on resilience).

2.5.5 *Emergence, escalation into 'bigger pictures'*
The following gives some examples of possible escalation routes into 'bigger pictures'. Terror, where the health services can be targets themselves (physical/cyber), is thought of as a possible scenario. Sensitive patient information may get lost, although health companies are subjects to the Security Act.

A refugee situation could escalate with people disappearing after crossing the national border, with a pandemic coming up. At the same time, some might bring forward violent attitudes and crime.

With changing traffic patterns in the north, mainly enforced by increased tourisms, etc. the health companies are challenged on capacity and logistics in case of simultaneous events. There is limited capacity in local hospitals to handle big events with lots of injuries. These situations may as well effect on the health preparedness served to the petroleum business.

2.5.6 *Expectations and revised risk governance*
Of the most important learning from incidents by the oil companies is:

- Risk governance being updated based on learning from incidents.
- Outsourcing of ICT services requires improved focus on contracts.
- Improved (risk) knowledge is achieved among actors involved in the (oil) business.
- Hospitals, police, etc. are more aware of possible new scenarios offshore.

From a Finnmark county perspective, the new 'cyber scenarios' are to be included in the 'national risk picture', but the emergency preparedness should be made Finnmark-specific. The council of county emergency preparedness plays an important role in improving the society's risk awareness by maintaining an open dialog, and arranging training exercises.

For the health companies, review of emergency plans is expected to adapt at new events and developments of the society. New emergency plans should also cover 'hybrid-war' scenarios. Here, the rescue function of the armed forces need close cooperation with the civilian health service to handle crises. Interaction competence will thus be more important. The 22. July terror attack gave us new views in that respect (Johnsen & Øren, 2015).

2.5.7 *Recognizing the usefulness of resilience*
When it comes to specific resilience capabilities the county emergency preparedness is used as an example. The county expresses they adapt to situations, and the degree of improvisation often occurs there and then. It is however, more difficult to improvise on ICT-problems due to lack of overview/knowledge in early phases of a situation. Each sector/actor carry out resilience, or resilient behavior in different ways, either as an organization or individuals. Early sharing of information to society (e.g. the municipalities) is one of the county governor's main responsibilities and should support such a behavior.

Safety and emergency events offshore are handled by the Norwegian rescue coordination center (RCC) in first instance. The oil business itself may

contribute by its own transportation resources to assist the health companies in specific rescue operations, etc. The Seeking helicopter squadron has become an important resource for the health companies as well.

Experience from a gas-leak event on an installation in the north lately tells that health companies nowadays are notified earlier without occurrence of a serious event with injuries, or having a real evacuation situation. The threshold level to establish preparedness is maintained as before, but notification to the health company comes earlier than before. The main reason is that the crisis management at health companies is more able to judge, or assess the seriousness of situations during the early stages than operators at the alarm receiving center.

Another aspect of resilience is that inhabitants of Finnmark tend to try out their premises extensively in crisis situations. The northern communities are characterized by their robust populations. Due to the region of small, often isolated communities, the ability to handle unforeseen situations is spelled out when events occur. There is, however, a variety of such skills. Living in the north involves some risks and the inhabitants are more used to stand-in the situation when required. Next, there is also a reliance of our neighbor countries on Norwegian assistance in crises, e.g. in north Finland and Russia. An accident near the border to Russia can also be supported by resources from Russia. There is no experience from real events on such, but the countries exercise together regularly.

3 THREAT LANDSCAPES OVERVIEW

Generally, emergency preparedness in oil companies is mainly designed to handle single accident events at a time only, e.g. a hydro carbon-leak or fire. However, problems may escalate if e.g. a production upset and a hydro carbon leak occur at the same time and in combination with outfall of critical infrastructures. An example of the latter is loss of electric power from onshore, or technical failures on critical communication systems. The following summarizes input to threat landscapes derived from the interviews:

- Long distances in the north between critical (emergency preparedness) resources may induce logistic challenges when facing emergency situations, e.g. easy/in time access to onshore equipment in case of an unexpected oil spill.
- The petroleum industry is not subject to the 'security act', which makes the involved actors less accountable to cyber-attacks than other domains, e.g., 'denial of service' types of viruses.
- Possible 'Spillover effects' from externals during a crisis, e.g. environment activists, political interests may interrupt a proper handling of situations.
- Critical operations at the same time of an infection disease spread among key offshore personnel may reduce the problem-solving capacity dramatically.
- Terror attacks in combination with bad weather makes it difficult with respect to accessing accurate information, and handle multiple demands to limited resources for normalization.
- 'Oil in high north' is currently a Vest-Finnmark domain. A major accident offshore may however, require the whole capacity of the regional health company. That means the capacity of single health companies might be too scarce in those situations.
- Extraordinary events (e.g. the refugee situation at Storskog) combined with a major offshore accident could cause trouble for the emergency assistance from the health companies due to limited resources.
- Ambulance services by air is a critical function in emergency situations offshore, and may easily be interrupted by bad weather or natural disasters, like the ash cloud in 2010.
- The avalanche at Svalbard in 2016 came as a surprise and challenged the health preparedness of health companies, especially with respect to transportation of personnel. An offshore accident at the same time would have been difficult to handle locally.
- Health companies are always challenged on capacity and logistics by simulations events. The companies are decentralized, often small units with focus on the 'acute' functions during events.
- Experience from an exercise at a hospital with a CBR-incident (Chemical, Biological, Radiological), and at the same time a real failure in the communication system did occur. Then there was a need to put the exercise on 'hold' to solve it.
- Resources to solve ICT-problems become scarce with communication difficulties. Access to troubleshooting capacity also becomes a scarcity resource by constantly introducing new technology.

The above aggregate to three major treat landscapes that could be elaborated on further (see Figures 2–4):

- Production upsets
- Cyber security
- Emergency preparedness at sea

A further elaboration of these landscapes is conceivable, drawing on a discursive support scheme (Grøtan, 2018) that supports development of polycentric resilience landscape, including cyber vulnerability issues.

3.1 *External conditions*

In addition to threat landscapes, the following issues were registered through the interviews as

major external conditions, i.e. kinds of 'labyrinths or moving horizons' (Grøtan & Antonsen, 2016):

- Changing conditions for the offshore petroleum industry in general, mainly due to lower oil prices, a continuous need for cost cutting with structural and organizational consequences.
- Hidden vulnerabilities in the 'system' for electrical power supply from shore.
- Development strategies for the electrical power grid are not fully predictable for the industrial actors. Uncertainty relates to further development, of which, is partly geographically conditioned.
- Uncertainty relates to the resilience capabilities and degree of informal collaboration between actors involved in a potential (offshore) crises.
- The degree of information and communication constraints occurring between governmental levels and actors in crisis situations that evolve.

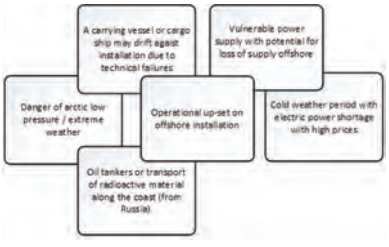

Figure 2. Threat landscape: Production upset.

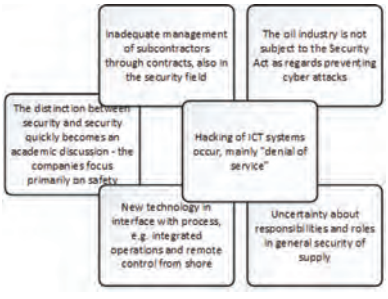

Figure 3. Threat landscape: Cyber security.

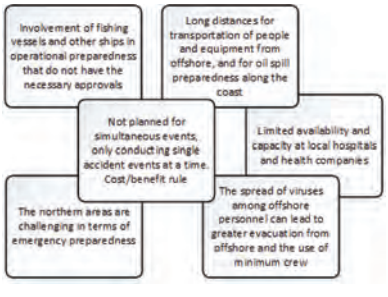

Figure 4. Threat landscape: Emergency preparedness at sea.

- The availability of personnel varies over time in the regional health companies depending on changing regional policies that may have effect on the quality of the health preparedness.
- The degree of shared information and communication between the actors in the petroleum business and health companies, has developed into new levels lately.
- The development of the expected 'total-defense' concept is uncertain. To what degree (and when) can actors rely on sufficient and steady interaction between actors according to such a concept?
- The technology change and degree of innovation in the hospital sector imply varying dependency on the Internet in rescue and health preparedness.
- Access to troubleshooting capacity (ICT related) may become scarce for the health companies in times of new implementations.
- Required manning in the northern health companies, and accessibility to personnel vary during the year due to individual work- and shift schemes.

4 DISCUSSION AND FURTHER WORK

Threat scenarios are elaborated on basis of threat landscapes with 'saturated' threat pictures and 'moving horizons' in Section 3 and 3.1. Scenarios may initiate from the offshore installation itself, from a passing ship in the area, enforced by bad weather conditions, or loss of critical infrastructures like electric power from shore. In combination with other events, scenarios may escalate into severe accidental events.

The important aim of scenario framing/delimitating in New Strains was to establish an appropriate foundation and discussion basis for the actors and stakeholders involved (Okstad, 2016). Any actor should take the opportunity to respond on knowable escalation factors of the identified scenarios, if they were involved or affected according to the given threat landscape.

The scenario should neither be too specific, nor to general. In case of the first it probably requires too detailed knowledge and extensive verification of its implications for the final acceptance as a scenario among actors. If scenarios become too general and vague, they will be counterproductive and of minor value in clarifying possible escalation factors and effects of such within a given threat landscape.

Another challenge was how far one should go to look for interconnections between contemporary threats and adverse circumstances as reinforcements to possible threat escalations. The right balance was found to be just making illustrations of possible spill-over effects, or the added effects of several overlapping events or vulnerabilities in the given threat landscape.

Threat scenarios that have been discussed related to 'oil in high north' are:

– Critical exploration drilling activities goes on in the North Barents Sea, and at the same time, a major ICT-system failure occurs. There is limited ICT infrastructure in the area. A well control situation escalates into a critical situation that require shutdown and immediate evacuation of personnel from the rig.
– A large passenger boat gets into fire at open sea, at the same time an ICT-problem strikes the health company. Combined with large discharges of oil/chemicals at a site of damage (CBR), situations quickly get out of control. Viewed from the health company's point of view, the size of the accident in sense of the number of injured people becomes the biggest stress factor.
– Simultaneous energy-power cut to an offshore installation and an oil spill, or operational problem at site. Challenges then occur related to fast and effective mitigation of consequences. Finnmark county is large, with the onshore recourses geographically spread. Then it takes time to move, e.g. by helicopter between west and east.
– Offshore event, international cyber-attack, critical failure in communication systems/infrastructure (random failure/out-fall, or a deliberated action, e.g. cut of cables).
– Ship collision with an installation, and at the same time an outfall of electric power from shore occurs. Finally, an escalating pandemic flu strikes the area. With a trend of increasing ship transportation with new production- and exploration drilling taking place in the north-east Barents Sea. In addition, system vulnerabilities exist connected to ICT and Internet of Things incorporated in every critical infrastructure and logistic function.

Our experience from the interviews is generally positive with respect to the interviewees willingness and engagement to share their opinions and thoughts on these aspects. However, we faced a challenge regarding confidentiality and security clearance at a degree that limited our contact with some actors.

Regarding the workshops, the participating people were motivated to contribute there and then. Discussions in interdisciplinary work groups was a success. People from authorities, research units and practitioners worked very well and the impression was that it was valuable spending of time. However, the discussions regarding threat pictures, and especially related to cyber security, quickly became technical. In some discussion groups, therefore, the discussion was raised a level and used more to elaborate around possible effects or consequences of the cyber threats. One drawback was the tendency of pulling out the consequences completely (to wide, or thinking 'worst case') instead of thinking possible event chains or sequences leading to such. Maybe we should have emphasized to concentrate on a limited set of consequences, i.e. linked to the given organization.

5 CONCLUSION

In line with the suggested approach to encircling and building threat landscapes, a preliminary threat landscape for 'Oil in High North' has been developed. Results from a study of pandemic handling in a municipality has also been included in the landscape. This threat picture sensitizes the 'oil in high north' scenario to be further scrutinized concerning operational presumptions and considerations of saturation effects.

For a further development to take place, crucial issues about not only classified information, but also sharing of obviously 'delicate' information on (e.g., cyber) vulnerabilities would have to be addressed. The authors judgement is that this should be possible, laying the foundations for stress-testing according to the New-Strains objective (Okstad et al. 2016).

ACKNOWLEDGEMENTS

The authors like to acknowledge contributors in interviews and workshops for providing valuable information to the discussion. The Norwegian Research Council through the research contract No. 238093/H20 sponsors the paper.

Interorganizational complexity—main challenges and opportunities in the petroleum industry

V. Milch & K. Laumann
Research Group for Safety and Human Factors, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: With growing outsourcing in the petroleum industry, operations are becoming increasingly interorganizationally complex. This raises the question of how interorganizational complexity influences safety. The aim of the research project "interorganizational complexity and risk of major accidents" was to gain a better understanding of safety challenges associated with interorganizational complexity. Three studies have been completed. In this paper, we present the main findings from the research project and discuss how the resulting knowledge can best be applied in the petroleum industry. The findings call for more awareness concerning interorganizational safety challenges in the industry, and points to specific areas in which challenges may arise. In particular, coordinating work processes, ensuring sufficient levels of competence and transferring lessons learned and best practices across companies, are identified as such areas. However, the findings also imply practices that help manage interorganizational complexity. The presence of high-quality work relations appear to be important to achieve safety performance across collaborating companies. In this regard, middle managers appear to play a central role in terms of aligning employees from collaborating companies towards a shared focus on operational and safety related goals.

1 INTRODUCTION

In the Norwegian petroleum industry, the outsourcing of safety-critical activities and services to contractors in petroleum operations, have increased in recent years. As a result of increasingly complex drilling operations and recent technological developments, work processes in oil and gas production have become more and more specialized over the years. Contractors and subcontractor companies hold specialist competence within specific domains and are hired to provide various types of equipment, such as drilling equipment or valves, or specialist services in operation, such as cementing or drilling fluids. As a result, work processes in the petroleum industry are fragmented across a large number of companies with different areas of responsibility and varying levels of involvement. Outsourcing is undoubtedly an advantageous strategy in that it contributes to enhance performance by expanding the pool of available expertise, enabling organizations to become more competitive in an increasingly high-paced marked. However, an increase in the number of stakeholders also entails increased complexity and added possibilities of how human, technological and organizational components within the system can interact (Perrow, 1984, Rasmussen, 1997). This does not only have practical implications in terms of organization by placing greater demands on aspects such as communication and coordination of work processes, but may also have significant implications for safety. With multiple stakeholders that operate independently, yet interdependently, within their respective areas of expertise, it is challenging to maintain a complete understanding of what is going on. Accordingly, discovering and responding to safety threats becomes more challenging.

The Norwegian Petroleum industry is known to demonstrate enhanced focus on safety and invest significant effort towards strengthening collaboration and trust across actors in the industry. However, there seem to be less focus on understanding safety challenges that arise at the interfaces between collaborating companies. The developments we see in the industry in terms of increasingly demanding drilling conditions due to depleted oil fields and the onset of petroleum production in the Arctic, with more demanding weather and temperature conditions, inadequate infrastructure, and larger distances to onshore facilities (Petroleum Safety Authority Norway, 2012) calls for more complex and technologically advanced drilling operations in the future. Such conditions will require more in terms of cooperation between the companies involved, which means that interorganizational complexity can have consequences for how well

safety is managed. It is therefore important to gain more knowledge about the safety implications of interorganizational complexity.

The research project *Interorganizational complexity and risk of major accidents*, funded by the Research Council of Norway (Grant nr: 220798), was initiated to develop knowledge about the safety implications of interorganizational complexity in petroleum operations, focusing particularly on major accident risk. The main objective was to investigate how interorganizational complexity contributes to safety challenges, and explore and discuss how challenges can be reduced. The project was commenced in 2013, and completed in 2017. During this period of time, we have completed three studies exploring the influence of interorganizational complexity on safety from different angles. These include: a review of empirical literature addressing interorganizational safety challenges (Milch and Laumann, 2016), a qualitative study of safety challenges and practices that help manage interorganizational complexity on a Norwegian petroleum installation (Milch and Laumann, 2018; Milch and Laumann, 2017), and finally, a qualitative analysis of investigation reports, exploring the influence of interorganizational factors on incidents in the Norwegian petroleum industry (Milch and Laumann, submitted). In this paper, we present the main finding from the tree studies undertaken in this project and intend to discuss practical implications of the current project for the petroleum industry. In particular, we would like to discuss how the knowledge from this project can best be utilized and applied in the petroleum industry.

In this project, to explore the findings in a nuanced manner, we have employed different theoretical lenses that represent long-held views as well as more recent theoretical developments. These are: The High Reliability Organizations Perspective (Weick et al., 2008, Weick and Sutcliffe, 2007, Weick and Sutcliffe, 2015), Reason's perspective on organizational accidents (Reason, 1997) and the perspective of migration towards the boundary/drift into failure (Rasmussen, 1997, Dekker, 2012).

2 METHOD

Because of the sparsity of research within the field and the topic's complexity, we opted for a qualitative approach. Qualitative research is particularly suitable for investigating complex phenomenon, particularly in circumstances where prior knowledge is limited (Miles et al., 2014, Elliott et al., 1999, Silverman, 2006). To illuminate different angles, the studies in this research project draws on different sources of data. Study 1 is a literature review of empirical literature to identify interorganizational safety challenges (Milch and Laumann, 2016). The aim of this work was to get a sense of key challenges that can arise due to interorganizational complexity. A literature search was performed to identify empirical literature describing interorganizational issues that negatively influence safety. The search resulted in 22 articles, which shows that existing research on this topic is limited. In study 2, we explored how interorganizational complexity was managed on a Norwegian petroleum producing installation (Milch and Laumann, 2018; Milch and Laumann, 2017). The aim of the study was to gain a better understanding of the main safety challenges. In addition, we were interested in exploring practices that help manage interorganizational complexity. Semi-structured interviews with informants representing various affiliations and hierarchical positions were combined with observations on site and onshore, and analyses of relevant formal documents. In total, 14 interviews were conducted. In the third and final study, we investigated how interorganizational factors have contributed to accidents and incidents in the petroleum industry through examining investigation reports issued by the petroleum safety authority between 2006–2016 (Milch and Laumann, submitted). The aim of this study was to explore how interorganizational factors are related to incidents, and gain knowledge about of what factors contribute to unwanted occurrences. 22 reports were identified in which interorganizational issues could be linked to incidents and accidents.

In all three studies, data were analyzed using thematic analysis as described by Braun and Clarke (2006). Thematic analysis is a qualitative method used to identify overarching patterns or themes in the data. The analytical procedure consists of five recursive analytical phases. The first phase is simply familiarizing oneself with the content, reading through all of the material to get a sense of its main features. Following that, the material is coded, whereby the aspects of the material relevant to the research question are examined line-by-line, and smaller segments are given informative and short labels. The next phase involves actively searching for themes. Here, resulting codes are examined and compared and similar codes are clustered together to form candidate themes. The thematic structure at this point is not fixed, rather, the entire analytical process is one of constant comparison, in which the content of codes and themes are constantly compared against each other for deviations and adjusted accordingly. When a list of candidate themes has emerged, the next phase involves a more thorough review of the candidate themes to identify what themes represent main themes and what themes count as sub-themes. In the last phase, a final review is made before the thematic structure is finalized and a thematic map is developed.

3 RESEARCH FINDINGS

3.1 *Study 1*

The findings from this study show that safety challenges arising from interorganizational complexity falls into four categories: *economic pressures between companies, disorganization of work processes, dilution of competence* and *organizational differences* (Milch and Laumann, 2016).

The literature suggests that economic pressures between companies can be a source of safety issues. This is because stakeholders pursuing different and perhaps conflicting goals in addition to collective operational goals, contribute to goal conflicts for employees at the sharp-end and a fragmented overall safety focus. Moreover, due to the potential economic consequences of errors or accidents for individual companies, the focus on assigning blame amongst involved companies can often displace the focus on learning from what happened. Another aspect that becomes problematic when multiple companies are involved is the organization of work processes. Processes such as coordinating tasks and responsibilities and communication demands more effort the more interfaces that need to be managed. The literature indicates that interorganizational complexity often results in more disorganized and fragmented work processes. Findings also suggest that interorganizational complexity often contributes to reduced quality in available competence. Contractor employees, who spend shorter periods of time on the site, tend to be unfamiliar with the workplace, and can often be inexperienced and have little prior training. As such, they are not necessarily equipped with the knowledge to deal with unexpected safety-critical situations or may not be familiar with the hazards and safety constraints in the workplace. The final theme identified in the literature concerns organizational differences between collaborating companies as a source of safety issues. Collaborating companies can vary greatly in terms of organizational culture and work practices. Such variations can hinder efficient collaboration and a shared orientation towards operational goals. Moreover, organizational differences can also create conflicts and distrust between employees from different companies, which hinders open communication about safety issues.

The interorganizational issues that we found in this paper can in various ways impede the ability of the organizational system to identify and respond to safety treats, as they are associated with the development of latent conditions and fragmented operational focus. Therefore, challenges that arise from interorganizational complexity may increase the risk of major accidents.

3.2 *Study 2*

With regard to safety challenges, informants generally expressed few challenges with the interorganizational elements of their work. The perceived challenges largely reflect structural aspects relating to managing and organizing operational processes between involved companies. Coordination of work processes, information flow and varying levels of experience among contractor personnel were identified as the most important challenges (Milch and Laumann, 2018).

The study also identified several practices that help manage interorganizational complexity. Employees from collaborating companies do not necessarily form close collegial relationships, but still engage in close collaborations. As such, high-quality relations, underpinned by friendly interaction and mutual respect, was deemed crucial for maintaining well-functional collaboration across organizational boundaries. High-quality work relations appear to promote a shared focus on operational goals, and were also found to stimulate constructive and open communication about safety matters across organizational boundaries. Findings also suggest that long-term organizational relationships between collaborating companies, worker involvement and managers' interactive role in the sharp-end represent important organizational elements stimulating high-quality work relations in this context (Milch and Laumann, 2018; Milch and Laumann, 2017). In addition, the similarities found among companies in terms of safety philosophies and practices also appear to be important for aligning companies in their efforts to achieve collective operational goals. Moreover, similar safety practices and philosophies also appears to be conducive to reporting behavior, as employees from collaborating companies seem to have similar perceptions about safe operational conduct.

The findings show that high-quality work relations may be a particularly important element in the pursuit of achieving and sustaining safety across collaborating companies in an interorganizational context. Moreover, since many of the challenges identified in the literature was not identified in the current study, it could suggest that the presence of high-quality relations, combined with shared safety philosophies and practices across companies, may potentially counteract some of the safety challenges that have been found to arise in interorganizational collaborations.

3.3 *Study 3*

Findings show that interorganizational issues contribute to both occupational incidents and major near accidents. Four themes were identified that describe interorganizational factors contributing

to incidents: *Ambiguities in roles and responsibilities between personnel from different companies*, *Inadequate processes to ensure sufficient competence across interfaces*, *Inadequate quality control routines across organizational interfaces* and *communication breakdowns between companies* (Milch and Laumann, submitted).

Roles and responsibilities between personnel from collaborating companies were often insufficiently clarified, which resulted in confusion regarding what company or organizational unit was in charge of what. Such ambiguities had consequences in the form of disruptions in the follow-up of operational processes and had in some cases also resulted in omissions of safety-critical activities. Another interorganizational issue identified was inadequate processes to ensure sufficient competence across interfaces. In several of the reports, the lack of installation-specific training and experience in personnel, and particularly in contractor personnel, was identified as a contributing factor to sharp-end incidents. Moreover, failure to ensure sufficient competence in planning of safety-critical activities was also evident in serious near major accident, where relevant contractor personnel with key expertise had not been involved in planning.

The study also suggest inadequate quality control routines across organizational boundaries, contributed to incidents. This was identified as a problem in the handover of equipment delivered by third party companies, and also with assembled structures made up of components delivered from multiple companies.

Finally, communication breakdowns between companies were identified as challenge in the incident reports. Important information is lost or not communicated. A central issue in this regard is that companies fail to communicate experiences and lessons learned from previous incidents. This means that known problems and hazards are not sufficiently communicated between companies, resulting in the repeated occurrence of similar incidents.

The study demonstrates the relevance of including interorganizational factors in the investigation process. This is important not just from a preventative perspective by increasing the learning potential from investigation reports, but more attention towards interorganizational factors is equally important from a proactive perspective, in terms of making such issues more explicit and finding ways to cope.

4 DISCUSSION

The aim of the research project *Interorganisational complexity and risk of major accidents* has been to gain knowledge about safety implications of interorganizational complexity by investigating how interorganizational complexity contributes to safety challenges, and exploring and discussing how challenges can be reduced. The findings from this project offer several practical implications. In the following, we will address the project's main implications and discuss how the current findings can best be applied and utilized in the industry.

The industry demonstrates a strong safety focus and a lot of effort has been made to strengthen collaboration and trust across actors in the industry. However, there seems to have been limited focus on safety challenges that arise at the interfaces of companies. The findings from this study show that interorganizational complexity contributes to several safety challenges in the petroleum industry that can increase the risk of major accidents. Even though the occurrence of adverse events is rare in the industry, awareness concerning such issues is important. Knowing what to look for can increase the capacity of petroleum organizations to recognize and respond to weak signals before they develop into major accidents (Weick and Sutcliffe, 2007, Weick and Sutcliffe, 2015).

One area that appears to be challenging is successfully coordinating work processes between companies. The sheer number of interfaces that must to be coordinated on a petroleum producing installation, involving interfaces onshore/offshore, as well as interfaces between the operator company, the drilling contractor and various contractor and subcontractor companies require continuous effort, which makes it difficult to ensure sufficient information flow and maintain a complete overview of operational processes. The findings imply that misunderstandings and confusion regarding roles and areas of responsibility between companies can occur. This not only impedes the quality of monitoring and follow-up efforts, but can even lead to the omission of safety-critical activities. This is because companies are largely focused on their own areas of responsibility, and may be unaware of what the other companies are doing. As such, the negligence of important activities or tasks can go unnoticed. Such fragmentation can contribute to the build-up of latent conditions in the system, which in combination with triggering events can cause adverse events (Reason, 1997).

The coordination challenge that we find appears in some part related to lack of clarification about roles and responsibilities among companies before projects are commenced. Moreover, it was also found that formal documents describing the distribution of roles and responsibilities among companies were in some cases inaccurate or not up to date. This implies that operating companies in the Norwegian petroleum industry do not necessarily have

adequate routines to ensure that work processes are sufficiently clarified and understood across organizational boundaries. This might suggest that there is a need for better systems to achieve more successful coordination of organizational and operational processes between involved companies in the petroleum industry. In practice, this may require that more effort is made by companies to ensure that formal documents such as organizational maps and documents describing roles and responsibilities across companies are accurate and up to date, and consistent with how the work is actually organized among involved actors in practice. Following up on these aspects formally fall under the responsibility of the operator company, as the actor that manages the operational processes. However, it could be questioned whether it is reasonable to assume that operator companies are able to oversee and check that all these documents are up to date. According to Perrow (1984), maintaining centralized control is problematic with high degrees of complexity. In this regard, a more decentralized form of control may be appropriate for these processes, whereby each individual company is responsible to ensure that formal documents are up to date and roles and responsibilities are adequately described.

Another way to reduce ambiguities and confusion between companies is through initiatives to ameliorate current communication practices between companies in the industry. The industry may benefit from developing better communicational strategies to ensure that all parties have the same understanding of their roles and areas of responsibility. Research on teamwork has shown that the use of closed-loop communication, where the receiver communicates the message back to the communicator for confirmation, contributes to better team performance (Salas et al., 2005). Similarly, collaborative cross-checks, where employees with different perspectives actively discuss and explore each other's assumptions, appear to be a promising strategy in terms of making processes more observable among employees with different perspectives (Patterson et al., 2006).

The second challenge that we find is the failure of experience transfer related to lessons learned from incidents, known problems or sources of hazards and best practices among collaborating companies. The challenge with transferring experiences and learning from incidents is not a new one, and has been quite frequently debated in the industry. The Petroleum Safety Authority keeps asking, why aren't we learning? The current findings suggest that interorganizational complexity may be one part of the explanation. Learning must not only occur in one organization, but across multiple organizations that differ in their expertise and operational focus, and vary in degrees of involvement. Ensuring that lessons learned are absorbed equally in all involved companies can be challenging considering that companies focus on different operational domains, and the resources and time available to follow up on lessons learnt may vary. Another obvious issue is information overload. Experiences and lessons learned can easily be lost in the vast amount of information that is transferred between companies. With an ever growing information load, telling relevant information from noise can be difficult (Edmunds and Morris, 2000). There is no simple solution to this challenge. However, industry-wide cooperative initiatives such as "Safety forum" and "Working together for safety" have shown to be successful in terms of promoting openness and collaboration across companies in the industry about best practices and sharing experiences about safety issues (Haukelid, 2008, Wiig and Karlsen, 2006). Several informants in study 2 emphasized these forums as important arenas for experience transfer between companies. Accordingly, such collective arenas appear to be very fruitful for supporting experience transfer and learning across companies. The industry may benefit from developing these areas even further to facilitate learning across companies.

Ensuring sufficient levels of competence across companies also appear to be a challenge in petroleum operations. Findings from analyzing investigation reports suggest that the competence requirements for doing specific tasks or operating specific equipment are sometimes not met. Possible explanations may be that competence requirements are not sufficiently appreciated or understood, that competence requirements are not clear enough, but it could also be a matter of capacity. In study 2, some informants mentioned that lacking experience and training among contractor company personnel could be a problem in times of high activity, which would suggest that it is also related to availability. This was also identified as a challenge in a study that looked at safety issues related to capacity and competence in the Norwegian petroleum industry (Skarholt et al., 2014). In the investigation reports, there were several examples where new and inexperienced contractor personnel had been put to operate equipment that they were not trained to handle. This does not only increase the risk of erroneous handling of equipment, however, the presence of new and inexperienced personnel can constitute a risk in itself because such personnel will most likely be unaware of local conditions and hazards that can influence safety. Moreover, inexperienced personnel will have reduced capacity to improvise in unforeseen or unfamiliar situations.

Companies in the petroleum industry normally have a buddy system in which new personnel are appointed a "buddy" responsible for familiar-

izing them with the installation and with their work station. In the investigation reports, there were some indications to suggest that the buddy program on some installations had a more social focus, and did not sufficiently equip new personnel with relevant safety information. Moreover, there were indications that training programs in some cases were too general, and did not detail specific tasks or equipment. The level of specialization we see today, which will likely increase in the future, entails that expertise is key to safe performance (Weick and Sutcliffe, 2015, Weick and Sutcliffe, 2007). Ensuring safe operations require that employees have specific training and experience to perform their work tasks, so that they can recognize when something is wrong. In fact, the ability to track small failure has been identified as an important characteristic underlying the reliable and stable safety performance of high reliability organizations (Weick et al., 2008).

While the findings from this project points at areas in which interorganizational safety challenges occur, the current research also illuminate several factors that appear to be important to achieve and sustain safety across organizational boundaries. The findings suggest that inter-personal factors are central in this regard. The presence of high-quality work relations between employees from collaborating companies appear to contribute to strengthen a collective orientation towards operational goals as well as being conducive to open communication about safety related matters. By the majority of informants in study 2, high-quality relations were pointed out as an important ingredient for well-functioning collaboration with employees from collaborating companies. Because employees from collaborating companies do not necessarily form long-lasting collegial relationships, but still collaborate closely in safety-critical activities, the character of work-relationships can be crucial in terms of how well the collaboration will work. The emphasis on ensuring high-quality work relationships that we find in our research, appear to reflect the efforts in the industry the recent decades to improve safety culture and strengthen collaboration and trust between actors in the industry. This may suggests that initiatives directed towards promoting high-quality work relations across collaborating companies may be beneficial to enhance collaboration. However, cultural similarities may also be an important contributing factor in this regard as the majority of employees in the Norwegian petroleum industry share the same cultural background. With a high level of cultural diversity, it may be more challenging to form high-quality work relationships when employees have different cultural values and beliefs and speak different languages. We still do not know enough about the specific preconditions and factors that are central to forming high-quality work relations across organizational boundaries. More research is needed to further explore how high-quality relations are formed across collaborating companies.

With the current level of specialization of work among companies that we see in today's petroleum industry, middle managers seem to play an increasingly important role in terms of achieving a joint focus among involved companies towards mutual operational goals, but also for monitoring concurrent work processes. In particular, the interactive role managers have, spending a lot of time in the sharp-end, was regarded as an important element contributing to well-functioning collaborations. Middle-managers offshore saw it as the most important part of their work, and reported that being present in the field was important to build trust with personnel from various companies, and to get a sense of what was going on in the operation. Sharp-end workers emphasized that managers being present and approachable, eased bringing up safety-related matters. A potentially worrisome tendency in the petroleum industry is the increasing amount of paperwork required of middle managers. Informants with management responsibilities reported concern about the extent to which increasing amounts of paperwork ate away the time they could spend in the sharp end, and were worried about the safety effects this may have in the long run. Research has shown that managers play an important role in terms of shaping safety performance (Mearns et al., 2003, Flin, 2003). While increasing paperwork in many ways is the result of a stronger focus on documentation of safety-management in the industry, our findings suggest that this may have the opposite effect than intended, at the expense of activities that have important, but perhaps less obvious safety functions. Arguably, the safety functions embedded in middle-managers' interactive role in terms of managing interorganizational complexity appear to be important, but seem to be poorly understood.

5 CONCLUSION

The aim of this paper has been to present findings from the project "interorganizational complexity and risk of major accidents" and discuss how the implication from this project can be applied in the industry. Findings call for more awareness concerning interorganizational safety challenges in the industry, and points to specific areas in which challenges can arise. In particular, coordinating work processes, ensuring sufficient levels of competence and transferring lessons learned and best practices across companies are identified as areas

in which challenges can arise. However, the findings also suggest that interpersonal factors and the presence of high-quality work relations are important to achieve safety performance across collaborating companies. In this regard, middle managers appear to play a central role in aligning employees from collaborating companies towards a shared focus on operational and safety related goals.

False alarm? Effects of reducing unnecessary dispatches by fire and rescue services

C. Sesseng
RISE Fire Research AS, Norway

ABSTRACT: Fire and rescue services in Norway dispatch more often to false and unnecessary alarms than to real fires and accidents. In 2016, 60% of the emergency dispatches were conducted on the basis of false or unnecessary alarms. These unnecessary dispatches are costly in terms of time and resources spent, and can in some cases lead to a weakened preparedness towards real incidents. Also, the risk for traffic accidents increases when big vehicles rush through the streets on their way to where the alarm was triggered. Hence, there are good reasons to work to reduce the number of these kind of dispatches. On the other hand, one may also argue that there can be some positive effects of a certain number of mobilizations for the fire crews. Based on interviews with relevant actors connected to fire and rescue services, as well as on statistics collected through the BRIS reporting system, we will discuss possible consequences of reducing the number of false and unnecessary alarms and potential effects of implementing measures for decreasing unnecessary dispatches.

1 INTRODUCTION

Fire and rescue services in Norway more often dispatch to different types of false or unnecessary alarms than to real fires and accidents. In 2016, 59% of the emergency dispatches were conducted on the basis of false or unnecessary alarms (DSB 2017). The numbers are increasing, from 20 000 in 2013 to 50 000 in 2016. An interesting point is that the number of emergency dispatches conducted on the basis of false or unnecessary alarms varies a lot between different municipalities in Norway; some have 40% and some as high as 75% (numbers from 2010). There is currently little knowledge about why this is so.

Unnecessary dispatches are costly in terms of the time and resources spent, and can, in some cases, lead to a weakened preparedness towards real incidents. Also, the risk for traffic accidents increases when big rescue vehicles rush through the streets on their way to where the alarm was triggered. Hence, there are good reasons to work to reduce the number of these kind of dispatches. On the other hand, one may also argue that there can be some positive effects to be derived from a certain number of mobilisations for fire crews.

As a response to the increasing number of false alarms, several fire departments in Norway are seeking to develop measures to reduce these numbers. This includes different technical measures and operational measures, as well as fines for building owners. We will discuss the effects of these measures, both in terms of reducing the number of unnecessary and false alarms, but also in terms of how they may affect the overall safety.

This paper is based on interviews with firefighters and other relevant professionals, as well as on existing statistics and reports. We will discuss the effects of false alarms from an organizational perspective. We will also discuss DSB's (Directorate for Civil Protection and Emergency Planning) reporting system BRIS, which was introduced in 2015 and contains all assignments registered at the alarm centrals. With this data as a starting point, we discuss how projects to reduce the number of unnecessary dispatches may be designed in a directed manner, so as to retain the positive effects of these dispatches in terms of training and reduction of risk and avoid the negative effects of implemented measures in terms of the response to real events.

2 BACKGROUND

The following section will provide some facts about the background of the paper and the kind of information and data it is built upon. It will give the definitions of false alarms and unnecessary dispatches, describe the new reporting system BRIS and also describe the qualitative data collected in order to secure a deeper understanding of the data collected in the BRIS reporting system.

2.1 *Definitions and terms*

Several different terms and concepts are used to address the issue of unnecessary and false alarms. In English-language literature, it is more common to talk about 'false alarms' for all alarms resulting in unnecessary dispatches (Chagger and Smith 2014; Karter 2013). In Denmark, it is also common to use the term 'alarm', and not 'dispatches', but there they differ between 'false' and 'blind' alarms (blind alarms being the same as unnecessary alarms). In Norway, the use of the term 'false alarm' is considered imprecise, and it is recommended to distinguish between 'false alarms' (intended), and 'unnecessary alarms' (unintended). Since the term 'alarm' can result in some confusion, the preferred mode of referring to this issue in Norway is to talk about the need to reduce 'unnecessary dispatches'. Since fire brigades responds to all types of alarms, reduction of unnecessary dispatches must involve the reduction of both unnecessary and false alarms.

This paper, will mainly use the term 'unnecessary dispatches' when addressing this issue. We have also chosen to use the term 'dispatch' and not 'response'. The term 'response' covers a range of actions instigated because of an alarm, while we, in this paper, only want to concentrate on response dispatches—when fire and rescue services vehicles rush out due to an alarm. The common practice in Norway is for the alarm central to dispatch a basic fire response unit, a standard vehicle with four firefighters, who investigate an incident at site, irrespective of their expectations of whether the alarm is genuine or not.

Another term that will be used frequently is Automatic Fire Alarm systems, or AFA-systems. An AFA system is an installation comprising detector units connected to a central. This is in contrast to a smoke alarm, which is a standalone unit. The AFAs described in the current paper are also connected to an alarm central. In Norway, these alarm centrals are called '110-centrals', and their primary task is to address emergency messages for the fire and rescue services, alerting and calling out crews, establishing connections between relevant emergency actors and logging events. The AFA system immediately, or after some pre-set delay, transfers the alarm, which in turn leads to a dispatch from the local fire and rescue service. AFA-systems are mandatory in a number of buildings where there are many people, such as nursing homes, schools and public buildings. In addition, companies voluntarily choose to install AFA-systems that are directly connected to the alarm central.

2.2 *BRIS—Reporting system*

DSB, the Norwegian Directorate for Civil Protection, introduced the reporting system BRIS (acronym for the Norwegian words for Fire, Rescue, Reporting and Statistics) from the first of January 2016. BRIS is a national reporting system, gathering information about the Norwegian fire brigades' assignments. The overarching goal of this system is to give the fire brigade a good foundation for developing targeted measures in their preventive work, develop emergency work and increase data quality in order to give local and national decision makers a better knowledge base for learning and improvement. Another goal of the system is to ascertain a more suitable user interface that allows reporting to be conducted at the event site or in the fire truck on the way back to the station.

Over the last few years, DSB and the Norwegian fire brigade have become aware of the high and increasing number of false and unnecessary alarms which leads to unnecessary dispatches. With BRIS, they have attained better statistics and data on what causes these alarms. Still, there are issues to be sorted out in terms of data quality, as the BRIS data depends on the categorisation of dispatches, and, in this respect, there are some differences between fire departments and alarm centrals.

Later on, examples will be provided as to how fire brigades can use this data to develop measures to counter the increase of unnecessary dispatches.

2.3 *Data collection*

This paper employs statistics from BRIS which can tell us something about the situation of false and unnecessary alarms and unnecessary dispatches. In addition, from March till November 2017, we collected qualitative data in:

- one large fire brigade; 4 interviews (group and single) in emergency department, alarm centre (110-central) and preventive department,
- two small fire brigades; interviews with the two fire chiefs officers,
- one emergency exercise in a small fire brigade; observations,
- the work done by a project group in a large fire and rescue service, established for developing

measures for reducing the number of unnecessary dispatches; observations, discussions and document study.

This paper also builds upon the knowledge gained in earlier projects; on the organisation of Norwegian fire brigades, and on measure development for reducing the number of fatal fires amongst vulnerable groups (Fenstad et al, 2013; Storesund et al. 2015; Gjøsund et al. 2017; Gjøsund & Almklov 2016; Halvorsen et al. 2016).

3 UNNECESSARY DISPATCHES AND ITS CONSEQUENCES

3.1 *The situation in Norway*

Data from BRIS shows that 60% of the Norwegian fire brigade's dispatches are unnecessary. On average, fire brigades in Norway had 137 unnecessary dispatches each day. The number of emergency dispatches conducted on the basis of false or unnecessary alarms varies a lot between different municipalities in Norway. Some have a proportion of 40%, whereas others have a proportion as high as 75% (numbers from 2010). There is currently little knowledge about why this is so, but it could be due to variation in the number of buildings that are directly connected to the alarm central, or to emergency controllers having different formal procedures and different assessments of response to incoming alarms. Also, variations in the demographics, housing stock and municipal organisation may count for some of the variation.

Norway consists of more than 400 municipalities that range in population from 200 inhabitants to 650 000 (Oslo). These municipalities are highly diverse in terms of their demographic profile, organisational structure and available resources. Equally diverse are the fire and rescue services, in terms of ownership, management and organisation. Some municipalities own and run their own fire and rescue services, while others collaborate with neighbouring municipalities on all or parts of the services. Large fire brigades consist of mostly full-time employees, while the small fire brigades have mostly part time employees. There are 335 fire and rescue service brigades and 620 fire stations, but we see a trend for merging brigades in order to attain larger and more specialised services. In Norway, the fire and rescue service is the only emergency agency that is municipal. It has a higher density, clear demands to response times, and thereby exhibits shorter response times than the police and health service.

Most of the alarms resulting in unnecessary dispatches typically come from automatic fire alarm (AFA) systems going off due to different perturbations or errors, smoke detectors reacting to cooking, steam or dust, people triggering alarms by error, or, in some cases, intentional triggering. Not surprisingly there is a correlation between the size of the municipality in terms of number of inhabitants, and relative number of unnecessary alarms due to AFA-systems, and the main reason thereof is most likely that small places have fewer objects directly connected to the alarm central than larger places do.

3.2 *Comparison with Denmark*

In Denmark, they have a reporting system very much like BRIS. It is called ODIN (acronym of the Danish words Online Data Registration and Reporting System). The latest version, complete with a registration of information about AFA-systems, was released July 2015. This means that the first year of complete data is 2016, the same as in Norway. In Denmark, 44% of the dispatches were due to false or unnecessary alarms, and 42% out of all alarms came from AFA systems. Of these AFA alarms, only 9% were real, the rest were categorised as blind (or unnecessary). In 2016, there were dispatches to over 6000 addresses. 143 addresses had 2507 dispatches alone. This means that 2.3% of the addresses had 16.3% of all dispatches.

As in Norway, the blind alarms (or unnecessary dispatches) are unevenly distributed throughout the country. The variation is probably an expression of uneven distribution of institutions, and thereby buildings with AFA-systems, throughout the country (Beredskabsstyrelsen 2017). Not surprisingly, the amount of blind alarms from AFA-systems have also increased from 9 000 in 2007 to 15 500 in 2016. The interesting thing is that even if the absolute amount of blind alarms has increased, the relative amount of blind alarms has decreased, from 8 blind alarms in 2007 to 5.7 in 2016 out of 1000 detectors (Beredskabsstyrelsen 2017). This could mean that AFA-systems in general are more reliable than they were 10 years ago. We have not been able to find good data on how many AFA-systems are in use at any time in Norway, and how many of these are connected to an alarm central. (It may be possible to get approximate numbers by contacting all the alarm centrals in Norway, but his has not been part of the project's scope.) It is likely that there has been a relative decrease in the amount of unnecessary alarms from AFA-systems in Norway as well.

3.3 *Consequences of unnecessary dispatches*

The negative consequences of unnecessary dispatches are both well-known, as well as the background for trying to reduce the number of these dispatches. First of all, it is resource demanding, as an unnecessary dispatch takes a crew and a vehicle

away from other duties such as training, maintenance and makes them unavailable for other call-outs. In the case of part-time personnel, it also costs additional money, since the crew is paid extra for dispatches. There is also a direct risk connected with the traffic hazard posed by vehicles speeding with blue lights through traffic. A longer term negative effect is the possibility, and a concern noted by several of our informants, of a cry wolf effect, both in the sense of a delayed evacuation of the buildings concerned but also for the fire brigade. However, possible positive consequences of unnecessary dispatches have been very little discussed.

4 SOME FINDINGS IN NORWEGIAN FIRE BRIGADES

While it has been generally recognised that a large and increasing amount of the dispatches for the Norwegian Fire and Rescue services have been unnecessary, the introduction of the national BRIS database represented a stepwise change in the documentation of dispatches. In BRIS, all call outs from the alarm centrals are given a preliminary code by the operator, and are later given a final code by the responding unit. While there are limitations to this database as well, particularly when it comes to how to categorise the different dispatches (something we will discuss later on), it has laid the foundation for directed efforts to reduce the number of unnecessary dispatches, both at a national level and for individual fire services. The statistics clearly demonstrate that a majority of dispatches, particularly for urban fire brigades, are triggered by automatic detectors, and that in the vast majority of these cases there is no fire triggering them.

4.1 *Developing and implementing measures*

There have been increasing concerns in the fire community about unnecessary dispatches over the past years; however, it is after the implementation of BRIS that the reporting and the statistics have become more accurate, and it has been possible to attain facts about the actual causes of the unnecessary dispatches. Based on this data, the directorate of Civil Protection (DSB) has requested the local fire brigades to try to find ways to reduce these unnecessary dispatches, and several fire brigades have started this work. Since the complete BRIS-data is quite new, few measures have subsequently been implemented.

4.2 *Large fire and rescue services*

We know that a large fire and rescue service in a large city in Norway introduced an increase in the fines for unnecessary dispatches from 5500 to 8000 N.kr. They hoped this would motivate house owners to better maintain their alarm systems in order to reduce unnecessary alarms. After 8 months, there was no registered improvement, but they still hope for a long-term effect. There is however a fear that increasing fees may result in lower fire safety, which will be discussed later on.

Another big fire brigade in Norway appointed a project group to develop measures which would reduce the amount of unnecessary dispatches by 20% by the end of 2018. The average measure of unnecessary dispatches in Norway in 2016 was 59%, while the average for this fire brigade was as high as 64%. They had, in several real fires, experienced that persons living in the building did not evacuate or follow instructions because they had lost respect for fire alarms due to too many unnecessary alarms. Through BRIS-data, they found that they had dispatched almost 2400 times to unnecessary or false alarms throughout 2016, and that less than 10% of these dispatches were the result of false alarms. Further, they found that a majority of the unnecessary dispatches were to addresses with Automatic Fire Alarms (AFA). There were 532 unnecessary responses to only 63 addresses, between 5 and 28 dispatches to each address. They found that the most common causes for unnecessary dispatches were: wrong use or placement of detector (34%), technical or unknown error in the AFA-system (19%), intentional false alarm (11%), dust due to construction work (8%) and water steam (7.5%). The project group in this fire brigade therefor decided to concentrate on and target measures towards countering these worst cases, noting that, if they succeeded, a reduction in such cases alone would make them reach the target of 20% decrease in unnecessary dispatches. The project group developed targeted measures for reducing unnecessary dispatches. The three most important are: 1) The provision of information and guidance to house owners/residents on how to avoid unnecessary alarms, 2) Focus on unnecessary alarms under the fire and rescue services supervision of AFA-systems, and 3) Particular and direct follow-up on the worst cases.[1]

The tendency of there being a large amount of dispatches to a few addresses with AFA-systems installed is the same as that found in Denmark.

4.3 *Small fire and rescue services*

None of the small fire and rescue brigades we talked to had started to implement measures for reduc-

[1]These number and facts are taken from BRIS-database and from a presentation the mentioned project group held in Forum for Fire Safety in Trondheim, Norway, 14th of November 2017.

ing unnecessary dispatches. In contrast to the big fire and rescue services, they did not see the same need to reduce them. The main reason for this was that the total amount of alarms was not very high. When the total number of dispatches is low, smaller fire brigades do not get the same opportunity as large fire brigades to maintain their skills through dispatches. Since most of the firemen in the small brigades are part-time firefighters, unnecessary dispatches are an important part of their training, much more than for the full-time fire fighters who meet and train together each day. If the number of unnecessary dispatches were reduced, they were afraid that their skills would decrease. Part-time fire personnel can earn as little as 20 000 N.kr a year, even if it is a requirement that they have the same skills as full-time fire fighters. However, they earn extra pay for each dispatch. Even if it is an assumption that small fire brigades are reluctant to reduce the amount unnecessary dispatches because of the earnings, this was never mentioned as a reason by the small brigades.

The regulation of the dimensioning of the fire department scales the size of the brigade depending on the size of the population. Places/municipalities with less than 3000 inhabitants have small fire brigades consisting of part-time personnel without fixed schedules, while big cities only employ full time fire personnel. For the small fire brigades, it is very difficult to possess the same specialised knowledge and skill-set as the big fire and rescue services with full-time employees. But, one advantage that public services in small places have is their situated and local knowledge. Part-time fire personnel have knowledge about houses and people from their regular jobs, as well as through neighbours and friends living in the small place. They are very much aware of this advantage, and try to strengthen it. In the interviews, they said that the unnecessary dispatches are a valuable source for gaining an even deeper local knowledge of the special objects and people in their neighbourhood.

5 UNINTENDED IMPLICATIONS?

As we have seen, the overall goal for the Norwegian Directorate for Civil Protection (DSB) is to decrease the numbers of unnecessary dispatches. Also, for large fire and rescue services this is an explicit goal, and they have started to develop and implement measures in order to reduce these kinds of dispatches. There are, however, some questions that it is necessary to reflect upon when it comes to deciding which kind of dispatches are to be reduced, and also if some measures could have unintended negative consequences.

5.1 *The big increase and uncertainty in categorisation*

As mentioned, there has been a large increase in unnecessary dispatches in Norway, from 20 000 in 2013 to 50 000 in 2016. Differences in reporting practices are central in order to understand this increase and also the implications of reducing the unnecessary dispatches. It is reasonable to think of at least three reasons for the increase: 1) The increase correlates with the number of detectors connected to the alarm centrals, which explains the majority of the increase, 2) The introduction of the BRIS registration system has led to a more accurate and systematic registration of not only real alarms but also of the unnecessary alarms and dispatches, and 3) Those who register the dispatches in the BRIS system are uncertain of how to categorise them, and systematic biases can occur. E.g. there may be different assessments of whether an alarm is unnecessary when the alarm is the result of smoke related to making food. In interviews with firemen and employees at alarm centrals, we have been told that it can difficult to categorise borderline cases, and that systematic tendencies can occur in the reporting of such incidences. One concrete example concerns food making—if the dish is still edible, the dispatch is to be categorised as unnecessary, and if it is not possible to eat the food, the dispatch is to be categorised as necessary, even in cases where there is no fire, since it can be seen as a preventive dispatch. But who is to decide if the food is edible or not? Further, is the dispatch unnecessary if it prevented further development of the situation or if the dispatch reduced the probability for this kind of scenario happening again?

Since the complete BRIS-data is available only for 2016, it is not yet possible to determine how much of the increase in unnecessary dispatches is due to these different variables. In a few years, however, it will be possible to evaluate the numbers and variables available in this registration system.

5.2 *Possible positive consequences of unnecessary dispatches*

An important question to ask when considering measures to reduce the number of unnecessary dispatches is whether there are also some positive effects. In some cases, one may expect that a certain number of mobilisations can be useful for training fire crews. As long as the dispatches are not too repetitive, they may provide the organisation with important training and expose it to a variability of scenarios that strengthens its resilience beyond the limits of normal training procedures. This is especially important for smaller fire and rescue departments with part-time employees and few dispatches.

Since real fires are rare, everything they can learn about emergency preparedness and risk is considered useful, and the unnecessary dispatches are used in the mobilisation phase for training in basic skills and catching up with colleagues. In large fire and rescue services, on the other hand, where the employees are with their brigade each day, unnecessary dispatches are seen as disturbing. The positive effects of unnecessary dispatches are therefore more obvious in small, rather than in large brigades.

Also, many of the unnecessary alarms are triggered in buildings (such as care centres for the elderly) and areas where the fire risk is high, or where there are vulnerable groups, so the dispatch to these locations might provide useful knowledge for future scenarios. It might provide information regarding incumbent risk, as in Turner's (1976:381) "incubation period", strong or weak signals that might trigger pre-emptive measures, or other forms of learning for the fire department. As such, it might help the fire crews prepare for future genuine alarms and can also be a way to prevent false or unnecessary alarms in the future. It can also be considered as an exercise for people who have to evacuate buildings. Studies has shown a reduction in evacuation times through the repetition of evacuation drills (Hamilton et al. 2017).

Thus, though a dispatch may be unnecessary, seen as an isolated response, it might contribute to reducing risk in some ways, and in some cases. Measures towards reducing the numbers of unnecessary dispatches must be seen in the light of these possibilities for learning and risk reduction, as well as the cost and risk associated with the dispatches.

5.3 *Possible negative consequences of measures*

It is possible that measures implemented to reduce unnecessary dispatches may directly or indirectly harm the emergency preparedness or the response time to some types of fires. Fines may, for example, lower the threshold for disconnecting automatic sensors, or for not installing them in the first place. As mentioned above, if the measures are successful in buildings where there is a greater probability of a fire starting, like buildings housing vulnerable groups (Gjøsund et al. 2017), the measures for reducing unnecessary dispatches could indirectly result in the loss of valuable knowledge, possibilities to detect fire hazards and chances to suggest and implement fire preventive measures amongst vulnerable groups and exposed houses.

Because of the reporting system, BRIS, it has been possible to develop more appropriate and targeted measures for reducing unnecessary dispatches. Since the measures for large fire and rescue services are in an early phase, and because BRIS was implemented relatively recently, there are currently no clear results indicating the impact or the implications of the measures. What is certain is that the reporting system BRIS will be a useful tool when analysing the results and implications of the implemented measures.

6 CONCLUDING REMARKS

By developing measures, like those of the large fire brigades, which are directed towards the "worst cases" (i.e. those with several unnecessary alarms due to dysfunctional AFA-systems), the chance of succeeding is greater than if there were no such measures. It is also likely that this strategy for reducing unnecessary dispatches will have effects on the recurring incidents that will not give valuable knowledge, while the dispatches which can give valuable knowledge (for instance, about vulnerable groups or local and demographic knowledge) are more likely to persist.

One should not regard unnecessary dispatches as a homogenous category and implement measures blindly aimed at reducing the numbers. Rather, the detailed statistics of BRIS provide the opportunity for more targeted and more effective reduction measures, by which one can also avoid some possible pitfalls that might lead to an increase in overall risk. We have suggested two such categories: 1) Measures may lead to increased fire related risk if they lead to responses on the user side to reduce the number of alarms, for example by removing sensors altogether, by reducing their sensitivity or increasing the time before they are triggered, and 2) Measures may lead to a decrease in dispatches that are unnecessary in the sense of putting out an actual fire, but that may have other positive consequences in terms of training for the personnel, or as opportunities to obtain a better knowledge of vulnerable buildings.

Still, as our case study has shown, this leaves many unnecessary dispatches to be eliminated. The project we studied addressed frequently recurring dispatches to certain buildings in a targeted manner, dispatches that clearly did not fall under the categories where the side effects might be negative. In sum, then, we conclude that measures to reduce the number of unnecessary dispatches is important, but that they should be implemented based on a careful evaluation of the potential negative effects they may have. Evaluating the different categories of reported data in terms of the positive and negative effects that measures have on a total fire risk, regarding both the likelihood and consequences, is an important first step.

Role multiplexity and home-grown resilience: A study of part-time firefighters in rural emergency management

Petter G. Almklov
SINTEF Technology and Society, Norway
NTNU Social Research, Norway

Marie Nilsen & Gudveig Gjøsund
NTNU Social Research, Norway

ABSTRACT: We discuss the role of part-time firefighters as a resource for local emergency management in Norway. Informal social relations, the trust between practitioners and the social capital of the organization, has been recognized as a resource for emergency management, particularly as it contributes to improvisation and coordination between actors belonging to different professional groups. Likewise, social capital, the trust among citizens, has been identified as a resource for societal resilience in crises. We discuss a combination of these forms, how the social embeddedness of the emergency practitioners in the community and the multiplexity of roles is important for community resilience. These professionals know each other through several different social roles, and have resources beyond the formal capacities their position should suggest. Thus, role multiplexity and social networks provides a functional redundancy and is a resource for resilience in the management of incidents and emergencies. These abilities are hard to make visible in a work plan and challenging to include in exercises. Moreover, these abilities are affected by recent developments towards professionalization of and centralization.

1 INTRODUCTION

1.1 *Background of our study*

Based on studies of part-time firefighters we discuss how the combination of professional roles and embeddedness in the community of this group is a resource for community resilience. This is done through discussing how local knowledge, social capital and role multiplexity influences practice and decisions in emergencies.

Our paper supplements the literature on community resilience and emergency management by studying the role of a "hybrid" group. Their role as members of the community and their professional roles are both important parts of their capabilities in the prevention and management of emergencies.

We understand community resilience as the adaptive capacity of a community when faced with emergencies. Key elements of this are improvisation and redundancy (both in terms of resources and competence). This will be elaborated in the theory section.

What we describe here as role multiplexity is the fact that these professionals have different professional and social roles, that their "hat", or in the case of the firefighters, helmet, does not represent their only relevant role for the way they solve their tasks in emergencies.[1] Moreover, role multiplexity is an important contributing factor for the firefighters' local knowledge, a competency that is well-recognized in the emergency management community.

Thirdly, the notion of social capital is used to describe the networks of trust relations as a resource for coordination in emergencies.[2]

These characteristics, we will argue, have proven to be important in the management of several

[1]The notion of role multiplexity is inspired by sociological theory on modernity and bureaucracy. Whereas one individual in a bureaucratic organization has one role only, and thus uniplex relations to the ones he interacts with, in small scale communities most people have several relations to each other. (Durkheim discussed in Brøgger (1993: 26ff), see also Almklov et al, 2017).

[2]The individual sense of the term social capital is inextricably related to the works of Bourdieu (1986), viewing social capital as a source of power individuals possess and use to further their interest. The collective view on social capital is particularly associated with Robert Putnam (1995), viewing it more as a property of a group, a community or a society. We are here referring to the latter, as a descriptor of how trust based networks are resources for collective action.

emergencies in rural districts in Norway. Interestingly, they tend to elude description in formal documents, and thus risk being undermined by administrative reforms in the domain of societal safety and emergency preparedness, such as developments towards centralization and professionalization of the fire departments. Understanding and documenting the specific competence and community role of this group is important input to such processes.

1.2 *Part-time firefighters in Norway, ongoing changes*

Norway consists of more than 400 municipalities that range in population from 200 inhabitants to 650.000 (the capital, Oslo). The municipalities are highly diverse in terms of demographic profile, geography, size, organizational structure, and available resources. Equally diverse are the fire and rescue services, in terms of ownership, management, and organization. Some municipalities own and run their own fire and rescue services, while others collaborate with neighbouring municipalities either by having joint fire brigades or just in providing parts of the services. The fire departments and placement of fire stations are dimensioned after specific criteria for response times, leading to a relative high density of fire stations and shorter response times in most areas compared to other emergency services.

Whereas large fire brigades in cities and towns rely mostly on full time personnel, smaller fire brigades are largely dependent on personnel in different forms of part-time employment. For a large fraction of the latter, their regular payment only covers mandatory training and a small reimbursement for being on call, plus additional pay for dispatches. This means that they typically have full employment in other trades. The composition of the fire and rescue services in Norway today are roughly 3500 full time firefighters, and around 8000 part-time firefighters. In principle, the competence demands for part-time firefighters are supposed to be equivalent with the basic requirement for full time personnel. However, in terms of technical skills and training, they tend to lag behind these demands, while full time personnel on the other hand train and rehearse their skills way beyond them. Recruitment, both for full time and part-time personnel, has often sought people with relevant technical skills from other trades, such as carpenters, electricians and people with military training. For part-time personnel, an additional requirement is often that they live close to the fire station, to be able to mobilize quickly. In rural districts, farmers often make up a significant portion of the crew.

1.3 *Societal safety and emergency preparedness*

In Norway, the municipality has a key responsibility in terms of risk management and emergency preparedness. In principle, the municipality "owns" the total risk picture within its borders, and should have updated all hazards risk and vulnerability analyses and emergency plans. The responsibility for this in small municipalities is usually given to an emergency management coordinator, typically an official in the technical department of the municipality that has this as a fraction of their position. In terms of operative resources, the Fire and Rescue Service (FRS) is a crucial first line of response, but the emergency plans also include other municipal personnel, as well as external actors (volunteers, industry, municipal technical department etc.).

1.4 *The fire & rescue service, the only remaining generalists in local emergency management?*

Societal safety as a term and policy area came about after the end of the cold war. Gradually, the resources available for emergency preparedness in the public sector in Norway in particular, and in Western Europe more generally, have been reduced since then. Moreover, as measures have been implemented to make the public sector more effective and goal oriented, through outsourcing and market based restructuring, generalist capabilities and functional redundancy have systematically been reduced. Other operative capacities in the public sector are trimmed (army, home guard, publicly owned technical services such as roads, energy, port authorities). Within this picture, the FRS is one of very few remaining generalists with a substantial redundancy. A result of this has, according to our informants in the FRS, informants from other sectors and public reports (DSB, 2013, Øren et al. 2016) that the scope of tasks for the FRS is expanding.

In addition, in the rural areas, police services and emergency health services are generally sparse, so the FRS tend to be first on site for accidents and incidents of all sorts. This means that they sometimes must fill in for medical personnel or the police while waiting for ambulances and police patrols.

The FRS still put out fires, but increasingly they respond to other accidents (in particular traffic accidents) and other emergencies. Due to the reduced operative redundancy in the public sector generally they are becoming increasingly important as first responders to other forms of emergencies, such as landslides, floods and storms and search and rescue operations. For many areas, climate change leads to increases in flash floods and associated landslides as well as an increasing risk of forest fires.

Another important development for the FRS is the implementation of the joint communication network for emergency services in Norway called Nødnett (lit. "emergency net"). This means that all part-time firefighters have a communication radio at home, serving both as a call out terminal and as a communication tool in operations. Their training in using these is an important resource for the coordination in emergencies both for the FRS itself, but also as they may act as liaisons with other municipal professionals (Tilset et al. 2015). In some FRS, the firefighters are supposed to have the radio nearby at all times. These radios further integrate the FRS with other emergency services, as they may communicate in shared working groups with the police, health services and other relevant actors. The FRS are owned by the municipalities, but often, and to an increasing degree, they are parts of inter-municipal collaborative arrangements. It is an explicit national strategy to increase the size and professionality of the FRS, and there are several ongoing changes in the sector. Understanding the unique role and competencies of the part-time fire fighters will be important to ensure that these changes are successful.

2 THEORY

2.1 *Resilience and robustness*

Resilience is employed here to describe how an organization, community or society absorbs shocks and 'bounces back' after a disturbance (Boin & van Eeten 2013). Resilience has become a central concept in the safety theory the last decades. One early contribution was Wildavsky's (1987) insistence that a "search for safety" should go beyond trying to mend known weaknesses, by including a creative exploration of ways to improve society's ability to sustain new challenges. Also, the descriptions and analyses of High Reliability Organizations (LaPorte & Consolini 1991, Weick and Sutcliffe 1995, see also Roe and Schulman 2008) stressed that designing robust systems was only one step of the way to achieve high reliability, stressing the need for redundancy, flexible organizing and organizational mindfulness to be able to cope with variability. The most prominent theory on resilience within safety research is found in the "resilience engineering" strand of research, where an intense focus on the management and learning from variability as a resource for safety has been a cornerstone (Hollnagel et al. 2006).

Outside the safety literature, the concept of resilience has also been important in studies on a societal and community level (e.g. Boin & van Eeten 2013), then often referring to the community or society's ability to bounce back (or even forwards) when confronted by major disasters. The literature on community resilience is broad and diverse within several research fields. (See e.g. Norris et al. 2008 for some background). In contrast, Resilience Engineering focuses heavily on the importance of resilience as a way of avoiding accidents.

Based on a study of the response to the 9/11 terror, Kendra & Wachtendorf (2003) identify some characteristics of resilience. These are redundancy, resourcefulness, effective communication, and the capacity to self-organize, undeterred by extremely challenging circumstances. They point out that resilience is essentially a set of attitudes concerning expediency of actions and the propensity to acquiring new capabilities.

There is a big difference between a well laid out plan and a plan that is well played out. The former points to the ability to foresee and predict while the latter refers to the ability to act when the situation calls for the use of a plan. Plans cannot guarantee the success of how emergencies are handled. They can only provide the backbone of an emergency response. A common example employed to explain resilience is to compare hard wood to bamboo. The former is strong and does not easily break when it encounters strong winds. This is, of course, up to a certain threshold. The robust hardwood tree will eventually break if the wind blowing is at hurricane-strength. In comparison, the bamboo sways with the wind. It has the ability to bounce back into place. This ability to bounce back is what defines resilience. It is able to adapt. A plan cannot be made for every single possible emergency situation in a community. It is the ability to adapt the plan according to the situation as it unfolds which will help a community to bounce back after a disturbance (Boin & van Eeten 2013).

The part-time firefighters add flexibility in the community response to local emergencies. There are at least three aspects that contribute to this flexibility: the firefighters' diverse backgrounds and experience (providing a functional redundancy), their local knowledge and proximity to the hazards and, that they possess a rudimentary organizational structure and means for communication and their social embeddedness in the community (easing swift coordination with volunteers and other external resources). Interestingly there is a good overlap between these characteristics and those identified by Kendra & Wachtendorf (2003). Though this is interesting, one should also draw comparisons between such different contexts with caution.

2.2 *Role multiplexity, social capital and community resilience*

Part-time firefighters have many ties in the community. They are members of their local fire

brigade. They are parents of children attending the local school, a colleague in the municipal organization or electricians, plumber, factory workers or farmers. They may also be members of the sports clubs, hunting groups, health professionals, janitors or a loyal customer of the local grocery store. They have social relations throughout the community and local knowledge of threats and resources. The repeated interaction and networks built in their local community, over time, develops and strengthens their social capital. Social networks, reciprocity and interpersonal trust are aspects that are critical to building social capital (Patterson et al. 2010). Social capital and networks among citizens are recognized to be critical to disaster survival and recovery (Aldrich & Meyer 2015) on a societal level. Importantly, here we also include the networks that go between the response organizations and the community, and that criss-cross organizational boundaries in the community (Almklov et al. 2017).

Local knowledge is an important element in disaster management. For instance, it can help build resilience to flooding in local communities by providing local information on actual flood patterns, frequency, and risk perceptions in the community (Ramsey et al. 2016).

While bureaucratic organizations are built around uniplex roles, where the person is his role and that is the only relevant feature (see Almklov et al. 2017, Brøgger 1993). In practice, however, we see, particularly in small communities that there are spill-over effects from other roles that the emergency professionals have in the community, and that these are often key both in terms of establishing trust relations that go beyond the formal relations and also that the multiplexity of roles provides the individual with a functional redundancy, in terms of knowledge and capacities. In the empirical section, we will give some brief examples of this.

3 METHODS AND DATA

This paper is based on an aggregate of data from several projects inspecting the roles of municipal emergency preparedness and the organization of the FRS in Norway: A study with scenario analyses for the future organization of the FR services in Norway (Fenstad et al. 2013), a study of different approaches for intersectoral collaboration between the fire departments and municipal services in prevention of deadly fires (Gjøsund et al. 2016, Halvorsen et al. 2017), a study of the implementation of Nødnett in Norwegian municipalities (Tilset et al. 2014), a process analysis for a project to improve regional collaboration between large and small FR services in Western Norway (Gjøsund & Almklov, 2017), and a study of municipal emergency preparedness (Øren et al. 2016). All these projects have been based on interviews with firefighters and personnel that they interact with on a daily basis. While the scopes of these projects have been diverse, they have all contributed pieces to the puzzle regarding the role and qualities of part-time firefighters.

We have, for the purpose of writing this paper, conducted five directed interviews with key informants, two leaders and one firefighter at part time fire department and two with fire fighters in an urban fire department that has some part time personnel affiliated. We also conducted an observation study (with some informal discussions along the way) of a training session with a part-time FRS. During a one day visit (observation and interviews) in a regional dispatch central, our discussions included the capacities, call out procedures and response times of the part time FRS under their control, and also their typical assignments. In addition, we studied reports from a selection of recent emergencies in Norway.

4 EMPIRICAL EXAMPLES

In this section we give some examples from our data, supplemented with reports from recent emergencies, to illustrate how the role of municipal firefighters in contributing to community resilience can be characterized by the concepts of role multiplexity and social capital.

4.1 *Two illustrative examples*

One fire chief leading a fire brigade in two rural municipalities explicitly valued of the varied competencies of his crew. The long distances meant that his part-time firefighters had to mobilize for all sorts of accidents, and he had employed personnel that who's day jobs were in the medical sector, i.e. nurses, adding to their ability to respond to both medical emergencies and to take better care of elderly people in trouble. But also, other occupations had qualities he valued. He told us about an accident on a farm where an old farmer had fallen and had to be rescued from a silo by the fire department and be evacuated by helicopter. When the helicopter and ambulance had left and the firefighters were demobilizing and consoling the old man's wife, they heard the cattle were in distress. They had not yet been milked. His crew, consisting of several farmers, would not leave the site before milking the cows, he said. Farmers just don't leave cows in distress! This example might seem little relevant, too trivial, for grand discussions of emergency management. However, it illustrates how their knowledge and professional values from other occupations spill over into their role as firefighters.

Another example from the same fire department illustrated the role of local knowledge and role multiplexity. An avalanche had hit a road, blocking the road and possibly covering some cars. While the police's operational leader, formally in charge of the rescue operations, was speeding to the site from the closest (yet distant) city, the fire department was first on site, starting a search and rescue on their own initiative. The leader of the first vehicle, realizing that they needed equipment to search under the snow, went to his other workplace, a skiing facility, to pick up search and rescue gear there. Thus, the firefighters had mobilized the necessary equipment before the other services even reached the site, again because of the knowledge and access to resources provided by the firefighters' day-jobs. It also illustrates the make-do attitude and improvisational skills they have to their job.

4.2 *The fires of 2013*

Some very prominent examples in the recent discussions of part-time firefighters and municipal emergency manager's improvisational skills in Norway are the fires in 2013. That winter had had a very rare weather situation, with a very dry winter with little snow in the normally humid coastal areas, leading to bushfires in winter, and a major fire in the wooden town of Lærdal. All these fires were testing to the local fire departments ability to mobilize, organize and execute an efficient response, and in the aftermath their effectiveness has been subject to debate (See Andresen 2017, PWC 2014).

Even before the fire in Lærdal started some of the firefighters had concerns to the fire risk due to the combination of strong eastern winds and dry weather. Thus, there was already an increased awareness before the fire started. This is underscored by the fact that the municipality on earlier occasions had implemented fire watches when this weather combination occurred, so this type of weather in was a risk recognized by the locals (Andresen 2017).

When the firefighters mobilized, the response had a very improvised nature, seamlessly integrating volunteers (such as farmers with manure spreaders) in the response. As many firefighters were municipal employees, they also had good knowledge of available resources, such as access to the waterworks (to get pumps started when the electricity failed) and equipment. When telecomservices and electricity was lost, coordination was done by improvised means. Evacuation was greatly helped by the firefighters' and volunteers' knowledge of where vulnerable people lived.

The response was improvised and organic. Representatives from the larger fire brigades that eventually assisted the firefighting, and the national fire authority (DSB), noted the lack of organization as a shortcoming, while the local community highlight the effectiveness in the improvised response. Both views have some have support in the eventual investigations. The initial response was clearly effective, and several problems were solved in creative ways, but as the fire grew and as more and more resources arrived and needed to be coordinated (without effective means of communication as the Nødnett broke down), the coordination based on local knowledge and social networks became less efficient.

The response to the Lærdal fire clearly shows how part-time firefighters may act as an integrated part of a closely-knit community, and how their role multiplexity and social embeddedness in the community proved invaluable resources for their response. However, it also shows that this mode of organizing has shortcomings in terms of tactical leadership and coordination of resources when the control span grows.

Similarly, an external evaluation of the response to the bushfire in Flatanger the same winter pointed to a deficient plan compensated by good local knowledge and well-oiled collaboration machinery in the region. According to the investigation report, the crew exhibited their willingness to go beyond what was expected of them despite the notably harsh conditions. Some of the firefighters even lost their homes while extinguishing fire to save other people's homes (PWC 2014:51).

4.3 *Responses to other emergencies*

An ever more common type of emergency in Norway the last decades are seasonal floods and flash floods, and water induced landslides. (DSB 2013, Fenstad et al. 2013) In particular flash floods and water induced landslides are commonly associated with climate change, as this leads to more intense precipitation.

In rural communities, the combination of part-time firefighters and volunteers (farmers and others with access to machinery) are the core first responders to such events. Again, the personal networks and role-multiplexity of firefighters and municipal employees, provide a combination of a rudimentary organization and access to resources beyond the standard gear possessed by the fire department. Moreover, floods and landslides are events that typically happen on locations that are known by the locals to be risky, so local knowledge is important both in prevention and response. During floods, the local fire department usually assists in pumping out water that has flooded buildings. Knocking from door-to-door, firefighters also often perform the task of informing the locals of possible flooding in the area, and hazards

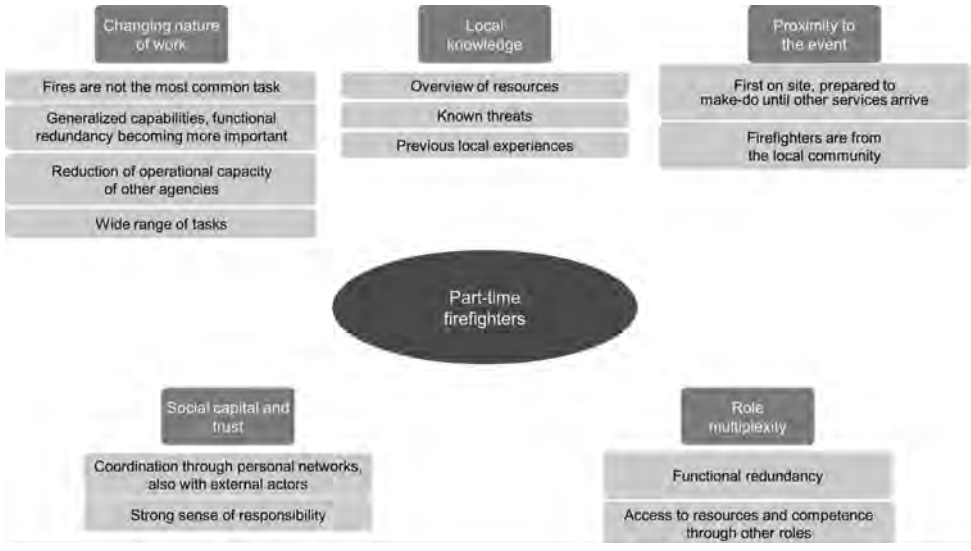

Figure 1. Summary of our description of the characteristics of the part time firefighters.

posed by landslides. The FRS also clears out trees that may pose a risk to the public or impede traffic. Other examples of notable cases of the rural fire department's new challenges is the 2013 triple murder in on a regional bus in Årdal. There, the fire department, together with ambulance personnel, managed to keep the perpetrator under control while the police response was severely delayed. In September 2011, a train at Rørosbanen was derailed. The first emergency personnel to arrive on the scene was the local part-time FRS. They started the evacuation of injured passengers and cared for them until the paramedics arrived. They also cleared out an evacuation path and organized an assembly point where the evacuated passengers were registered before they were allowed to leave the area.

The cases here illustrate some of the variation and complexity of the tasks facing these fire and rescue workers. City firefighters face some of the same complexity, but they have more support from police and health services and other professionals and experts. This difference is also a source of the respect city firefighters have for part time crews. The demands for generalist competencies are higher for the part time crews. The part time personnel are sometimes (incorrectly) referred to as volunteer firefighters, but their response is based on a rudimentary organizational structure and basic training, and it is also better integrated with more professional responders than most volunteers. In a discussion of volunteers' response to the large storms in the southern US (Katrina and Harvey), Wachtendorf & Kendra (2017) stress the importance of such coordination for the efficiency of volunteer responses. Though the part time FRS are not volunteers in the strict sense of the word, the part time FRS can be regarded as a hybrid form of response, connecting the volunteer community and official response to events.

5 DISCUSSION

5.1 *Are part-time firefighters only part firefighters, or do they bring some unique resources to the table?*

Based on our studies in different fire departments in Norway, it is clear that the part-time firefighters are less skilled and have less training for advanced firefighting than their full-time counterparts. The part-time fire departments also have shortcomings on formal communication procedures and on the management side, particularly when faced with larger incidents requiring coordination outside of their personal networks.

One should be very surprised if this was not the case that these firefighters lacked some skills, as they have highly limited time for courses and training. This is also noted in the national "Fire Study" (DSB, 2013). They also lack resources in terms of equipment, and several firefighters lack formal qualifications. Moreover, due to the low frequency of call outs, many of them struggle to gain practical experience with firefighting. There is no shortage of problems in these fire departments. Notorious underfunding has also led to some FRS

operating antiquated vehicles. Still, when we talk with full time firefighters and other professionals in the emergency community, they generally have great respect for the part-time crews for their general skills and for their ability to solve their tasks. One city fireman described how impressed he was by a nearby part-time FRS near an accident-ridden highway, how they responded quickly to horrible accidents, and how they on their own initiative had started taking first aid courses as a response to the slow response of the ambulances in that area. Their high motivation, and sense of responsibility was generally recognized by several of our informants.

The part-time firefighters are seen, by full-time firefighters, as generalists with improvisation skills based on their additional occupations. Also, the full-time fire departments have traditionally strived for this quality, by actively recruiting people with a variety of professional backgrounds, but this is even more pronounced in the part-time corps. Their local knowledge (of terrain, threats, resources, people and buildings) and embeddedness in the social fabric of the community is important for their ability to respond to emergencies, and their day job is sometimes an important resource.

As professional firefighters, they are inferior to the well drilled crews that practice every day, but they have other qualities that should not be underestimated, and that should be evaluated in the larger context of societal safety and community resilience, not only as actual fire fighting, which is only a minor part of their task portfolio.

5.2 *Role multiplexity and part-time resilience*

The fire-department in general, and the rural ones in particular, are organic parts of their communities. The qualities of the part-time firefighters that we have discussed here are important parts of what we have labeled community resilience. Their social relations in the community make them more effective than their fractions of positions may suggest, and they make up a critical part of the local communities' ability to withstand and respond to emergencies of a highly varied nature. We introduced two sociological explanations for this:

Role multiplexity: They have many hats, many forms of competence which give them a broad skill-set, competence and access to resources when faced with novel situations. In particular professional roles such as jobs in the municipality's technical services, farmers, carpenters or medical professions gives highly valued additional competencies.

Social capital: They have social networks, trust relations, that can be very useful for coordination in emergencies, and also for mobilizing equipment and resources. This also contributes to high motivation. Informants throughout the sector are clear that the economic incentives, the paycheck, is not the primary motivation for most of the firefighters. Rather, it is the sense of doing an important job for the community that is the main motivation for most.

6 CONCLUSION

One conclusion, not a very daring one, is that we (researchers and especially policy makers) need to know more about the specific role of these firefighters as Norway is about to restructure our fire departments. They might not be as competent as full-time fire fighters, but they are different and fill other roles and are organically involved in community preparedness and response. From a societal safety perspective, the part-time fire fighters are possibly the most cost-efficient operative emergency management resource in Norway.[3]

Beyond the discussion of firefighters in Norway, our paper emphasizes the importance of role multiplexity and social capital in the management of societal emergencies. Part time firefigthers are not volunteers in the traditional sense but not fully professional actors either. For effective emergency management, they represent an important hybrid resource as they both possess rudimentary means in terms of coordination, communication (most importantly by being equipped with and trained to use radio communication terminals) and leadership while simultaneously being well engrained in the social fabric of the communities they serve.

Reorganization and downsizing in the petroleum sector

L.I.V. Bergh, R. Høydal & J.E. Tharaldsen
Petroleum Safety Authority Norway, Norway

C. Aagestad & T. Sterud
STAMI—The National Institute of Occupational Health, Norway

ABSTRACT: In the petroleum sector low oil prices, high cost pressures and rapid technological development have led to higher demands for cost reductions, reorganisations and employee downsizing. The aim of this paper was to: 1) Assess trends and development related to reorganisations, downsizing, job insecurity, psychosocial factors and safety climate from 2013–2015; 2) Explore the correlation between reorganisations, downsizing and psychosocial factors, safety climate and occupational injury in 2015. The study is based on cross-sectional survey data collected every 2nd year, involving all offshore and land based personnel in the petroleum sector. Results show that employees have experienced an increase in reorganisations, downsizing and job insecurity in the period 2013–2015. Furthermore, the results show that employees who have experienced reorganisation and downsizing report higher risk of occupational injuries, poorer safety climate and psychosocial work environment, compared to employees who do not report such changes. The analyses also indicate that the higher risk of injuries reported by those who have been affected by downsizing and reorganisation may be associated with a poorer safety climate and psychosocial work environment.

1 INTRODUCTION

Over the years' significant changes have taken place in the petroleum industry. Technological changes and fluctuations in market dynamics have caused demands for cost reductions, organisational restructuring and downsizing (PSA 2017a, ILO 2013). Organisational changes at the workplace is a wide-ranging concept which often have implications for the way work is designed, organized and managed, also referred to as psychosocial work environment (Leka & Jain 2010). Over the years, a growing amount of research has explored the link between psychosocial and organisational factors and incidents in the petroleum industry (Bergh et al., 2014, Cricthon 2005, Mathisen & Bergh 2016, Olsen et al. 2015, Kongsvik et al. 2011).

Organisational change that influences the employees' job situation and involve modifications of the core system of an organization, including values, work practices, organizational structure and strategy, are likely to affect employees' well-being more than less-pervasive changes (Bamberger et al. 2012). Among the most dramatic organisational changes are restructuring, because these type of processes may involve aspects such as relocations, offshoring, closure, mergers/acquisition, outsourcing and internal restructuring including downsizing (Eurofound 2014, Mathisen et al. 2016). A review study performed by Quinlan and Bohle (2009) found that downsizing was associated with job insecurity and negative impact on health and safety. Furthermore, organisational change processes have been regarded as an important aspect in accident investigations, and might be highly relevant to the level of both process and worker safety (Baker, 2007; Grote, 2008). However, research on the relationship between organisational change processes, such as restructuring and downsizing, and risk of major accident is still limited (Grote, 2008; Koukoulaki 2009, Lofquist 2008).

Changes in the work environment are an everyday reality in the petroleum industry, partly due to demands for efficiency and cost-reductions. Development in knowledge, technology, and society brings about unavoidable changes in our working practices and experiences. Based on what we know from research, there is reason to assume that these changes can lead to increased risk level in the petroleum industry. It is important to understand the impact of the changes, which furthermore enable us to implement appropriate actions to respond and adapt appropriately to these changes, learning from experiences. The RNNP questionnaire survey is a data source that can help to highlight key issues related to these concerns.

In light of this, this study assessed the impact of organisational changes on psychosocial work

environment, safety, health and occupational injuries develop in the petroleum industry. To explore this topic the results from the RNNP survey (Trends in risk level in the petroleum activity) was utilized to:

1. Assess trends and development related to reorganizations, downsizing, job insecurity, psychosocial factors and safety climate from 2013–2015.
2. Explore the correlation between reorganizations, downsizing and psychosocial factors, safety climate and occupational injury in 2015.

2 METHOD

2.1 *Sample and measures*

This study utilized survey data from personnel on offshore facilities on the Norwegian Continental Shelf (NCS) and onshore installations, covering all employees offshore and onshore in the petroleum industry. The RNNP questionnaire-based survey is conducted as a cross-sectional study every other year, for the first time in 2001 and most recently in 2015. The analyses in our study are based on data from 2013–2015 with a response rate in 2015 of 27% for onshore installations and 29.7% for offshore facilities (PSA, 2016a). In spite of a rather low response rate, from year to year the sample is relatively stable over a range of variables such as gender, age, facility, the area of work, ratio between operators and entrepreneurs, permanent and temporary employees and proportion with managerial responsibilities. The RNNP data provide a good comparative basis for survey analyses from year to year. The large number of responders in the survey contributes to make the results more robust. It should be noted that the regression analysis used data from the last offshore surveys in 2015 (n = 8509).

The analyses included indicators related to reorganization, downsizing, job insecurity psychosocial factors and safety climate (RNNP, 2016). The following item measured reorganizations: "During the last year, have you experienced reorganisations that affect the way you plan and/or carry out your work on the facility?". The response scale for this item were: "Yes" or "No". Furthermore, the following item measured downsizing: "During the last year, has your workplace been subjected to workforce reductions or redundancies?". The answer categories were: "I have experienced reorganisations with significant consequences" to "I have not experienced reorganisations".

Based on the results from a factor analysis described in the RNNP-report from 2014, four factors that measure the psychosocial work environment were established. The psychosocial work environment dimensions measures employee's subjective experience of job demands, job control, supporting leadership and supporting colleges and was measured with five scales. *Job demands* was measured with the three items ($\alpha = 0.65$). *Job control* was measured with three items ($\alpha = 0.77$). *Supportive leadership* was measured with the three items ($\alpha = 0.76$). Finally, social support from colleague was measured with two items ($\alpha = 0.62$).

The answer categories were: "Very rarely or Never" to "Very often or always". The mean scale score was converted into three categories: Low (1.0–2,0), medium (2.1–3.0) and high (3.1–5.0). By dichotomizing job control (low = 1, medium and high = 0) and quantitative demands (high = 1, medium and low = 0), we constructed a job strain variable of the combination of low job control and high job demands (yes = 1, no = 0). All variables were coded so that high exposures indicate assumed negative exposure such as high job demands, low job control, low supportive leadership, and low support from colleagues.

Safety climate was measured by using an index consisting of 11 items divided into three dimensions. The items are described in greater detail in (Birkeland, et al, 2013; Tharaldsen, et al, 2008). These dimensions measure the employee's assessment of: 1) *Individual intentions and motivation* ($\alpha = 0{,}73$) 2) The *management's prioritization* of safety ($\alpha = 0{,}73$) and 3) *Safety routines* ($\alpha = 0{,}74$). The response scale for each item was: "Fully agree" "Partially agree" "Neither agree nor disagree" "Partially disagree" "Fully disagree". The statements are both positive and negative. The scales are therefore reversed on some of the items and higher value indicates a poorer safety climate. The mean scale score of the 11 items was converted into three categories: Good (1–1.53), medium (1.54–2.04) and poor (2.05–5). The cut-off point (2.05) for being included in the "poor category" is the 66.66 percentile. That is, respondents who are among the third with the highest score on the index in the 2015-material are included in the poor category. The cut-off point in 2015 is as such set as a reference. In addition, occupational injuries were measured with a single item "Have you been injured in a work accident while at the facility during the last year?". For further information about the items can be found online in the RNNP summery report (RNNP, 2016a).

2.2 *Analysis*

We used the chi-square tests to determine whether there were significant changes in the levels of reorganization, downsizing, job insecurity, psychosocial factors, safety climate and occupational injuries in offshore facilities in the period 2013–2015.

RNNP data from 2015 were used to compare psychosocial factors, safety climate and occupational injuries between employees reporting downsizing and reorganizations and employees not reporting such changes in the petroleum industry (offshore and onshore facilities). For the trend analyses data from the offshore population was utilized. Furthermore, for the multiple logistic regression analysis both the offshore and onshore data was assessed. Associations between reorganization or downsizing and work injuries were calculated as the odds ratio (OR) and 95% confidence interval (95% CI). Statistical analyses were conducted using SPSS Statistics for windows version 23.0 (IBM Corporation, Armonk, NY, USA).

3 RESULTS

3.1 *Reorganizations and downsizing*

Reorganization and downsizing vary over time, however results from this study show that there has been a considerable increase in the proportion of employees who have experienced reorganizations, downsizing and job insecurity in the period 2013–2015 (Table 1). Results show similar development for the operators, entrepreneurs and the mobile facilities.

3.2 *Psychosocial work environment, safety climate and occupational injuries*

The trend analyses for 2013–2015 show a significant change in employees who report increased levels of job demands (19% to 22%) low job control (10% to 12%) and the combination of high job demand and low job control (4,3% to 5,6%), in the industry as a whole. If we look further into offshore facilities (Table 1), we see that between 2013 and 2015, there is a significant change in the percentage reporting low job control among entrepreneurs (6.8% to 9.8%). However, among operators, no change is observed in the same period, and about 10% report low job control in 2015 (Table 1). Table 1 show a significant change among entrepreneurs with regards to high job demands (16% to 20%). While for employees working for operators, no change is observed in the same period. Furthermore, entrepreneurs also report a significant change related to the combination of high job demands and low job control (2.8% to 5.4%). At the same time, no change is observed among operators. There are no significant changes in the prevalence of low supportive leadership and low colleague support among operators, entrepreneurs and among workers on mobile facilities. However, it should be noted that operators report lower leadership support then entrepreneurs and workers at mobile facilities. There are however only smaller differences in the psychosocial working environment for entrepreneurs and operators on offshore facilities in 2015. As such, there are few changes in the psychosocial working environment on offshore facilities overall, but in the period 2013–2015, a deterioration of the psychosocial work environment is observed among entrepreneurs and workplaces with a large number of entrepreneurs. Table 1 show that the proportion of employees reporting poor safety climate (see description) decreased overall until 2013, while there was a significant increase in 2013–2015 among entrepreneurs (30% to 36%) and operators (from 34% to 38%) on offshore facilities. A similar change is however not observed for employees on mobile facilities (27% to 28%). In the period 2013–2015 no significant changes in occupational injuries were

Table 1. Change in reorganization, downsizing, psychosocial factors, safety climate and occupational injuries 2013–2015, offshore facilities (2013 n = 7952/2015 n = 6675).

	Operators		Entrepreneurs		Mobile facilities	
	2013	2015	2013	2015	2013	2015
Downsizing	17.0	67.4***	35.7	79.0***	5.0	77.0***
Reorganization	40.3	51.2***	31.5	47.3***	24.4	44.6***
Job insecurity	7.2	12.2***	9.0	33.2***	4.5	40.4***
High Job-demand	20.9	20.9	15.5	20.4***	19.2	24.7***
Low Job-control	10.0	10.9	6.8	9.8***	11.0	13.8*
Job strain	5.2	5.0	2.8	5.4***	4.0	6.7***
Low supportive leadership	21.3	22.6	14.1	14.8	14.3	15.8
Low colleague-support	3.2	3.5	2.9	2.8	3.0	3.6
Poor safety climate	34.4	38.1*	29.9	35.7***	27.1	28.4

*P ≤ 0.005; **P ≤ 0.01; ***P ≤ 0.001.

reported among entrepreneurs and operators, but a significant reduction in injuries was found among employees on mobile facilities (Table 1).

3.3 *Reorganization, downsizing and occupational injuries*

In total, 4.1% (246/5977) of employees in the petroleum industry (offshore and onshore facilities) experienced downsizing and 2.8% (61/2159) not experiencing downsizing reported occupational injuries. In total, 4.4%, (175/3939) experienced reorganization and 3.1% (130/4163) not experiencing reorganizations reported occupational injuries.

Employees reporting reorganization or downsizing reported also a significant higher prevalence for all psychosocial exposures and poor safety climate with the exception for low colleague support compared to employees not reporting such changes (Table 2).

3.4 *Logistic regression analysis*

A logistic regression analysis were conducted to examine if downsizing and reorganizations are associated with an increased risk of occupational injuries, and to examine whether this association may be mediated by psychosocial factors. In the initial model (adjusted for age, gender and education) employees who had experienced downsizing had a significantly higher risk of occupational injuries compared with employees not affected by downsizing (OR = 1.54; 95% CI 1.14–2.06) (Table 3) Adjusting for psychosocial factors and safety climate reduced the OR by 44%. The most important factor was safety climate.

Table 2. Description of occupational injuries and explanatory variables for employees in the petroleum industry (n = 8102).

	Reorganization			Downsizing		
	Yes	No	p-value[a]	Yes	No	p-value[a]
Job insecurity	29.9	22.2	0.000	29.7	16.1	0.000

Low Job control	1.38 (1.09–1.75)	–0.17
Low Supportive leadership	1.35 (1.07–1.72)	–0.23
Low collegue support	1.38 (1.09–1.75)	–0.17
Poor safety climate	1.25 (0.98–1.57)	–0.46
All factors included	1.13 (0.88–1.44)	–0.72

[a]Adjusted for age, gender, education.
[b]Number of respondents (cases of injuries).
[c]Percentage change in OR after comparing the initial OR with further adjusted OR (i.e., the initial OR adjusted for work-related factors).
[d]p = 0.002.

The same procedure was applied when analysing the association between reorganizations and the risk of occupational injury, and to determine if this association may be mediated by psychosocial working conditions and safety climate. In the initial model (adjusted for age, gender and education) employees who had experienced reorganizations had a significantly higher risk of occupational injuries compared to employees not affected by reorganizations (OR = 1.46; 95% CI 1.15–1.84) (Table 4) Adjusting for psychosocial factors and safety climate reduced the OR by 72%. The most important factor was safety climate.

4 DISCUSSION

Our study set out to explore whether exposure to downsizing and reorganization increase the risk of occupational injuries and to test whether the association between downsizing, reorganizations occupational injury may be mediated by psychosocial working conditions and safety climate. As expected, the results showed that employees in the petroleum industry report a considerable increase in reorganizations, downsizing and job insecurity in the period 2013–2015. In the same period, significant changes in the psychosocial work environment offshore are observed among entrepreneurs and among employees on mobile facilities but not among employees working for operating companies. In terms of safety climate items, a deterioration on production facilities is observed, but not among employees on mobile facilities, and during the same period there have been minor changes in the occurrence of self-reported injuries.

The analysis also indicate that a higher risk of injuries is reported by those who have experienced reorganizations and downsizing and that is again associated with a poorer safety climate and psychosocial work environment. The results show that employees who have experienced reorganization and downsizing report higher risk of injuries, poorer safety and psychosocial work environment compared to employees who do not report such changes. Organizational changes, such as restructurings involving issues such as relocations, offshoring, closure, mergers/acquisitions, outsourcing, and internal restructuring including downsizing (Eurofound 2014) have been found to be linked to of ill-health as well as incidents (de Jong et al., 2016, Serck-Hanssen 2002).

Overall, the changes in the psychosocial working environment appear to be somewhat more pronounced on mobile facilities and may be seen in the context of ongoing change processes. Looking at the differences between operators, entrepreneurs and mobile facilities it might be argued that employees from operating companies does not show a negative development with regards to psychosocial risk and safety climate because they have not been affected by change in the same time period. Operating companies are now moving into a period with more organisational changes being implemented, which might have implications for psychosocial and organisational factors such as job demands, job control, leadership support and social support. Research have found that psychosocial

risks factors, such as high workload, inadequate resources, increased time pressure, staff conflicts and lower levels of autonomy or loss of job control may be exacerbated as a result of organisational change (Leiter & Maslach 2009, Rafferty and Griffin 2006, Rabatin et al. 2015, Day Crown and Ivany 2016). As such, performing the same analysis for the upcoming RNNP survey in 2017 might shed some light on this particular issue.

4.1 *Strengths and limitations*

This study is cross-sectional and provide a snapshot of a particular group at a given time. In research, cross-sectional studies are used in order to determine prevalence. Cross sectional studies are the best way to determine prevalence and are useful at identifying associations that can then be more rigorously studied using a cohort study or randomized controlled study (Mann 2003). As such, this may limit the ability to draw firm conclusions about relationships observed between exposure (for example, downsizing and reorganization) and outcomes (for example, occupational injuries), and the extent to which exposure precedes outcome (for example, occupational injuries) in time. Given that the data was cross sectional, we cannot draw conclusions about causal relationships. Thus, there is a possibility that those who have been injured during the reorganization are somewhat more "negative" when they answer the survey or that the changes have more and more affected groups that initially reported poorer psychosocial work environment and safety. However, it is important to note that research over at least the last decade, including longitudinal studies, has shown that psychosocial hazards can have a negative impact on health and safety (Leka & Jain 2010, Mackey, Palverman Saul et al. 2012). Another important limitation is that those who are absent from work due to sickness, health complaints or injury during the survey are not included in the data. As such, studying potential consequences of downsizing or termination of employment is difficult, because those who has been terminated are not included in the data. In other words, those remaining after the downsizing processes are those included in the data.

A strength of this study is that the questionnaire survey contains questions that cover many background variables that can be explored in relationship to downsizing, reorganization and HSE outcomes. The sample is also large enough to permit analyses of different sub-groups of employees, i.e. employees in different areas of work and job categories, and in risk groups defined in the RNNP report from 2014. It is also important to note that research over at least the last decade, including longitudinal studies, has shown that psychosocial hazards can have a negative impact on health and safety at the workplace. In the way forward these analysis should be replicated in order to explore whether the changes the industry are currently undergoing will have a more pronounced long-term effect on psychosocial work environment and safety climate.

4.2 *Implications for follow-up of the industry*

Psychosocial and organisational factors in relation to health and safety have been the subject of research for the last twenty years. The Petroleum Safety Authority (PSA) have also over the years focused on areas and themes relevant to the promotion of psychosocial work environment. One example are the theme collaboration and employee involvement highlighted in PSA's main topic for 2017 "Reversing the Trend". Other examples are PSA's followed-up of company's organisational change processes over the last years and the focus on organisational and human factors in barrier management (PSA 2016b, PSA 2017b).

Despite the amount of evidence collected and described in the literature, one of the biggest challenges may seem to be for companies to translate knowledge into workplace interventions. For employers it is a legal obligation to assess and manage all types of risk to workers' health and safety (Arbeidstilsynet 2017). Organisational changes represents such a process where the risk should be assessed and managed. As such, for employers and business owners it is vital to see psychosocial and organisational factors as an important element of managing risk and ensuring a sound change process. Risk management of these issues through risk identification, assessment and prioritization including allocation of resources to minimize, monitor, and control negative impact from occurring support the organisation's objectives for implementing lasting changes (Langenhan et al. 2013). As with health and safety in general, the successful promotion of the psychosocial and organisational work environment requires integration into daily work processes, avoiding treating it as a separate project. At last, employers must ensure the interventions implemented should target the work environment as well as the individual, in order to create safer workplaces and to improve the capacity of workers to protect their safety and health and to maximize their overall effectiveness.

Since both risk of injury and exposure of psychosocial hazards are unevenly distributed among groups, the follow up should be able to reflect this. Informative and user-friendly risk profiles will support the promotion of risk-based initiatives in times of change. Nevertheless, in the way forward it is important to monitor the developments

from an inspection authority perspective especially when there is a significantly higher risk of injury, reports of poorer psychosocial work environment and safety climate environment among employees affected by changes.

ACKNOWLEDGEMENT

We gratefully acknowledge the contributions to the project from all the project members and numerous other discussion partners.

Reviewing macro level factors as a foundation for understanding quality and patient safety improvement efforts across countries

T. Johannessen, E. Ree & S. Wiig
University of Stavanger, Norway

H. van de Bovenkamp & R. Bal
Erasmus University Rotterdam, The Netherlands

ABSTRACT: This paper takes a macro perspective on quality and safety in elderly care, focusing on the role of the macro level context in two European countries; Norway and the Netherlands. The aim is to conduct a comparison of the healthcare systems as a foundation to understand quality and patient safety improvement efforts in elderly care across the two countries. Our methodological approach is to conduct a review of macro level factors as suggested by previous studies such as governance and financing structure, role of different actors, and types of initiatives taken. Data was collected from open sources such as national statistics, governmental reports, and web pages of key actors at the macro level. The similarities and differences are discussed to highlight the main areas where improvement efforts need to take country-specific factors into account when learning across countries.

1 INTRODUCTION

1.1 *Background*

In many European countries, there are continuous policy demands for efforts to improve healthcare quality and patient safety. Why improvement interventions and efforts are successful in one context and not in another, and the role of macro level factors are still under-researched (Krein et al. 2010). Efforts to improve quality may work better in some situations than in others. Thus, quality improvement strategies requires information about context (McDonald, 2013). There are large variations in the organization, financing and delivery of the healthcare services in elderly care between countries and these variations can be expected to have an impact on the quality and safety work (Ennoo et al. 2015). European healthcare policy makers looking for sustainable ways to organize healthcare should take these differences in context into account (Eenoo et al. 2015).

This paper takes a macro perspective on quality and safety in elderly care, focusing on the role of the macro level context in two European countries; Norway and the Netherlands. The aim is to conduct a comparison of the healthcare systems as a foundation to understand quality and patient safety improvement efforts in elderly care across the two countries. Improvement efforts have to be adjusted to the specific contexts in which organizations are embedded in order to be effective. The following research question will guide this paper: What do differences in macro level factors mean for quality and safety improvement efforts in elderly care in Norway and the Netherlands?

2 METHODS

Our methodological approach was to conduct a review of macro level factors as suggested by previous studies (Wiig et al. 2014; Wendt, 2009; Grosse-Tebbe, 2005; Leijten et al. 2017) such as governance and financing structure, role of different actors, and types of initiatives taken. Data was collected from open sources such as national statistics, governmental reports, and web pages of key actors at the macro level (e.g. regulators, inspectorates, knowledge centers). We mapped and compared data on governmental expenditures on health, actors and types of community health care services, funding, governmental vision and regulation on community care, involvement of informal care, and national quality and safety indicators. Elderly care in this paper is limited to quality and safety improvement efforts in nursing home and home care.

3 HEALTH SYSTEM IN NORWAY

3.1 *Governance of elderly care*

Norway is a parliamentary democracy, divided into three different administrative levels, the state, the 19 counties and the 426 municipalities (Kartverket, 2017). The organizational structure

of the Norwegian health-care system is built on the principle of equal access to services for all inhabitants, regardless of their social or economic status, country of origin and geographical location. This overarching goal has been a long-standing feature of the Norwegian welfare system and has been embedded in the national health-care legislation and strategic documents (Ringard et al. 2013).

Since the beginning of the 2000s, the emphasis was both on achieving structural changes and to organize health care better. In addition, reforms have been carried out to strengthen patient and user involvement. In recent years, efforts have been directed towards better coordination of health services, while quality and patient safety has received increasing attention (Ringard et al. 2013).

The Norwegian health care system can be characterized as semi-decentralized. At the national level, parliament serves as the political decision-making body. The responsibility for specialist care lies with the state, administered by the four Regional Health Authorities (RHAs), which in turn own the hospital trusts. Municipalities are responsible for primary care including rehabilitation, physiotherapy, nursing homes, midwife, home care and after-hours emergency services. There is no direct command and control line from central authorities down to the municipalities and the municipalities have a great deal of freedom in organizing primary care services (Ringard et al. 2013).

The principles for determining who is responsible for health services varies in different parts of the system. Local politicians are therefore accountable to local inhabitants through local elections. Municipalities are also responsible to the government to follow policies and regulations. Further internal auditors control municipality's budgets and have access to other economic factors of importance.

The Coordination reform was introduced in 2012, and was part of an effort to improve care coordination and quality of the services. It implied that municipalities became responsible for more treatment tasks. Because of the reform, the municipalities now receive more patients with need for long-term treatment, but there are still challenges regarding capacity and competence of the staff at the municipal level (Meld. St. 11. 2014–2015; Gautun et al. 2013).

The main task of the central government is to assure the high quality of services across the municipalities through funding arrangements and legislation (e.g. the 2011 Municipal Health and Care Act). The Directorate of Health issues an annual circular letter to the municipalities. The circular letter of 2016 contained recommendations on preventive home visits in the municipalities. The letter described how the municipalities could use preventive home visits as part of their service provision to the elderly. The purpose of preventive home visits is to strengthen the individual's ability to stay healthy and active as long as possible (Rundskriv, 2016).

3.2 *Funding and legislation*

In 2017, health-care expenditure accounted for approximately 10.5% of Norway's GDP, placing it in 16th place in the Western Europe in terms of the share of GDP spent on health (OCED, 2017).

Government spending accounted for 85% of overall health spending, among the highest in the OECD mostly comprising financing from the central and local governments (73%) and from the National Insurance Scheme (12%) through fee-for-fee service payments and reimbursement of user fees (Ringard et al. 2013).

Primary care is funded from municipal taxes, block grants from the central government, and earmarked grants for specific purposes. Private sources mainly in the form of out of pocket payments account for approximately 15% of health expenditure (Ringard et al. 2013; OCED, 2017).

Private actors are involved in the provision of primary care services. The majority of general practitioner are self-employed but are in most cases fully embedded in the public system through contracts with the municipalities. Services provided by for-profit institutions include long-term nursing care (about 10% of nursing homes in 2010) (Ringard et al. 2013).

The Norwegian healthcare system is regulated through a large number of acts and secondary legislation. Legislation broadly reflects the decentralized nature of the healthcare system. Specialized healthcare, organized at the level of the RHAs, is regulated by the Specialist Care Act of 1999 and the Health Authorities and Health Trusts Act of 2001. Primary care which in Norway comprises long term elderly care is regulated by the Municipal Health and Care Act of 2011. A key act is the Patients' and Users' Rights Act (1999) with the aim of ensuring "equal access to health services of high quality". Strengthening the role of patients and next of kin has been a policy priority since the turn of the millennium, for example, through stronger patient choice and complaint procedures (Ringard et al. 2013).

The central government is currently focusing on "the patient's health and care service" putting the patient's need in the center of healthcare provision. (St. Meld. 34. 2015–2016). There are no dedicated rights for the elderly today. The responsibility for the elderly rights is divided between a variety of administration levels, supervision, and agencies. Elderly rights are mainly regulated by the Patients' and Users' Rights Act, which applies to all health services in Norway. Municipalities often coordinate the services of the elderly (Rundskriv, 2015).

There is no specific patient safety act in Norway. Demands for improving quality and safety in healthcare are incorporated in several acts and regulations. The Health and Care Act (2011), covering all health and care services provided by municipalities, requires service providers to work systematically to improve quality and patient and user safety (Health and care Act (2011) § 4–2).

A recent regulation on leadership and quality improvement in the health and care services (2017) requires all service providers to establish a management system to ensure internal control of the service provision. This includes overview of risk areas and how to plan activities, carry them out, evaluate, and correct deviances. Municipalities have the responsibility to supervise own activities in line with internal control regulations (Ringard et al. 2013), but there are also external supervisory bodies with mandate to supervise the service provision. The Norwegian Board of Health Supervision (NBHS) is the national regulatory body for health and care services. It is a public institution organized under the Ministry of Health and Care Services. At the regional level, 18 county governors oversee services within primary and specialized healthcare.

3.3 *Knowledge infrastructure*

National professional guidelines exist to help ensuring that health and care services have high quality, proper priorities, not unwanted variety in service provision, resolve coordination challenges and provide comprehensive patient care. The Directorate of Health develops, disseminates and maintains national professional guidelines. National professional guidelines provide recommendations for service provision, but are not legally binding. The health service providers are responsible for organizing the services to ensure that recommendations given in national professional guidelines can be followed (Helsedirektoratet, 2014).

There is a National Patient Safety Program (2014–2018) working on quality and safety improvement by strengthening the competence of health professionals and managers, and implementation of measures to reduce patient injuries. Intervention bundles are offered in areas such as medication list, prevention of fall and pressure ulcers, prevention and treatment of malnutrition, and early detection of deterioration (Pasientsikkerhetsprogrammet, 2017).

It is voluntary for municipalities to participate in the national patient safety program activities. Five municipalities currently participate in a pilot "patient and user-safe municipality", which aims at ensuring systematic and sustained work on patient and user safety at all levels in the municipal health and care services (Pasientsikkerhetsprogrammet, 2017). The National Patient Safety Program is co-operating with the developing centers for Nursing Home and Home Services (USHT). There is one USHT in each county and they establish networks with the municipalities. The development centers play a key role in supporting nursing homes and home services in quality improvement efforts, including organizing of learning networks (Pasientsikkerhetsprogrammet, 2017).

There is a National Quality Indicator System in Norway and the quality indicators for the municipal health and care services have increased the last years. Examples of quality indicators in nursing homes and home care are follow-up of nutrition; health services associated with infections; available medical time; medication review; and occurrence of readmission among elderly 30 days after discharge to the municipality (Helsedirektoratet, 2014).

4 HEALTH SYSTEM IN THE NETHERLANDS

4.1 *Governance of elderly care*

The Netherlands is a parliamentary democracy. The two governance levels that are most important for health care are the national and the local (municipal) level. The Dutch health care system can best be described as a hybrid governance system, with a mixture of top-down government regulation, market elements (e.g. free choice of provider and insurer), self-regulation by professionals and consultation amongst relevant actors (Van de Bovenkamp, De Mul et al. 2014).

Since the 1980s different themes figured on the national agenda. From the mid 1980s onwards, controlling health care costs, improving quality and safety and strengthening the position of patients have figured prominently on the agenda. Already in the 1980s a system of regulated competition was proposed which was officially implemented in 2006 after a process of incremental change (this applies to care covered under the Health Insurance Act). During the 1990s several acts were introduced aimed at regulating health care quality, such as the Medical Treatment Agreements Act (1995), the Quality of Care Act (1996) and the Individual Health Care Professions Act (1997). These acts came about as a result of consultation with the field and reflected an emphasis on self-regulation. The Quality of Care Act for instance dictated that health care organizations, including those providing elderly care, should have a 'quality management system' installed. However, what these systems should look like was largely left up to the field (Grol 2006). In the last decade, mostly in response to quality incidents, top down regulation has become more stringent which caused the health care inspectorate (responsible

for quality supervision) to play a more stringent role.

In addition to more stringent supervision, many national quality projects have been implemented also in elderly care. These national quality projects stimulate organizations to improve their quality and safety and provide funding to work on quality and safety projects. The short term focus of these programs (they only last for a couple of years) has caused the problem of fragmentation and projectification as organizations move from one project to the next which limits the sustainability of improvements (Slaghuis 2016).

Controlling costs and stimulating patient participation have been key issues of health care policy for some time now. These principles were also the goals of a large decentralization process that also affected elderly care. While part of elderly care is still governed at the national level (care that falls under the Health insurance act and Long-term care act) other parts have become the responsibility of the 388 municipalities from 2015 onwards (care that falls under the Social support act). These acts are further elaborated on in the next paragraph.

Dutch quality and safety policy of the last decade has strongly focused on making quality of care transparent through the use of indicators. This means that health care organizations have to put a lot of effort in registering and providing actors such as the inspectorate and insurers with performance information. Partly because of this, there is now much debate about regulatory pressure in health care. Professionals are calling for attention to the fact that they spend too much time on administration which limits their ability to provide care (Bovenkamp, Stoopendaal et al. 2017). In response to this, there is now much debate on working on quality in a different way that allows for local variation and focus on reflexivity (ibid.). In elderly care this has also been taken up in the latest national quality framework.

4.2 *Funding and legislation*

In 2016 13.8% of GDP, 96 billion euro, was spent on health care (including welfare) in the Netherlands.[1] This makes the Dutch healthcare system one of the most expensive worldwide. Hospital care comprises the largest part of the health care budget, 27 billion. Elderly care comes in second with almost 17 billion.[2]

Health care and elderly care in the Netherlands are regulated and financed through a variety of acts. Partly these acts determine how care is financed and who is responsible for the provision of care. In this section, we focus on the legislation especially relevant for elderly care. The Heath insurance Act (*Zorgverzekeringswet*), works through private insurance (and for a small part through out of pocket payments). The basic package is obligatory for all citizens (this package is set by the Dutch Health institute). Citizens can voluntarily choose to buy additional packages (e.g. for dental care, more physiotherapy). Under the Health insurance act a system of regulated competition is established. Health insurers compete for insured and can selectively procure care. Health care providers compete for patients. The care offered under this act includes acute and curative care (primary, secondary & tertiary, mental health).

The Long-term care act works through social security and is paid for through taxes and for some services small out of pocket payments. A 'care indication' is needed through an indication office to get access to this care (which includes 24 hour institutional or home care). The Act also provides for the possibility of personal budgets, empowering patients to organize their own care.

The Social support act, for which the municipalities are responsible also works through a combination of taxes and some out of pocket payments. For this type of care, which includes home care, special services and public mental health care, municipalities are responsible for care indications and financing. Municipalities can selectively contract health providers.

Elderly can be subject to all three laws, which means that a lot of coordination is needed between insurers, municipalities and providers.

As stated above there are also different acts to regulate health care quality, ensuring amongst others that organizations have a quality system in place and professionals comply to certain norms.

4.3 *The position of patients*

There is much focus in the Dutch system on strengthening the position of patients. Much effort, also in the national quality programs, is paid to let patients participate more in their care. This includes elderly care where the latest national program Dignity and Pride (*Waardigheid en Trots*) focuses on providing care according to the wishes of patients. The expectation is also that patients are active as much as possible themselves. For instance, the Social support act argues that people have to be as self-reliant as possible; only if people cannot take care of themselves, or cannot find help in their social network they are eligible to professional care.

[1]http://statline.cbs.nl/Statweb/publication/?VW=T&DM=SLNL&PA=83075NED&D1=a&D2=0,3,8,13,18,23,29,34,39,(l-2)-l& HD=160517-1206&HDR=G1&STB=T.
[2]http://statline.cbs.nl/Statweb/publication/?VW=T&DM=SLNL&PA=83038NED&D1=a&D2=a&D3=(l-2)-l&HD=170512-1505&HDR=T,G2&STB=G1.

There is also legislation ensuring patients' rights such as the right to informed consent, to choose providers and insurers and to file complaints. In addition, all health care organizations have to have a client council that has been given far reaching rights of advice (Van de Bovenkamp 2010, Schillemans, Bovenkamp et al. 2016). Furthermore, patients are increasingly involved in quality improvement projects in health care organizations. Next to client councils, methods used include patient surveys, mirror meetings, focus groups and experience based co-design (Bovenkamp, Grit et al. 2008, Schipaanboord, Delnoij et al. 2011, Vennik, Bovenkamp et al. 2016).

4.4 *Knowledge infrastructure*

The Dutch healthcare system has an elaborate knowledge infrastructure (Bekker, van Egmond et al. 2010). For elderly care, specifically, a knowledge institute exists at the national level (http://www.vilans.nl/) which is especially concerned with quality improvement. In the early 2000s, the Health Council of the Netherlands nevertheless argued that an intensification of research directed at elderly (care) was called for, which resulted in the establishment of a National Program Elderly Care (Grit, Dwarswaard et al. 2012, Wehrens, Oldenhof et al. 2017). The program, with a budget of almost 90 Million Euro, stimulated regional network building between elderly care organizations, municipalities and universities and the experimentation with and implementation of many quality programs. Participation of elderly was an explicit aim of the program. In addition, the national improvement project Dignity & Pride offers a platform for knowledge exchange between care organizations. Professional organizations also play a role in knowledge exchange. One of these organizations organizes a yearly benchmark for example based on quality indicators with the aim to help elderly care organizations to improve their care. However, this data is (as of yet) not public.

5 DISCUSSION

The similarities and differences between countries are discussed to highlight the main areas where quality and safety improvement efforts in elderly care need to take country-specific factors into account.

5.1 *Similarities and differences*

The healthcare systems in Norway and the Netherlands are listed as some of the best in Europe (OCED, 2017). Both countries have high health expenditures, but there are major differences in how healthcare services are organized and funded. The Dutch system is based on regulated competition and insurance, while the Norwegian system is based on taxes and public funding. For the Netherlands, this could have an impact on how working on quality and safety improvement is conducted, because it involves a high number of external actors in the market, and a more competitive system. In Norway there are less actors in the market and the public role is stronger. As a consequence, quality work in Dutch elderly care tends to be more fragmented, with many organizations pushing quality agendas and elderly care providers taking part in a diversified set of improvement initiatives (or not). While this on the one hand means that there is a very diversified set of quality and safety initiatives, which can be attuned to local contexts, there is also a lack of a building up of knowledge about quality and safety improvement across the sector. Several national initiatives that enable cross-organizational learning now try to fill this caveat, e.g. by organizing national meetings on specific quality subjects. In addition the national quality framework also states that organizations should develop learning networks as part of their quality policies.

In both countries, the patients have a strong position. The Netherlands had early on the agenda (around 1990) to strengthen patients' position, and Norway established a specific Patient and User Rights act in 1999.

There are no specified rights for the elderly, but the rights of this user group are governed by the strong patients' rights and legislations in both countries. In the Netherlands, there is a stronger focus on informal healthcare, compared to Norway. The expectation is also that patients themselves are active as much as possible. For instance, the Social support act argues that people have to be as self-reliant as possible; only if people cannot take care of themselves, or cannot find help in their social network they are eligible to professional care.

Both countries require that service providers develop quality management systems. The Quality of Care Act in the Netherlands, and the Health and Care Services Act in Norway require a systematic quality improvement work and systems in place. But, what these systems should look like is largely left to the field in both countries (Grol 2006). However, over the past decade, mostly as a result of quality assaults, regulation has become stricter in the Netherlands, which has led to a stricter supervisory role by the healthcare inspectorate. In terms of national quality indicators, knowledge structure, and national quality improvement projects the Dutch context has experienced a stronger pressure over years compared to Norway. The Norwegian indicator system has developed an increasing number of indicators the last years. Until a few years ago,

it mainly consisted of indicators covering the specialized healthcare services (Wiig & Lindahl, 2015). For the Netherlands, although there is much debate about indicators, a quality standard for elderly care has been developed and the sector engages in benchmarking in order to learn from best practices.

5.2 *Maturity*

By comparing the countries on macro level factors, the results indicate that the Netherlands has come further in their method development in user and next of kin involvement and in terms of initiating national improvement projects and indicators. At the same time, this can make healthcare providers more reserved to additional quality and safety improvement interventions and efforts since they might already have knowledge and tools in place, while this is still under-developed in the Norwegian context, according to our mapping (Meld.St. 26. 2014–2015). It appears as a challenge for the Dutch system, that nursing homes and home care services experience a strong pressure from external short-term projects, implying fragmentation and possible difficulties for implementation and sustainability. While policy makers in Norway emphasize the need for increased focus on quality and safety improvement and strengthen external knowledge support structures for nursing homes and home care, the Dutch system has national proposals on how to prevent these organizations from feeling such a strong external pressure that requires a lot of documentation and takes time from daily patient care.

6 CONCLUSION

In this study, we have mapped and compared macro level factors in Norway and the Netherlands as a foundation for understanding and learning from quality and safety improvement efforts across countries. Having an overview of funding mechanisms, patient rights, quality and safety requirements in the law, and the maturity of the knowledge infrastructure supporting the institutions in elderly care, are fundamental macro level contextual factors that should be mapped to understand the responses from institutions in quality and safety improvement efforts.

ACKNOWLEDGEMENT

The study Improving Quality and Safety in Primary Care-Implementing a Leadership Intervention in Nursing Homes and Homecare (SAFE-LEAD Primary Care) has received funding from the Research Council of Norway's programme HELSEVEL, under grant agreement 256681/H10, and the University of Stavanger.

ABSTRACT: A multi-method case study, including interviews, a survey and participatory observations, was undertaken to describe opportunities and challenges related to multicultural workplaces in the Norwegian construction industry, and the consequences for occupational safety, working environment and work performance. The findings show that challenges related to language and cultural differences are the most common, and that employment relationships and duration of relations have proven to affect many of the challenges. Consequences due to challenges related to language and culture were found more prominent for working environment and work performance than for safety. The focus on opportunities is limited and the potential is not fully exploited. Measures implemented to improve the conditions at multicultural workplaces mainly focus on solving the challenges and mitigating the consequences in a short-term perspective. A more future-oriented focus is needed, including measures that may lead to long-term gains for the industry.

1 INTRODUCTION

With the free flow of labour in most of Europe, companies in Norway are experiencing potential for innovation and effectiveness, but also some challenges. In the Norwegian construction industry, it is estimated that around one-third of the work force are migrant workers (BNL, 2017). This paper discusses the opportunities and challenges found in a study on multicultural workplaces in the Norwegian construction industry which was conducted between August 2016 and August 2017 (Kilskar et al., 2017).

The study was carried out to bring more knowledge on how internationalisation influences the working environment and safety in the construction industry, including culture, management, attitudes, expectations, communication and behaviour amongst both workers and their employers.

The overall objective of the study was to enable organisations and businesses in the Norwegian construction industry to work systematically in improving performance and productivity through good working environment, collaboration and increased safety at multicultural workplaces. An important aspect has been to not only look for problems and challenges at multicultural workplaces, but also to find the potential benefits of having a multicultural working environment.

The study aimed at solving three research questions:

1. What are typical characteristics, strengths and challenges related to safety and working environment by using multicultural labour in the construction industry?
2. How do challenges related to multicultural work force influence safety, working environment and work performance?
3. What measures exist and are proposed by the construction industry to create good multicultural workplaces?

1.1 *Concepts and definitions*

Construction can be used as a collective term for more sectors. In Norway, the construction industry is divided mainly in the building sector (e.g. building houses, commercial buildings) and construction sector (e.g. construction of roads, railways).

This study was limited to the building sector; however, the term *construction* is used in this paper.

The study mainly focused on migrant workers from eastern Europe, but interviews were also conducted with workers from other nationalities to get a broad understanding of multicultural workplaces in the construction industry. In this study, *eastern European workers* are defined to include nationalities from countries in the old Eastern-Block (i.e. former Soviet countries; Bulgaria, Czech Rep., Hungary, Poland and the Balkans). However, the large focus of the study was on workers from countries which joined the European Union (EU) in 2004; Czech Republic, Estonia, Hungary Latvia, Lithuania, Poland, Slovakia and Slovenia.

2 BACKGROUND

2.1 *The Norwegian construction industry*

The construction industry is one of the fastest growing industries in Norway and it stands for approximately 12.5 percent of the Norwegian BNP. In 2016, the industry turnover reached 521.8 billion NOK, and the combined work force was at almost 235 thousand employees (SSB, 2017a). It is characterised by many small and medium sized companies, with union density lower than average in Norway (43 percent in the construction sector versus 54 percent for other industries in Norway) (Nergaard, 2016). The industry is project based with temporary organisations consisting of multiple actors, which are forming and dissolving with each project. The large companies account for a smaller share of the construction output.

Unemployment rates in Norway have been stable on a low level, which has resulted in a shortage of skilled workforce. Traditionally, the majority of Norwegian workers have been permanently hired, and possibilities for temporary employment are somewhat limited through the Norwegian Working Environment Act. However, in recent years, there has been an increase in use of temporary staffing agencies hiring migrant workers in the construction industry.

2.2 *Working environment and occupational safety in the construction industry*

The construction industry in Norway is one of the main-land industries in Norway with the highest number of fatal accidents. In 2016, 8 out of 45 work-related fatal accidents occurred within this industry (NLIA, 2017a). There has also been reported 5.8 accidents at work that resulted in prolonged absence from work per 1 000 employees in the construction industry, whereas the average for other industries was 3.7 (SSB, 2017b). The Norwegian Labour Inspection Authority (NLIA) focuses on controlling and guiding companies and workers in the construction industry, highlighting the importance of preventive measures.

2.3 *Migrant workforce*

With low unemployment rates and shortage of skilled workers, the enlargement of the EU in 2004 gave companies access to recruit migrant workers, while at the same time foreign service providers got access to the Norwegian construction marked. Between 2007 and 2015, work has been the most common reason for immigration to Norway, followed by family reunions. The largest groups of immigrants are from Poland, Somalia and Lithuania (SSB, 2017). Many of the male immigants that came to Norway from eastern Europe after 2004, came to work in the construction industry. The process was not free of tension, as the work migration led to many challenges concerning migrant workers' wages and working conditions, accommodation standards, undeclared work, examples of exploitation and so called "social dumping" (Dølvik et al., 2005).

One of the serious concerns is the question whether migrant workers are more prone to work related accidents, which previous research both abroad and in Norway suggests (NLIA, 2012; Salminen, 2011). To look further into the background of such numbers, a mixed approach was chosen with a focus on the qualitative studies.

3 METHODS

Triangulation was used to combine the advantages of qualitative and quantitative methods; collecting data through semi-structured interviews, participatory observations and a survey. Additionally, a literature study was performed by searching in Scopus and Google Scholar for scientific documentation prior the data collection. Further, searches on the internet were done for news-articles. Search words used were "multicultural workforce", "building/construction industry", "management" and "migrant workers". The focus was on Norwegian publications.

As workers from Poland constitute the largest group of migrant workers in Norway, this is also the nationality most represented in the interviews and observations.

3.1 *Interviews*

Interviews were undertaken with 35 persons in seven cases, each case being either a construction

project or a construction company. The majority of the informants were from Norway (17) and Poland (10), while the remaining (8), came from other countries; Germany, Denmark, Russia, Estonia, Afghanistan and Ethiopia. The interviewees were managers, work team leaders, safety deputies and workers (including hired labour and apprentices).

A semi-structured interview guide was developed in Norwegian, and questions were adjusted for managers, Norwegian workers and migrant workers. The interview guide was translated into Polish and English for interviews with workers, and to English for managers. As a quality assurance, the interview guide was discussed with persons from the construction industry, and a pilot study was performed.

The interview guide was divided into five sections. Section A included questions about the informants' background, views on safety and working environment in general, and general questions about migrant workers in Norway. Section B consisted of questions about characteristics, opportunities and challenges at multicultural workplaces. Section C dealt with implications of having multicultural work teams, e.g. communication and cooperation between workers and managers, management and follow-up at the worksite, and characteristics of good multicultural workplaces. In section D, the focus was on good practices and solutions for creation of good multicultural work places. Finally, section E included questions to summarise the interview.

Interviewees were identified by the Federation of Norwegian Construction Industries (BNL). Factors addressed in the selection process of the interviewees were persons from different companies, disciplines, countries, and according to geography in Norway. Additionally, size of the project/company was one criterion. The projects where the interviewees worked varied from being small projects to large housing complexes.

The interviews were performed in the period from November 2016 to May 2017.

3.2 *Observations*

To verify data from the interviews, participatory observations were conducted at two construction sites over a period of three weeks. BNL facilitated contact with observation objects. The field work was performed by two anthropology students supervised by one of the project members. Two different methodological approaches were used; 1) observation with a high degree of participation in the daily work, supplemented with a limited number of interviews, 2) interviews, as well as observation, but less participation in the daily work.

The observations were important to gain knowledge about interactions and cooperation between Norwegian and migrant workers. The focus in the observations was on eastern European workers.

3.3 *Survey*

A survey was performed among managers in companies that are members of BNL.

The questionnaire was based on the results from the interviews and participatory observations, thus making it possible to lift the findings up to a general/national level. The questionnaire was based on the same topics as the interview guide (see 3.1).

A pilot test of the questionnaire was performed as a quality assurance of the content. BNL performed the submission of the questionnaire to the respondents electronically.

In total, 5 774 managers were invited by e-mail to answer the survey. 350 e-mails were returned because of "unknown recipients". Moreover, several persons replied and told they were not managers, but in the administrative or economical department. This was estimated to be about 870 persons. Finally, 886 persons in 562 distinct construction companies answered the survey, resulting in an approximate response rate of 19.5 percent for individual respondents and 21 percent for companies.

3.4 *Limitations*

BNL is a business and employer policy organisation for companies in the construction industry, and an umbrella organisation for 15 industries that organise a wide range of companies (in total over 4000 companies with nearly 70,000 employees). The companies range from the smallest companies to the largest in the industry including manufacturing companies, plumbers, carpenters, landscape gardeners, masons, painters and entrepreneurs (BNL, 2018). Most of BNL's branch associations have defined requirements for a company to apply for membership. The organisation advocates that Norwegian society should be built by serious, honest companies and that customers should be able to trust their suppliers.

Most of the companies that participated in the study were members of BNL. These companies are thought to be performing in a serious way, as well as ensuring health, safety and environment (HSE) according to regulations. This could have influenced the results.

The survey was directed only towards managers, since BNL has contact information only to managers and administrative personnel among their members.

4 RESULTS AND DISCUSSION

The results of the study show the importance of several factors for ensuring the working environment, cooperation and safety at construction sites. The main findings of the study are presented in the following.

4.1 *Differences between migrant and Norwegian workers*

The study looked at perceived differences between migrant and Norwegian workers. In many aspects, including skills, competence and quality of performed work, the differences were found to be minor. However, it was seen that groups of migrant workers and Norwegian workers often have different views on each other. In example, several of the Polish workers that were interviewed perceived themselves as more efficient and solution oriented than Norwegian workers. The Norwegian workers on the other hand, had the same perception, but in their own favour. This can be a source of misunderstandings as their perception differs. However, the survey showed that there is, in many aspects, a minor difference in how managers perceive Norwegian and migrant workers, respectively.

Even though there were many similarities between workers, one aspect appeared to be very different. When it comes to reporting of unwanted events there was a major difference between eastern European workers and Norwegian workers. The eastern European workers report fewer unwanted events and dangerous conditions. One reason the workers gave was that they do not wish to report on others to the management. These findings also coincide with previous research (Wasilkiewicz et al., 2016). However, these major differences were not found for all aspects related to safety. For compliance with safety regulations the results from the survey showed that the managers observe differences, however in much smaller degree than for reporting unwanted events.

Findings from the survey further shows that perceptions on migrant workers to a large degree depend on managers' experiences with migrant workforce. Managers from companies with permanently employed migrant workers were less critical towards migrant workers, than managers from companies without permanently employed migrant workers. As an example, the leaders were asked the following question: "To what degree do you experience that migrant workers do not comply with existing safety requirements (e.g. do not use required protection equipment)?" Nearly 44 percent of the respondents from companies with no permanently employed migrant workers answered this question with "to a large degree" or "to a very large degree". The corresponding proportion among the respondents from companies that do have permanently employed migrant workers was only close to 23 percent. The interviews also supported this finding, as managers with a lot of experience with permanently hired migrant workers were the most positive when discussing this topic.

The perceptions of managers on migrant workers also appear to be somewhat influenced by the size of their respective companies, as managers in medium sized companies (which in the study was defined as companies with 22–51 employees) answered in more positive terms than the managers from smaller and larger companies did.

This shows that there are large individual differences between workers within a nationality, as well as individual differences between managers (e.g. their expectations and requirements) and their experiences with migrant workers, resulting in different opinions.

4.2 *Potential not fully exploited*

The interviewees were asked what Norwegian workers and managers and migrant workers can learn from each other. Additionally, it was looked at what the benefits are, related to having migrant workforce, as well as possible opportunities.

The opinions varied; some stated that there is nothing to learn, while others had examples of what they had learned. The opinions in large degree reflected personal experiences.

When Norwegian managers were asked about what they think is positive with migrant workers, their *flexibility* was accentuated, e.g. migrant workers' higher willingness to work overtime, stability in the workforce (e.g. not taking work days off due to sick children), and willingness to continue work to complete tasks before the day is over. According to the managers, these points were in large degree related to culture. However, they can also be related to other factors, such as the fact that many migrant workers have their families abroad, and therefore want to work as much as possible while they are in Norway. It is important to be aware that the described behaviour can also be related to power relations. Persons form different cultures can have different expectations and relations to mangers (House et al., 2004; Warner-Søderholm, 2012a; 2012b), and thus perceive mangers' requests, such as working over-time, as duties rather than options.

When it comes to learning potential in general, most Norwegian interviewees did not see that they could learn anything from the migrant workers, however several managers pointed out that Norwegian workers could take advantage of learning better *working moral* from the migrant workers and to be "less lazy". A few pointed out that migrant

workers could teach local workers other *working techniques* and vice versa.

Some of the migrant workers pointed out that they value the *characteristics of the Norwegian working life*, e.g. "calmness" and less stress, thinking things over before starting a work task, and that they could learn this from Norwegians both for work, as well as for their personal life.

The industry is not highly conscious of the benefits and learning opportunities, and utilisation of the potential that migrant workers might bring in. Earlier research shows that multicultural and diverse groups can be both more efficient and less efficient than groups consisting of one single culture (Adler & Gundersen, 2008, p. 140). Through good collaboration, multicultural teams can be more efficient and innovative than homogeneous teams. By sharing knowledge and having different perspectives and experiences, such teams can achieve better solutions for common problems.

From the free text field in the survey undertaken, an example was found of how the construction industry can benefit from the knowledge of migrant workers:

> *"Migrant workers and Norwegians have discussed product alternatives from abroad (…) with the consequence that products or alternative products are being imported from abroad now. (…) This resulted in economic benefits in the company because of a better calculation of the price, and often easier handling in production (a win-win situation for workers and the company)".* (Survey respondent).

Migrant workers in the construction industry represent a larger resource than what is being utilised. The full utilisation of their potential is often prevented by poor linguistic skills (in Norwegian or English) and insufficient recognition of their formal competence from abroad.

4.3 *Challenges affected by employment relationships and duration of relations*

Results from the interviews, the participant observations, as well as the survey indicate that language is the most common challenge related to multicultural workplaces. The Norwegian informants did, however, consider this more of a problem than many of the migrant workers did. Shortage in Norwegian skilled workforce is part of the issue, as illustrated by the following response when asked whether speaking Norwegian should be an absolute request:

> *"Yes, I believe so. It is, however, hard to get hold of enough people. Finding a man who knows both the language and how to do the job is not easy".* (Eastern European work team leader).

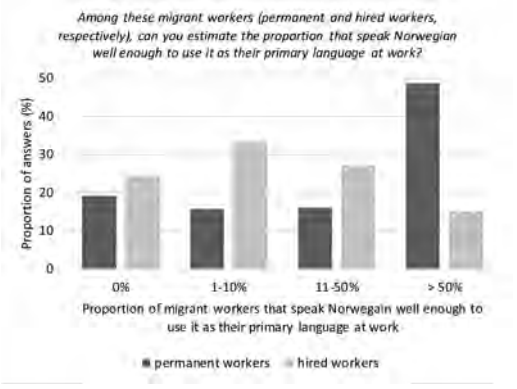

Figure 1. Distribution of manager's answers regarding linguistic skills among their permanent and hired migrant workers.

Figure 1 shows the distribution of managers' answers regarding linguistic skills among their migrant workers.

Close to 50 percent answered that more than half of their permanent migrant workers know Norwegian well enough to use it as their primary language. However, only 15 percent said the same about their hired migrant workers. In fact, close to 60 percent answered that less than one in ten hired migrant workers speak Norwegian well enough.

In addition to language related challenges, issues related to cultural differences were often mentioned. As an example, many migrant workers and eastern European workers particularly, tend to say "yes" and give the impression that they understand messages when they do not. The following quote from a worker from Poland is illustrative:

> *"I sometimes make mistakes when I don't understand. I don't know why I don't ask again. I don't know people working here, and I think I should understand".* (Eastern European worker).

Thus, in several cases where communication fails, language related issues cannot be seen irrespectively of those related to cultural differences. The respondents of the survey mostly agreed that managing migrant workers is more challenging than managing Norwegian workers. It is thus important both for managers and fellow workers to gain necessary understanding of such differences, and how, for example, differences in perceiving hierarchy and power distance can make Norwegian and eastern European workers act differently.

Other challenges included some migrant workers feeling that they were treated differently from their Norwegian co-workers, arguing that they were assigned to "harder" and more boring work.

In addition to specific challenges that may occur at multicultural workplaces, several of the Norwegian managers and workers raised a concern that an extensive use of migrant workforce may negatively affect the recruitment of young, Norwegian workers to the industry.

What is common for many of the identified challenges, is that they appear to be enhanced by employment relationships and conditions. The study shows that employment relationships are of greater importance than nationality when it comes to the challenges at multicultural workplaces. Hired workers from staffing agencies are less likely to learn the language, and companies are equally less likely to invest in language courses for these workers.

As mentioned, many managers find it harder to manage migrant workers, than Norwegian workers. Findings from the interviews, however, indicate that leadership challenges are greater when involving hired workforce rather than permanent workers. It is also the hired workers that most often claimed to be treated differently. As an example, some had experienced having to accept poor working conditions due to the fear of not being hired again.

The findings also show that the challenges seem to be affected by the duration of relations; that is, when workers are staying at a building site for just a short amount of time, which may cause problems:

> *"You know, when a subcontractor comes to the construction site, like those balcony fitters, they are staying for two, maybe three weeks before finishing their work. You don't have the time to get to know them. You don't know what they stand for and what their interests are for doing the work in a safe manner".* (Norwegian project manager).

4.4 *Greater consequences for work performance and working environment than for safety*

Some argued that the number of unreported unwanted events is larger among migrant workers, and quite a few imagined migrant workers being harmed at work more often than Norwegians. Despite this, most of the informants said that they had no basis for stating that migrant workers are overrepresented in their company's accident records.

Results from the survey clearly indicate that language related challenges and culture related misunderstandings cause building errors or disagreements at work more often than they cause accidents or near accidents. This implies that language and culture related challenges cause greater consequences for work performance and working environment than for safety. The distribution of the answers is shown in Figure 2. The proportion of respondents answering that they have experienced construction errors due to language related challenges and culture differences were 66 and 44 percent, respectively. Some would argue that these numbers, and the corresponding numbers regarding the working environment and safety are unacceptably high. Still, when asked, very few could tell of any concrete examples in which any of these were the case. It is also important to note that the percentages represent the number of respondents that have either experienced or observed any of these things within the *past three years*. Thus, they do not necessarily indicate that these are common problems over time. Also, when asked related questions in the interviews, almost no one could tell of any concrete events in which language or culture related challenges caused accidents or near accidents.

Segregation at the construction site leaves many workers with an experience of being divided into "us and them". The various nationalities typically keep to themselves during lunch and other breaks; especially in cases where the different professions constitute pure national working groups. This minimises the chances of extensive inclusion and involvement. The study also revealed several examples of Norwegians that felt alone among eastern European co-workers.

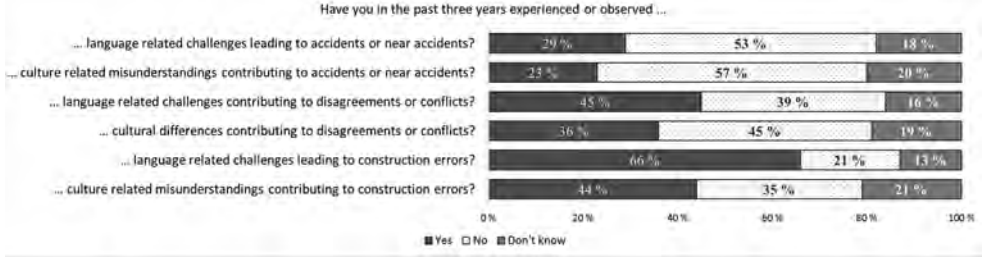

Figure 2. Results from survey. Managers' answers as to whether they have experienced or observed construction errors, disagreements/conflicts or accidents/near accidents due to culture or language in the past three years.

As described in 4.3, challenges may be affected by the duration of relations. As such, focusing on duration of relations is also important to maintain safety and working environment at multicultural workplaces. For the workers, getting to know each other may affect whether one is able to communicate well about the daily work. This may again influence everyday working environment and safety. For employers, on the other hand, the duration of relations affects how much one is willing to invest in the workers, for example through training and competence building. This, in turn, influences the prerequisites for the individual worker to work safely and in accordance with expectations from the employer and colleagues.

4.5 *Many measures focus on short-term solutions*

The study explored measures that exist to utilise the opportunities and cope with the challenges that come with using migrant workforce. It was found that most employers and construction sites do not put in direct efforts to promote the opportunities and fully utilise the resources that are represented by migrant workers. Measures in large degree aim to cope with specific challenges in the present. As language is mostly brought forward as a challenge, most measures are also related to cope with linguistic issues. These include among other, translations of safety materials, HSE training in other languages, language courses, language requirements at work sites, and arrangements of working groups by language.

In practice, some measures, such as language requirements can be difficult to comply with due to available workforce. Further, measures such as arrangement of working groups by language contribute to a bad spiral where migrant workers do not get the opportunity to learn Norwegian as they only work with people that speak the same language as themselves. And again, they do not get to work with Norwegians because they do not speak Norwegian. This is an example of a measure that is reactive in nature and contribute in a short-term perspective to reduce linguistic challenges at a specific construction site, but do not focus on coping with the challenges in the long run.

Many of the informants highlight communication as a key to success at multicultural workplaces. Language is a large part of communication, however not the only part. Cultural differences also influence communication at workplaces.

In the study, it has been seen that duration of relations is important for successful construction sites. Knowing each other and having a relation to each other is also important for understanding and communication between workers, and between workers and managers.

The study indicates both opportunities and challenges with multicultural workplaces. However, to reduce the challenges and to benefit from the potential that lies in a migrant workforce, further solutions need to be developed, e.g. tools and measures. The study shows that there are already many measures in place, especially to cope with challenges, but many of them aim to solve problems in a short-term perspective. There is also a need for measures and tools which aim to reduce the challenges in the future, rather than reducing consequences here and now. Further, there is a need to look for opportunities that come with migrant workers.

5 CONCLUSIONS AND FURTHER RESEARCH

The challenges with migrant workers are quite well documented and studied both internationally and recently in Norway. There has, however, been many unjustified assumptions when it comes to multicultural labour and consequences for safety, working environment and work performance. This study has documented both challenges and strengths by using migrant workers, and also a construction industry that has introduced different measures to create well-functioning multicultural workplaces.

The findings in this study cannot conclude that migrant workers are involved in more accidents than Norwegian workers. However, when it comes to reporting of unwanted events, significant differences were found between migrant and Norwegian workers.

Rather than resulting in many accidents or near accidents, challenges related to language and culture were found to lead to more consequences for work performance and working environment. Several informants said they imagined language and culture causing safety related consequences, but few could provide concrete examples of events in which this had been the case.

Further, it was found that employment relationships are of greater importance than nationality when it comes to challenges related to multicultural workplaces. Duration of relations is important to maintain safety and working environment at multicultural workplaces.

The study also shows that the potential for benefitting from knowledge and experiences among migrant workers is to a small degree realised, and the obvious focus in the industry is on the challenges.

Measures to cope with the challenges were found to mostly be of a short-term nature handling challenges right here and now, whereas few measures are of such a nature that they improve long-term conditions.

Migrant labour has become a natural part of the Norwegian construction industry, and the industry partners must take responsibility and work together to cope with the challenges and promote the opportunities. Measures to promote good multicultural workplaces include improving managers' understanding of cultural differences, adapting leadership style, as well as making conscious decisions regarding organisation of the work. A future-oriented focus is needed, including measures that may lead to long-term gains for the industry, and measures to lift the opportunities and exploit the potential that lies in the inequalities between different groups of workers at multicultural workplaces.

ACKNOWLEDGEMENTS

The project was initiated by BNL and funded by the Confederation of Norwegian Enterprise's (NHO's) Working Environment Fund.

Observations were led by Bjørn Nygaard from ideThandling in Denmark.

Reliability and safety engineering: The principles innovation and optimisation of German and Japanese product constructions

S. Bracke
Chair of Reliability Engineering and Risk Analytics, University of Wuppertal, Wuppertal, Germany

M. Inoue
Department of Mechanical Engineering Informatics, Meiji University, Kanagawa, Japan

ABSTRACT: The industrialisation of Europe and Asia leads to the development of innovative and reliable technical complex products. Industrial nations like Germany and Japan took separate ways to highly developed industrial nations. This leads to different goals and philosophies in terms of reliability and safety design regarding product and manufacturing process development. This paper shows essential aspects of the differences in German and Japanese reliability and safety engineering. Base of operations is the fundamental difference of the realisation of the principles "innovation" versus "optimisation": German product functionality contains often innovative solutions; Japanese product functionality shows often optimised solutions. These different designs are caused by different engineering philosophies and factors: The paper discusses the historical factors, cultural factors and geographical conditions, which lead to the different technical reliability and safety engineering solutions in Germany and Japan. Finally, the paper shows two examples of German and Japanese technical products and engineering solutions to illustrate the different strategies in German and Japanese product design.

1 INTRODUCTION

The industrialisation of Europe and Asia leads to the development of innovative and reliable technical complex products. Industrial nations like Germany and Japan took separate ways to highly developed industrial nations. Both countries have the ability to develop and manufacture technical complex products on a high reliability and safety standard. But a detailed look at Japanese and German products shows different characteristics regarding the principles "Innovation" and "Optimisation", especially in case of reliability and safety aspects. New developed German product generations include often innovations regarding functionality. Japanese product engineering considers very often the optimisation in relation to the previous product generation. An example for illustration is the comparison of the Japanese and German railway system—including trains, railway net and ticket machine logistics—with the focus on criterions like innovation, optimisation, efficiency and reliability. The railway system was invented in Europe (Great Britain, afterwards also Germany; cf. (Griffin 2010) and (Pollard 1981)). Subsequently the U.S. established the railway system in Japan after opening the country for trade. The Japanese engineers adapted and optimised the railway system: The concept (e.g.: Separation of high-speed and regional train system, as well as rail cargo), the logistics (e.g.: entering and leaving trains by passengers) and the ticket machine (e.g.: parallel paying, non-limited bank-note); cf. (Nussbaum and Roth 2005).

However, both approaches "Innovation" and "Optimisation" lead to different engineering solutions regarding technical complex products in terms of reliability and safety. Both reliability and safety design approaches have advantages and open the chance to learn from each other. This paper shows essential aspects of the differences in German and Japanese reliability and safety engineering within a research study. Base of operations is the fundamental difference of the approaches "innovation" versus "optimisation" within the product development process. Subsequently the paper shows different impacts—e.g. historical, culture and geographical—on innovative and optimised engineering.

2 GOAL OF RESEARCH STUDY

In this research study, the main influences which support product innovation and optimisation within an engineering process are analysed. The goal of the

research study is to work out the reasons, why German product functionality is mostly characterised by innovative solutions, whereas Japanese products often show optimised solutions.

In a first step, this paper illustrates the principals and influences with supporting or restraining impacts on creative engineering and product innovations (cf. section 3.1 and 3.2). Furthermore indicators for the measurement of innovation are shown (cf. section 3.3). Subsequently, the paper discusses main influences and aspects of Japanese and German historical factors, culture and education factors, as well as geographical conditions, which lead to the engineering preference regarding the approach "Innovation" or "Optimisation" (cf. chapter 4). Lastly, German and Japanese product examples are explained to illustrate the applied approaches with focus on innovative or optimised engineering.

3 BASE OF OPERATIONS: INFLUENCES ON CREATIVITY AND INNOVATION

The principals and main influences, which are supporting creativity and innovative thinking, are worked out by several authors, e.g. Linneweh, Rammert et al. and Dehio et al. Section 3.1 shows a summary of influences, which support creativity and innovative thinking within engineering processes. Section 3.2 shows a short overview regarding influences with restraining impacts on innovations. Finally, section 3.3 shows essential indicators, which can be used for the measurement of innovation capability.

3.1 *Influences with supporting impacts on creative thinking and innovative engineering*

The main influences supporting creative thinking and the development of product innovations are as follows:

1. Possibility of free thinking (Linneweh 1984),
2. Possibility for realisation, especially financial support, state subsidy; cf. (Rammert et al. 2016) and (BDI et al. 2017),
3. Consumer society based on customer expectations based on life style thinking (Rammert et al. 2016). Note: In the past, the customer expressed requirements; in the present the life style is an essential part of the decision making additionally,
4. Supply and demand, the base of a free market economy; cf. (Rammert et al. 2016),
5. Social innovations based on customer's expectations; the customers are familiar with dynamic changes, cf. (Rammert et al. 2016),
6. Motivation and incentive (e.g.: cash/money, reward, appreciation, cf. (Linneweh 1984)),
7. Knowledge and new technologies lead to new product functionalities; cf. (Rammert et al. 2016),
8. Digitisation (BDI et al. 2017) and
9. Wish for diversity (e.g.: Gender, Ethnos, Religion; cf. (BDI et al. 2017) and (Linneweh 1984).

3.2 *Influences with restraining impacts on innovations*

The main influences, which are restraining or stopping creative thinking and the developing of product innovations, are listed below:

1. Organisation with rules, structure, norms and regulations (Linneweh 1984),
2. Bureaucracy (Linneweh 1984),
3. Huge enterprises (combined with hierarchical structure); cf. (Dehio et al. 2006),
4. No possibility for creative thinking, combined with the hindrance of personal development (BDI et al. 2017),
5. No possibility for experiments and mistakes; cf. (BDI et al. 2017).

3.3 *Indicators to measure innovation capability*

The measurement of the innovation capability is based on fundamental indicators in relation to a country/state, which are shown in the following list (cf. (Dehio et al. 2006) and (BDI et al. 2017)):

1. Patents per inhabitant,
2. Scientific publications per inhabitant,
3. Investments regarding science in relation to the gross domestic product (GDP),
4. Turnover/sales based on new or improved products and
5. Balance of trade.

4 COMPARISON OF GERMAN AND JAPANESE ENGINEERING

Industrial nations like Germany and Japan took separate ways to highly developed industrial nations leading to different focuses regarding the approaches "Innovation" and "Optimisation" within engineering processes. This chapter works out the impacts leading to different philosophies and designs in terms of "Innovation" and "Optimisation" within product and manufacturing engineering in the respective countries. Section 4.1 discusses the historical impact in relation to the different ways of the industrialisation of Japan and Germany. The culture and society impact—especially the value

of education—is shown in section 4.2. The section 4.3 gives an overview regarding the main geographical and locational impacts.

4.1 *Historical impacts: Industrialisation in Germany and Japan*

The industrialisation of Europe and Asia led to the development of innovative and reliable technical complex products. Industrial nations like Germany and Japan took separate ways to the level of highly developed industrial nations. The industrialisation started in Europe within the second half of 18th century in England, and subsequently in Germany; cf. (Griffin 2010) and (Pollard 1981). Within the time of the German empire, the industrialisation was growing rapidly. Exemplary, the industrialisation process can be explained by the development of the railway system. The beginning of the railway history was in 1804 with the introduction of the first steam locomotive by Richard Trevithick. Shortly afterwards in 1825, the first public railway system was opened by Stockton and Darlington Railway in England (Tomlinson 1915), enabling the transport of people and rail cargo. Due to the fact that traveling times were reduced in Europe and North America, the industrial revolution itself was supported by the railway system. Furthermore it was pushed by the European wars, especially the German-French war from 1870 to 1871, where the transport of war goods was important. Today, the high-speed train ICE ("Inter City Express") is an essential part of the German traffic system: The four ICE generations were developed between 1990 and 2017 (Jehle et al. 2006).

However in Japan the industrialisation starts in the end of the 19th century caused by external pressure from the United States. The external pressure led to the end of the Edo era (1603 until 1867) starting the new Meiji area (1868 until 1912) with the rapidly growing industrialisation (Nussbaum and Roth 2005). Within the Edo era, Japan was encapsulated to the rest of the world. Entry and departure for foreigners were not allowed (exception: small exchange with china and Netherlands; colony island Dejima) and contact to other states were on a minimum level. In 1854, four war ships led by Matthew Perry were entering the harbour of Uraga. Based on a message from US president Millard Fillmore, the Tokugawa government was pressurised to start trade with the United States (otherwise U.S. go to war); cf. (Morinosuke 1976). The arrangement included the opening of the harbours Shimoda and Hakodate and the possibility for trading. Parallel, the Edo era ended and the reform of the empire led to the Meiji era, starting in 1868. The gentry of war ended, the constitution was modernised and the development of the country—especially from the engineering point of view—started. This point is exemplary illustrated with the Japanese railway system; cf. (Givoni 2006): Within the Meiji era, the railway system was developed—but limited to a track range of 1067 mm. Therefore, the speed level was limited to 100 km/h until 1950. Huge steps of the railway system development followed in the sixties and subsequently resulting in the development of the high-speed trains ("Shinkansen" – high speed) in the nineties parallel to Europe (1992: Series type 400, 1997: E3; 1999 E3–1000). Today the railway system in Japan is the most reliable and accurate system worldwide (Givoni 2006).

The other historical aspect impacting Japanese product development is World War II. Japanese companies trained their engineers for multiple tasks and skills (called "Tanoko" in Japanese) based on long-term employment and long-term trading with suppliers because of the labour shortage after World War II. As a result Japanese engineers are able to work in many different teams on a very efficient level. Furthermore, Japanese engineers are able to find optimum design solutions faster than their colleagues in other countries through a trial and error processes by "*Suriawase*" which is the Japanese way for negotiation among several teams of engineers including design teams, production divisions, and parts manufacturers (suppliers) from the initial design phase to the detail design phase concurrently (Inoue et al. 2011).

As a comparison between Germany and Japan: In Germany, the innovative engineering was pushed by the industrialisation under environmental conditions, which allows free thinking. Prussia and the subsequently following German empire's education system ("Humboldtian Model"; (Baumgart 1990)) allow free thinking and development of creative solutions (cf. section 4.2). However Japanese engineering was pushed to open the country, caused by external pressure from the U.S. Many technologies were imported during Meiji era from Europe and U.S. and adapted to Japanese environment (Nussbaum and Roth 2005). This was a part of the base of operations for Japanese focus on optimisation of imported technical products and processes.

4.2 *Culture impacts: Education system, society and work environment*

The culture and society of Germany and Japan is very different. Germany society is influenced by a hierarchical system parallel to an established social market economy. As mentioned in section 4.1, the Prussia educations system, founded by Wilhelm Humbold, focusses on a comprehensive education based on a combination of research and teaching. The

"Humboldtian Model" (Baumgart 1990) includes arts and sciences with research. The goal is comprehensive general learning and cultural knowledge. Nowadays, the model is still base of the German education system and is the fundament for creative, innovative thinking. Furthermore the social market economy is established since 1949 in Germany. Social market economy allows free entrepreneurial acting while social compensation is considered. The social market economy was pushed by Chancellor Ludwig Erhard and is an important factor to ensure free thinking in a secured environment.

The Japanese society is influenced by a strong hierarchical structure. Acting within the society is characterised by discipline. Furthermore, education has a high value within Japanese society (like in all Confucian orientated Asian countries).

Important character of the Japanese working environment is the principal of life long employment (until 20th century); cf. (Japan 2012). Furthermore, the loyalty regarding the employer is very important. Loyalty, discipline and healthy food lead to low numbers of employees absence due to illness (Japan: Average 1%; Germany: Average 3.2%). The strong connection between working environment and personal life style leads to a strong identification of Japanese employees with their work.

Both countries have an education system, which ensures a high educational qualification level. The differences are the social market economy, hierarchical system, employee identification with work and discipline. These aspects have a high influence on different engineering philosophies regarding product innovation and product optimisation. On the one hand strong hierarchical structure, discipline and loyalty support product optimisation. On the other hand, free thinking within a social market economy supports creative product innovations. The requirement for the ability to create product innovation or optimisation is the educational fundament, which is given in both countries.

4.3 *Geographical and location impacts*

A strong impact on innovative or optimised solutions are geographical impacts. The comparison between Japan and Germany shows obvious differences: Japan is located at the rupture zone of four tectonic plates of the earth crust:

- North American plate in the north,
- Eurasien plate in the west,
- Philippines plate in the south and
- Pacific plate in the east.

Each year, the plates are drifting within a range of some centimetres. The pacific plate moves below the Eurasien plate which leads to volcano eruption and many earthquakes. In average, 73 earthquakes with a Richter magnitude of 4 or higher occur in Japan per month (thereof nine per month with magnitude 5 or higher; 1.4 earthquakes per month with magnitude 6 or higher), cf. (Earthquake Research Committee et al. 2011).

However Germany is located in the centre of Europe, nowadays without any influences regarding earthquakes and volcano eruption.

This facts lead in Germany and Japan to very different strategies in case of safety and reliability engineering in many subjects, like facility engineering (e.g. buildings), mechanical engineering (e.g. railway systems) and electromechanical engineering (e.g. consumer goods). Japanese risk- and reliability analysis always considers safety aspects based on earthquake-vibration impacts in comparison to German products. This is reflected e.g. in constructional, material and electrical aspects as well as shutdown strategies for respective product concepts.

5 COMPARISON OF JAPANESE AND GERMAN CONSUMER PRODUCTS CONSTRUCTION

The comparison of Japanese and German consumer products—e.g. water boiler (section 5.1) and ticket machine (section 5.2) – shows the influences on historical, culture and geographical impacts on reliability and safety engineering solutions.

5.1 *Safety related construction: Water boiler*

Electric consumer goods like water boiler, micro waves and other electric devices, need electricity within the operation mode. The stressing of the connection cable between power source and electrical device—e.g. tensile force, folding force or torsion—can lead to a damage. As a consequence, a cable damage can lead to fire. The construction of Japanese electrical consumer products often includes an easy detachable connection between electric device and power source (cf. Fig. 1).

The reason regarding this construction is the geographical impact (cf. section 4.3): In case of an earthquake and the involved vibrations, the electrical devices within households are directly disconnected from the power source. This leads to a prevention of damage cases based on an electrical failure rout cause (e.g. damage of cable or technical device, which can cause fire). In comparison, the construction of electric consumer goods based on European respectively German standards mostly do not have such a safety related construction (cf. Fig. 2). The geographical location of Germany or Europe allows the negligence of possible earthquake impacts.

Figure 1. Japanese safety related construction: Easy detachable connection to avoid electric cable damage in case of force effect (e.g. caused by earthquake and involved vibrations).

Figure 2. Fixed—non-detachable—connection between electrical device and power source (European standard).

5.2 *Functionality related optimisation: Ticket machine in railway system*

Part of the industrialisation in Great Britain was the establishment of the railway system (cf. section 3.1), including the train, net, logistics and ticket machine. This transportation concept was an innovation regarding the transport of goods and people. It was built in Europe (especially Great Britain and Germany) and afterwards in North America. Subsequently the railway system was transferred to Japan at the end of 19th century. Each component was optimised by Japanese engineering, e.g. the functionality of the ticket machine.

A direct comparison of the basic function "paying process" shows the aspects of the European respectively German standard construction and the optimised Japanese construction.

European/German standard (cf. Fig. 3):

- Paying with coins, procedure is one-by-one,
- Paying with bank-note in limited form (e.g. 20 or 50 Euro), procedure one-by-one,
- Money return are coins in case of bank-note paying.

Japan optimised construction (cf. Fig. 4):

- Paying with coins can be parallel, because the slot has a hopper form, furthermore the automat has a sorting function,
- Paying with bank-note 10,000 Yen (approximately 100 Euro) is possible; procedures are "parallel" or "one-by-one",
- Money return in case of bank-note paying are bank-notes in optimal standard units.

Figure 3. Ticket machine: Standard solution, focus: single coin slot regarding paying by coins, procedure is one-by-one.

Figure 4. Ticket machine: Optimised solution based on Japanese Engineering. Focus: Parallel paying (e.g. coin slot hopper form).

6 SUMMARY

This paper shows essential aspects of the differences in German and Japanese reliability and safety engineering. The engineering approaches are based on the fundamental difference of the realised technical approaches "innovation" versus "optimisation": German product functionality is often characterised by innovative solutions, Japanese products show often optimised solutions regarding the previous product generation.

Base of operations are the influencing factors, which support or restrain creative thinking and, as a consequence, support product innovations or optimisations. Afterwards, the historical factors, culture factors and geographical conditions in Germany and Japan are analysed respectively, which leads to the different technical reliability and safety engineering solutions of German and Japanese engineering solutions.

Finally, the paper shows two examples of technical products and engineering solutions in Germany and Japan to illustrate the different strategies in German and Japanese product design.

However, both product design approaches—innovative on the one hand and optimised on the other have advantages and gives the chance to learn from each other.

Safety and risk management in oil & gas industry: Development of safety x-factor model

Deshai Botheju
Independent Researcher, Sandefjord, Norway

ABSTRACT: It is noted that difficult market conditions faced by the oil industry during last several years have been manifested in a negative safety performance. No direct relationship exists to explain this trend. Even though many stakeholders instinctively believe that extreme cost-efficiency drives seen within the industry are somehow responsible for this outcome, any clear-cut mechanisms or pathways have not yet been proposed. This paper presents the preliminary development of a schematic model basis intended to explain the impacts of economic pressure on safety performance of a profit oriented organization when faced by market challenges. Further development of this model basis is expected to provide a clearer picture of this interrelation between safety performance and economic performance.

1 INTRODUCTION

Due to the downturn of oil industry ensued during last several years, many dramatic changes have been seen within the management structures of commercial entities engaged in the business. Some of these changes have unintentional consequences on the safety culture, barrier management, and the overall safety performance of organizations. These consequences can manifest as long lasting, and sometimes delayed, impacts and could lead to catastrophic major accidents as well as gradually deteriorating HSE performance. Therefore, timely recognition of these impacts and the pathways are crucial to avert short-term and long-term loses. Reasons (1998) pointed out that technologically complex high-tech industries are more vulnerable to organizational (major) accidents due to their intricate systems and subsystems that no single person could comprehend in isolation. Accordingly, weaken barriers or latent flaws accumulated during an economically hard time period could stay dormant for years or decades before they come into play a role in a major accident.

This paper explains possible mechanisms behind the recent negative trend in safety performance observed within the oil & gas industry proposedly instigated by the dramatic downturn of the crude oil economy seen during the last couple of years (Botheju & Abeysinghe, 2017). While recognizing the necessity of adopting certain organizational changes in order to face the new economic reality of the industry, the paper highlights the importance of understanding the drivers behind this discomforting trend that is threatening the prudent safety management procedures established over decades. It is recognized that there can be certain chain-linked relations between some innocent looking cost-cutting measures and the organization's safety culture dictating the overall behavior towards its safety performance and barrier management.

This article can also assist in developing prudent guidelines that could be used to implement a robust safety management system that performs even under challenging economic circumstances without compromising the safety and well-being of the organization.

The article is based on long-term experience of the authors, and careful observation of industrial dynamics related to safety and risk management. It is intended that this paper provides a much needed insight into the driving factors behind safety performance change currently being observed within the oil & gas industry, while establishing a schematic model basis to comprehend its safety dynamics under cost-efficiency pressure.

2 RECENT TRENDS IN SAFETY PERFORMANCE

The previous works of the authors (Botheju & Abeysinghe, 2017; Botheju & Abeysinghe, 2016) have argued that the downturn of oil industry has manifested itself as a sudden nosedive of the overall safety performance. Even more threateningly, some of the resultant impacts, especially regarding the process safety risks, could come into effect years later from now. In relation to Norwegian petroleum industry, Engen et al. (2017) have pointed out

that, while the level of safety and working environment conditions still remain relatively high, several safety challenges and serious conditions were starting to be manifested during the last few years.

The existence of an apparent correlation between economic pressure and the safety performance had previously been identified by other authors as well (Rasmussen, 1997; Coles, et al., 2000; Barden, and Lodestone, 2006; Young, 2015). However, many of the past case examples that were relating major accidents to cost-cutting measures, had straightforward links connecting key management decisions to poor safety barrier management (Chauhan, 2005; US Chemical Safety and Hazard Investigation Board, 2007). The current trend in the oil industry, that we are experiencing right now, is more intricate where such clear-cut pathways are still difficult to be observed. Among previous modelling attempts, Rasmussen's (1997) migration model is quite unique. He proposed the existence of a boundary of functionally acceptable performance; operating outside of that would lead to accidents. Rasmussen further theorized that there exists a gradient created by management's pressure directing the organization towards higher efficiency. This gradient, unless sufficiently counterbalanced by a gradient of safety culture, can gradually migrate the activities towards the functionally acceptable performance boundary.

The challenge, therefore, is to exactly recognize the driving mechanisms behind this recent trend. The most of the commercial entities continue to emphasize that they are still prioritizing safety as a paramount factor during their operations, and refuse to accept that any of their management actions could have led to a deteriorated safety performance.

In a way, what companies are claiming has a surface truth. Unlike in the past eras, the modern socio-ethical context and the associated legal and regulatory frameworks leave only a limited room for management bodies to initiate direct actions that could openly jeopardize safety. And above all, the most companies understand the gravity of such detrimental actions nowadays. Therefore, no sensible management would consciously support any action that clearly leads to poor safety performance.

Nevertheless, this paper argues that there are certain pathways linking the dramatic cost-efficiency actions and deteriorating safety performance. We denote these links as "Safety X-factors". The schematic model so named as "Safety X-factors Model", which is currently in its development stage, tries to explain these enigmatic connections and establish them within a model structure.

3 SAFETY X-FACTOR MODEL

As indicated in section 2, the overall safety performance within the oil and gas industry is being influenced in a negative trend aligned with the market downturn, with much visible evidence. Nevertheless, no management is accepting that they are actually driving this trend. This raises the question "what mechanisms are responsible for this trend then ?". The Safety X-factor model (abbreviated as SXF model) is presented as a basic attempt to answer this question. Note that this paper only presents its preliminary development. Figure 1 provides a schematic illustration of this model showing some of the key components and pathways proposed.

3.1 *What is SXF model*

SXF can be introduced as a basic schematic model in development aimed at explaining the safety performance outcome of an organization (or an entire

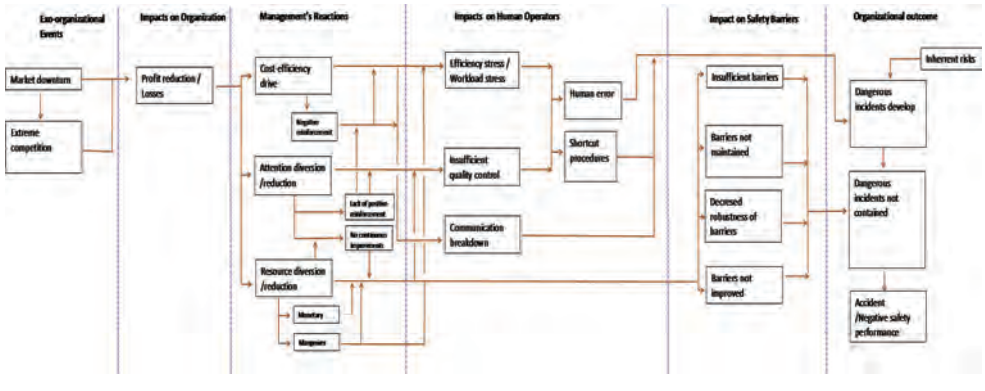

Figure 1. Schematic Illustration of the *Safety X-factor Model* (Preliminary).

industry in a broader sense) when faced by one or more exo-organizational events bearing certain economic impacts to the organization. In the current context, the relevant exo-organizational events are the market downturn triggered by low crude oil prices, and the extreme competition (the second is actually, to a larger degree, a resultant of the first in this case). The consequential prime organizational impact is the reduction of profit or even losses.

3.2 *The model structure*

The model is included with the behavioral dynamics of three (3) entities; namely, (i) Management, (ii) Employees/operators (Executors), and (iii) the technical safety barrier systems. In the current version of the model, the organizational and procedural safety barriers are not separately addressed, but considered to be embedded within the human operators behavior.

The model describes various influence pathways between the above 3 entities, that eventually lead to negative safety performance materialized as near misses, accidents, poor health, or degrading environmental impacts.

3.3 *Management reactions*

The SXF model describes the apparent management reactions as a threefold approach; i.e. (i) cost-efficiency drive, (ii) Attention diversion/reduction, (iii) Resource diversion/reduction; the each of these is briefly described below.

3.3.1 *Cost-efficiency drive*

This is the natural "panic action" by most managements when faced by market threats. Loss of profits forces top management to run for extreme cost reduction /efficiency enhancement measures. While the necessity of some such actions is justified, some extreme measures could significantly change an existing positive safety culture as explained by Botheju & Abeysinghe (2017). It is argued that such cost-efficiency measures could lead to negative reinforcements on behavioral safety under certain situations.

3.3.2 *Attention diversion/reduction*

When good economies exist backed by favorable market conditions, top managements usually have high attention to HSE aspects. This is the normal behavior of organizations possessing an adequately good safety performance history. However, a management is tested when it faces difficult market conditions and poor economic performance. Will they be capable of maintaining the same level of commitment to safety under pressing economic situations? Often, many managements yield under such situations and their attention is significantly drawn from their usual emphasis on safe performance to other more urging matters such as economic issues and profitability of operations. This in turn reduces the positive reinforcement previously received by operators for their good safety performance.

3.3.3 *Resource diversion/reduction*

Diversion of monetary and human resources to other purposes, than for the continuous improvements of safety systems as well as for proper maintenance of existing safety barriers, is a natural trend that can be observed under economically challenging periods.

When it comes to many technical safety barriers, they are costly to establish and their benefits are not immediately apparent, or may be perceived as "it can wait". Meanwhile, the actual cost components associated with such safety systems are very real and will have to be immediately dispatched from the existing economic resources. Under this scenario, many managements could be tripped into abandon or delay various continuous safety improvement actions and maintenance/upgrade actions. This forever conflict between production vs. protection (Reasons, 2000) can lean heavily towards production when the resources are more limited.

3.4 *Human operator impacts*

The above described management reactions generate multiple responses from human operators, as briefly described below.

3.4.1 *Efficiency stress and workload stress*

The extreme cost-efficiency drives combined with negative reinforcements, and the lack of positive reinforcements originating from attention diversion reaction leads to high level of worker stress which is further accelerated by reduced amount of human resources (Resource Diversion/Reduction).

3.4.2 *Insufficient quality control*

Both the attention diversion management reaction and the resource diversion/reduction reaction generate this impact on human operations. The lack of positive reinforcements further aids safety quality control barriers.

3.4.3 *Communication breakdown*

The extreme cost-efficiency drives coupled with associated negative reinforcements lead to increased rift between the management and the executors leading to the breakdown of efficient two-way communication. A coherent safety management becomes increasingly difficult under such communication breakdown situation.

3.4.4 *Human error*

A human error is an inadvertent event generated through the actions of human operators while trying to follow a preplanned course of actions. The likelihood of human error rapidly increases when operators are under stress. The probability of discovering such error is also diminishes in the face of insufficient quality control.

3.4.5 *Shortcut procedures*

A shortcut procedure is an intentional diversion from the planned (safe) course of action. Operators resort to such short-cut procedures either because such actions are indirectly promoted by the organizational culture or else as a way-out from the high workload and stress. The lack of safety quality control would further contribute to this situation. The short-cuts may work during most of the times but eventually can trigger chain reactions leading to dangerous incidents/accidents.

3.5 *Performance of technical safety barriers*

Stemming primarily from the resource diversion management reaction, technical safety barriers experience following impacts described below.

3.5.1 *Insufficient barriers*

If the amount of barriers are not sufficient to cover all the high-probability accident scenarios, then the risk of an incident developing into a full scale accident is high.

3.5.2 *Barriers not maintained*

All technical safety barriers require certain maintenance to keep them under optimum performance level. The lack of maintenance leads to their degradation over time and therefore their reliability decreases.

3.5.3 *Decreased robustness*

The robustness can be defined as the spare capacity of a safety barrier to handle accident scenarios beyond the normally expected magnitudes, frequencies, and operational conditions. A more robust safety system has a high tolerance for errors, so that it can still break the propagating incidents originating from significant human errors.

3.5.4 *Barriers not improved*

All safety systems need continuous improvements /adjustments over time. The facilities face different kinds of risks during their lifetimes. For example, an old facility may have a different risk picture compared to a similar but newer facility. Similarly, plant modifications lead to changed risk scenarios. Therefore, the safety barriers must continuously be adopted or upgraded according to the changing conditions.

3.6 *Organizational outcomes*

On top of the existing inherent risks of a facility, additional pathways leading to the development of dangerous incidents are generated as a result of the aforementioned human operator impacts. Meanwhile, due to the simultaneous weakening of the safety barriers, the possibility of containing/resisting dangerous incidents under propagation becomes increasingly difficult. This makes the likelihood of accidents higher. The term "accident" here also embodies other slow phase outcomes such as poor health and weak environmental performance.

4 CONCLUSIONS

This paper briefly presents the preliminary development of a schematic model aimed at recognizing mechanisms behind the apparent correlation between economic pressure vs. safety performance of a profit oriented organization. It is theorized that there exists several indirect pathways leading to a deteriorated safety performance initiating from an economically stressed management, even when the management may not intentionally compromise safety for economic gains.

So named Safety X-factor (SXF) Model is to be further expanded in order to fully explain the negative safety performance trends observed under market downturn situations. The eventual aim is to describe an organization's safety culture using more concrete and measurable terms.

Contributors to successful safety level in the Norwegian railway sector

Dag Wilhelm Aarsland
The Norwegian Railway Directorate, Oslo, Norway

Jørn Vatn
Department of Mechanical and Industrial Engineering, NTNU, Trondheim, Norway

ABSTRACT: The Norwegian government is reforming the railway sector. The reform was formally implemented 1st of January 2017. This has transformed the structure of the sector to ensure clearer division of responsibility, better coordination of service and infrastructure improvements, better aligned incentives and a more customer focused industry. As with any major change in any sector a concern is raised regarding the potential negative safety implications. This paper investigates safety implications of the reform and overall safety responsibilities as the reform progresses. Focus is on factors that can contribute to a future successful safety level. A risk analysis of safety implications of the reform, lessons learned from a similar restructuring in the Norwegian aviation industry and general safety literature, are combined and compared to factors that contributed to a railway accident. A railway accident will be investigated to search for correlation with risk factors in a reformed sector. Special focus will be on the responsibilities of the Norwegian Railway Directorate.

1 INTRODUCTION

1.1 *Background*

To reduce costs within the railway sector and to help build a better railway for its customers, the Norwegian government is reforming the railway sector. The reform has transformed the structure of the sector into several government owned shareholding companies for a better coordination of service and infrastructure improvements. To put pressure on the Infrastructure Manager (IM) and Railway Undertakings (RU) to improve for a more customer focused industry, an incentive regime is implemented.

The Norwegian Railway Directorate was established to ensure coordination and to achieve political goals within the sector. To open for a competing passenger transport marked, the Directorate have requested for quotation for future operation from RUs within the international market.

The Directorate shall have the overall responsibility for coordination and safety measures of the safety level in the sector.

Bane NOR SF is the government owned infrastructure manager and shall carry out work according to budgets. Contracts between the Directorate and Bane NOR regulate the overall responsibilities for Bane NOR, and follow-up of Bane NOR is based on long term effect achievement. This gives Bane NOR a flexibility for future development and to manage their construction-, operation-, maintenance- and safety work within budget limits.

Statens Jernbanetilsyn (SJT) is the National Safety Auhority (NSA), and is responsible to supervise and follow-up the actors according to the railway safety regulations. SJT has certified Bane NOR and existing Norwegian RUs accordingly.

The Railway Undertakings (RUs) such as, passenger transport and cargo transport use the railway for the purpose which is stated in their certificate.

The responsibility for safety level delegated to the Directorate is not well defined, and what kind of responsibility the Directorate can or shall have concerning safety aspects is still under considerations.

To adapt to the reform, Bane NOR implemented a significant organizational change in 2016. To be more cost efficient, costs during the period 2016–2017 are reduced by NOK 750 Mill. For the next period of 4 years, an increase in cost-efficiency is planned. This may increase the organization financial pressure. Focus areas will be economy, staffing, new technology, increase of productivity at all levels and extended use of contractors.

The complexity within the sector has increased due to increased number of interfaces, contract arrangements, splitting of competence among companies and potential reluctance to share information.

The following 3 findings is a backdrop and motivation to proceed with the search for preventive safety factors:

1. To study safety implications before implementation of the reform, the Government ordered an overall risk analysis from SafeTec AS. SafeTec AS identified nineteen main hazards. Three of these safety hazards are identified as; (i) the interaction capability within the sector, (ii) importance and necessity to control the overall risk picture, and (iii) postponed maintenance due to financial pressure.
2. SJT reports 13 serious accidents in the first eight months of 2017, compared to 10 in 2016. Five more accidents are under investigation.
3. SINTEF (2005) investigated safety aspect during restructuring in the Norwegian aviation industry in the period 2000–2005. Lessons learned from this restructuring are used as a starting point for the investigations. Four of the main threats which affect safety were found to be:

   - Reduced organisational ability to discover and interpret development of hazards.
   - Loss of barriers due to loss of organisational capability to make decisions critical to safety.
   - Uncontrolled reduction of safety margins.
   - Problems connected to interaction

Special focus will be on the responsibilities of the Norwegian Railway Directorate which holds a sector responsibility for coordination and development of safety level. Companies that operates within a competing market may focus on the incentives of decision makers with a short-term finance and survival criteria instead of the focus of long term safety effects. This may lead to a systematic and silent migration toward an unacceptable safety level. Accidents or faults which affect a cost-effective operation will create conflicts and probably lead to an issue among the actors.

1.2 *Objective*

The objective of this paper is to focus on ways to structure the risk management, the importance of an overall risk-picture, interaction and cooperation among the different actors to achieve successful operation.

1.3 *Approach*

A risk analysis of safety implications of the reform, lessons learned from a similar restructuring in the Norwegian aviation industry and general safety literature, are combined and compared with factors that contributed to a railway accident. As a case study a railway accident is investigated to search for correlation with general findings in a reformed sector.

Special focus will be on the responsibilities of the Norwegian Railway Directorate.

2 A MOTIVATING EVENT FOR THIS STUDY

The event is a cargo train on a route at line Hovedbanen from Åndalsnes to Oslo, weighting 600 tons loaded with dangerous goods and driving at normal speed limit. Close to Bøn station the cargo train four rearmost wagons derailed caused by rail buckling. Both rolling stock and infrastructure were badly damaged, and the line was closed for 4 weeks.

We will return to the course of events considering obtained relevant literature.

The accident was investigated by the Accident Investigation Board Norway (Accident Investigation Board Norway, 2017). The intention from this investigation is to use and draw points for improvements of a future safety level in the railway sector.

3 THEORY AND BASIC TERMS

The objective of this section is to define the term interaction considering organisational and inter-organisational interface within safety of the railway sector. Conflicting goals in the interface in an organisation and between organisations and the potential of incremental drift towards an unsafe state of operation, need to be explained. The need for an overall coordination of the actors within the sector also need to be explained.

3.1 *Relevant safety perspective*

In theory and practice on safety management related to organisations and to prevent accidents, it is in the past decades developed several safety perspectives. However, accidents still happen. The perspective of Resilient Engineering (RE) is developed from earlier safety/accident perspectives as the 6th perspective (SINTEF, 2010).

> Hollnagel (2008) claims that '*… a resilient system….the intrinsic ability of an organization (system) to adjust its functioning prior to or following disturbances to continue working in face of the presence of a continuous stress or major mishaps*'

This ability to adapt can be done both before and in response to changes and disturbances. This system-change capability allows continuity of operation, even in the case of major accidents or continuous disturbances.

The Resilient Engineering perspective, suggests that an organization must follow, thus observing the

daily normal situation of change, thereby identifying changes that may be a chime for an undesired event. The uniqueness of the RE is not the focus on proactivity, but the ambition of being proactive in a system sense. In other words, a resilient organization can be summed up as resilient when knowing that unexpected problems are present and unpredictable. This involves a form of proactive control where the system (organization or sector) anticipates what is coming and minimizing or eliminating unwanted variation and taking advantage of productive variability (SINTEF 2010).

3.2 *Investigation method and root-cause analysis*

The situation is analysed by the STEP investigation method (Sequentially Timed Events Plotting, see Hendrick & Benner, 1987). STEP is a multi-sequential accident analysis method and is a good method that helps to illustrate events and hazards that causes an incidents/accident (Herrera & Woltjer, 2009).

A Fault Tree Analysis (FTA) is used to investigate the root cause of the basic event Risk Influencing Factors (RIFs). A fault tree is a logic diagram that displays the interrelationships between a critical event (accident) in a system and the causes for this event. The strength of FTA is the deductive reasoning to establish the basic events. However, the influences of contributing factors cannot be handled in the FTA. Therefor a hybrid approach motivated by see Gran et al. (2012) is used where the RIFs obtained from the STEP is linked to the basic events.

3.3 *Risk Influencing Factors (RIFs)*

A RIF is a set of relatively stable conditions influencing the risk. It is not an event, and it is not a state that influences over time. RIFs are thus conditions that may be influenced or improved by specific actions.

A risk model often comprises a formal logical representation of the system. Fault- and event tree analysis is often building blocks in such a representation. Barriers, safety functions and/or layers of protection are typically represented by basic events. Probabilities are assigned to the outcome of the basic events, i.e., success or failure. A wide range of factors and conditions will influence the outcome of the basic events, and these need to be considered. In the literature we find many approaches to link such "soft" factors to the formal logical representation. The literature also presents different names for such factors. In human reliability analysis (HRA) the term performance shaping factors (PSFs) and error producing conditions (EPCs) are used (see e.g., Rausand, 2011). The term contributing success factors (SCFs) has also been used in an attempt to establish resilience based early warning indicators (Øien et al., 2010). To avoid different set of factors for positive and negative issues, we will in the following use the term risk influencing factor (RIF) as a general tem, see e.g., Vinnem et al., (2012) for risk modelling of planning and execution of critical tasks. Interaction and coordination as factor for successful operation

The term interaction in terms of safety can be explained as the way the actors cooperate to coordinate their actions, to obtain a safety achievement, e.g. proactively cooperate to reduce a risk for an incident or accident.

> Rasmussen (1997) claims that '*individual decision makers cannot see the complete risk picture and judge the state of multiple defences conditionally depending on decisions taken by other people in other departments and organisations.*'
>
> Maidment (1998) claims; '*to keep safety levels intact, safety must have a very high-profile aspect in the contractual arrangements between the separate companies.*' To monitor the overall risk-picture in a sector it will be important to coordinate all assigned contracts on a higher level.

3.4 *Monitoring safety*

The safety in restructuring processes can be monitored most effectively by following up on all levels, from individual and technical equipment to sector level. Symptoms of security issues may appear on all of these levels. Security researchers have until now been interested in technical conditions, human factors and organizational levels and to some extent the level of interaction. Today, therefore, there is a lack of knowledge and methods at inter-organizational level/sector level, as well as knowledge and methods that embrace all levels (Rasmussen, 1997).

Problem connected to interaction might arise in connection with restructuring processes with a high level of conflicts. Conflicts will arise, and to avoid safety problems the conflict level need to be regulated to an overall acceptable level.

Management and work planning in any organization apply different control strategies, depending on time horizon, stability of systems, and predictability of disturbances. Management is based on monitoring of performance with reference to plans, budgets and schedules, and control is aimed at removing deviations (Rasmussen 1997). Risk management in a dynamic market in which all actors continuously strive to adapt to changes and the dynamic markets, require an explicit identification of the boundaries of safe operation together

with efforts to make these boundaries visible and to learn and cope with these boundaries.

To give a mental model as a basis we borrow the "layer of protection" concept from the process industry. A layer of protection can be seen as safety barriers, and they are often structured in the way they will be activated in an accident scenario. Compared to the presentation given by e.g., Rausand (2014) and CCPS (2007) we simplify and distinguish between:

a. Process design (by using inherently safe design principles).
b. Control, using basic control functions, alarms, and operator responses to keep the system in normal (steady) state.
c. Prevention, using safety-instrumented systems (SISs) and other safety barriers to act upon deviations from normal state and thereby prevent an undesired event from occurring.
d. Mitigation, recovery and emergency response in case of control is lost.

Figure 1 shows the layers of protection.

Having these categories of layers as a basis we now define: A normal operation corresponds to layer (b). Normal operation may involve adaption to varying conditions as emphasized by resilience engineering. But normal operation does not involve use of extraordinary safety functions representing layer (c). If the primary control is lost and there is a deviation from the normal state, layer (c) is intended to bring the system into a safe state. We define successful operation as a situation where layer (c) is invoked, and can bring the system back to the primary control state. In some situation layer (c) is invoked but without being able to bring the system back to the primary control state. This is often referred to as a state of system outside engineering control. If this is the case, we define successful recovery as the situation where the system could be brought under control and back to its normal state (after repairs, clean-up and so forth).

Figure 1. Protection layers (adapted and simplified from CCPS, 2007).

In the literature, we also find other mental models for accident avoidance than the protection layers understanding shown in Figure 2. One class of such models is the safety envelope model shown in Figure 2, the inner ellipsis limited by the defined operation boundary (DOB), corresponds broadly to what is controlled by protection layers (a) and (b) in the protection layer model in Figure 2.

We may also treat the elliptical band limited by the boundary of controllability (BC) very similar to what is controlled by protection layer (c) in Figure 2. However, there might be differences since the layer of protection concept in Figure 2 is usually based on very explicit identification and design of safety functions, whereas the safety envelope perspective in Figure does not have such an explicit understanding of safety functions. The outer elliptic band limited by the safe envelope boundary (SEB) represents extra safety margins with is a conceptual link to what is controlled by protection layer (d) in Figure 2 but at this level, similarities are not that evident.

A conceptual advantage of the safe envelope model over the layer of protection model is the visualization of the track of the activity over time. In the safe envelope, safe operation is defined as an operation where the operating boundaries are exceeded, but where the boundary of controllability is not exceeded (as illustrated in Figure 2). We will consider an operation to be safe if we are able to remain in the inner ellipsis of Figure 2. We will, however consider two special cases (sub sets) of normal operations as successful operation. The first situation is where there are extraordinary conditions making it very difficult to operate within defined operating boundaries. Examples could be a situation where a long-term development of a fault is hard to control for example due to a situation where the energy in a track is building up close to a rail buckling, or it could be related to extreme weather conditions. If we, despite these challenges, are able to operate within the defined boundaries

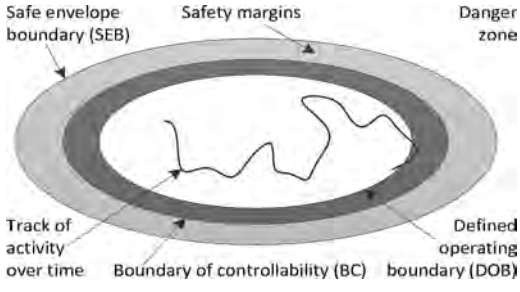

Figure 2. Safe envelope (Adapted from Hale et al., 2007).

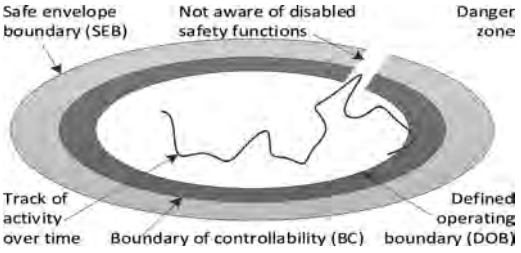

Figure 3. Safe envelope with broken boundaries due to unnoticed deficiencies or problems (Based on Hale et al. 2007).

we will define that the particular operation to be within safety margins. This will most likely represent a situation where operation runs smoothly and production performance will be high. A smooth process represents a situation where we use minimal effort to control the operation, and presumptively better prepared to handle any process upset that might occur. However, there is an argument in this latter situation that would question how safe such an operation is. The fact that there are no process upsets or situations to act upon, could be passivizing the operations crew in the sharp end limiting their situation awareness (see, e.g., Endsley, 1995, for a thorough discussion on situation awareness).

In the safety envelope model in Figure 2 the boundaries are illustrated as static in time. For many operations the boundaries or safety functions cannot be seen as static. We will in the following distinguish between a situation where (i) operating personnel is aware of this situation, and (ii) operating personnel is *not* aware of the status of a safety function or the limits for safe operation. A very easy example of situation (ii) is car driving where the temperature has decreased below zero degrees Celsius on a wet road without the attention of the driver.

Another situation is obvious very critical.

In a situation where the operation is following a trajectory towards an accident without the attention of operating personnel for a while, and then operating personnel become aware of the situation, and succeed in bringing the situation under control. This is visualised in Figure 3. If personnel become unaware of the situation, and unable to bring the situation under control, will cause the operation to move into the danger zone.

4 ANALYSIS OF THE EVENT

The Hovedbanen line is the oldest line in Norway and was opened in 1854. During the last 20 years it has been reported that the line has had several defects and geometry faults, and was planned for renewal in 2020. The national network track geometry condition is regularly measured with a special inspection vehicle. The inspection vehicle takes pictures every 10 meter of tracks during inspections, these are available to all employees in Bane NOR. To detect long term changes or establish fault trends to track and surroundings, Bane NOR need to compare pictures from different periods. The local staff and train drivers often observe changes, and their knowledge is an important input to achieve a good safety level.

The vegetation clearing along the railway increased exposure for direct sunlight to the rails, increased temperature and tension in the track. Missing reference points to be able to measure track position was unknown to the management.

The investigation of the situation is split into two STEP diagrams: One (long-term) shows the period from 2014 until May 31st in 2016, and the other shows the situation causing derailment. The STEP diagrams show that track faults were present already from April 2015 and further escalated until the accident occurred in Mai 2016. STEP diagrams will be published in a master thesis in September 2018 (Aarsland, 2018).

Track irregularities escalated due to construction work, and reported in August 2015, this was interpreted to be within acceptable limits.

From the *long-term* STEP-diagram the following safety problems were obtained during the analysis:

1. Economy: Maintenance back-log, renewal planned in 2020. Missing overall risk-situation picture. Late plan for setting out lacking exact track position marks.
2. Inadequate risk-assessment before construction work to be on an already faulty track.
3. Construction work affects track stability, and vegetation clearing along track increases sun exposure to rails.
4. Project management reports potential buckling problem to the Hovedbanen line management.
5. Several reports from drivers of irregular track conditions.
6. Inspection vehicle 4th measure, again reports geometric track fault.
7. Missing overall risk-situation control. Temperature rise and direct sun exposure to rails results in increased compression forces in track.
8. Track lateral forces on limit to buckling.
9. Overall cost-reduction scheme implemented in 2016.

From the *short-term* STEP diagram (situation causing derailment that day) the following safety problems were obtained during the analysis:

10. Loaded cargo train at regular line speed releases track forces.
11. Track buckles and results in derailment.

The fault tree in Figure 4 displays the interrelationships between the accident and causes of accident. The purpose of this FTA is to look at and

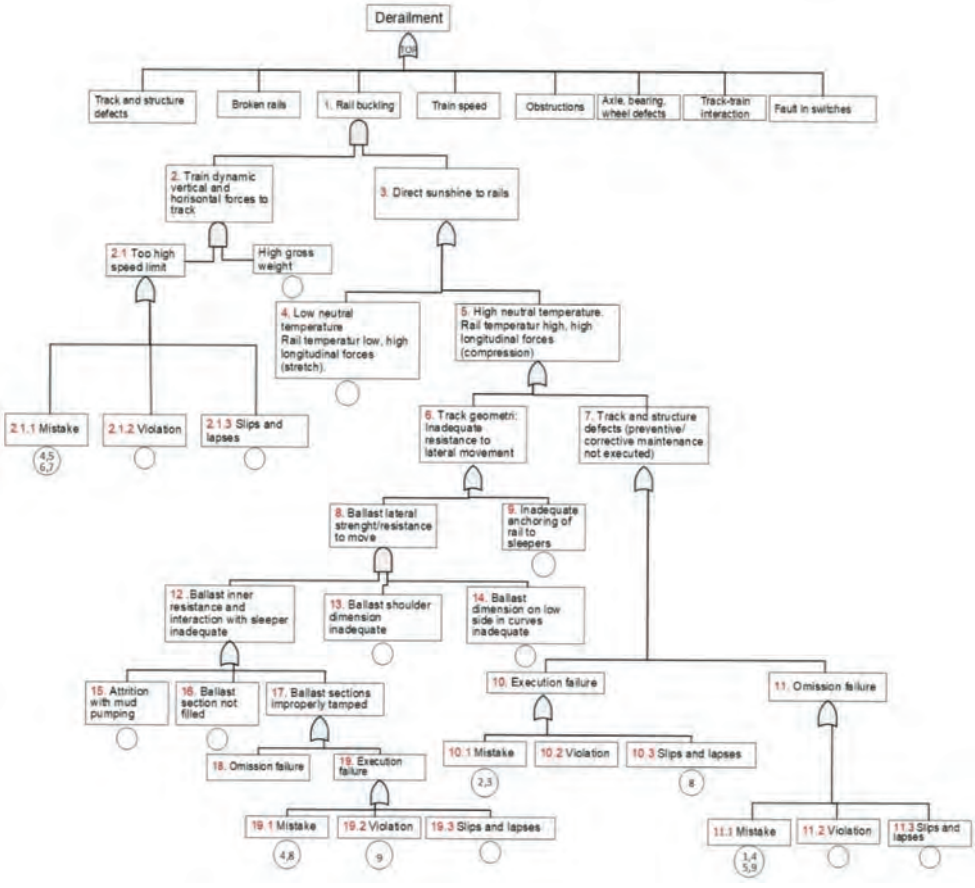

Figure 4. Fault tree with listed RIFs.

evaluate the prerequisites that led to the TOP event 'derailment'. The TOP event is deducted to causal event and further to basic events.

The RIF model developed by Gran et al. (2012) shows that it is advantageous to split basic events into mistake, violation and slips & lapses. We have considered this expedient and used the model in this study. RIFs found as contributors to the accident are shown in the diagram with the following corresponding numbers:

1. Missing overall risk-situation picture as a fundament for renewal investment.
2. Competence to carry out risk assessment.
3. Competence to understand risk of construction work on a degraded and faulty line.
4. Knowledge about neutral state of forces in the track (neutral rail temperature).
5. Missing overall risk-picture to prevent derailment
6. Missing management situation awareness and hence a wrong decision to keep planned traffic level and at regular train speed limit.
7. Management situation awareness, when track geometry is at critical level and in case of increased rail temperature, failure to establish barriers against buckling and derailment e.g. reduce train speed or close line.
8. Management risk awareness of construction work on an already degraded and faulty track.
9. Inadequate shared risk understanding at organisational management levels.

Based on the railway line quality, each of the network line managers reports annual renewal requirements. Requirements are considered and given budget priority in a national network renewal plan by Bane NOR senior management. The management policy is that safety measures always have first priority.

The track geodetic control marks along the railway line were not established, and made it difficult for the line management to know position of the track and hence critical rail temperature for buckling.

Such a condition requires special attention and measures. Risk assessment was carried out by the project management, but did not consider local aging condition, possible weakening lateral stability due to piling of a cable duct or the curvature of the track. Clearing of vegetation causing increased sun exposure was neither considered in the risk assessment.

It seems clear that a missing overall risk-situation picture, situation awareness, competence level, and interaction in the interface between the actors were contributing factors to the accident.

5 DISCUSSION

Comparing previously described SafeTec AS hazards and the SINTEF (2005) bullet points with the contributing factors for the derailment accident case, the ability to control overall risk situation is important to discover, interpret and control safety level.

A premise in a restructured sector, is that all actors shall have the responsibility for their own safety under the supervision of SJT. SJT shall ensure that Bane NOR and the RU's operation in the interface complies with railway safety regulations. However, not all actors in the sector are under the supervision of SJT.

Cooperation between and contribution from all actors are important input to achieve a dynamic risk-picture for managing risk in a sector. In the contract agreement between the Directorate and Bane NOR, Bane NOR shall establish and maintain a railway sector risk-picture, reflecting types of hazards and locations, and be based on risk assessment and incidents.

The risk of drifting away from safety margin, and 'Silent Drifting' due to financial pressure are indicated both in the SafeTec study and as uncontrolled reduction of safety margins in the SINTEF (2005) investigation. In the accident case, missing situation risk picture and ability to understand risk development, and decide priority to renewal of the line, resulted in long-term track fault development. Increased competition, and the future arrival of new railway undertakings and railway maintenance companies, will increase financial pressure. This can cause a risk of "Silent Deviation" in the operative sharp-end.

The term "Silent Deviation" is used by companies in the oil industry to describe the mismatch between procedures and actual work practices (Tinmannsvik, 2008). This is an attitude among the staff to reduce the conflict between getting the job done and compliance with procedures, and is an expression of how routine violations of written procedures tacitly become accepted practice. Reason (1997) uses the term "necessary violations", where operators adjusts the balance between procedures and knowledge based problem solving to get acceptable workload.

Problems connected to organizational interaction (SINTEF. 2005), SafeTec hazard 3., and the contributors to the accident: Lack of interaction between project, railway line management, Bane NOR management and involvement of maintenance personnel resulted in lack of shared safety related information.

In the restructured sector with an increase of organisational and inter-organisational interfaces, with increased financial pressure, might these challenge the safety margins. To understand how safety are affected at all interfaces, interaction and coordination at all levels is crucial. According to Rasmussen (1997) individual decision makers cannot see the complete risk picture and judge the state of multiple defences conditionally depending on decisions taken by other people in other organisations. Therefor monitoring of safety level depends on sharing of information, interaction and cooperation.

The Directorate has the responsibility for the development of a good sector safety level. SJT shall ensure that certified actors have a system for continuous improvement of safety, but do not have the mandate to set specific goals. The Directorate can however, set goals to be achieved in the contract agreements.

Exception from this is railway vehicle maintenance workshops, entities in charge of maintenance, vehicle owners or manufacturers. According to Maidment (1998) contracts must be coordinated on a high level in the sector. This is the responsibility of the Directorate.

6 SUMMARY AND CONCLUSIONS

A case study is used to shed light on overall safety responsibility, and possible risk factors in a reform with high political focus on the main success factors 'cost efficiency' and 'safety level' in the railway sector. An accident has been analysed with a traditional investigation method to reveal safety problems. The STEP method (Hendrick & Benner, 1987) has been used as a basis for the investigation. A fault tree analysis is carried out as a basis to find the Risk Influencing Factors contributing to the accident.

The case study shows that interaction in the interface between different organisational units is important to ensure safety. The study also shows that a situation risk-picture is required as an input to make safety related decisions. Risk management in a dynamic market in which all actors continu-

ously strive to adapt to changes, require an explicit identification of the boundaries of safe operation. Main threats learned from the investigation after restructure of the Norwegian aviation industry can be closed as follows:

The Directorate should contribute to strengthen overall cooperation within the sector for Bane NOR to be able to implement and monitor a process for interaction in the different interfaces, and manage boundaries of acceptable safety level. The following points are essential for organising and to allocate responsibilities.

- Ability to regulate safety at an overall level. A resilient railway sector requires a dynamic risk-picture with contribution of risk-assessments from all actors at all levels. Bane NOR should develop and to actively use the risk-picture as a sector risk management tool.
- The Directorate should contribute to strengthen level of safety among actors in the contract agreements within the sector.
- Bane NOR should have responsibility to establish an appropriate level of information sharing, coordinate and propose safety measures in the interfaces between all actors in the sector.
- Bane NOR should establish an expedient level of risk monitoring.

Actor independent safety aspects that are important to follow up:

- Success Contributing Factors (SCFs) should be used to establish resilience based early warning indicators.
- High level of competence to understand RIFs at all levels in the sector, and as part of risk assessment.

It is recommended to extend the investigation to search for visible explicit boundaries as a tool for monitoring overall safety within the railway sector.

Tough men cry—learning from sharp end military aviation II

T.J. Steiro
Institute for Teacher Education, The Norwegian University of Science and Technology, Trondheim, Norway

C. Moldjord
The Norwegian Defence College, Department of Air Force Academy, Trondheim, Norway

ABSTRACT: The current study is scaffolding on the paper *"Tough Men Cry—Learning from Sharp End Military Aviation",* and presented at ESREL 2010. The previous paper reported on findings from a specialist course at the Royal Norwegian Air Force Academy (RNoAFA) termed *"Effectiveness in the Cockpit—Developing and Taking care of the Man in the Machine"* held in 2005. In 2010, five of the pilots were re-interviewed in order to understand more of the human side of military aviation and see more of the effects out in the squadrons. In the data from 2010, we see a transfer of knowledge taken back to the squadrons. We see from the interviews strong focus on performance and improvement. On the same time, there is hierarchy to reflect on regardless of hierarchical position. There is a need to protect ones position (professional hierarchy. However, the professional hierarchy can also be used positively to lead by example and pave the way for learning.

1 INTRODUCTION

The current study wanted to follow up on a previous study that was named "*Tough Men Cry—Learning from Sharp End Military Aviation*" that was and presented at ESREL 2010 (Steiro, Moldjord, Fredriksen & Firing, 2010). The previous paper reported on findings from a specialist course at RNoAFA named "*Effectiveness in the Cockpit—Developing and Taking care of the Man in the Machine*" in 2005 (Moldjord, 2007). All seven pilots participating in the course were interviewed and through a thematic analysis, the following topics were identified and discussed:

1. Challenging events
2. Emotions on the table
3. The role of the teacher/coach
4. Group based dialogue
5. Meaningful narratives
   (Firing & Moldjord, 2007; Steiro, Moldjord, Fredriksen & Firing, 2010).

In 2010, five of the pilots were re-interviewed in order to understand more of the human side of military aviation and see more of the effects out in the squadrons.

2 THEORETICAL FRAMEWORK

Historically, the educational practice in the military can be characterized by a behavioristic view of learning where teachers and instructors transmitted knowledge to the students. A wide set of reinforcements were used; both negative and positive consequences were systematically related to bad or good behavior respectively (Skinner, 1953). In the last 20 years process-oriented coaching seems to have turned the attention within educational practice in the direction of each student's thinking and feeling. Interviews indicate that students at the RNoAFA value practical exercises and cases and post-action reflection in groups as the most valuable learning for them (Steiro & Firing, 2009). Each student is addressed, stimulated and challenged to engage in their own process of assimilation and accommodation (Piaget, 1977). This method emphasizes the process of raising students' awareness and the development of each student's own thinking, emotions and reflection. In the same process a culture of coaching has arisen which supports this educational philosophy. Experienced officers serve as coaches and mentors in the process of constructing new knowledge. Their intention is to help the students in their own process of growth and realization of their potential as officers (Vygotsky, 1978). Today, The RNoFA has founded its educational practice in the concept of learning from experience as educational philosophy (Dewey, 1997, 1961; Skjevdal, Solheim & Henriksen, 1995). The RNoAFA has chosen to build its educational philosophy on three pillars:

1. Theory
2. Practical training
3. Reflection
   (Firing & Lien, 2007; Steiro & Firing, 2009)

The course "Effectiveness in the cockpit" was a single semester course offered in the autumn 2005 and winter 2006. The level is on both the individual and on a group level. The same level as we have kept on the analysis in this paper.

The course the cadets were provided aligned with the pedagogic model at the RNoAFA. I In accordance with how Bruner addressed the link between cognition, action and emotion (1986), these three pillars were also included in the curriculum as a second triangle. This is based on Bruner's thoughts (Bruner, 1986). Bruner (1986) addressed the link between cognition, action and emotion. One problem, however, with most military debriefing is that it often lacks the focus of emotions and individual inner experience (Folland, 2009). One way to get more aligned with Bruner is to broaden the debriefing by a more holistic reflection of thoughts, emotions, actions, team relations, and communication. In a Holistic Debrief (Moldjord 2015, Moldjord and Fredriksen 2017) we asked questions such as "how did you experience the event?", "what affected you most?", "how did we communicate?", and "how did we cooperate?" In addition to provide feedback to each other. In order to establish a sound safety culture, Reason (1997) pointed out the following elements as central for a safety culture in an organization:

- A reporting culture
- A just culture
- A learning culture
- A flexible culture

In order to obtain a sound safety culture, sensemaking can be seen as an important framework for safety. Sensemaking denotes processes of interpretation and meaning production through which individuals and groups engage their worlds on an ongoing basis (Cation & Patriotta; 2013; Patriotta & Brown, 2011; Weick, Sutcliffe, & Obstfeld, 2005). Sensemaking arises when people encounter situations that defy their current understandings and call for adjustment.

Several scholars have pointed out that learning from errors allows organizations to improve safety, reliability, and resilience (e.g., Reason, 1997; Ron, Lipshitz, & Popper, 2006; Weick, 1987; Weick & Sutcliffe, 2007; Catino & Patriotta, 2013). *"Errors, whether actual or anticipated, provide an empirical intersection between sensemaking and learning. In fact, learning—the detection, reporting, and correction of errors—is contingent upon the way in which individuals or groups interpret a problematic situation to themselves. In this respect, errors play an essential role in processes of construction of reality. This construction revolves around cognitive, emotional, and cultural sensemaking, which may or may not lead to processes of learning from errors"* (Catino & Patriotta, 2013:462). Zhao (2011) found that negative emotions can stimulate motivation to learning from errors when leaders encourage a positive and constructive view of errors and thereby alleviate individual tension and stress.

Bennis and Thomas (2007) claim that defining moments in a persons life is an opportunity to learn and to grow. Folland (2009) found that all the staff at the helicopter squadron had some challenging events that they brought up. Several had never shared the incidents or more precisely how the incidents had influenced on them. In our study, putting challenging events on the table made it more clearly for the other pilots to talk about each others experiences. Language does not transfer but also create and construct knowledge or realities (Bruner, 1986). Through the course, the cadets have transferred the experiences to meaningful narratives. This might have a positive health effect. Pennebaker (1997) argue that narratives organize overwhelming events to smaller units that hare easier to handle (Pennebaker, 1997). By constructing a narrative, the person goes through a process that helps the person to better understand both the experience and himself. The experiences have now got a structure and a meaning, which in turn may provide a feeling of solution. Something that has been viewed negatively might now be viewed more positively.

3 METHODS AND MATERIALS

We observed systematically throughout the course. The military psychologist took notes and recorded reflections, and the students also used writing reflection as a tool. These records of reflections were made available for a researcher at the RNoAFA who was not a part of the course. The same researcher conducted semi-structured interviews. The interviews with each of the seven pilots were carried out at the end of the half year course by one of the authors. The interviews were taped and later transcribed for analysis (Yin, 1994; Creswell, 1998; Thagaard, 1998). The research team consists of both teachers and researchers. One potential disadvantage is that the work can be viewed as action research (Greenwood & Levin, 2007), meaning that certain norms are imposed on the group and that the research then of course is not objective. These interviews were used as a background for planning and executing the research in 2010.

In the spring, just after the paper to ESREL 2010 was submitted, all pilots were invited to a new interview. Two of the pilots were not available due to practical reasons. Five of the pilots were available and agreed to be interviewed. The interviews were conducted at the pilots' respective workplaces

during 2010. The study of 2010 demonstrated that new learning had come up due to the educational framework created in the RNoAFA and in particular in the course "Effectiveness in cockpit". Military pilots are often performance orientated and aiming at high professional performance. Talking about incidents or accidents can put them in difficult position. All informants were informed of the purpose of the study and signed an informed written consent. All the informants also agreed that the interviews could be recorded. Most of the interviews lasted approximately 70 minutes, while one interview lasted 120 minutes. The recordings were later fully transcribed so both authors and interviewees had the full access to the material. A thematic analysis was performed and centered on challenging events, the way emotions played a role and what would happen in the dialogue after something had happened. This was scaffolding on the elements from the study of 2010. The categories were made through item-centered analysis (Thagaard, 1998).

The research questions was how did they use their experiences and how did they reflect on learning from experiences in the cockpit?

4 RESULTS AND DISCUSSION

In the interviews the pilot talked a lot of characteristic of being a pilot. So we identified this as an important theme for analysis. First, we extract from the interviews the pilots' perception of characteristics of being a military pilot and how it might enable and limit the ability to learn and share. Further, we have extracted three incidents that could serve as illustrations and situations that can complement each other in understanding the experiences of the pilots, how they are dealt with, and the role of the group. The three situations can be termed as:

- A potential dangerous situation of coming out of course
- A near miss within the envelope with the instructor taking over
- An actual severe incident and the handling of it afterwards

The examples illustrate different situations but also how the group might shape the narratives. Narratives and the reshaping of narratives are important to understand safety.

4.1 *The pilots perception of characteristics of being a military pilot and how it might enable and limit the ability to learn and share*

The first theme is of interest since it is about characteristics of being a military pilot and how it might enable and limit the ability to learn and share. All the pilots refer to the systematic processes of sharing in a debrief. The debrief is mission oriented and performed after each flight, and it is structured to focus on technical and tactical aspects. It can also include more emotional aspects. First, experiences after a flight is shared within the flight or crew members. In addition, other personnel can be brought in to contribute, for instance in a near miss or incident. The severity of situations such as a shooting accident calls for others to be brought in, typically flight safety officers second in command of the squadron, and additional personnel. The pilots talk of early selection and intensive training particular in earlier part of the careers. They also talk strongly of a performance culture where they measure each other, or are measured within a group. The professional hierarchy is of importance. The date of receiving the wings are important, the number of hours flown are typically shown on patches (i.e. *"1000 hours in Fighting Falcon",* that is the F-16, courses and check-outs you have been through and experience from international operations). A check-out in aviation means that the pilot is testet and has "passed the exam" and are allowed i.e. to operate the 20 mm machine canon in an F-16. Other Check-outs are for instance leading other aircraft, lead a formation at night etc. The peers from flight training are important, since they are able to share experiences and bonds from the pilot training in the United States. A pilot will go through training and check-out at the squadron. In the current study, there are both fighter pilots and helicopter pilots. The fighter pilots operate alone in the aircraft, except when an instructor sit in the back in a tandem F-16B. Otherwise, they always operate in pairs of two, implying that the relational aspect is present at all times. The helicopter pilots fly minimum with a system operator, and in addition there might be rescue divers, nurses or gunners, depending on the mission and type of helicopter. The team aspects is always there. At the same time, they will always be evaluated individually. In the interviews, all pilots in the current study touch upon their status and reflect on their ranking. They are all reflecting on their position at the squadron, acknowledging that being a newcomer is demanding regarding speaking up. All informants point out that it is easier to speak up for a more senior pilot. However, the senior pilots like themselves play a crucial role in facilitating openness in for example a helicopter crew. The pilots should be aware of the hierarchy and make sure that the other crewmembers are free to speak out or to speak first because of the hierarchy. At the same time it is important to have established a position as a good pilot. Informant 4 express the positioning of the pilots in the following way:

"You do not need to be the best. But overall, you must avoid being the worst. However, it is not communicated, it can be expressed by who gets some courses or positions to a greater degree than others, but not communicated and stated very clearly, but we still know it"

Pilots lower in the hierarchy can be too focused on not getting blamed and pointing to others mistake that might put them self in a relative better position. The same was reported in a study in the Italian Air Force (Catino & Patriotta, 2013). Informant 1 thinks that the youngest pilots are not necessarily that concerned of their position since they are in a learning phase and that there are so much to learn at the start in the squadron. However, this can vary from person to person. For some pilots, flying a fighter is their main purpose in life. For others it can be viewed as a job, and other aspects of life are as important. Informant 1 reflects on the balance between learning and performance:

"Where is the boundary between learning and achievement, the limit of how bad you can present your own presentation for learning purposes? I think there is a limit there. I can contribute a lot for learning purposes, but at one point I need to protect myself".

Informant 2 remember commanders that had stepped out and announced within the squadron:

"If the boss could share his biggest mistakes, so can I. Nevertheless, I do not trust for sharing everything with everyone. We have examples of people in the hierarchy uttering something that makes us suspicious. The utterings do not seem very thought through". If you are unsure you learn for yourself or only share experiences among the closest".

Informant 3 reflects regarding facilitating debrief after the introduction of Holistic Debrief in the Norwegian helicopter detachment in Afghanistan in 2010 (Folland, 2009; Moldjord, 2016).

"A system operator approached me and expressed concern whether he had to share all my feelings with me". I said, "You do not need to if you do not want to. But you can if you like". The system operator seemed happy with the answer. But we, the older ones, need to do it, otherwise the youngest will not follow".

Informant 4 points to another reflection looking at his pilot career describing an environment that is very focused getting on goals, focusing on improvement and performance. Informant 4 reason that this lead to focusing on the past and the future, but less on the present.

4.2 *A potential dangerous situation of coming out of course*

The first situation is reported by the pilot of a Bell 412 SP flying with a system operator. The system operator had little experience and they were going to fly for a long distance at wintertime in Norway. The pilot saw this as a good opportunity to let the system operator have more experience. In addition, he did not choose to have a more experienced system operator to sit in the back seat. They were flying and they missed some spots, they needed to reroute and the weather was getting worse with lower visibility. Informant 2 explains:

"We start talking. I adjust the speed to the weather the conditions, I do it, and we wrongly navigate, I support him on the map while flying the route … I use him, asking him questions. I see this far. How long distance can you see? I further asked him what he is looking forward. I think he is too much focusing on a spot that he is concentrating on". Also his vocalization, how much/little he talks, what he talks of, what he is talking of, he is focusing far out"

The system operator identifies their position and the tension decreases. They continue flying the route, but the visibility in a valley gets below 800 meter. The pilot remembers he was no longer confident with the situation. What happens is interesting. There is calmness in the cockpit, however;

"I say that we will turn and land, and then, very sudden, he agrees wholeheartedly. We land in a farm field, and I shut down the system. At the same time I reflect that this is not something overly dramatic. It is dramatic within acceptable boundaries".

While the engine was shutting down, the pilot starts by asking the system operator what he thinks first. In the informant's view, it is important that the system operator is not overly influenced by the hierarchy. The system operator was very concerned that he did not find geographical features from the map such as a wire and a church. He is very concerned with his own mistake. Informant 2 underlines that we did not find it out. The informant also explained to the system operator:

"I explain to him that it was my feeling that it was not ok to fly further. Then I will raise my voice. I also say to him that I expect the same the other way. We have talked about this before, but now we have an actual shared experience of this".

They are invited in for a meal at a farmer's house and stay there for a while. They arrive at the destination one day later. It was a trip with a lot of learning. After landing at the final destination they debriefed the mission. The informant sums up the experiences:

"It's a matter that I was particularly pleased with when I recognized my activation (of fear). This is the activation we have talked about, written about. This I've experienced before, and it's ok. So it's not disturbing, what's going on with me now, it never turns in to high stress. This is information that means that I'm affected and I have to take some extra consideration, calm down. I have the opportunity to make some bigger margins now, so I can do that. In several situations on the same trip, I have been activated, but not done anything about it and put it away, more like an emotionally oriented coping strategy, (telling myself) this I have to take care of after landing"

We see an interesting example of the social interaction in the helicopter. We see that the pilot by opening up for questions invites and encourage the system operator to also have a saying. The pilot report that the system operator very quickly agree, assuming that he might have thought of the same. The professional hierarchy play an important role and by reducing the authority gradient (Rosness, 2001). Authority gradient was first defined in aviation when it was noted that pilots and copilots may not communicate effectively in stressful situations if there is a significant difference in their authority, experience, or perceived expertise (Crosby & Croskerry, 2004).

4.3 *A near miss within the envelope with the instructor taking over*

The next situation is told by informant 2 which was flying with a new fighter pilot. They were sitting in an F-16B tandem with the instructor (informant 2) sitting in the back seat. The student was about to be checked out on firing the 20 mm machine gun on ground target. The limit is 5 seconds to ditch the fighter aircraft down, aim, fire, and then you are at minimum distance. Then there are additional 4–5 seconds to pull up. In the first part of the training mission the pilot student has dropped bombs which is quite usual on that type of training missions. The shooting is always at the end of the mission. At that time the type of ammunition required the pilots to get near the target, meaning that this is very stressful for both student and instructor. The student had already tried shooting but fired too far out and then missed the target too much. The student aimed for a third time. Informant 1 explains further that on the next round the student was very concentrated and he was paying extra attention.

"I imagine he's going to come in and get closer, and he comes in too close, so I yelled at him that he should get off the target, which means he's going to pull the stick back, but he did not hear that because he was aiming, aiming and shooting while I was once again roared to him that he should get off. Then I pulled the stick back at the same time as him. I wanted him to become aware of what was going on, so I pulled the stick back"

This is explained by the informant as target fixation: The student was too focused on the target, aiming at the target and forgetting about assessing the distance. It was a very brief window to interfere. As instructors, we want them to succeed.

"He immediately understood what had happened and became, I think, perplexed. I took over the flying in order for him to get back. We talked briefly; however, we were running out of fuel, so there was not much else to do than landing".

After landing, they talked about the situation. The student was expressing his views. He said he was close, but further expressed that he was not too fixated on the target, that he had some degree of control. They agreed that they had been within the safety limit. They performed a debrief. This was his first mission shooting with the 20 mm machine canon. Grades are assigned. The student fails one or two points, and one of them is safety, meaning he has to do the mission all over again. At the same time the informant explains central elements in the debrief session:

"The student had a need to explain what kind of situational awareness he had in the situation, what he thought and why it happened. (First) I explain what I thought, what I did and why I did it. It's on that level. I say that I'm an instructor open for that I might have made a mistake, perhaps intervening too early or doing something that's not good (for the student). Then he's able to explain how he experienced the situation".

We see from the example that student pilot and the instructor have a different risk perception. The instructor pilot get an uneasey feeling and instruct the pilot student to pull up. When there is no reaction, the instructor pilot shout and pull the stick at the same time. We see an interesting process of making sense of the situation. They both agree that they were within the safety envelope. At the same time, the instructor do not pass the pilot student. And the pilot student needs to perform the shooting with the 20 mm machine canon again.

4.4 *An actual severe incident and the handling of it afterwards*

The last situation is from informant 4. The informant was not directly involved and is about how the situation was handled afterwards. During night time shooting, a pilot missed the targets and the

bullets hit the shooting observation tower. There were no injuries on personnel, but it was a potentially very dangerous situation with possible several fatalities. Informant 4's role was being part of the squadron command team, responsible for following up on the involved pilot, knowing what was going to happen to him afterwards and prepare him for that. Informant 4 was also a part of the command team responsible for facilitating the debrief setting for the involved person. In addition, he was responsible for informing the rest of the squadron and the involved families. The challenge was that the pilot reported a high degree of blame and guilt. The informant attributed a lot of his 'follow up' handling to what he had learned at the RNoAFA:

> *"The most central aspect in my knowledge is what I learned at the Air Force Academy and the focus on reactions and experience with feelings like fear, shame and guilt. Now I looked at the person carefully and looked for facial expressions to see and meet his needs. I avoided making him sit alone in a blood test session for hours, although the formal test was alright. But to have someone there to talk with a familiar face so trust became focus versus procedures. That was the most important knowledge that I brought with me. I steered consciously clear of such thing as "have you taken care of the video", "can I see your data card", all things that indicate that we must check in order to understand what the pilot did wrong, versus take care of the person. The others can handle the formal things".*

The informant reflected on what his perspectives might have been earlier, that typically would have been focus on the individual, little training, little flying lately, should have been better prepared, tried another round. The informant reported that they did focus on the circumstances. As illustrated in 3.2., the ammunition had changed, now allowing for firing at longer distances. However, the shooting range was built in a period when firing at closer range. In addition, light conditions, the arrangement of flashlights, different location of the towers that were hit could have been better designed. So informant 4 points to the root causes and seeing the pilot in the wider context;

> *"Looking at the system he was part of".*

This quote can be seen in relation of learning at the organizational level as well as the individual level (Reason, 1997). The informant told us how important it is to take care of the person behind the mistake, not just the role of the pilot. The most important thing is to get the pilot back in the cockpit, and then it is crucial to take care of the person. Also, it is important to avoid blaming and too much focus on procedures right after an accident. At the same time, this incident has an organizational perspective. The entire organization can learn from the error and how it was handled afterwards. Before one can focus on learning, one needs to calm down strong emotions such as fear, guilt, anger, and pride. Creating an arena where emotions can be expressed is important before focusing on learning. In such a situation, Holistic Debrief is very relevant (Moldjord and Fredriksen, 2017). This aligns with the practice of double loop learning (Argyris & Schön, 1978). The informant reflects on differences between the squadron and other environments he knows of and claim they are good at sharing mistakes. Not everything is fine, but they are sharing experiences after a mission. If you experience a close encounter with a wire, you raise up in the morning meeting and share it with the others.

5 CONCLUSION

We see from the interviews strong focus on performance and improvement. On the same time, there is a hierarchy to reflect on regardless of position. There is a need to protect one's position. However, the hierarchy can also be used positively to lead by example. In the current study, all the pilots had experiences and lead several missions, and three of them had management positions meaning they had significant positions in the squadron. They all reflected on how their position can be used to lead and facilitate learning. All acknowledged the challenge of the degree of openness and position in the hierarchy. They also report of something that is "private" and not shared widely. This is in accordance with the findings of Catino & Patriotta (2013). It is also a challenge to create a learning safety culture (Reason, 1997). The informants talk of what we would term a generative reporting culture. That would also be termed as double loop learning (Argyris & Schön, 1978). Some of the learning that involves blame is linked to a more internal learning or is only shared with peers. This is especially evident if it threatens one's overall position as a pilot or in the hierarchy. Being in a strong position means that you easier can lead by example. All pilots reported favorable learning of the course Effectiveness in the cockpit. Moreover, as we interpret it, there has been some transfer of knowledge from the course to practical military leadership. It seems important that operative leaders have the knowledge of addressing the balance between performance, caring and learning after an error event or a mistake. Furthermore, it is important that such experiences are lifted from an individual level to something that the

entire organization can learn from. Therefore the organization needs to create arenas where trust is established and there is enough openness to share important experiences, like a Holistic Debrief (Moldjord and Fredriksen, 2017).

5.1 *The need for further studies*

It is of great value to follow a group of officers over a period of time since long term studies are often missing within this research field. We therefore plan to conduct a third round of interviews which hopefully will be accepted by all the pilots. We will look more in detail into the topics covered here in the current paper. The analysis in this paper indicates the strong effect of the context. Further studies on how the processes are shaped and could be managed is of interest. Also, we want to further examine how a squadron can enable for more sharing and learning. We will look more into the organizational and management and leadership aspects of learning. The pilots in the current study has now moved on to administrative positions. That means that it might be easier for them to understand the environment on the inside, but still obtain an analytical distance to the subjects, all while examining sensemaking processes over time and seeing the interplay between professional hierarchy and sensemaking processes.

Applying elements of the STAMP method to the reorganization of the German nuclear waste management

Heinz-Peter Berg
Braunschweig, Deutschland, Germany

Stephan Griebel & Birgit Milius
Siemens AG Braunschweig, Deutschland, Germany

ABSTRACT: Over the last years, the structure of the legal entities to govern all issues of the German nuclear industries has changed significantly. What used to be just one company is now divided into four entities between which responsibilities were shared and new tasks allocated. For this actual example of comprehensive structural changes, in particular regarding conditioning, handling and interim/final storage of radioactive waste in Germany, we apply the STAMP (System-Theoretic Accident Model and Processes), approach in order to demonstrate how the STAMP structure can be used to monitor and master this change. The choice of the industry area of nuclear is solely motivated by scientific interest and excludes commercial aspects. Siemens is not active in the "nuclear waste" management industry.

1 MOTIVATION

Reorganisation is always a very complex task in any undertaking. When dividing existing organisations and establishing new ones with new stakeholders, formal and informal processes and tasks have to be considered and adapted where necessary. This becomes even more important when safety-critical aspects are involved. As a safety-critical area we will be focusing in this article on the Nuclear Waste Disposal in Germany. A very clear and structured approach is helpful to keep track of the relevant changes, but also to visualize those changes in a clear manner. The last aspect especially helps to inform all concerned parties and can be used as a starting point for the discussion and verification of the model.

The described difficulties can be modeled as a control problem. Instead of developing a completely new theory it seemed sensible to use an existing theory. The advantage of using an existing model framework is that a certain set of conditions exists on which the ongoing work can be based on. In our paper (Berg, Griebel, Milius 2017) we have shown that STAMP, a theory developed by Nancy Leveson, can be used to model organizations on a high level. We applied some elements of STAMP to the current situation in the German nuclear industry. We modeled the current organizations and the existing interactions and discussed some fictional examples. In this paper, we will elaborate the example further, detailing a certain part of the existing STAMP structure for the German nuclear industry, i.e. by clearly visualizing the structure and the processes using elements of STAMP we gain further insight

The paper is structured as follows:

In the first chapter, we explain the area of application that is the expected changes to the process of nuclear waste disposal. We will address the current situation, the planned changes the expected challenges. Afterwards, we will give a short overview of the basic concept of STAMP and explain our chosen modeling approach. In the third chapter, we will present today's situation in nuclear waste disposal as well as the future situation using the visualizing elements of STAMP. We will compare both structures and discuss interesting aspects.

2 NUCLEAR WASTE DISPOSAL IN GERMANY

2.1 *General*

In general, most radioactive waste in Germany comes from nuclear electricity production. However, it is also generated in hospitals from the use of radioactive material to diagnose and treat the sick and sterilize medical products, in the production of radiopharmaceuticals, at universities in conducting vital research in biology, chemistry and engineering.

These wastes must be safely managed at all stages prior to and including final safe disposal. Storage is an integral part of the waste management process.

In Germany, disposal in deep geological formations is intended for all types of radioactive waste. However, there are strong debates concerning various nuclear waste disposal options including direct deep geological disposal with and without waste retrievability, long-term interim storage, as well as new conditioning and treatment concepts such as partitioning and transmutation. Scientific research to provide input to the decision-making process is essential, as this is the only guarantee for reliable data and models required for any sound, scientifically-based safety assessment.

Decentralised storage facilities for spent fuel were licensed under nuclear law and constructed and commissioned at twelve sites with nuclear power plants. They are designed as dry storage facilities in which transport and storage casks loaded with spent fuel are emplaced. Storage casks for spent fuel in the three central storage facilities have the same properties as the storage casks in on-site storage facilities.

By means of conditioning of the radioactive waste, intermediate or final products shall be produced which fulfill the requirements on safe handling, storage and transport also for the period of extended interim storage. The radioactive waste is to be safely stored until it can be delivered to a facility of the Federation for disposal.

Currently, there are still eight operational nuclear power plants left in Germany. For one further nuclear power plant the authorisation for power operation expired on 31 December 2017 in accordance with the German Atomic Energy Act (Federal Law Gazette 2017c).

Moreover, there are currently three research reactors, three reactors for training purposes and one reactor for educational purposes in operation.

However, many nuclear facilities are already in the process of decommissioning as listed below:

- seventeen nuclear power plants in the process of decommissioning as at 30 April 2017,
- nine research reactors with an electric power of more than 1 MW permanently shut down, in the process of decommissioning, or decommissioning completed and released from nuclear regulatory control, as at 30 April 2017,
- twenty-nine research reactors with an electric power of less than 1 MW permanently shut down, in the process of decommissioning, or decommissioning completed and released from nuclear regulatory control, as at 30 April 2017,
- eight experimental and demonstration reactors in the process of decommissioning, or decommissioning completed and released from nuclear regulatory control, as at 30 April 2017,
- six commercial fuel cycle facilities in the process of decommissioning or decommissioning completed and released from nuclear regulatory control, as at 30 April 2017.

This underlines the necessity of urgent solutions.

2.2 *Explanation of current structure*

The Federal Ministry for Environment, Nature Conservation, Building and Nuclear Safety (BMUB) is the nuclear regulatory authority of the Federation. As defined in Article 73 of the Basic Law (Federal Law Gazette 2014), the Federation shall have exclusive legislative power with respect to "the production and utilisation of nuclear energy for peaceful purposes, the construction and operation of facilities serving such purposes, protection against hazards arising from the release of nuclear energy or from ionising radiation, and the disposal of radioactive substances".

The "Gesellschaft für Anlagen—und Reaktorsicherheit (GRS)" carries out research and analysis in its fields of competence, namely reactor safety and radioactive waste management, and supports the BMUB on technical issues.

The Nuclear Waste Management Commission (ESK) advises the BMUB in nuclear waste management issues (conditioning, interim storage and transports of radioactive material and waste, decommissioning and dismantling of nuclear installations, disposal in deep geological formations).

The Federal States carry out their tasks under nuclear law on behalf of the Federation (federal executive administration). Federal supervision extends to the legality and appropriateness of execution by the Land authorities. According to Article 85(3) of the Basic Law, these shall be subject to the instructions from the competent highest federal authority (BMUB).

In performing their activities, the Federal State authorities may consult technical expert organisations or individual experts according to § 20 of the Atomic Energy Act (Federal Law Gazette 2017c). Today, this is mainly ensured by the technical expert organisation (TÜV) for specific issues. With the involvement of experts, an examination on the safety-related issues is made which is independent of that of the applicant.

The Federal State Authority for Mining, Energy and Geology is the mining authority and is granting mining legal licenses for nuclear waste disposal in deep geological formations.

The Federal Office for Radiation Protection (BfS) is a subordinate authority of the BMUB in the area of radiation protection and nuclear safety is the BfS. The four technical departments of the BfS deal with the statutory tasks in the areas of environmental and industrial radiation protection, radiation biology, radiation medicine, nuclear fuel supply and waste management and nuclear safety. The BfS supports

the BMUB technically and scientifically, especially in the execution of supervision of legality and expediency, the preparation of legal and administrative procedures, and in intergovernmental cooperation. Moreover, the BfS is license holder for nuclear waste disposal facilities. Furthermore, the nuclear supervisor, for example responsible for monitoring compliance with waste acceptance requirements for the respective final disposal facility. These requirements result from the safety-analytical investigations that need to be complied with when waste packages to be disposed of will be delivered to the repository in future, is also the BfS by a self-monitoring section—directly tied to the vice president Of BfS.

The German Company for the Construction and Operation of Repositories (DBE) has been exploring, constructing and operating the German repository projects and mines in Gorleben, Morsleben and Salzgitter (Schacht Konrad) since 1979. After a legally enforceable plan approval decision has been in force since 2007, the Federation has decided to set up the Konrad mine as a repository. DBE is responsible for the comprehensive construction work.

The Asse GmbH is an operating company and as such responsible for all operational work in the Asse mine. Shareholder is 100% federal. The Asse GmbH implements the measures ordered by the BfS. The Asse-GmbH will also be responsible for the implementation of the decommissioning work and until then ensure operation in accordance with the requirements of nuclear legislation.

The Company for Nuclear Service (GNS) carries out services in the field of radioactive waste disposal and decommissioning of nuclear facilities and operates through several subsidiaries interim storage depots for spent fuel and radioactive waste. Further activities are related to the development of conditioning methods, including the development and qualification of the cask and emplacement systems, processing of the waste, loading of the casks, documentation of the containers, and control of delivery to the Konrad repository. GNS owns 75% of the DBE.

2.3 *Explanation of future structure*

On January 1, 2014, the Federal Act on the establishment of a Federal Office for Nuclear Waste Management (BfE) entered into force, so that BfE was formally founded on this day. However, the Federal Office for Radiation Protection (BfS) and its tasks remained unaffected at this time. By the Act on the Reorganization of the Organizational Structure in the Field of Final Disposal, BfE was renamed Federal Office for Nuclear Safety in Waste Management as of July 30, 2016 (Federal Gazette 2016a). The main reason for the renaming was the intention to differentiate the BfE more clearly against the Federal Company for Radioactive Waste Disposal (BGE).

Against this background, the BfS was divided in-to three organizations.

The Federal Office for Radiation Protection (BfS) is now responsible for the safety and protection of man and the environment against damage caused by ionizing and non-ionizing radiation (Federal Law Gazette 2016b). In the area of ionizing radiation, for example, X-ray diagnostics in medicine, safety in the handling of radioactive substances in nuclear technology, and the protection against increased natural radioactivity. Non-ionizing radiation workplaces include, inter alia, protection against ultraviolet radiation and the effects of mobile phones.

The Federal Office for the Safety of Nuclear Waste Management (BfE) advises the BMUB on nuclear waste disposal and safety issues for other nuclear facilities. In addition, BfE is bearer of the public participation in the process of determining the location in Germany for final disposal of high level radioactive waste. BfE has the task to check the safety of the disposal at all process steps. Thus, for the first time in Germany, BfE is now an independent regulatory, licensing and supervisory authority for the transport of radioactive waste and its interim and permanent storage.

Transitional provisions apply to the Konrad repository and the Morsleben repository for radioactive waste (ERAM), according to which the Federal States remain responsible for licensing until this responsibility is transferred to the BfE with the granting of the approval of commissioning by the nuclear supervisory authority for the Konrad repository or until the plan approval decision on decommissioning will be enforceable for the ERAM. A part of the workforce which is still planned for the BfE, mainly from the administrative sector, will still be involved in BfS by December 2017.

Furthermore, two additional Acts were recently set in force (Federal Gazette 2017 a and 2017b), partially in extension of the Act on Search and Selection of a Site for a Repository for Heat-Generating Radioactive Waste and for Amending Other Laws (Federal Law Gazette 2015).

The Federal Company for Radioactive Waste Disposal (BGE) is a state-owned company in which several tasks have been merged: operational tasks of site selection, construction and the operation of the repositories for high level nuclear waste as well as, e.g., for the Asse II salt mine site where in the past low and partially medium level radioactive waste has been stored. Moreover, the "Act for the Reorganization of Responsibility in Nuclear Waste Disposal", which came into effect in June 2017, has been redefined regarding the responsibility for the decommissioning and dismantling

of nuclear power plants and for the the interim storage of radioactive waste (Federal Law Gazette 2017b). Some sections of the BfS have been transferred to the BGE. The Asse GmbH and the DBE will also be incorporated in due time.

Moreover, the Company for Interim Storage (BGZ) has become in August 2017 a company of the Federal Government. From now on, the existing two central interim storage facilities will be part of the business of the BGZ. At the beginning of 2019, the twelve decentralized temporary storage facilities at the nuclear power plants—currently operated by the electric power utilities—will also become the responsibility of the BGZ, one year later additionally the twelve storage facilities with low- and medium radioactive waste resulting from the operation and dismantling of the German nuclear power plants.

3 WHAT IS STAMP?

STAMP is an acronym and stands for System-Theoretic Accident Model and Processes. The theory was developed by Nancy Leveson. The necessity for the model has arisen when it became clear that the traditional mechanisms to explain incidents were no longer valid. Typically, incidents were explained as linear chain of events, with a failure of one system at the beginning of the chain. However, due to the complexity of today's systems this does not need to be true. Every part of a complex system can work perfectly as specified but under certain preconditions it might lead nevertheless to an incident. For more examples of the general idea of this model, you can look at (Leveson and Stephanopoulos 2014). Leveson argues that in the future incidents should be considered as control problems. Actors and interactions need to be defined in a strict manner.

A typical STAMP control structure is shown in Figure 1. An example for a more complex situation can be found, e.g. in our paper (Berg, Griebel & Milius 2017).

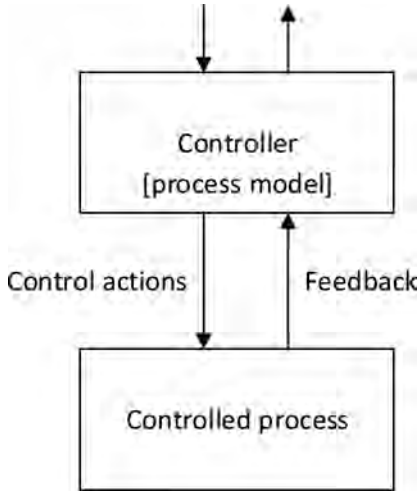

Figure 1. General description of the idea behind STAMP.

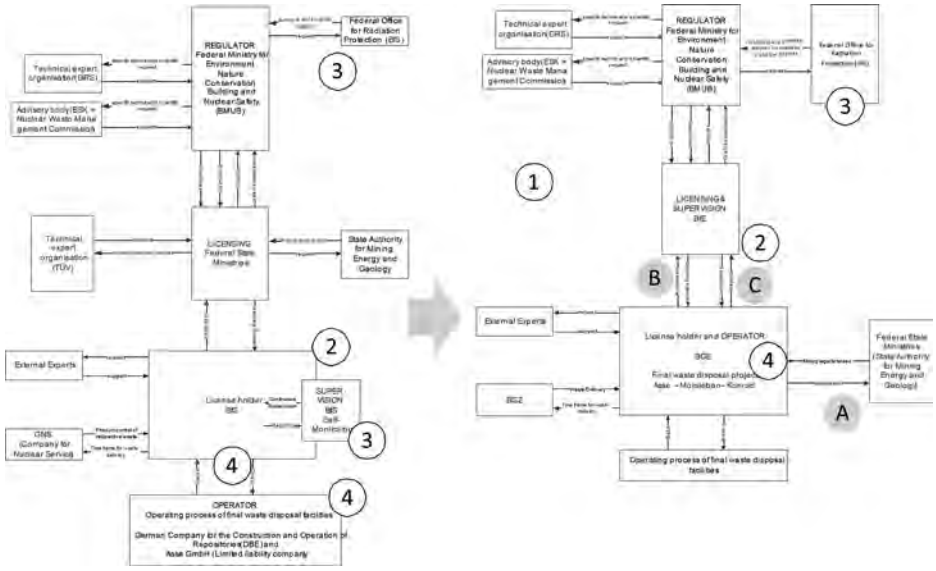

Figure 2. Comparison of the current (right) and future (left) STAMP structures; numbers indicated areas of change (1, 2, 3 and 4) discussed in the text; letters indicate the discussed control loops.

STAMP is the basis for different applications. (Thomas 2013) distinguishes CAST (Causal Analysis using System Theory) and STPA (System-Theoretic Process Analysis). For our work, STPA is the relevant component as it helps to identify the potentially hazardous control structures which can lead to failures in the process.

To identify controls which are potentially hazardous, four types can be distinguished:

- Control commands required for safety are not given
- Unsafe ones are given
- Potentially safe commands but given too early, too late
- Control action stops too soon or applied too long

The paper will not allow applying the issue of the controls in detail; however, we will highlight some examples where even on first look problems become obvious.

4 COMPARING AND ANALYSING THE TRANSFORMATION PROCESS

Using elements of STAMP the structure and control processes of the current and future situation are shown in Figures 3 and 4 at the end of this paper. Looking at how the elements of STAMP

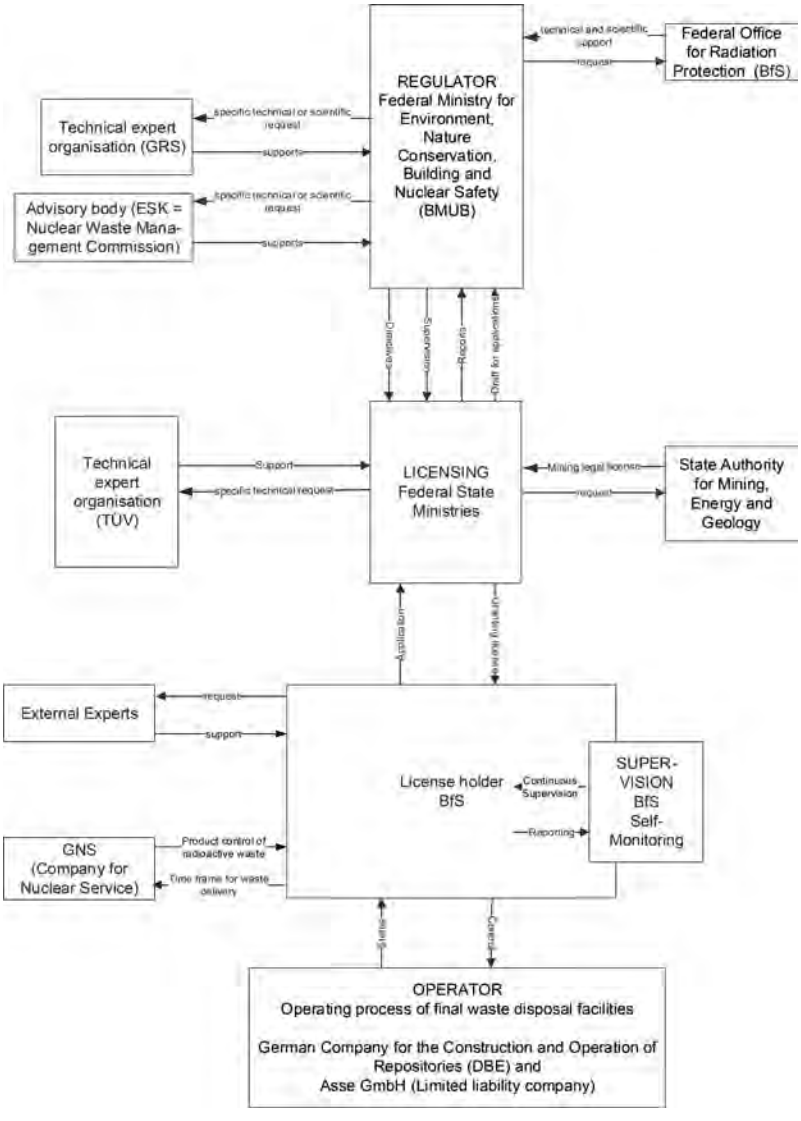

Figure 3. Current structure of German nuclear waste disposal process.

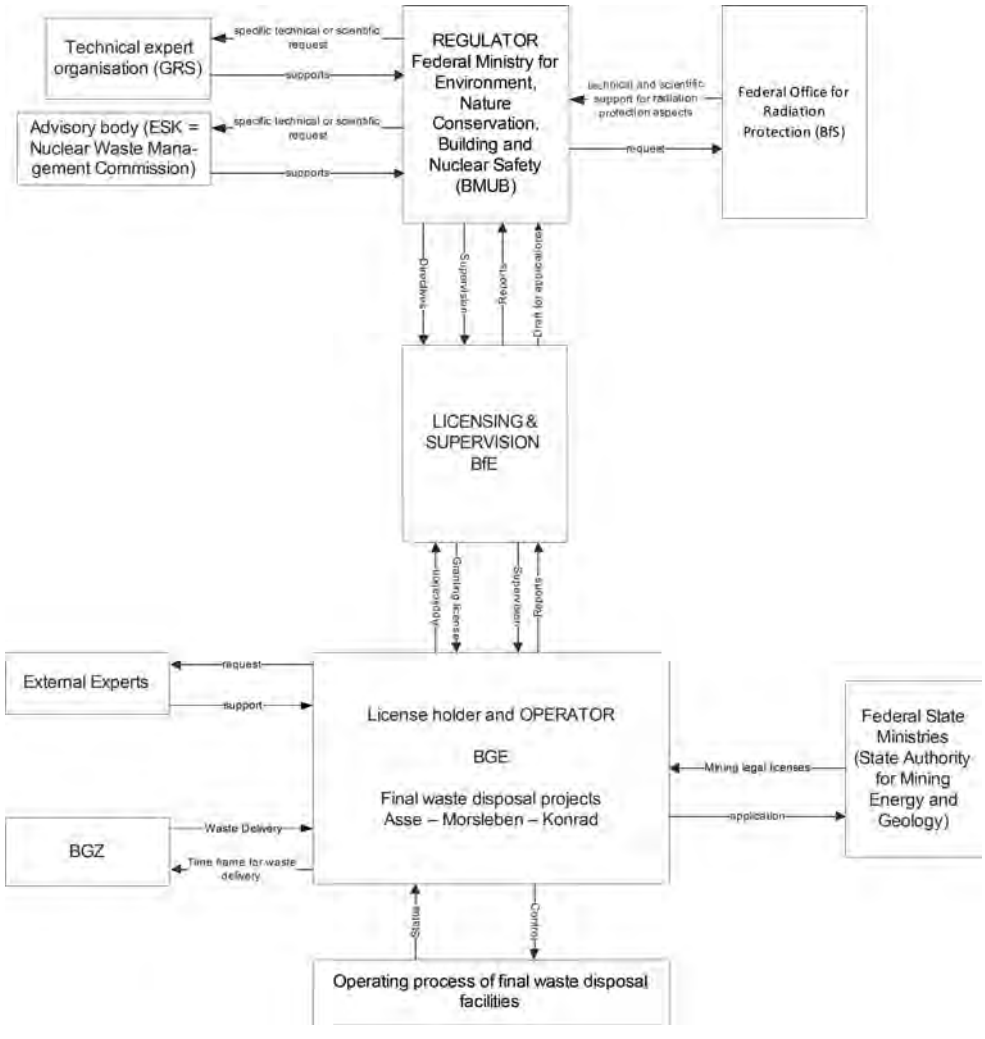

Figure 4. Future structure of German nuclear waste disposal process.

can contribute to a better understanding and evaluation of the change in the processes, the following aspects can be identified by looking at the structure (Figure 2).

1. The new process is more streamlined with a strong focus on the licensing and supervisory authority on the one hand and the license holder and operator on the other one.
2. The BfS as a self-monitoring organization of final waste repositories is replaced BfE which is not any more license holder and supervisory authority. Moreover, the new picture shows a clearer structure because in future all licensing and supervisory activities were performed by BfE whereas in past the Federal States were licensing authority and BfS operator and supervisory organization. The new legal basis also concentrates the responsibilities for licensing (in the past BfS) and supervision (in the past Federal States) of interim storage waste facilities not discussed in this paper in detail.
3. The general structure regarding the involvement of the BfS is now much clearer. Whereas in the old structure the BfS was having several, very different functions, this is now clarified and more focused on safety and protection of man and the environment against damage caused by ionizing and non-ionizing radiation.
4. The license holder and the operator were used to be separated from each other. This led to an additional need for control. Now they are subsumed under one roof. This would be a good

example to look deeper in the structure to see, if all aspects of the external control structure are now integrated in the internal processes of the license holder and operator.

Overall, all tasks of nuclear engineering disposal after dismantling have now been fully distributed to authorities (BfE) and federal private companies (BGE).

A central prerequisite for the credibility of the now responsible actors has been created by the reorganization of the responsibilities which leads to a clear functional description of the company's ownership as well as the operation in a private-law company on the one hand and the supervision and intensification of the public participation on the other hand.

Regarding the site selection of a repository for highly radioactive waste, BGE has improved structural preconditions for a rapid and well-founded presentation of results by the concentration of the project owner in the site search as well as all operator tasks.

BfE has the task of supervising the implementation of the site selection procedure in accordance with § 19 (1) to (4) of the Atomic Energy Act (Federal Law Gazette 2017c). It, therefore, supports the entire procedure from a scientific point of view and is the competent authority for the monitoring of the enforcement of the site selection procedure at all stages of the procedure (Federal Law Gazette 2017a).

5 ANALYSIS OF CONTROL LOOPS

The structured depiction of the control processes enables the identification of possible gaps in the control and information loops.

One example of a rather simple and clear loop consists of the requesting and granting of mining licenses (A). If we would apply here the different possibilities of hazardous controls, we could, e.g. discuss in detail what happens when a request is done at a wrong time or an application is granted to early. STAMP/STPA can help us here to better understand the process and guide the user to potentially hazardous situations which then can be counteracted by e.g. processes.

As for the area of the interdependence between the BfE and the BGE the situation is rather more complex: The loop regarding the application of license changes and the granting of revised licence seems a closed one (B). Yet when it comes to the issue of supervision by the BfE and providing reports by the BGE the causal relation would need more detailed analysis (C). One example for this fact is that supervision also contains inspections in the waste disposal facility, i.e. not only paper work is involved. This is different from the other reports&supervision loops in the structure, where only documents are transferred and checked.

This succinct analysis already shows that is important to clearly and comparably construct and describe the elements of the control loops. Without this structured analysis one might face the danger of leaving out pertinent aspects in the process of transforming and streamlining existing control and supervision structures.

6 CONCLUSION

In this paper we have applied some of the elements of STAMP to the reorganization of the German nuclear waste management of the German Nuclear Industry. We focused on the process of final waste disposal.

By structuring the process we have made a decisive leap towards

- Transparency (by providing a method of displaying lucidly the complex process)
- Elucidation of areas for improval
- Enabling checks if the yearned objectives have been attained.

Thus we have showed that even without going into much detail of the daily work, some areas of change became obvious and can be used as basis for further discussions. The identified changes can now be analyzed further to make sure that the responsibilities of changed ownership (partially spread and partially concentrated compared to the earlier structure) are taken care of in the new processes.

Furthermore it could be checked in future analysis, which effect envisaged changes would have on the overall safety of the processes and the site by highlighting the risks

ABSTRACT: As the world's first tourist destination in 2015, with a target of 100 million visitors in 2030, the French tourism sector, is a national priority and a strategic challenge for the country. However, the dramatic events of 13 November 2015 (in Paris) and those of 14 July 2016 (in Nice) led to a reversal of the trend, and a substantial and worrying decline in activity. The events raise two key questions in terms of crisis management: The first is linked to the ability of regions and organizations to recover, as quickly as possible, their capacity to meet the needs of the public. The second, which is the direct consequence of the first, is the capacity of regions and tourism industries to re-establish their reputation, notwithstanding the fear that is generated by the threat

This paper presents a review of the management of major risks and the tourism sector at the international level and in France. It presents an ongoing qualitative study conducted in partnership with an association of event professionals on the management of crises on the French Riviera. The roles of the different actors in a crisis are studied from the perspective of organizational resilience.

1 INTRODUCTION

Whether resulting from natural or industrial causes, or due to terrorism, disasters and crises take a heavy toll on tourist activities. In a country like France, where tourism accounts for 7% of GDP, and represents 2 million direct and indirect jobs, a crisis can threatens the sector. Although in different ways and in different places, the terrorist attacks in Paris in 2015, and the attacks in Nice in July 2016 badly affected the sector's economy,

While crisis management is well-understood in conventional industrial activities (nuclear, oil and gas, chemistry, aeronautic…), it is clear that the academic literature contains few references to the tourism sector. Reasons for this oversight is that the sector is diverse, geographically dispersed with a high proportion of small businesses, thus making it a challenging topic to investigate. Having a good understanding the typology of crises and the consequences for the sector is, however, essential in order to prepare the resources that are required to recover the loss of patronage and business.

This paper reports an ongoing, longitudinal French study located in the tourism sector that identifies the key elements needed to successfully manage a crisis after a terrorist attack. Applying a systemic approach, the aim of the study is to increase our understanding of why and how regions and organizations become resilient after an acute crisis. We also argue that the findings of this study could inform the way in which other crises are managed. It should be noted that the study concentrates on crises associated with acts of terrorism. We begin, however, with presenting research on the perception of risk and tourism-related crisis management. We then introduce the concept of resilience applied to crisis management, and the leisure and business tourism sectors.

2 GLOBAL TOURISM, RISK PERCEPTION AND IMPACTS ON THE DESTINATION

The globalization of tourism has created a highly competitive environment. As a result, both the leisure and business tourism sectors are subject to fierce competition within and between destinations. Although France is one of the most popular destinations, aiming to welcome 120 million tourists in 2020, (Huchon, 2016), it has to compete with other destinations. Studies of terrorist crises

(2001 in New York, Hua hin and Phuket 2016 etc.) also show that there is a negative economic impact on destinations that have experienced a terrorist attack, (Enders, 1992, Fainstein, 2002, Beirman, 2003, Drakos, 2003, de Sausmarez, 2003). In this context, knowing the reasons for selecting a particular destination, (ie the level of risk associated with the chosen destination) is necessary.

Moreover, a number of studies highlight the fact that the level and perception of risks are key dimensions in the decision-making process. In a study of 290 young adults born in the United States, Lepp & Gibson (2003) report that there are seven risk factors associated with tourism: health, political instability, terrorism, unusual food, cultural barriers, political and religious dogmas and crime. However, the study found that men and women differ: women care more about health risks. A second difference is found in the type of destination: some look for a familiar destination, while others seek out novelty. The latter group are less sensitive to risk.

With regard to natural and technological risks, Chew & Jahari (2014) analyze the impact of per ceived risk on the image of a destination. Taking the case of the Fukushima disaster in Japan in 2011, where a natural disaster that combined a tsunami and earthquake caused a nuclear accident, the authors analyze the relationship between the image of the destination, perceived risk and the intention of returning to the destination. Their findings show that tourists' perception of risk is an important element in the destination's image and plays a key role in the choice of destination. In practice, although increased risk may play an inhibiting role in the choice of and return to a destination, the authors note that recent studies highlight repeat purchases despite a rise in the level of risk or a recent disaster. Acting on the image of the destination would therefore appear to help to mitigate the effect of perceived risk on the intention to return.

In sum, risk perception is a component of the decision-making process in the visit and revisit of a destination. The perceived risk associated with the destination, therefore, can play a role in mitigating the image of a destination.

3 CRISIS MANAGEMENT AND TOURISM

In order to understand risks and resilient organizations it is necessary to examine the literature on crisis management, with particular reference to the tourist sector. Aktas & Gunlu (2005) note that, although the concept of crisis management has existed as a research field since 1970, studies located in the tourism sector only began to emerge in the 1990s.

It is useful, however, to first distinguish between "disaster" and "crisis". Faulkner (2001) notes that the difference between the two is that a disaster is an external phenomena while a crisis is an internal phenomena and relates to the organization itself and management failures. Aktas &Gunlu (2005), taking Faulkner's example (2001), show that the Izmit earthquake in 1999 could be likened to a catastrophe on account of its unpredictability and external nature. On the other hand, the lack of respect for earthquake-resistant standards reflects organizational failures and, therefore, a crisis.

Atkas & Gunlu (2005) further explain that in practice, the unpredictable dimension of an unforeseen external event can degenerate into a if there are management failures. In this case, the disaster and the crisis can be subsumed. Here both share three elements: a trigger, damage, and a threat to the life or property.

Further, crises can be linked to events at different levels. At the micro level, a crisis can be limited to the organization (an industrial relations strike or epidemic that affects the workforce). Crises can also occur at the international level, moving from a micro to a macro level, for example a terrorist attack or a pandemic. Moreover, a crisis can be extend over many years (Ritchie, 2004, Ritchie & Campiranon, 2014). In this context, Both Ritchie (2004) and Laws and Prideaux (2006) argue that the complexity of crises suggests that there is a need to establish a typology in order to provide appropriate strategic management plans. Ritchie (2004) states that crisis management should be based on appropriate plans, trained staff, communication plans and established relations with the media. That is, crisis management is based on a capacity to mobilize resources and communicate at the right time. It also requires appropriate lobbying of decision-making bodies to rapidly allocate the funds that are needed to meet the needs of crisis management activities.

The ability to manage a crisis therefore depends on a number of factors that can prepare managers to cope, and also to communicate at the right time to contain the crisis and avoid changing the image of the destination. In addition, a significant part of crisis management is based on the creative ability of actors and in particular, it relies upon the support of actors, or even drawing from the group solutions that could not have been imagined. This observation is echoed by Atkas and Gundu (2005), who consider the implementation of strategic crisis management and post-crisis marketing plans are necessary for the revival of the destination. Finally, proactive and holistic management as well as an evaluation of each crisis and its management are essential to ensure that visitors return (Laws & Prideaux, 2006, Ritchie & Campiranon, 2014).

While a great deal of this discourse is located in the disciplines of marketing and economics, studies in other disciplines, such as resilience engineering and emergency engineering have provide another perspective.

4 RISK AND RESPONSE

There have been a number of scholars who have made a significant contribution to the research on risk and resilience. One of the most notable is Hollnagel (2007) who only studied the concept and the attributes of risk but also introduced the concept of *resilience engineering*. He defines resilience as a system's ability to adapt before, during or after changes or perturbations in order to continue a set of operations that are identified in expected or unexpected conditions (Hollnagel, et al. 2006). This key contribution to our understanding of crisis management is part of a rich field of research on the human and organizational factors. Others scholars have also made a contribution. For example, Perrow's (1981) work on complex organizations and risk in which he examines the organizational factors that underlie systemic and catastrophic accidents. His central argument is that accidents are normal in complex, socio-technical systems because they are by their very nature, susceptible to an elevated level risk. His work initiated critical thinking about industrial systems that are exclusively controlled by managed safety procedures.

Similarly, the work of the High Reliability Organization group at Berkeley University (see La Porte, 1996) have examined the resistance criteria in complex socio-technical systems. What brought the Berkeley colleagues together was their shared observation from three different disciplinary perspectives that the attention being paid to studies and cases of organizational failure was not matched by parallel studies of organizations that were operating safely and reliably in similar circumstances (Rochlin, 1996). They found that the role of technology and structure was not fixed, but varied from task to task. The organization had not one, but many overlapping cultures, tied together by a common purpose. Its performance was shaped not only by the skill and dedication of the operators, but also by intelligent and sensitive management. Weick (1995) also observed that in the event of a crisis, following procedures without begin able to innovate or rethink procedures can hamper action, or even end in a catastrophic scenario.

Taking the analysis to the next level, Hollnagel (2007) argues that it is critical for an organization to anticipate and learn from previous crises. Moreover, the resilience of organizations is linked to the ability of actors to adapt to changing conditions. Organizational resilience, according to Hollnagel (2007), is based on four central pillars: the ability of a system to respond to normal and abnormal conditions; its ability to control threats and performance in the short term; its ability to anticipate threats and opportunities in the long term; and its capacity to learn from the positives and negatives of past events.

Research on the management of major crises, including those in highly-regulated sectors, shows that comprehensive planning together with innovative solutions are necessary to deal with a crisis that is unexpected and has far-reaching, long-lasting consequences (Vogus & Sutcliffe, 2007; Burnard & Bhamra, 2011). The analysis of the Fukushima Daichi crisis is an example of the innovative capacity of one man and his team when faced with an unprecedented crisis that went far beyond any previously planned action (Funabashi & Kitazawa, 2012). Travadel, Martin and Guarnieri (2017) also highlight the need for this capacity. They introduce the notion of acting into extreme situation as a way of effectively responding to a long-lasting, hitherto unknown crisis.

In addition, Ritchie (2004) recommends scenario-based planning as a foundation for an appropriate response to a crisis. He notes that there is value in identifying and planning responses to a crisis but given what we know about complex systems, there will still be a need for some flexibility in order to support innovative responses.

Finally, it is crucial to not only link the capacity of government with sectoral institutions in order to generate a joint action and commitment but also necessary to understand the role of the various actors and their capacity to respond to crisis conditions (Glaesser, 2006).

With this in mind, the following section presents the main features of a longitudinal study looking at the response to the recent crises in the French tourism sector.

5 THREE TIERED RESPONSE SYSTEM

Over the past two years France has experienced several major terrorist crises that have had a significant impact on tourism activity. While the French government had predicted a significant growth in the tourist sector, the terrorist attacks of 12th November, 2015 brought the predicted growth in tourist numbers to a halt, and put a great deal of economic pressure on all the stakeholders in the sector. Paris was particularly affected. The *Huchon Report* (2016) (Governmental Report on Tourism) notes that in the days following the attacks, the various businesses operating in the sector suffered

significant reductions in visitor numbers and turnover. The report also noted that commercial activities in central Paris were particularly badly affected.

Despite efforts to revive tourist numbers, the end of 2015 and the whole of 2016 was still marred by more terrorist attacks and natural disasters, all of which continued to tarnish the image of France and in particular Paris and the Côte d'Azur, as a tourist destination. The terrorist attack of July 2016 on the *Promenade des Anglais* in Nice was one of the worst as it occurred in the middle of the summer season and targeted the second most popular tourist destination after Paris: the French Riviera.

Faced with the loss of its foreign clientele and a decline in hotel bookings, the sector asked the government to take measures to revive activity, similar to the actions that were taken after the 11th September terrorist attacks in New York. The *Huchon Report* (2016) argued that the response must be organized around a few, key measures. The first was to set up, at inter-government level, a *crisis unit* to revive activity by reassuring the public about the safety of the destination. The second was to provide *economic support* for the sector. The third was to coordinate crisis *communication and recovery actions*, with special attention on Paris as the country's flagship destination.

Based on the *Huchon Report's* recommendations, a three tiered, response system was put in place. At the national level, a recovery plan was developed focusing on coordinated action involving key stakeholders in both the public and private sectors with the aim of reviving tourist numbers in Paris and other key tourist destinations. In the South of France, the Regional Tourism Committee also established a recovery plan based on a communication strategy located centrally on the Côte d'Azur brand and uses existing well-established social networks. At the sector level, a communication plan for tourism professionals was created to reassure providers

As a result of these concerted efforts of the combined private and public stakeholders at the different levels, tourist numbers began to recover. In the French Riviera, one year after the attack of 14 July 2016, figures showed that foreign visitors were returning. Following a 10% fall in hotel bookings in the last quarter of 2016, figures for the summer of 2017 indicate that activity is recovering.

However, the tourist sector in the Côte d'Azur not only had to respond to the terrorist attacks, it also had to respond to climatic disasters. In particular, the storms of October 2015 badly affected the destination in which there was a heavy toll both human (20 people lost their lives) and economic (damage to tourist infrastructure). As the region tried to cope with the aftermath, those working tourist sector had to prepare for the arrival of 13,000 people attending a large international conference. These efforts by all the parties made the conference a success and were emblematic of the region's ability to respond to crisis and its resilience.

6 LONGITUDINAL STUDY

The aim of this qualitative study is to examine the tourism sector's processes and structures created in response to a series of crises in the Côte d'Azur. In particular, the study aims to understand the dynamics underlying the preand post-crises processes and structures. The focus of this two year study is on Provence Côte d'Azur Event Center, which represents 160 event management companies in the region (a total of 1.2 billion euros turnover).

Although Côte d'Azur Crisis Unit provided an initial impetus, the successful recovery of the tourist sector is highly dependent on the ability of key actors reassemble the affected areas of the sector during and after the crisis.

In practice, actors' ability to adjust to contextual conditions deserves to be studied in order to understand its modalities and reproducibility in other regions. The current study thus addresses, on the one hand, the organization of the actors during the management of the crisis. Was this organization, despite procedures, the result of management led by the institutional crisis unit, or was it an emerging organization of stakeholders and, possibly, the fruit of discussions and initiatives taken jointly by professional organizations, economic actors and institutional actors?

On the other hand, it addresses the innovative capacities of actors to respond, on a case-by-case basis, to the technical problems generated by the floods (loss of means of communication, transport, etc.). Are these capacities for innovation and adjustment part of a culture that is specific to the region, its actors and the experience of professionals?

The qualitative study will run for two years, and will involve professionals and actors that were involved in the crisis.

The plan is conduct 40 open-ended interviews with the various socio-economic actors who participated in the management of the crisis. So far, only exploratory interviews have been conducted with the governing bodies of companies involved in the event. A total of 12 informal interviews were carried out lasting an hour and a half that explore the role of actors in the management of the crisis, and report their perception of the event.

In addition, a systematic study of the regional press that covered events will be conducted, in

order to understand its role in the construction of the image that actors may have developed of the crisis, or even their role in the emergence of a crisis culture specific to the sector and the region.

The initial interview data indicates that recovery was driven by the desire to continue to provide a superior quality service while at the same time minimizing the crises. Statements like "the show must go on" and "putting on a brave face" were common. There was also a collective effort to portray the Côte d'Azur tourist sector as a dependable in spite of the previous crises.

Understanding the resilience of organizations—that is how they respond to a crisis—requires an understanding of the attitudes of the individuals involved. In this case it was the attitudes of the individual actors who lived through the crisis and who then have had to accommodate the effects of the crisis in their daily life. How are they able to create a world that encompasses the crisis? In practice, following Moreau (2017). Despite the tragedy, the world goes on. The way of thinking about the crisis in the tourism and events world, anchored in the mindset of the region, then becomes a condition for the commitment of actors and their capacity to innovate.

7 CONCLUSION

The tourism sector is considered to be a key economic player in France. However, it is exposed to a variety of crises and disasters at the micro, national and international levels. Risk perception is an important part of the tourist's decision process in both leisure and business tourism. Risk perception can also be mitigated by presenting a positive image of the destination and in particular how the sector was able to effectively respond and manage the crisis. The question here is how is that constructed and what are the key features?

Although an increasing number of studies have begun to appear in the literature in the past decade, there is still a lack of research on crisis management in the tourism sector. Those studies that are available all point to the need to implement a strategic plan at each stage of the crisis management. Moreover, our findings show that a three-tiered system is an effective way of providing a comprehensive response that incorporates input at all levels of the sector.

The literature also highlights the need to move beyond overly procedural plans but instead allow for innovative responses when required. That is, from a resilience perspective, it is necessary to allow individuals to be innovative and responsive to the environment. Our findings support the literature in that any crisis management approach must have a level of flexibility. By tapping into the mindsets of "the show must go on" and allowing individuals to be innovative, a more committed workforce will emerge, thus ensuring that the crisis management plans are deployed. But the key ingredient is to create a dynamic, sectoral environment that is responsive and resilient during and after crises.

Validation of a gamified measure of safety behavior: The SBT

C.B.D. Burt, L. Crowe & K. Thomas
University of Canterbury, New Zealand

ABSTRACT: Safety behavior is defined by constructs such as safety compliance, safety participation, and risk-taking. A safety complaint employee follows safety rules and policies, and if they engage in safety participation, goes beyond their job to ensure everyone's safety. In contrast, risk taking and safety violation behaviors can cause accidents and system failures. The significance of safety behavior argues for its measurement in job applicants, and the use of the resulting data to select applicants in and out of high risk situations, and/or allocate to training programs. The development of the Safety Behavior Test (SBT) which is a gamified assessment tool operationalized within an animated work simulation environment is described. Participant's SBT score was correlated with data on their actual safety behavior provided by an independent source. Results indicate the SBT has good criterion-related validity, but this is influenced by computer-game playing experience. The advantages of using gamification to measure safety behavior are discussed.

1 INTRODUCTION

Research varies in the estimation of the influence of behavioral safety in accident causation. Some researchers have suggested as much as 90 percent of accidents can be shown to have a behavioral safety component as a contributing factor (see Hofmann et al. 2017 for a useful review). It is also clear that specific cohorts of employees, such as young employees (e.g., Salminen, 2004), or those new to a job can engage in less safe behaviors and more risky behaviors (e.g., Burt, 2015). Behavioral safety not only requires an individual to engage in safe behaviors, but also to avoid a spectrum of unsafe or risky behaviors, including routine rule-breaking (e.g., Darby et al. 2005). While behavioral safety is clearly an important factor in the overall safety performance of a system, organizations are somewhat restricted in their ability to manage it. Research has examined the influence on safety behavior of generating a positive safety culture (e.g., Cui et al. 2013, Diaz-cabera et al. 2007), and the impact on safety behavior of having a positive safety climate within work teams (e.g., Christian et al. 2009, Clarke, 2006). From this work it is clear that a positive safety culture and climate can help promote safety behaviors, and the avoidance of risky behavior.

A further option to manage safety behavior is to recruit people into the organization who are likely to behavior in a safe way. In order to do this organizations need to use measures during recruitment which allow for the prediction of individuals' on the job safety behavior. In examining the relationship between recruitment processes and safety, a number of studies have highlighted the need to ensure all employees have the skill, knowledge and training to complete their work in a safety manner (e.g., Ford & Wiggins, 2012, Grandell-Niemi et al. 2003, McMullan et al. 2010, Postlethwaite et al. 2009), suggesting that appropriate ability tests should be used during recruitment. A considerable body of work has also attempted to understand the link between personality and safety behavior, with the idea of an accident prone personality receiving research attention for almost 100 years (e.g., Dahlback, 1991, Green & Woods, 1919, Visser et al. 2007), along with the idea that risk-taking is a personality trait (e.g., Dahlback, 1990, Eysenck & Eysenck, 1977). More recently, Clarke and Robertson (2005) used meta-analysis to examine the criterion-related validity of the big five personality factors as predictors of accident involvement, and concluded that conscientiousness and agreeableness were valid and generalizable predictors of safety.

In addition to ability and personality testing, organizations may attempt to predict safety behavior using questions about safety behavior or the individual's past accident history in an application blank, or in an employment interview. While these measurement options have the potential to contribute to an organization's understanding of how a job applicant might behave in the future, they have serious limitations. Under these 'self-reporting' conditions, it is very obvious what is being measured, which makes responses susceptible to social desirability biases. Social desirability

bias refers to a phenomenon where participants over-report favorable opinions and behavior, while under-reporting those that are unfavorable, and is most common when the subject under investigation is considered to be sensitive by the respondent (Krumpal, 2013). Sensitive subjects are defined as those where there are potential costs or risks to the respondent for responding in a particular way, or to the collective population that the outcome of the question represents (Sieber & Stanely, 1988). Clearly, a focus on safety within a job application process would represent such a situation.

Given the importance of employee safety behavior, an ideal way to assess it would be to use a work sample approach where the job applicant can demonstrate their behavior. However, there are clear ethical reasons why job applicants' can not be placed into a risky situation to measure how they will respond. A way to avoid this ethical issue is to use a simulation, and as such this study reports on the development of a measure of safety behavior that uses a work simulation developed using the *gamification paradigm* which is rapidly growing in its application across a number of areas (e.g., Chen et al. 2015, Rodrigues, Costa & Oliveira, 2016, Singh, 2012). Gamification can be defined as the use of game design elements in non-game contexts, and is predominantly used to make real world activities more engaging (Deterding et al. 2011, Shrofeld, 2010). Organizations have also started applying gamification to their selection procedures (Chamorro-Premuzic, 2015). The popularity of gamification in the work place is likely due to the positive impact it has on engagement and motivation (Gagne & Deci, 2005, Harter et al. 2013). Within the area of safety behavior measurement during employee recruitment gamification has considerable potential to avoid measurement bias.

To be of value a gamified psychometric test must be valid, must accurately measure the construct intended, and be predictive of future performance related to that construct. Very few studies have investigated the implementation of gamified assessments, and even fewer have investigated the validity of gamified measures. Of those which do report on gamified assessments, validity results are mix. Some studies have reported the gamified measure examined was not valid (e.g., Jaffal & Wloka, 2015, Kim & Shute, 2015, Whetzel et al. 2012), while others report they were able to develop a valid gamified measure (e.g., Mislevy, Almond & Lukas, 2003, Shute,Ventura & Kim, 2013), supporting the use of a gamified measure as a way to observe authentic behaviors (Clarke, 2009, Clarke-Midura & Dede, 2010, Ketelhut et al. 2008, Shavelson et al. 1991). These mixed results may not necessarily reflect on gamified assessments as a whole, but the design of the measurement points within the specific gamified assessments which were examined in each study.

Gamified assessments contain two key design components, measurement and game design. Measurement design is developed first and contains the construct intended for measurement, and the design of measurement items for this construct. During this phase of gamification design the virtual environment is created and the measurement items are applied to decision points within the game (Halverson & Owen, 2014, Ifenthaler et al. 2012). Each decision point is recorded by a play log and summed to provide the user with a score or scores on the measured construct. Game design helps determine a game-based assessment's validity and ability to predict employee behaviors in terms of its similarity to a work-sample test (Gangadharbatla & Davis, 2016). Work samples have been consistently regarded as one of the most accurate and valid measures in predicting performance (Hunter & Hunter, 1984, Reilly & Warech, 1993, Roth et al. 2005). As noted it is difficult, if not impossible to use traditional work sample testing to measure safety constructs (e.g., to measure the constructs of safety compliance would require an individual to complete a potentially dangerous task), a gamified assessment can replicate a work-sample by requiring the individual to provide a performance based sample through a virtual rather than physical environment. In doing this safety behavior should be able to be assessed with no actual danger to the participant.

In summary, this study reports on the development and initial validation of a gamified measure of safety behavior: the *Safety Behavior Test* (*SBT*). The SBT was designed to be used during the employee recruitment process. The validation process involved correlating the SBT scores with data on safety behavior obtained from independent raters.

2 METHOD

2.1 *Design*

A concurrent criteria-related validity design was used. The participant completed the SBT followed by an Individual Characteristics Questionnaire (ICQ). The participant was then given an Acquaintance Questionnaire (AQ), and they nominated an individual (e.g., supervisor, co-worker) to complete it. The AQ provided the independent data on the participant's safety behavior against which the SBT score was validated. The ICQ data was used to determine if any of the variables measured showed adverse impact on the SBT score, and thus needed to be controlled for in the validation

analysis. The study was reviewed and approved by the University of Canterbury Human Ethics Committee, reference number HEC 2017/26.

2.2 *Sampling*

Haphazard sampling (Weisberg & Bowen, 1977) was used to obtain the SBT participants. The recruitment criteria were the participant had to be working (responses to a question on this indicated all participants were working), and had to agree that they had adequate vision to use a computer to complete the SBT. Acquaintances (e.g., supervisor, co-worker) for the collection of independent data on the participant's safety behavior were recruited by the SBT participant. To participate as an *acquaintance*, the individual had to have knowledge of their respective SBT participant's safety behavior. SBT participants and acquaintances each received a $10 petrol voucher for their participation.

2.3 *Participants*

The study involved 200 individuals, 100 participants who completed the SBT who had a mean age of 41.6 years (range 18–66 years), and 100 acquaintances with a mean age of 43.5 years (range 18–66 years). SBT participants reported an average total work tenure of 286.8 months (SD = 158), and an average job risk rating on a 100 point scale of 42.4 (SD = 28.3). Acquaintances indicate they had known their SBT participant for an average of 144.7 months (SD = 172.9), and using a 100 point scale rated the strength of their relationship with their SBT participant on average as 73.4 (SD = 22.1). These results suggests that acquaintances should have had ample opportunity to observe the SBT participant's safety behavior, and thus be able to provide valid ratings.

2.4 *Materials*

Data was collected using three sources: the SBT, the individual characteristics questionnaire, and the acquaintance questionnaire.

2.4.1 *Safety behavior test*

The SBT is a fully animated computer test of the point and click game genre, meaning that the test taker can point the cursor at an area on the screen and click in order to interact with the test environment. First person views are used in the SBT, thus the test taker experiences the test as if they were a character navigating the test environment. A number of gamification design elements providing feedback to the test taker are included in the SBT, including a timer shown in the top left corner of the screen which displays play time in seconds, a click counter also shown in the top left hand corner of the screen which displays the number of times the player has clicked the mouse, and feedback on some decisions, such as a red cross appearing if an incorrect choice is made within the game.

To protect the security of the SBT only a general description of it is provided here (note the testing procedure and pre-test instructions are described in the procedure section). The SBT requires the test taker to assume the role of a worker in a waste disposal company. The SBT starts with the animation opening a door and moving into an office scene. A sign on the desk reads "Press red button if unattended", which indicates that the participant needs to click the red button. Clicking the red button plays a narrative instruction: "*Hello forklift driver number 1. Sorry, I am up on level 6. It's good that you are here on time, there is only one job for you today. You have a shipment for disposal at the incinerator. The empty shipping container for the shipment is in loading dock C. A truck will take the loaded container to the incinerator as soon as you have finished loading it. I have already put the shipment items into the system, so when you get in a forklift the item list will be on the display screen. The new semi-automatic forklifts are working great, just click an item on the list and off you go to the relevant floor. Remember that control buttons appear when you need them. We have fixed the problem with the red right and left directional control arrows, and the central yellow stop button is working fine on all forklifts. Remember to load the items in the order shown on the list. The cloak room is nice and tidy this week, so let's keep it that way. Don't muck around as the transportation firm will charge us if they have to wait, but be careful. When you have got the order loaded come back here and let me know. If you would like me to repeat the instructions, just click the red button again*". After the participant had listened to the narrative (they can only play it twice) they make a number of decisions which allows them to navigate through the game/test by first entering the cloak room, followed by another room where they select a forklift. They then control the forklift to 5 different levels within the building. On each level they collect an item and move it to a container in the loading bay. During this process they encounter various hazards, and have safety related decisions to make. Once they have loaded all the required items into the container they exit via the supervisor's office where they complete a check list which has questions about the work they have just completed. Submitting the answers to these questions closes the test. During the SBT the player encounters 35 decision points. These decision points vary in terms of whether the decision has a safety aspect (e.g., following directional

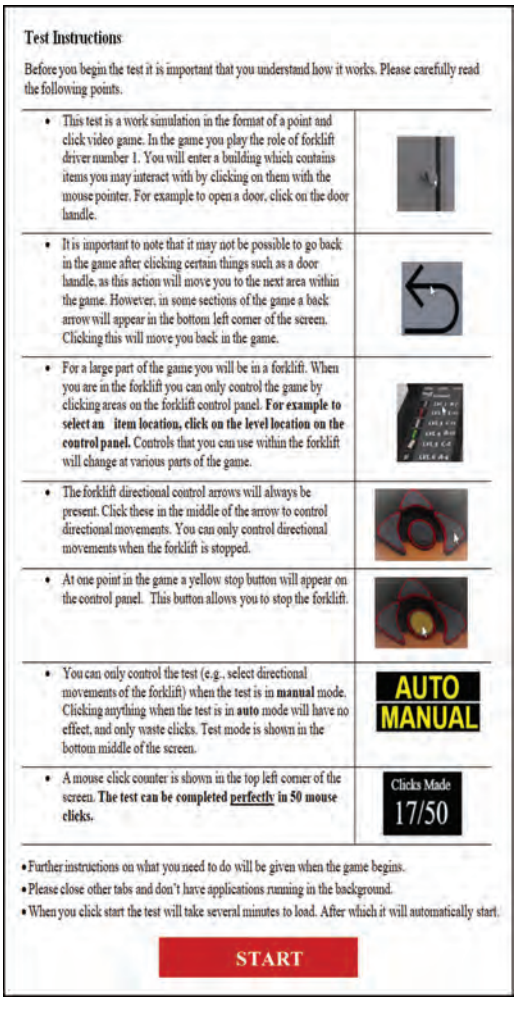

Figure 1. The SBT instruction page.

arrows on the floor while driving the forklift), or a risk aspect (e.g., avoiding driving over a hose in the forklift), or is simply a decision required to advance in the game (e.g., clicking a door handle to open a door). Safety and risk related decisions were used to form the SBT score. A safe decision was given 1 point and these points were summed to produce the score, with a possible SBT score range of 0 to 13. The SBT instruction page which participants were asked to read before taking the test is shown in Figure 1.

2.4.2 *Individual characteristics questionnaire*

Demographic information on age and gender, along with job tenure, experience driving a forklift, and computer game playing experience was collected. For the later variable, SBT participants' indicated how many *months* they had played computer games. Safety risk of the SBT participant's current job was assessed by placing a mark on a 100 point scale (0 = not risky at all, 100 = extremely risky).

2.4.3 *Acquaintance questionnaire*

The relationship the acquaintance has with their respective SBT participant was measured by how long the acquaintance had known the SBT participant for (months), and a rating of how well they know them on a 100 point scale where 0 = *Not very well at all* to 100 = *Extremely well*. Additionally, the SBT participants' safety behavior was rated by the acquaintance using scales measuring safety participation, safety compliance, safety voicing, safety consciousness, rule-bending and risk taking. The wording of scale items was adjusted from a first person format to suit third person acquaintance ratings. For example, "*I always use all the necessary safety equipment to do my job*" was adjusted to "*… *always uses all the necessary safety equipment to do their job*". Acquaintances were instructed that the *… referred to the individual that asked them to complete the questionnaire. Each scale item was responded to on a 5-point Likert scale anchored with 1 = strongly disagree and 5 = strongly agree. Scales were analyzed for internal consistency, and coefficient alphas are reported below. Scale scores were formed by summing the item ratings and dividing the sum by the number of items in the scale. Depending on the scale, a higher score is indicative of a higher level of safety behavior, or a higher level of risk-taking/rule-bending behavior.

Safety compliance and participation, were measured using a third person adapted version of Neal and Griffin's (2006) six item scale. Three items measured safety compliance, defined as core activities an employee needs to engage in to maintain workplace safety. The other three items measured safety participation, defined as behaviors which help to develop an environment that supports safety. An example items for safety participation is "*At work *… puts in extra effort to improve the safety of the workplace*". Coefficient alphas for safety compliance and participation are .87 and .83, respectively. Propensity for the SBT participant to breach workplace safety rules and procedures was measured using an adapted version of Chmiel's (2005) four-item bending the rules scale. An example item is, "*… *sometimes cuts corners if it makes the task easier*". A coefficient alpha of .87 was found for this scale. Safety consciousness and risk taking were measured using the 12-item safety consciousness and risk-taking scale developed by Westaby and Lee (2003). Safety consciousness is defined as "a positive attitude and awareness toward acting safely in general", and risk-taking is

defined as an "individual's willingness to engage in activities that knowingly have elements of physical danger" (Westaby & Lee, 2003, p. 228). An example item for safety consciousness is "*… *gets upset when seeing other people acting dangerously*", and an example for risk-taking is "*… *values having fun more than being safe*". The safety consciousness scale coefficient alpha was .82 and the risking-taking scale coefficient alpha was .82 after removal of one item. Acquaintance's perception of their respective SBT participant's safety voicing behaviors was measured using an adapted version of Tucker et al.'s (2008) five-item *safety voicing scale*. Safety voicing is measured as "any individual communication directed at improving safety conditions" (Tucker et al. 2008, P.319). An example item is "*… *makes suggestions about how safety could be improved*". The obtained safety voicing scale coefficient alpha was .87.

2.5 *Procedure*

SBT participants were tested individually in a quiet room. Participants read a consent sheet, and an information sheet which indicated they were being asked to take a safety test, complete a questionnaire and give a further questionnaire to an acquaintance who would be asked to complete questions about them. After consenting, participants were told "*Please read the instructions* (see Figure 1) *carefully, as you will only be able to see them once. Press the start button when you are ready to take the test. I will leave you to take the test privately, and will be waiting outside of the room for when you have finished. Please imagine that you have applied for a job. The test you are about to complete is being used to determine your suitability for the job. As a job applicant, try to do your best on the test*". A Lenovo ideapad 510–15ikb laptop which has a 15.6 inch screen was used to run the SBT.

After completing the SBT, the participant completed the *individual characteristics questionnaire*. The participant then received an unsealed envelope containing an *acquaintance questionnaire*. The SBT participant gave this envelop to their selected acquaintance, who completed the questionnaire and sealed it in the envelope which was then returned to the researchers.

3 RESULTS

Missing data for acquaintance rating scale items was replaced with the variable mean. Missing data for demographic questions was left as missing, and resulted in some n = variance across the analyses. SBT participants took an average 17.9 minutes (SD = 2.84, range 13.1 to 26.1) to complete the SBT. The average SBT score was 8.0 (SD = 2.72, range = 0 to 13, skew = –.454, kurtosis = –.067). Table 1 shows the comparison of SBT scores by gender, computer game player versus never played computer games, and previously driven a forklift versus never driven a forklift.

Inspection of Table 1 indicates that being a computer game player significantly increased the participant's SBT score. Thus computer game experience in the form of how many months the participant had played computer games (mean = 177.9, SD = 130.3) was used as a covariate in the criterion-related validity analysis. Correlational analysis using Pearson product moment correlations showed no significant relationship between the participant's age and SBT score (r = –.02, n = 99), total work tenure and SBT score (r = .02, n = 96), or rated safety risk of their current job and SBT score (mean = 42.4, SD = 28.3, r = .01, n = 98). Overall, the SBT score data shows a distribution suitable for validation analysis, and of the variables examined is only significantly impacted by computer game playing experience.

To examine the criterion-related validity of the SBT, several correlational analyses were performed. Table 2 shows the descriptive statistics for the independent safety behavior scale data from the acquaintance questionnaire and the correlation between each safety behavior scale scores and the SBT score. The first correlational analysis (column 5 of Table 2) used all 100 participants. The second analysis used the number of months the participant had been playing computer games as a covariate, and thus shows partial correlations. The partial correlation analysis resulted in a decrease in sample size (n = 30) due to the small number of computer game players in the total sample, and that only 30 of these reported their playing experience

Table 1. Comparison of SBT score by gender, computer game playing experience, and forklift driving experience.

	SBT Score Mean & (SD)	SBT Score Mean & (SD)	t-test
Gender	Male, n = 62 7.91 2.92	Female, n = 38 8.26 2.39	= –.611
Computer game player	Yes, n = 36 8.91 (2.61)	No, n = 62 7.66 (2.66)	= –2.263*
Driven a forklift	Yes, n = 57 7.96 (2.90)	No, n = 43 8.16 (2.49)	= .358

*P < .05.

Table 2. Safety behavior measure descriptive statistics and correlations with SBT scores.

Safety behavior measure	Mean (SD)	Skew (Kurtosis)	Correlation with SBT score N = 100	Partial correlation† with SBT score N = 30
Voice	3.67 (1.1)	–1.27 (1.88)	.02	.25
Compliance	4.03 (.95)	–1.33 (2.39)	.13	.42*
Participation	3.52 (1.2)	–.92 (.63)	.00	.22
Consciousness	3.63 (.78)	–.59 (.14)	.08	.42*
Rule bending	2.35 (2.2)	.08 (–.80)	–.20*	–.46**
Risk taking	2.06 (.92)	.82 (.90)	–.08	–.41*

†Controlling for months of computer game playing, *P < .05, **P < .01.

in months (mean = 177.9, SD = 130.3, range = 19 to 480). Inspection of Table 2 indicates SBT criterion-related validity evidence is shown when computer game playing experience is controlled for.

4 GENERAL DISCUSSION

The SBT scores across the 100 participants produced a distribution consistent with the SBT being a useful measurement tool. The overall mean SBT score was close to the score range mid-point, and the standard deviation and skew statistics are indicative of a normal distribution. These measurement characteristics are ideal for a measure which is attempting to scale job applicants or employees on their safety behavior. The overall average test time of approximately 18 minutes is also likely to be acceptable within the process of employee recruitment. Tests that run too long are said to be associated with response burden, where participants feel strained by the test experience and this could adversely impact their test score (Rolstad, et al. 2011). Of the variables examined, computer game experience showed an impact on SBT performance, and this is very evident in the criterion-related validity analysis shown in Table 2. The implications of this are discussed below.

The SBT was developed to help avoid bias associated with self-report measures of safety behavior. Using the assumption that behavior within a gamified work environment simulation would accurately reflect behavior in a 'real' situation, the SBT was designed to include decision points which could be scored as either safety or unsafety (risky). Individuals with a propensity to behave safely, not bend the rules or take risks should score higher on the SBT, and the correlations with the independent rating of safety behavior shown in Table 2 are consistent with the SBT being able to achieve this objective. However, a key factor in the SBT's measurement ability is the participant's experience with the gamification mode, their experience with computer game playing. When computer game experience is controlled for the partial correlations support the criterion-related validity of the SBT, and the size of the obtained partial correlations are sufficient to ensure that the SBT would have utility within an operational situation, such as employee recruitment.

The finding that computer game experience influenced SBT performance is consistent with other validation research into gamified tests (e.g., Kim & Shute, 2015). Kim and Shute (2015) examined the influence of computer game experience on participant's performance on their gamified physics test, and reported performance on the assessment was influenced by game playing experience. Participants identified as gamers were found to have had an advantage over non-games on achieving test points. A number of explanations for the influence of computer game experience on SBT performance need to be explored in future research. In completing the SBT it is possible that non-computer game players had to focus on learning how to control the game/test, made decision errors because of their unfamiliarity with the test mode, and this reduced their SBT score. Under such conditions their SBT behavior, as reflected in their SBT score, would not be expected to be associated with their acquaintance's ratings of their safety behavior. The influence of test mode unfamiliarity should be able to be easily addressed through the use of sufficient pre-test instruction given in the operational aspects of the test mode. The SBT instructions shown in Figure 1, while assumed to be sufficient, are static and further work on enhancing them using brief animation clips which include point and click control trials similar to those used in the SBT simulation environment need to be developed.

It is also possible that computer game players may have characteristics which are associated with behaving safely, and their SBT performance has less to do with game control familiarity, rather is a reflection of their tendency to behavior safely. Teng (2008) found that computer game players had higher scores on openness to experience, conscientiousness, and extraversion than non-computer game players. Geller (2004) suggested that being open to experience would make people more likely to accept and engage in new health and

safety related initiatives, while being conscientious would see people being more inherently interested in safety processes, and being extraverted would make it easier for people to use safety procedures that require communication between people. Furthermore, in a meta-analysis of personality traits and accident involvement, Clark and Robertson (2005) found low conscientiousness to be a valid predictor of occupational accident involvement.

There may also be a cognitive aspect associated with computer game playing which has relevance to safety behavior. Pillay (2002) revealed in an investigation of the cognitive processes engaged in by computer game players that children who played recreational computer games performed better on subsequent educational tasks than a control group of children that did not play computer games. Higher levels of intelligence have been shown to be associated with lower rates of accidents. Specifically, the information processing skills of being able to recall relevant information, quickly identify problematic situations, and react quickly to unforeseen situations are said to be key skills in accident prevention (Gottfredson, 2004).

While a number of issues need to be addressed in future research on the SBT, the evidence from this study suggests the SBT has the potential to be a useful tool for both employee recruitment and research on safety behavior. The merging of traditional psychometrics and animated game technology provides for measurement which might be less susceptible to bias than self report. In the case of safety behavior this may result in significant benefits to organizations through accident reduction, and help protect individuals from injury through the identification of those who could benefit greatly from instruction around safe work place behaviors.

Professionalization in safety: A study of the professional context of a post master safety program's alumni

Wim van Wassenhove
CRC – Centre de Recherche sur les Risques et les Crises, MINES ParisTech, PSL Research University, France

Christian Foussard
Consultant Risk Management and Process Safety, Dubai Festival City, UAE

ABSTRACT: Our contribution to the ESREL conference will present the first results of a qualitative and quantitative study on the professionalization of alumni of a post master safety program. The post master Management of Industrial Risks has graduated 197 students since 2004. We addressed an online questionnaire to all the alumni, five in depth interviews will be realized with alumni and their work colleagues and a focus group discussion will be held. The online questionnaire will investigate their careers (company, position and wages) but also how safety is organized in their company, with whom they interact, what are their missions. For the job missions, we focus on their personal convictions, the importance given by their organization or company and the real time spent doing the job missions. We will also investigate the characteristics of their work conditions and what are, from their own point of view, the real contributions for safety in their organization. Finally, the knowledge and competencies they mobilize or want to mobilize doing their job will be assessed. Those findings intend to, firstly, dress a picture of the safety professional daily job, secondly, identify factors that shape the safety professional's role in the organization and, finally, elaborate a more adapted curriculum for the training and development of future safety professionals.

1 INTRODUCTION

The safety science is a rather young science. As it is a multidisciplinary science mixing social science with engineering science, education programs are also very young compared to the education of traditional professions (like medicine, law and applied sciences professions like engineers) who are depending on one traditional and identified discipline. Although INSHPO, the International Network of Safety and Health Practitioner Organizations (Pryor et al. 2015), considers that OHS (Occupational Health and Safety) is an emerging profession that is often not well defined, locally or globally, the safety profession in France can now be considered as a structured and recognized profession: several curriculums and descriptions of the safety or risk profession exist (APEC 2017, AMRAE 2013). This doesn't mean that before this period safety wasn't managed by professional people in organizations or companies, *Ecole des Mines de Paris* was founded by King Louis XVI in 1783 to ensure the management of the mines of the kingdom. Two issues in mining business were important at the moment, economy and safety. The school disappeared at the beginning of the French Revolution but was re-established by decree of the Committee of Public Safety in 1794. So engineers were trained to the traditional engineering disciplines (mathematics, physics, mechanics and chemistry) but also social sciences were developed and delivered, as economics and management.

The past years, a keen interest in «*professionalization in/of safety*» has emerged in the safety science community (Gilbert 2015). The FONCSI (Fondation pour une culture de sécurité industrielle) has initiated in 2015 a strategic analysis on "*skills and competencies for industrial safety*" in which several international researchers are involved (Bieder, Journé, and Laroche 2015, Bieder et al. 2018).

Professionalization in/of safety can be seen two ways: the professionalization of persons who will become experts in safety (professionalization in safety – PiS) and the integration of safety into the general professionalism of employees (Professionalization of Safety – PoS). Although Andrew Hale has worked since the eighties (Hale et al. 1986, Hale 1995, Booth et al. 1991, Hale et al. 2005, Hale and Ytrehus 2004) on the topic of the professionalization of the profession (PiS), this renewed interest gives birth to new models and tools like the Australian OHS Body of Knowledge (Paul and Pearse 2016). This article will present a study of

the professional context of a post master safety program's alumni.

The general research questions we want to tackle are the following: what is the career path of alumni of a post master program in risk management? Can we define their daily professional environment? Which knowledge and competencies are actually used? What is their position and role in an organization? What is the contribution of the post master program to their professionalism? How to develop better education in risk management to bridge the theory to the professional real life context? And in a very general way, what could be the safety professionals' contribution to safety?

In this article, we will introduce the context and the research methods with some early results. First, we will differentiate *professionalization of* and *professionalization in* safety. For information, we will use the concept of "*safety professional*" in this article, as "*safety practitioner*" is a person who is vocationally-educated where the safety professional is university-educated (or has attained a similar level of higher education) (Pryor et al. 2015).

2 PROFESSIONALIZATION OF SAFETY

Industry recently wonders if the amount of effort put into safety training of employees was worth it (Gilbert 2015). Although a lot of time and money is consecrated to safety trainings, accidents still occur. The professionalization of safety, the way how workers integrate safety issues in their daily work, is subject of attention of researchers. The concepts of ordinary and extra-ordinary safety have been developed by Claude Gilbert (Bieder et al. 2018). A new way of safety training is also a topic of interest. It is clear that the safety professional has a major role to play as he is the referee person for safety in the organization. Thus we see a clear link between professionalization « in » and « of » safety. This makes us wonder about the place of the safety professional in his organization. Gilbert states that the difficulties for good safety training program in a company (PoS) are that they have to fulfill internal performance obligations and requirements and external justifications (accountability).

3 PROFESSIONALIZATION IN SAFETY

There is significant literature about safety professionals, Andrew Hale has done a lot of work since the eighties (see above), professional associations have also contributed to the subject (Pryor et al. 2015) and even in the sixties, people (scientifics) have written pertinent insights concerning the safety professional and his role in organizations that are still very actual today (Harper et al. 1962). Scientific and professional courses have emerged since the seventies (Arezes and Swuste 2012). The last decennium, in France the curriculums who are dealing with risk management, safety or HSE (Health Safety and environment) grew in a significant way. Private organizations in France propose rankings of (business) education programs and since several years the category « risk management » exists (www.eduniversal-ranking.com). Last November, the author of this article for ESREL was solicited to review an article for Safety Science. Chinese contributors examined the professionalization of safety in China: « *Development of safety science in Chinese higher education* ». The last decade, we can observe a development of education of safety professionals in all industrialized countries.

Dekker investigated the role shaping factors about the safety profession (Provan et al. 2017). This work is interesting because it can give an idea of the importance on a safety professional in his organization and the way how he can influence, model or create safety in the organization. This is a topic that has to be investigated and taught to future safety professionals. This present study tends to bring some answers to that question also. The following part presents our study object, the post master degree industrial risk management.

4 POST MASTER DEGREE INDUSTRIAL RISK MANAGEMENT

In 1997, the top management of MINES ParisTech decided to launch a research department dedicated to risk and crisis with the mission of developing studies in cooperation with industrial partners and training activities. In 2002, the decision was taken to build a post-master program for training HSE professionals for the industry.

The post master degree ("*Mastère Spécialisé*" in French) Industrial Risk Management was launched in 2004 on demand of French industry and in collaboration with Tongji University of Shanghai (China) to form, besides French students, also Chinese students on risk management for French companies developing in China.

The design of the curriculum was achieved from an analysis of academic literature and current practices, in close cooperation with companies' representatives, in order to fit the contents of the training and the pedagogical methods to the needs of the industrial sector. The program has known several important changes in organization and content while its existence. In the actual form (promotion 2017–2018), it contains 500 hours of courses during one year (begin October to end September). The rest of the time, students realize

a professional mission with an industrial partner. The program forms future safety professionals in the occupational, environmental and industrial (process safety) field. The curriculum contains six main tracks:

- Safety regulations,
- Hazard and risk assessment,
- Safety Management Systems,
- Human and organizational aspects,
- Management and leadership aspects,
- Emergency and crisis management.

Lectures, exercises and practical work are provided and supervised by a faculty group composed of an equal number of academics and professionals.

Currently, 31 students attend the program, almost all of them alternate academic training and apprenticeship. This apprenticeship program consists in 5 weeks courses, 3 weeks enterprise, 3 weeks courses, 4 weeks enterprise, 3 weeks courses, 2 weeks enterprise, 1 week study trip, 5 weeks courses and 6 months enterprise followed by the defense in front of a jury of their professional project. The program in its current form contains six main tracks, a study trip (United Arab Emirates in 2017) and a professional conference, organized end of March by the students themselves.

The program has known an evolution from a «double degree or double competence» point of view to a program that forms «specialized» safety professionals. The students that apply for the program now have, for the great majority of them, already a Master degree in Health, Safety or Environment. The MS MRI makes them more "specialized", whereas in the past, students had degrees in chemistry, engineering, psychology or law. This is also the result of the increase in HSE Master Programs and the result of the demand of industry. Industry wants a student already trained in HSE for their professional missions and collaborations. This eliminates from the program the students who have no knowledge of risk and/or HSE.

The scientific transfer of HSE findings to the industry takes some time. HSE practitioners often lack the knowledge of the genesis and relations between HSE theories and methods, models and metaphors developed since World War 2 (Swuste, Gulijk, and Zwaard 2010, Swuste et al. 2014). It is also important to know the evolution of the HSE job. The integration of a HSE professionals' training program in a dedicated research laboratory (CRC—MINES ParisTech) facilitates this knowledge transfer and informs the future HSE professionals of the latest advances in the field. They will probably keep an intellectual curiosity all the rest of their career and hopefully will participate in co-developing tools using the latest safety models (Besnard et al. 2009).

Post master programs are known to be «*professionalizing*», the student will pass from the state of student to be a professional. Several characteristics of the MRI program tend to influence this transition: participation and courses of a lot of safety professionals, students pass a great deal of the program in the organization of their industrial partner, projects and case studies are real industry problems (with participation of industry), executive summaries are demanded on several topics, they work in teams, they do a lot of presentations, they learn to present their work to decision makers, the courses on "management and leadership" makes them aware of the importance of soft skills on the work floor.

The program has grown since 13 years to be more and more professionalizing. But finally, what is the contribution of the post master program to their professionalism? How to develop better education in risk management to bridge the theory to the professional real life context? For what kind of professional context do we prepare them? The next part will present the missions of a safety professional.

5 MISSIONS OF THE SAFETY PROFESSIONAL

Several studies on the missions of safety professionals have been done. Wybo and Van Wassenhove (Wybo and Van Wassenhove 2016) present the missions of safety professionals (Table 1), the needed skills to do the job and modeled the MRI program to correspond. They conclude by proposing requirements for a HSE professional training curriculum: students getting their degree in HSE must be fully operational and demonstrate their professionalism when they start their first job. So the curriculum must prepare them to their future work. From the literature review and the analysis of a HSE professional's job content, they identified the important matters our HSE professional's curriculum must address:

- Domains to teach:
  - Regulations and HSE management systems,
  - Hazard and Risk analysis in occupational health, system safety and environment,
  - Human and organizational matters,
  - Emergency and crisis management,
  - Communication, management and leadership,
- A strong implication of safety professionals,
- The use of realistic case studies,
- Interactions with industry practitioners:
  - "Field work" in industrial sites,
  - Annual conference for industry practitioners,
  - A long internship/presence in a company,

Table 1. Missions of safety professionals in literature (Wybo and Van Wassenhove 2016).

Job content topic	ENSHPO 2005	AMRAE 2013	ASSEF 2007	Wu 2011	INRS 2004	De Joy 1993	Hale 2004	Kohn 1991	Total

Monitoring and reporting	++	+	++	+	+	+	+	++	**11**
Knowledge management	++			+	+				**4**
Insuring and costing risks	++	+		+					**4**

Nevertheless, questions still remain on other aspects of their professional context. What are the knowledge and the competencies they mobilize? What is their position and role in an organization? What is their vision of safety and what can be their contribution to safety? A first step is to look closer to what alumni of a post master program in risk management do once graduated. We developed a methodology to search for some first answers.

6 METHODOLOGY: GENERAL QUESTIONNAIRE

The post master program MRI has now about 200 alumni. To investigate the professional context of the safety professional, we dispose of exactly 197 persons to consult.

A similar study on the context of a profession has been conducted in the Netherlands (Corporaal et al. 2016). They investigate the Human Resources (HR) professional and they use the following methodology: several students (544 students participated to the study) have asked HR professionals (571 persons), their hierarchical boss (542 persons) and a line manager (553 persons) to fulfill a questionnaire. That questionnaire was used afterwards as guide to do in-depth interviews with those persons. This study is repeated yearly (!). Every four years, a synthesis is done and an education profile is created. This profile enables to adapt the curricula of the HR programs. The research themes are the missions of the HR professional, role and position of the HR professional, competencies needed for the HR professional and the relations with line management.

In the field that interests us, the OHS Professional Capability Framework is a framework for practice developed by the International Network of Safety and Health Practitioner Organizations (Pryor, Hale, and Hudson 2015). INSHPO differentiate competence and capability. The difference between competency and capability is that competency is about delivering the present based on the past, while capability is about imagining and being able to realize the future. Capability goes much further than competency, it's also about confidence and adaptability. For our study, we use "competency". With the first results, we will see and judge if there is a need to differentiate between competency and capability.

From the literature, personal work and observations, a general questionnaire was developed. This development was done with the support of co-researchers (Gilbert De Terssac, sociologist, research director CNRS) and was tested on some alumni. The remarks were integrated into the questionnaire. The questionnaire was proposed to the alumni through an on-line version. Each alumnus was personally contacted mid November 2017 by email with the request to take some time to answer the questions. The time to respond is set to two months. Several solicitations are done, the aim is to have at least 100 responses. To answer all questions, the participant has to take at least 30 minutes of his time and has to do some critical analysis of his work situation. Answering the questionnaire takes a real effort.

The questionnaire is structured as followed:

- questions about the identity
- career description
- job description
- benefits of the MRI program for the professional career
- comments

The job description is the most important for our research questions and is composed of twelve questions. Four questions are very important, we will present them here.

One question concerns the missions of the professional. From a synthesis from the literature, personal observations and discussions with safety professionals, fourteen missions are proposed (Table 2). For each mission, the respondent has to notify on a scale going from 1 (not important) to 10 (very important) the importance of the mission in his current job, according to several levels:

- according to his or her personnel conviction
- according to the organization in which he or she is working (his superiors)
- according to the real time he or she spent on the mission

In this way, we can identify discordances between the professional and his organization.

The second important question concerns the characteristics of the professional's job (Table 3). Sixteen descriptions of work characteristics are proposed. The professional is asked to score 1 (not agree) to 10 (totally agree) for each situation.

The third question is about the concept of safety. Twenty-two ideas are formulated about what contributes to safety (Table 4). The professional has to score (1 not important and 10 very important) the ideas according to his personal conviction and

Table 2. The fourteen missions of the safety professional.

Missions of the safety professional
1. Inform and advice the direction
2. Organize the safety management system
3. Follow up of regulations
4. Control compliance with regulations
5. Manage risks (identification/evaluation/treatment)
6. Develop safety culture
7. Inspections on the work floor, organizing information collection (bottom up)
8. Train and communicate about safety and risk
9. Analyze incidents and accidents
10. Manage crises and emergencies
11. Measure performance: monitoring and reporting
12. Give expertise for a specific type of risk
13. Manage the insurance and financial side of risks
14. Realize business continuity plans

Table 3. Job characteristics description.

Characteristics of the job
1. Presence of an administrative workload and an important "safety bureaucracy"
2. A big diversity of objects and subjects to handle
3. A lot of subjects to handle with urge
4. No time to treat subjects in depth
5. A lot of traveling
6. A lot of simultaneous missions with different deadlines
7. Recognition of the direction
8. Recognition of middle management and workers
9. Feeling of being isolated in an organization that is not much concerned by safety
10. Interruptions and adaptations of planning
11. Difficulties to conciliate safety prevention with regulatory compliance, requirements of inspection of the administration and the politics of the organization
12. Interactions with a lot of stakeholders
13. Lack of means
14. Necessity to adapt constantly the rules (theory) to the reality of the work floor (practice)
15. Frequent interactions with the work floor
16. Autonomy and liberty of initiative

Table 4. Safety "ideas".

Composantes de la sécurité
1. Engagement of the direction
2. Engagement of middle management
3. Compliance with regulations
4. Safety culture
5. Safe technical conception
6. Bottom up consultation
7. Consultation of administration and inspection
8. Consultation and information of the neighborhood living near the company
9. Presence of a Safety Management System
10. Safety training
11. Team spirit and cooperation on the work floor
12. Respect of procedures
13. Sharing of good practices
14. Sharing of information on accidents and incidents
15. Comprehension and modeling of hazards
16. Presence of a degree of liberty in interpreting procedures in function of the context
17. Analysis of root causes after an accident
18. Considering the variability of human performance by analyzing the work conditions
19. A good technical knowledge of the system by the stakeholders
20. Human error analysis
21. Give sense to work: organize debates on work situations
22. Organize crisis and emergency exercises

according to what he thinks is the conviction of his organization.

The fourth question (Table 5) concerns knowledge and competencies (skills or even capabilities) mobilized by the professional and the competencies that he or she would like to mobilize more. It should be noticed that knowledge and learning can be characterized at six levels. These levels are based on the well-known Bloom taxonomy (Murtonen, Gruber, and Lehtinen 2017) and go from 'simple' remembering to 'elaborated' evaluating. But we can consider the levels of analyzing, synthetizing and evaluating as hierarchical equal levels.

- Remembering (knowledge)
- Understanding (comprehension, translating, interpreting or extrapolating information)
- Applying (using principles or abstractions to solve novel or real-life problems)
- Analyzing (breaking down complex information or ideas into simpler parts to understand how the parts relate or are organized)
- Synthesizing/creating (creation of something that did not exist before)
- Evaluating (judging something against a given standard)

A safety professional who is fully competent is expected to operate minimum at level three (applying knowledge) for every knowledge category (Pryor, Hale, and Hudson 2015).

Skills can be categorized in three sections: personal skills (example: verbal communication), professional practice skills (example: problem solving and critical thinking) and professional technical skills (example: implements tools to assess risk). We chose to list in table four knowledge and skills but with differentiating neither the type of skills nor the taxonomy of Bloom. The last item of the list, 'ethics', is rather a personal value than a skill. Those aspects will be studied more in depth when doing interviews with selected people (see below).

The next paragraph will present some first results and a discussion about how to complete this methodology (the questionnaire).

Table 5. Knowledge and competencies.

Knowledge and competencies
1. Knowledge of regulations
2. Knowledge of hazards
3. Knowledge of the technical system
4. Knowledge of accident models and theories
5. Knowledge of risk analysis methods
6. Knowledge of business management: finance, human resources, organization, technologies, innovation…
7. Competency of applying risk analysis methods
8. Competency of « constructing » a risk analysis methodology adapted to the problem
9. Competency of crisis and emergency management
10. Competency of situation/activity/accident analysis
11. Competency of translation of politics into real actions
12. Competency of translation of accidents statistics into action plans
13. Competency of strategic planning
14. Competency of hierarchizing problems
15. Competency of looking for the right information and learning
16. Competency of critical analysis
17. Competency to propose solutions
18. Competency of written and spoken communication
19. Competency of synthetizing and adapting of wording to the public addressed
20. Competency of organizing personal work
21. Competency of listening
22. Competency of leadership
23. Competency of being exemplary
24. Competency of teamwork
25. Competency of working in an multicultural organization
26. Competency of using new communication technologies
27. Ethics

7 FIRST RESULTS, DISCUSSION AND PERSPECTIVES

The questionnaire is on-going and at this date, 61 alumni of the 197 persons contacted have responded and completed the questionnaire. To complete the questionnaire (the majority of questions are compulsory) at least 30 minutes and a great effort of reflecting on professional practices is needed. Another 50 respondents started but didn't finalize the questionnaire yet. The aim is to have about 70% of the alumni. Each alumnus will be contacted individually, and several times if necessary.

Several biases are present for this study. We will discuss the most important ones. We find that the youngest alumni completed in priority the questionnaire. The elder ones 'lost' probably the implication with their former school and are less motivated to respond. Also, several contact addresses of the elder alumni are obsolete. A work to trace them on Linked In is ongoing. The Chinese alumni are also difficult to contact. This could give a slightly distorted image because we will have only data from young professionals: the description of the professional context of a junior safety professional.

The curriculum of the program has been modified all along its existence. Several important modifications have been done: in 2010 an important content modification, in 2014 the introduction of alternate training and apprenticeship. The

respondents will evaluate a program that was not the same for all the alumni. We hope that the first results will give us insights on the importance on professionalization of the introduction of the alternate training and apprenticeship with an industrial partner in the curriculum.

A complementary methodology will allow us to gather more data. The first results will able us to organize focus groups with alumni to discuss several aspects or findings. A couple of monographies will be done also: a safety professional, his superior and his colleagues will be interviewed and observed in their daily work. It could be interesting to interview also line managers who are in contact with the safety professional.

The findings of this work will able us to:

- Have an idea of the careers of our alumni (company, wages, function,…)
- Have an idea of the professional context of our safety alumni (missions, job profile, organizational culture…)
- Have an idea of the knowledge and competencies they mobilize
- Have an idea of the impact of the MRI program on their professionalism

The perspectives of this work are of different nature. On one hand we continue to implement changes and modifications and we improve the program of MRI to prepare the students to the "real life" context of the safety professionals' job. This is managed by new pedagogical approaches: role plays, case studies, close interactions with safety professionals and collaboration of *Safety Scientifics* and *Safety Professionals* together on the same project. We discussed in a former paper (Wybo and Van Wassenhove 2016) the pedagogy used for education of safety professionals. The present study will be able to bring some data for improving the pedagogic approaches of the program.

In order to improve the program, we must absolutely question ourselves on the ways we evaluate the program. The four-level training evaluation model of Kirkpatrick (Gilibert and Gillet 2010) is widely known. We could think of integrating a yearly survey of alumni and/or interview and observation of alumni in work conditions in a general evaluation plan based on Kirkpatrick's model. Kirkpatrick proposes four levels of evaluation of learning: reaction (satisfaction of learners), learning (what knowledge do they acquire, behavior (do they use the new knowledge in work situation) and results (outcome for the organization). Paul Swuste (Swuste and Sillem 2018) is interested in the quality approach to evaluate a post academic course 'management of safety, health and environment'. Having a feedback of alumni is not enough to have a global evaluation of the program.

What is the goal to form and educate students in safety curricula? Teaching them theoretical risk analysis methods (HAZOP, FMECA, QRA...)? Preparing them to the real world problems when applying those approved methods? Maybe the role of an education program is also to form "new" professionals who are importing new (scientific) insights into the profession. They are the bridge between science and practice. Probably, it is all this and even more.

Last but not least, in our understanding of safety in organizations, the role of the safety professional is very important. David Provan (Provan, Dekker, and Rae 2017) did a literature review of the factors shaping the role of a safety professional (bureaucracy, influence and beliefs). This present study will certainly contribute to identify some factors. Being aware of those factors will surely enable future safety professionals to be more effective in their job: bringing more safety to our world. And this is exactly the fourth level of Kirkpatrick's evaluation model.

Reversing the trend through collaboration in the petroleum industry

K. Skarholt & G.M. Lamvik
SINTEF Technology and Society, Trondheim, Norway

ABSTRACT: The purpose of this paper is to discuss the importance of bipartite and tripartite cooperation in the Norwegian petroleum industry and how it contributes to improve safety conditions. Lack of trust between the parties and pressure on the Norwegian model has great attention in this industry today, related to major cost reductions and downsizing the last 2–3 years. We discuss these challenges and how to re-build trust between the parties. The empirical material is mainly based on qualitative data from the ongoing four year RISKOP research project (Managing Risks in Offshore Operations). In addition, the data is based on a document study about the safety conditions and collaboration in the petroleum industry.

1 INTRODUCTION

In the Norwegian oil and gas industry there is a long tradition for employee participation at work, both at an individual level, and through formal bipartite and tripartite collaboration, inviting for employees' ideas and concerns about safety issues. A tripartite collaboration consists of the authorities, employers' association and worker unions, while bipartite collaboration is a local collaboration between employer/management and worker unions within a company (Levin et al., 2012).

Employee participation is about involvement in work-related matters, with the intentions to have influence on working conditions. The term employee voice is an expression of participation at work, and is defined as an employee's discretionary communication of ideas, suggestions, concerns, or opinions about work-related issues with the intent to improve organizational functioning (Morrison, 2011:375). The contribution of employee voice is to influence decisions and contribute to improvements in a company. According to safety, it is crucial that employees' opinions and voices are listened to, if not it may lead to dangerous safety conditions and accidents. However, the conditions for employee voice are challenged in periods with economic crisis (Farndale et al., 2011; Skarholt et al., 2017). Economic crisis and downsizing has led to a more fragile bipartite collaboration where the parties and authorities experience decrease in trust. Increased economic pressure has led to concerns about possible negative effects on safety and work environment. Figures from the latest study of trends in risk level in Norway's petroleum activity (RNNP 2016) from the Petroleum Safety Authority Norway (PSA), shows that more employees report higher work pressure and less influence on HSE than in previous RNNP studies. This negative development has led to campaigns and initiatives from both the PSA and the Ministry of Labor and Social Affairs in Norway.

Through the campaign "Reversing the trend", the PSA address what they see as a worrying development over the past years (PSA, 2016). How to actually improve bipartite and tripartite collaboration is one of the main issues in this initiative. According to PSA good collaboration between employers and employees has helped to boost the level of safety in Norway's petroleum industry. This interaction now appears to be under pressure. PSA stress the importance of employee participation in handling safety matters, stating that involvement of employees is a requirement in all phases of the petroleum sector for every issue which relates to safety. These rights and duties are to be practiced both directly by each individual worker and through union representatives and safety delegates. A good collaboration between the parties depends on mutual trust.

The Ministry of Labor and Social Affairs in Norway appointed a HSE committee representing authorities, employer organizations and employee unions in the petroleum sector in 2016, to discuss and consider the state- and development of HSE conditions in the Norwegian petroleum industry. The background for this was a negative safety trend in 2015 and 2016 with serious conditions and safety challenges. The report from this work (HSE committee—Ministry of Labor and Social Affairs, 2017) refers to that there have been major change processes with downsizing and restructuring that may be a challenge to the established collaboration between employers and employees. Indications

suggests that cooperation between the parties is more fragile compared to earlier, although disagreement prevails between the parties over how far this collaboration has come under pressure. A main conclusion in the report from 2017 is to keep and build mutual trust and respect to each other's role and responsibilities between the parties—to be able to take care of and develop the safety level in the petroleum industry.

The aim of this paper is to discuss the role of bipartite and tripartite collaboration due to develop and improve safe operations in the petroleum sector in Norway. We discuss how employee participation at work influence on safety conditions—as a mean of reducing risk of injuries and major accidents.

2 THEORETICAL BACKGROUND

2.1 *Collaboration, trust and safety*

The Norwegian oil industry, or rather the oil industry on the Norwegian Continental Shelf has been characterized by its social agreements grounded in the Norwegian model, producing alliances between all core stakeholders, thereby a "we" including the whole of the industry. The Norwegian model on a local company level is about the collaboration between management and union representatives. In Norway, this cooperation has been characterized by; trustful relations, willingness to collaborate for increased competitiveness, low level of conflicts at work (Levin et al., 2012). The voice of employees has thus to a large extent been listened to and have influenced over decisions made in the company.

Improved safety is something that all parties want for the industry. The Norwegian petroleum sector has been characterized by trustful bipartite and tripartite collaboration, and the participation among employees has been important for improving safety conditions. Important arenas for tripartite collaboraton is "Working Together for Safety" (Samarbeid for Sikkerhet/SfS) and Safety Forum (Sikkerhetsforum). The aim of their work is to increase safety in the petroleum industry and strengthen trust and cooperation among the actors of the industry. These arenas are central for cooperation among the parties in the industry and the authorities as regards health, safety and environment in the petroleum activities offshore and onshore. Here, the unions, the employers' organizations and the authorities have a significant influence on the safety agenda in this sector. One could say that this trust-based tripartite collaboration is a key cultural value related to how safety is maintained in the Norwegian petroleum industry. Trustful bipartite collaboration about safety matters have also been an important cornerstone of the safety regime. Bipartite collaboration is an integrated and critical part of the regulatory regime for HSE in the Norwegian petroleum sector (Rosness & Forseth, 2014). To report about dangerous safety situations and conditions is easier to obtain in a bipartite collaboration, where you can have an open relation between leader and employees/unions. The economic crisis in this sector has however put the collaboration between the parties under pressure. Indications from several actors claim that the Norwegian model with bipartite and tripartite collaboration is under pressure (PSA, 2016; Ministry of Labor and Social Affairs; Falkum et al., 2017). Safety Forum was established in 2000, based on distrust from unions to the employer association Norwegian Oil and Gas—stating that they constantly failed to include the employees in decisions concerning safety (Rosness & Forseth, 2014). Compared to the situation in 2000, we are seeing a similar development today with decrease of trust between the parties.

Trust in organizations has been studied in different ways to address positive outcomes on organizational phenomena, such as positive impact on safety culture and safety performance (Burns et al., 2006; Conchie et al., 2006; Reason, 1997). Trust also affect improved communication, knowledge sharing, commitment, and organizational learning (McEvily et al., 2003; Nonaka and Takeuchi, 1995).

Research has shown that the cultural aspects of work practice influence safety as much as technology and formal organization structures (Antonsen, 2009; Guldenmund, 2000; Haukelid, 2008). Also, the work from Tharaldsen (2011), addressing differences in safety climate and trust between UK and Norwegian sector, fits this picture.

In high reliability-organizations (HRO) organizational culture/safety culture influence on safety (Weick and Sutcliffe, 2007). The key aspect of building safety culture is the level of openness and trust and access to information that may indicate compromising of safety. Reason (1997) argues that the safety culture is based on an underlying element of trust, and research shows that high levels of trust in relationships contributes to high levels of safety in high risk enterprises (Conchie et al., 2006). Their study of safety performance in the offshore industry concluded that the impact on trust and distrust on safety performance is determined by the act of being trusted (or distrusted).

Trustful relations and openness requires the existence of a variety of channels, both formal and informal. Bipartite cooperation is a relation between managers and union representatives (and safety delegates) in a company. The Norwegian Working Environment Act from 1977 regulates

the rules for formal participation at work among union employee representatives, where they have influence through information- and discussion meetings with the line management. They thus take part in problem-solving in different matters at work, such as improvement of safety, change processes and similar.

A good bipartite collaboration demands good leadership, listening to the ideas and concerns from the employees. How the dialogue and trust is between the parties will influence on how the employees are involved and have influence on their work and safety matters at work. The presence of union representation at work contributes to increased individual employee participation (Trygstad & Hagen, 2007). The relations between managers and union representatives at work will influence on employee participation outside the formal bipartite cooperation, where an involving leadership style will strengthen open communication. To make individual employees actually speak up about safety concerns, leaders must invite to openness and involvement about safety among the employees. How managers respond to employees' opinions about safety improvements, will influence on the motivation and willingness to speak up. If they signal interest and willingness to act on employee voice, the employee's motivation to inform about safety concerns are enhanced (Detert & Burris 2007; Edmondson, 2003). Detert and Burris (2007) found that management openness and transformational leadership behaviour are consistently positively related to voice. To speak up involves sharing one's idea with someone who has the power to devote organisational attention or resources to the issue raised (French & Raven, 1959). To openly speak up about work environment and safety concerns at a work place without fear of being sanctioned/punished, is a prerequisite for reporting (Antonsen, 2009; Trygstad et al., 2014). Mutual trust between managers and employees also influence to which extent the employees will tend to keep silent or use their voice when safety concerns occurs (Skarholt et al., 2017).

3 METHODS

To highlight these issues we have drawn upon various sources. An important one is the project RISKOP (Managing Risks in Offshore Operations). This project has been run by Western Norway University of Applied Sciences in Haugesund, in collaboration with SINTEF and University of Stavanger, supported by the Norwegian Research Council and nine companies in the industry. In this project, we interviewed 16 managers from five different shipping companies. These shipping companies, that constitutes an important part of the petroleum cluster in Norway, are operating advanced vessels (e.g. supply vessels and anchor handling vessels) in the offshore petroleum industry, working for different oil and gas companies at the Norwegian Continental Shelf. Also, a broker, the Norwegian Maritime Directorate and trade unions were interviewed with topics pivoting around issues as: How the informants/shipping industry experience the crisis; What they actually do to meet and handle the situation, and; How the situation may affect safety operations offshore?

Besides the RISKOP project we have analysed some documents covering certain aspects of safety and collaboration at work. First, the Petroleum Safety Authority (PSA) and their campaign "Reversing the trend" (2016) has played an important basis for this topic. Second, in the extension of this campaign we have made use of the report "HSE in the petroleum industry" (HSE committee—Ministry of Labor and Social Affairs, 2017) to shed some light on the safety situation in the petroleum sector. Third, the survey "Participation Barometer" (Medbestemmelsesbarometeret) (Falkum et al., 2017) measure; "Is participation in Norwegian working life under pressure?" Moreover, participation as is described as main elements of leadership- and managerial practice is the focus. The survey is owned by six trade unions, covering private- (included the oil and gas industry) and public sector in Norway.

4 RESULTS

We present 1) results from the interviews with leaders in shipping companies, union leaders and broker—conducted in the RISKOP project, and 2) results from document analysis about the trend and development of safety in the Norwegian petroleum industry.

4.1 *Strong bipartite cooperation—to survive*

The economic crisis in the petroleum industry has led to fewer jobs in the offshore shipping industry, where the competition for jobs is tough in a marginal market. One of the companies we interviewed had reduced their staff with 400 employees, and feared further layoffs. Consequently, shipping companies have removed a considerable portion of the offshore fleet from the market. In December 2017, there are 134 vessels from the offshore fleet in layup, out of a total fleet of around 550 vessels. Ordinary Platform Service Vessels (PSV) were the largest category of these ships (61), while Anchor Handling Tug Supply (AHTS) were 42 vessels and the number of Seismic vessels were 14.

This layup activity has resulted in downsizing of personnel for oil companies, shipping companies and subcontractors. Another challenge for this industry, is the fewer long-term contracts compared to before the crisis. Today, most of the contracts are in the spot market, meaning short-term assignments with a maximum of one month, especially operations done by PSV's (Platform Supply Vessels) and anchor handling vessels. Leaders from shipping companies we interviewed accepted contracts they knew to be too low, not even covering basic running costs, solely to decelerate the decline of the company. When the market is weak and undergoing a crisis as today, there are many subcontractors that are weakened and not in a position to negotiate.

We find that one way to deal with this crisis is actually to fight for the survival of the work place—together in a bipartite cooperation. As a coping strategy in the offshore shipping industry, collective local organizational arrangements have been strengthened. Our material show proves of strong and solidarity constellations inside the shipping companies, e.g. close collaboration between managers and employee's in finding new solutions to handle the crisis in the industry. It seems that the major challenges in the offshore sector has made all the staff in the companies, to realize that they have a common interest in collaboration and find shared solutions. They realized that this is the time for dancing rather than boxing, to paraphrase the famous book by Huzzard et al. (2005).

Many of the shipping companies we interviewed pointed out that the unions and employees was willing to find ways to save money in the company, such as reducing salaries for a period. One of the shipping companies in our study reduced the wages by 29 percent among the crew from laid off vessels, so they could keep more of their staff and the competence in which they held. Cut in company specific bonuses was another instrument to reduce costs. Another example was change in the shift system; from four to five shifts, to be able to keep more of the employees working. This allowed for an extra shift, or crew onboard the ships, allowing extra leisure time at home. This way, the economic crisis made the cooperation between the management and the employees/union representatives really strong. As one of the leaders from a shipping company said; *"New solutions to survive is established because of the unions"*. Problems and crisis become like an outer enemy that may build strong alliances between employer and employees in an organization. Labor relations become a positive force, building trust and a good working environment. We see that this is what happens in the shipping industry. Other means of survival in the Norwegian shipping market has been mergers of shipping companies the last years.

4.2 *The Norwegian model under pressure*

On the other hand, there are many indications that the climate for collaboration between the parties has become worse in recent years. Increased economic pressure has led to more concerns about possible negative effects on safety in the petroleum industry in Norway. We have made analysis of documents describing the development and trend about safety in this industry. The analysis is mainly based on these documents; Reversing the trend (PSA, 2016), HSE in the petroleum industry (HSE committee—Ministry of Labour and Social Affairs, 2017) and The Participation Barometer (Falkum et al., 2017).

Five decades after the Norwegian oil adventure began, the petroleum sector faces important safety challenges. Trends are moving in the wrong direction in a number of areas (PSA, 2017). The development over the past two years have involved safety challenges and serious conditions: Figures from the 2016 study of trends in risk level in Norways's petroleum activity (RNNP) show an increase in serious hydrocarbon leaks and well control incidents. The major accident indicator is evaluated to be at a too high level (PSA, 2016). It is a reason to believe that this situation is affected by the economic crisis with restructuring and downsizing. Changes and demands for greater efficiency raise the level of conflicts.

To get safety development back on the right track, PSA have started a campaign; "Reversing the trend". PSA has put *collaboration* as one of the main issues in Reversing the trend: *"Collaboration between the various sides in the petroleum sector is under greater pressure, both between companies and unions and between them and the government. Such bi- and tri-partite interaction occupies a key place in Norwegian safety efforts."* PSA's concerns is that a weakened cooperation could include a poorer basis for important decisions by company managements, and weaker entrenchment with employees of important choices for the way forward. They are worried about that weaker employee participation may have negative consequences for safety in the petroleum industry. Numerous examples from major accidents in the petroleum industry show that information that could have prevented the accidents, was available, but was either not communicated or not acted upon. This indicates a safety culture lacking openness and trust for reporting and telling about dangerous situations. A key aspect of safety culture is the level of openness and access to information that may indicate compromising of safety. PSA's focus on bipartite cooperation is to emphasize the role industrial relations has on safety, where they address the responsibility of improvements towards the management

in oil and gas companies. PSA want to remind the management how safety can be taken care of and improved through formal collaboration between employer and employees. The voice of employees in decision-making is under pressure, and so the Norwegian model is under pressure.

A leader from one of the major trade unions in the petroleum sector we interviewed, stated that he/the union did not recommend employees to involve themselves in union activities at the moment, since it has become very troublesome to ask for leave for the individual representatives to involve themselves in trade union work. This opinion from such a strong voice in the industry can be seen as a barometer or an indication of a lack of trust or lack of collaboration in the offshore industry.

The report from the HSE committee—Ministry of Labor and Social Affairs (2017) "HSE in the petroleum industry" also emphasize collaboration between the parties—to enhance safety conditions in the petroleum industry: *"Bipartite and tripartite collaboration is an important cornerstone of the safety regime, and must be strengthened and further developed."* Participation and influence among unions/employees about safety in this industry has been given high priority for many years, and has influenced positively on safety results offshore and onshore. The Working Act law define the rights among employees to speak up and participate at work. There are both formal and informal arenas for cooperation between the employees' organizations and the employer organization, with collective agreements regulating the bipartite cooperation. The work group with participants for employer and employee organizations recommends to strengthen the collaboration between the parties in the future, but they disagree about how far the collaboration between the parties has come under pressure. They have different experiences and interpretations weather the cooperation and the Norwegian model is under pressure or not. Further, they conclude that the level of HSE and the working environment in the Norwegian petroleum sector is high. At the same time, safety challenges and serious conditions have arisen the past few years.

The aim of the "Participation Barometer" (Falkum et al., 2017) is to analyze the development of how employees experience their influence on work, and their perceptions of control/management, organization and leadership at work. This survey is conducted annually. According to Falkum et al. (2017), *"Employee participation and trustful relations influence on company development. It serves both employees and the company's interests at the same time"*. In the literature, leader performance/practice distinguishes between management and leadership; management means to lead through systems and routines, while leadership means to lead through dialogue and hands on relations with employees (Ladegård & Vabo, 2010). The study measure if participation at work (the Norwegian model) is under pressure or not, and shows the development over years. The analysis emphasizes the relations between leaders, union representatives and employees. The hypothesis is that leadership practice affects the relations and cooperation between leader, union representatives and employees to a large extent. The sample was totally 3053 respondents—from private sector and public sector (county council/municipality and state). According to the results, 42 percent of the respondents answer that Norwegian working life develops to be more authoritarian, while 12 percent answers a more democratic development. 28 percent of the respondents answered no change (status quo). In the oil and gas industry there is 56 percent of the respondents answering that work life is being more authoritarian, meaning reduced participation at work and high degree of control (management) and loyality. The analysis of the results from the survey are based on a model based on characteristics of ideal management and leadership performance/categories. And how management and leadership influence on; trust, restructuring, professional integrity and conflict handling in Norwegian work life in 2017.

The conclusions from this survey is that participation at work is the most widespread form of leadership in Norway, compared to standardization/management, despite of that many experience that working life has become more authoritarian than before.

5 DISCUSSION

5.1 *Reversing the trend—through trustful cooperation*

Based on our findings, the collaboration in the Norwegian petroleum industry is both weakened and strengthened during the economic crisis. We discuss the relationship between safety, collaboration, trust and leadership in the petroleum industry. How to improve the collaboration and re-build trustful relations—to collectively develop the safety level in this industry? On one side we find that the Norwegian model is under pressure and that bipartite collaboration needs to be improved, and the employee voice need to be heard. On the other hand, we find examples of a strengthened bipartite collaboration in the shipping companies we have studied—in the struggle of survival.

Traditionally, the Norwegian petroleum industry has been known for its high degree of safety

and trust—both in bipartite- and tripartite collaboration. However, the collaboration between the parties has been under greater pressure, both between companies and unions and between them and the government. Related to the negative trend and development with safety challenges and serious conditions in the petroleum industry over the past years, the safety has been a "hot topic" both from the authorities, oil and gas-companies, employer- and employee organizations, and researchers.

The Ministry of Labor and Social Affairs and authorities (PSA) has put effort in how to enhance safety conditions onshore and offshore at plants and installations—through collaboration. To strengthen collaboration between the parties, both bipartite- and tripar- tite cooperation has been one major goal and priority. PSA has through the campaign addressed cooperation, stressing the responsibility held by leaders in the oil and gas companies—to involve employees more actively in problem-solving about safety matters at work. If not, PSA are worried about that loss of employees' opinions in problem-solving may lead to poorer safety conditions.

The voice of employees is important—to build a safety culture characterized by open communication, where one could speak up about concerns and ideas of improvements. Cost reductions and downsizing in the petroleum industry may have influenced the organization culture in a negative way with less openness and increased fear of sanctions as response of reporting. As one of the union leaders we interviewed said; he would not recommend anyone to take a role as a union representative or safety delegate today because of the pressure on employees having such positions in a company. He experienced that the free voice of union representatives was not appreciated and listened to as it used to be.

How the leaders respond to employees' voice and how they deal with concerns will affect problem-solving about safety matters. If the leaders signal willingness to act on employee voice, the employees' motivation to speak up are enhanced (Detert and Burris, 2007; Edmondson, 2003). The relation between worker and manager will thus impact on the degree of employee voice and the employees' participation and influence on work and development of work. According to safety, trust is a key factor to get safety issues on the agenda and to inform the management about what the sharp end in the organization experience and know related to how to run the operations safely. Trust opens up for good communication, commitment and sharing of information and knowledge (McEvily et al., 2003). The workers are close to the operations and every day productions, with a hands on experience and knowledge about dangerous situations and possible incidents. Trust has positive impact on safety culture and safety performance in high-risk organizations (Reason, 1997; Conchie et al., 2006).

It is assumed that trust in organizations is beneficial for safety, (e.g. promotes open communication) and distrust is detrimental (e.g. leads to failed safety initiatives) (Conchie & Donald, 2007). What may be the consequences of distrust in tripartite and bipartite collaboration related to safety? According to Falkum et al. (2017), Norwegian work life are being more authoritarian, and the oil industry are going in that directions according the survey about participation at work. Authoritarian ledership style means less involvement and participation at work among the employees. So, their voice and opinions will not be listened to in the same manner compared to a work place characterized by a good formal bipartite collaboration, and the possibility for employees individually to bring their concerns up to their line manager (closest leader), trusting that it is safe to speak up without fear of sanctions.

Leadership practices affect the relations between managers, union representatives and employees to a large extent. Models of leadership practice inviting to participation at work, leads to higher agreements both in matters about restructuring processes and enhanced commitment towards company strategies and values in the organization (Falkum et al., 2017). They find that trust decrease with a management style (control), while trust decrease related to participation at work and trustful relation with nearest leader. According to safety, authoritarian management style may lead to poorer safety because of the problems of communication not build on trust. The problems associated with distrust or lack of trust are failed safety initiative and an absence of shared inter-group safety perceptions (Clarke, 1999). Reason (1997) argue that trust promotes open communication about safety (reporting culture) which enhances organization learning about accidents (informed culture). The main problem associated with under-reporting (or biased reporting) are the reductions in organizational learning and development of informed strategies to improve safety.

There are however bright spots regarding collaboration in the petroleum industry. The findings from the RISKOP project show how the collaboration between management and employees/union representatives in the offshore shipping industry have strengthened during the economic crisis. When human societies face an obstacle or an external enemy, they seem to seek collaboration and alternative solutions. One fruitful example of such a mechanism is described by Evans-Pritchard when he discusses the political system and decision making among the tribe Nuer in Sudan (Evans-Pritchard, 1940). The core term in this book is that this community consist of "a system of segmen-

tary opposition" and illustrates that local groups and communities can be united when it is a conflict on a higher level in the society. The Nuer society consist of potential of alliances and fissions, or as one informant told the anthropologist: "We fight against the Rengyan, but when either of us is fighting a third party we combine with them" (Evans-Pritchard 1940: 143).

Transferred to the Norwegian offshore sector, it gives sense that the local shipping company see a shared value in finding common solutions. When they are facing a crisis in the sector as they are at the moment, they see new and unusual internal arrangements. Both managers and employees will seek dancing rather than conflict, to survive as a company. So once again the metaphors "boxing and dancing" are useful to illustrate the strategic choices the staff of certain companies have, when it comes to strategic choices in the daily work during extraordinary times (Huzzard et al., 2004).

6 CONCLUSION

In this paper we have discussed the relation between cooperation, trust, and safety in the petroleum industry. The authorities (PSA), employee unions and employer organizations all want to improve safety in the oil industry. The economic crises with downsizing and cutting costs seems however to have changed the cooperation climate between the parties. Union representatives and employees experience that it is more difficult to tell- and report about dangerous situations that may lead to accident and unwanted incidents. This may lead to a safety culture not responding to dangerous situations at installations/plants offshore and onshore. We argue that the voice of employees must be listened to and taken notice of as an important instrument of improving safety.

On the other hand, in the RISKOP research project, studying safety at offshore operations in the shipping industry, we found examples of that bipartite cooperation actually was strengthened. In the struggle of existence in a marginal market, there has been collective initiatives between management and employee unions fighting for the company's survival and to keep as many jobs as possible. This way, the employees have gone a long way to find solutions, such as reduced pay in periods and abolish bonuses, and similar means of savings. Local alliances have become stronger—to fight the economic crisis.

Production and protection. Seafarers' handling of pressure in gemeinschaft and gesellshaft

ABSTRACT: Seafarers experience conflicting objectives of production and protection in most operations. This study explores how seafarers deal with such pressures, through an analysis of interview data from 20 seafarers working on Norwegian- and Greek-controlled coastal and international passenger and cargo vessels of different sizes. Despite the various contexts, the results show similar conflicting objectives and pressure handling. The pressure is experienced differently, however, due to diverse organizational relations. Seafarers on the *large* vessels in large companies describe business-like relations (gesellshaft) and direct efficiency pressures from superiors. Seafarers on the *smaller* vessels in small companies contrastingly report of close relations (gemeinschaft), devotion to the company and thus an internal wish to be efficient.

1 INTRODUCTION

Seafarers, as personnel in other industries, have in recent decades experienced increasing work pressure. Fewer persons are to complete more tasks in less time (Österman and Hult, 2016), on shorter sea passages and rapid turnaround (Hetherington et al., 2006) without added resources (Lappalainen, 2016).

On top of the work pressure, seafarers need to take care of safety for themselves, the crew, vessel and cargo. Safety can be understood as the presence of organizational conditions making operations to be carried out without accidents or harm, in the short and long run (Kongsvik, 2013).

Conflicting goals of protection and production are present in all organizations (Reason, 1997). Production includes costs, work, and time pressure for the personnel. Protection is about making sure no one is harmed by production, and is related to competence, procedures, and material and immaterial support. Protective measures can also be viewed as pressure.

In this paper interviews of seafarers are analyzed to explore how they deal with pressures of production and protection. The seafarers work at Norwegian- and Greek-controlled coastal and international passenger and cargo vessels. We find that the seafarers across contexts handle the similar pressures similarly. The main difference involves how the pressure is experienced, and this seems to be defined by whether organizational relations are close (gemeinschaft, mainly on the small vessels, that usually are owned by small companies) or business-like (gesellshaft, mainly on the large vessels owned by large companies).

2 LITERATURE

2.1 *Research about conflicting conditions*

Operations are influenced by organizational structure and management, regulation and policymaking (Reason, 1997). Within this context, operational personnel constantly face conflicting goals.

Managers often value short-term financial criteria over safety, giving conflicting goals of production versus protection, or efficiency versus safety (Rasmussen, 1997, Reason, 1997). Production will generally be prioritized, since "production creates the resources that make protection possible"

(Reason, 1997). Vaughan (1997) shows how personnel often want thorough rule-complying operations, but that cost and time pressures slowly drive work practice away from the original quality ensured routines. Hollnagel (2009) describes an efficiency/thoroughness trade-off principle. Managers want efficiency, but if the personnel work quickly instead of thoroughly, lower safety might be a result, which paradoxically is not efficient. Likelihood "of failures grow[s] when production pressures do not allow sufficient time—and effort—to develop and maintain the precautions that normally keep failure at bay'' (Hollnagel, 2009). This efficiency paradox is also noted for seafarers by Fenstad et al. (2016). Seafarers are known to be efficient to help their company remain in business (Sampson et al., 2014). Personal injuries, violations and risk acceptance on board are related to work pressure and poor organizational safety culture (Nævestad et al., 2017). Crews' immaterial conditions, like time, concentration and competence, largely influence how safe they can work (Størkersen, 2017). Critical conditions are minimal resources, fast pace and accompanying lack of discretionary space, while regulation can moderate such pressures (ibid). Ferry personnel have several strategies on how to meet schedules rather than comply with rules:

> *The ability to keep the schedule and not canceling a departure, are associated with high competent navigators. Being delayed, or even worse, canceling a departure, may damage the navigator's reputation (Aalberg and Bye, 2017).*

Still, operational personnel are expected to comply, even though for example Hale and Swuste (1998), Bieder and Bourrier (2013) emphasize that safety is not assured by blind rule-following. Compliance with bad rules that do not fit the real-world situation can lead to accidents (Reason, 1997). Safe work vitally depends on personnel's skills and experience (Dekker, 2017), for example about which rules should be avoided. Formal rules are not viewed as a positive contribution to the traditional professional values of seafarers: "Good seamanship" belongs to a seafarer with practical and social abilities who maintains safe practices with professional judgment, without being told what to do (Antonsen, 2009a, Knudsen, 2009). Since rules usually define operations that everyone knows, vessel operations are rather performed using experience (Bhattacharya, 2012, Aalberg and Bye, 2017). Many companies implement safety management systems that are not tailored to specific vessels and activities. This makes procedures too numerous, detailed, and distanced from actual operations (Lappalainen, 2016, Bhattacharya, 2012). For some situations there are more than one procedure, or too few crewmembers to comply (Aalberg and Bye, 2017, Størkersen and Johansen, 2014). Seafarers are also required to perform documentation "essentially outside their primary functions of ensuring safe and efficient sailing" (Silos et al., 2012). It can lead to stress and exhaustion, particularly because it is viewed as unnecessary and disproportionate (Österman and Hult, 2016).

2.1.1 *Research about different types of relations*

The early sociologist Ferdinand Tönnies (lived 1855–1936) characterized relationships in different societies, applicable to maritime companies. *Gemeinshaft*, on the one hand, means close, personal relations with shared language, norms and values, based on feelings, habits and consciousness (Falk, 2000). *Gesellschaft*, on the other hand, define impersonal business-like relations characterized by strategic decisions and exchange of means (ibid).

Relations have also been a topic in safety research. Subordinate levels depend on trust and support from upper levels to be able to do their work safely. This can include care and concern (Jeffcott et al., 2006), personnel, equipment, leadership, time, rest, etc.

Vessel operations rely on a balanced relationship between shore management and crews (Xue et al., 2015), with effective communication (Bhattacharya, 2009) and a management that is committed to safety (Lappalainen, 2016). The safety level on each vessel depends on safety prioritization on board the vessel, in combination with seafarers' interactions with ship owners and regulators (Fenstad et al., 2016).

Most maritime studies report a lack of trust and communication inside organizations (Bhattacharya, 2009). The conclusion of Bhattacharya's (2009) double case study of vessels and ship owners from several countries is that managers and seafarers had fundamentally different understandings. Seafarers wanted to communicate as little as possible with shore-based management. Distant managers' top-down instructions about compliance bureaucratized the entire system. The personnel were offered only low-discretion roles, due to a lack of trust by managers. This is mainly what Oltedal (2011) found on Norwegian-owned tankers, leading her to urge managers to trust their highly skilled seafarers to adjust safety management systems. Employer engagement correlates with safety levels on vessels (Bhattacharya, 2012). Top management in poorly performing shipping companies have been found to be not committed to safety issues (Lappalainen, 2016).

Seafarers on short contracts are seen as particularly vulnerable, as they are in an asymmetrical relationship with their employers, which prevents them from speaking up for their labor rights

(Bhattacharya, 2009, Lappalainen, 2016). Seafarers on long contracts are reluctant to offend their managers since that can jeopardize their future plans and lives on the vessel (Xue et al., 2016). The dangers of a non-functioning relationship are described by Antonsen (2009a):

> *… asymmetrical power relations seem to influence on the decisions regarding when working conditions are to be considered safe enough. … The role of such asymmetries in safety-critical decisions should not be underestimated.*

Two companies studied by Xue et al. (2015) aimed to balance decision-making involvement but met limited success. Interviews with managers showed little tension between shore and vessels, but the personnel on four vessels had contrasting views. The seafarers had to follow management instructions, even though it compromised their decision making and even their safety. They felt obliged to maintain hectic sailing schedules and to accept prolonged working hours despite experiencing fatigue. The crews did not complain to management, as they saw that as useless, but sometimes they made decisions against management's wishes. Their contribution to safety management was weak overall. These conflicts in interests between management and vessel staff worsened safety practices on board.

3 METHOD

The data material consists of 18 qualitative in-depth research interviews with 20 seafarers from a range of ship-owning companies. The interviews were conducted in Greece and Norway (see Table 1).

The interviews give perspectives from different parts of maritime transport. They targeted seafarers of passenger and cargo ships, with coastal and international activity around Norway and Greece. These cargo vessels transport different types of gas, dry bulk cargo, general cargo, fodder for fish farms, or live fish.

The Greek material includes personnel from the passenger and cargo sectors, where the passenger vessels are Greek registered and operate in Greece, while the cargo vessels operate internationally and are registered both in Greece and countries with laxer regulation (called Flag of Convenience) and thus mostly foreign crewmembers. All of these vessels are rather large, usually have crews of some size (10–40 persons) and are owned by companies with many vessels.

In the Norwegian data material, however, there mainly are small vessels transporting cargo on the Norwegian coast. The vessels have Norwegian owners, and some are registered in Norway and carry only Norwegian personnel, while other have

Table 1. Information about the data material.

	Greece	Norway
Interviewees	10	10
Interviews	10	8
Background of interviewees	Crew members with professional experience between 3 and 30 years	Ship officers and educated navigators. Eight work as captains or mates on cargo vessels. One work in management. One is partly captain and partly ship-owner (common in Norwegian coastal cargo)
Nationality of interviewees	8 Greek, 2 Turkish	9 Norwegian and 1 Latvian officer
Gender	9 men, 1 woman	10 men
Contract length	4–7 months contracts—on the ship all the time. Unemployed after, but usually new contract and back on the ship after a month	Norwegians: Permanent contracts, working 4 weeks and staying at home 4 weeks. Foreigners in the crews: Often 4–8 months' contracts
Watch schedules	Cargo: Two shifts, commonly 4–4 (but in practice flexible). Passenger: One shift, and sleep at night.	One or two shifts. Two shifts commonly have 6–6 watchkeeping schedule, but in practice flexible.
Size of crews	10–40	6–15
Vessel type	Passenger ships with national routes (5 vessels) and cargo tankers with internet activity (5 vessels)	Cargo (7 vessels), mainly with coastal activity, some international activity
Registration of vessels	Greek and Flags of Convenience	Norwegian and Flags of Conv.
Data gathered	Spring 2017	Spring 2017

Flag of Convenience, a Norwegian captain and often Asian or Eastern European crew.

The seafarers volunteered to be interviewed after information about the project from the researchers through their companies to all their seafarers. In further studies one should work to include more voices from groups such as ratings and machine chiefs.

We conducted eight semi structured research interviews of 1–2 hours. The interviews were based on an interview guide constructed to explore safety culture and its relations to organizational and societal aspects. Among the subjects asked about, were conditions for work and rest (manning, watchkeeping, tasks, etc.), and perceptions of safety, leadership, team culture, safety management, safety regulation, and organizational and national values. In Greece, all interviews were face-to-face on board vessels. In Norway, six interviews were on phone, with one researcher talking to one ship officer. The other interviews were conducted on vessels, each with one researcher talking to two ship officers. One of these interviews were recorded and transcribed in verbatim. For all interviews, detailed and anonymized research notes were written. Categorization and pattern-analysis was performed manually. The quotes in Section 4 are direct citations from the interviews.

This study is not a comparison of the Greek and Norwegian maritime industry, since there are many groups and characteristics within the data collected in Greece and in Norway. It is a part of the SafeCulture project, funded by the Research Council of Norway, and undertaken by the Institute of Transport Economics (Norway), NTNU Social Research (Norway) and the National Technical University of Athens (Greece). The project's survey results show how work pressure and organizational safety culture are related to work, which is related to personal injuries (Nævestad et al., 2017, Nævestad et al., forthcoming).

4 RESULTS

Seafarers from many different groups are interviewed, and they describe many common features in how they deal with pressures of production and protection. Some conditions are special for certain groups. The differences are most evident between seafarers on large and small vessels, since the size of the vessel is connected to size of the company and activity, and to closer or more distant organizational relationships.

4.1 *Protection: Competence of the crew*

Most seafarers are aware that they are responsible for the safety of their shipmates, the vessel and the cargo. Many have great knowledge of and interest in company procedures, and national and international regulation and policymaking. They know their job by hearth, and have various opinions on the large changes derived from the implementation of electronic devices and equipment.

The seafarers tell that they always do the tasks as safe as possible—at the same time as being efficient. Most of the interviews indicate a pressure to go through with risky operations and to work while tired. Handling contradictory goals are talked about as a key characteristic of a good seafarer, but it differs how much of the decision-making is left to the seafarer.

On the *large* vessels, an efficiency pressure is sometimes stated directly to the seafarers from the company managements. This is described in interviews especially at the international and large vessels from large companies. It is not uncommon that officers order seafarers to work faster or under other conditions that they find dangerous, or that onshore management order navigators to take shortcuts to arrive in port on time. (Of course, many international seafarers say their company respect seafarers' judgement and do not force them to hurry up or push the ship into its limits.)

At most of the *smaller* vessels, however, the judgement or handling of conflicting goals is up to the seafarers. It is underlined as an internal criterion of being a good seafarer and employee. The pressure is not from management, but within each seafarer. They take responsibility for their company to stay in business, and thus indirectly for them to keep their job. The coastal seafarers agree that some operations cannot be accomplished, but their doubts and perception of pressure vary. Navigators on the small vessels have much decision-making power, and emphasize how they make their considerations and handle the pressure.

> *Sometimes you feel it. Maybe when you're approaching the quay, "will this work or not", but usually it works okay. You have to use your common sense, and know your limitations. You can lie at sea until the conditions are better. Even if someone stands at shore and waits, they just have to wait. But you do feel it. But in the end, you don't care, even though you think about it afterwards*. Captain, small bulk vessel

4.2 *Production pressure: Costs*

Maritime transport companies are in competition with other types of transportation, with each other and with vessels of different registration and conditions. Succeeding, buyers focus on price rates.

> *It's awful, just prices. It's nothing to ask about, just price and price and price. They don't look at what's in the dock, just as long as it floats it's okay*. Captain, small bulk vessel

Both small and large companies need to save costs, and a result is low manning, limited potential to buy new equipment, small time margins in routes or port calls, and so on. The seafarers on all vessels want quality in spare parts and other technology, for the sake of safety, but usually they need to cut costs.

> *What can I do with a Chinese spare part? I don't trust it but it's cheap. An employee behind a desk can't understand the difficulty or the danger*. Engineer, large cargo vessel

On *small* vessels, many seafarers see it as their responsibility to handle the economic production pressure. Mostly production can be performed as planned, but sometimes there is doubt whether or not one should start or continue an operation, for example because of bad weather. If they do not go through with operations they will miss out on essential earnings. In such situations seafarers themselves can make cost saving or profit their decision-criteria.

> *Yes, we can feel pressured to work. […] There are situations where we wouldn't have approached in that weather, but when we're already there we continue the operation. No one wants to make the decision to abort. It costs a lot to run this vessel*. Mate, coastal live fish carrier

Some conditions are truly different on the *large* vessels compared to the small vessels. There seem to be more cost-saving, more pressure from management, more sanctions, less discretionary space and less labor rights. Two interviewees mention that their equipment is of so poor quality that they have to buy new equipment on their own expenses. If they do not buy new equipment, they are not able to comply with procedures. They cannot risk being reported to the company for ignoring procedures, as this will affect their future in this job. Another seafarer tells about one time he got ill and did not get sufficient treatment, but he would not press charges to the company because that can spoil his reputation so he never can work on a ship again.

4.3 *Production pressure: Time*

Seafarers experience a pressure to work fast, sometimes under risky circumstances. Our interviewees especially feel the time pressure in situations related to port calls. They describe narrow time margins in all schedules, and too much work to keep the schedule. Vessels in large ports can be delayed by port authorities or logistics even if they get the work done in time themselves.

Time is a reason why seafarers experience a pressure to go through with operations that should have been stopped.

> *We take short cuts; we don't have manning to get everything formally right*. Captain, small general cargo vessel

Time pressure is common for every interviewee, but it varies where the pressure is perceived to come from. On a *large* vessel, an engineer mentioned that he felt terrible when he was given a few hours in order to fix a serious damage on board. On a *small* vessel, the seafarer with engineering tasks would typically not be given a deadline for repairing the damage, as they rather describe an internal pressure or a wish to fix the damage before planned departure from port. Time pressure limits the seafarers' possibility to rest and work safely.

4.4 *Production pressure: Much work, less sleep*

In addition to the production pressures of costs and time, seafarers experience a pressure of additional work and tasks.

On some *large* vessels, there usually are more than one shift on board, which is not common on *smaller* vessels. Deck personnel mostly rest during sailing, or in some rare periods of long inactivity. For both types, port calls prolong watch-keeping hours and gives no potential for rest until the vessel is back in clear waters (or anchored or docked). This results in limited discretionary space for all seafarers.

> *You've chosen an occupation and it's been like this since I started at sea. Since I started as deck boy. Everyone had to chip in when we loaded, and we could relax when the ship was at sea. It's a culture that It's not possible to change a culture that's been there forever. When the load's ready: «Oh, no, I have to sleep ten hours, I can't work», right. I won't make money and the company won't make money. Then I'd have to quit. I'd have to get home and stay on welfare, that's next*. Captain, small bulk vessel

Some vessels, both *large* and *small*, have sailing schedules with frequent port calls and short sailings. An engineer on a large vessel told us that he was continuously on duty for a long time because the ferry docked in many ports and there was no shift replacement. This made him feel weak and tired, but he accepted it as "how it is" for seafarers. A similar situation is common on some small vessels too.

> *Particularly on timber runs, some ports are close to each other. You get two-three hours on the pillow before it's up again. And we load for four-five hours and continue. Four-five hours to next port, and loading again. And maybe you have four ports like that after each other. Then you'll be tired when you're finished*. Captain, small bulk vessel

Organizational conditions contribute to lack of rest, like the amount of work compared to manning

level, watch-keeping schedules and sailing schedules. Even though ship-owning companies are in charge of this, sleepiness is mostly talked about as something that all seafarers experience and need to handle. They mostly blame the vast horizon view, darkness, or the weather.

The majority of the interviewees admit that it is easy to fall asleep on duty. On the *large* vessels, if their shift is on the bridge, they might ask for permission to leave and take a "power-nap" or just ask for a cup of coffee. On *small* vessels one usually consider and make such decisions for oneself.

Seafarers on *large* vessels also mention that in their valuable situations of rest, they still have to stay alert in case someone asks them a question. Especially electro-technicians and officers who have specific and special responsibilities are often asked to solve a problem. To stay alert, even off-duty, is an "unwritten law" on board on the international vessels in this study. Even though rest is a luxury on board, these interviewees point out that in case a superior demands your help, you must present yourself.

4.5 *Compliance and violations*

Protection equipment is essential and seafarers wear it as a habit and a necessity. They use gloves, googles and boots for their own safety, and not only to follow procedures.

All the interviewed seafarers report that it is compulsory to read and sign the vessel's safety management system and take part in drills. Still, the seafarers report that their system is violated on a daily basis.

> *For instance, it says you're to test the emergency radio every day. That's something you just don't bother*. Mate, small bulk vessel

Most of the work is done safely and according to procedures, and violations mostly happen because procedures do not fit the situation, the vessel do not have time or manning to comply, the seafarer do not know the procedure, or because of slips. Common slips are to forget to use a hard hat or life vest, but according to the seafarers this has decreased over time. As we have seen, «short cuts» or «calculated risks» to work efficient seems to be a regular part of work among all interviewees in the study. Through the stories in the interviews is evident that many procedures are neglected regularly among the coastal vessels. One of the interviewed seafarers notice that it is dangerous with too many procedures; Now no one has oversight, and some tasks might be neglected over a long time.

In general, it is common for seafarers on both large and small vessels to violate procedures to do the job more efficient.

At the *large* vessels, we are told it also happens that crewmembers are ordered by superiors to violate procedures. One interviewee tell he has been forced to pass alone through a tunnel under the holds of the ship, even though this involved risk of intoxication.

4.6 *Production pressure: Bureaucracy*

Seafarers on all the studied vessels underline that there is too much paperwork and bureaucracy every time they approach or leave a port. Many feel this as exhausting.

> *There is too much bureaucracy. Each country has regulations outside the IMO. There should be a list for when we arrive at the port. Not every country sends its own list and in many cases it is sent in the local language, not even in English*. Deck officer, large gas tanker

All interviewees talk negatively about their safety management systems. They are too complex, and with procedures that cannot be complied with. For example, the procedures for maintenance are seen as detailed and unfitting for especially *small* vessels. Gas tankers have additional regulations to follow. If a company owns gas tankers and also other types of vessels, procedures applied for tankers are usually implemented on the other vessels too.

> *The problem is that the ISM-system's too big and extensive for the ordinary man to take the trouble to get to know it. So it's usually the ship management that knows what it's about. This is an overstatement, because most [crewmembers] know the basics, but not more than that*. Mate, small bulk vessel

On the *large* gas tankers, it is told that foreigners sometimes quit because of the extended bureaucratic procedures.

> *The bad thing is that paperwork is harvested. For example, for each drill done, everyone must sign. In these 2 hours I lose, and I lose them every day, I would have learned a lot of things*. Deck crew, large gas tanker

4.7 *Production and protection: Social conditions*

In the interviews, it is described how the crews take care of another and do not let each other ignore safety measures. If someone finds themselves extremely tired, colleagues can replace them or change shifts. Inconsiderate actions are neither allowed nor forgiven. Interviewees often speak about themselves and their colleagues as one, as a crew or a team. One's safety depends on the others' safety and vice versa. This study has revealed a deep trust between many crewmembers. On *small* vessels this trust is often shared among all crewmembers.

From the *large* vessels, there are many stories about hierarchy and a gap between crew and ship management. Seafarers on large vessels follow and respect hierarchy on board. If something happens, they usually report to the next rank. If the situation is of minor importance it does not reach to higher officers or the captain. On cargo ships, it is reported that it depends on the atmosphere and the captain's attitude as a whole. A very strict captain is better to be avoided. In this study we have heard only a few stories about managers giving positive feedback for crewmembers' compliance with safety rules. Still, most interviewees tell that they always remind forgetful coworkers to wear their personal protective equipment, even if it is someone of higher rank. Safety is perceived as not a reason for misunderstanding or fight. A cadet with three years of experience gave a relevant example:

> *I saw the captain without his helmet. I felt weird, but I finally told him "captain you forgot it" and I gave it to him. The captain then praised me for this*. Cadet, large passenger ferry

On both small and large vessels, problems of behavior may occur when the "atmosphere" on board is not so warm and friendly. Such problems are usually confronted on board and without intervention of the company. Several interviewees informed us that problems can be the result of long contracts (of 6–7 months or seasonal) as nerves becomes tight when the crewmembers are on board for a long time. Long working periods on board are more common on large vessels.

> *You're always under pressure at work because you live in a prison. It's a small place because we live on the sea and beneath is the unknown. At most, we take a five-minute walk on the ship, we see the horizon, but we cannot take five steps*. Deck officer, large gas tanker

5 DISCUSSION

5.1 *Common pressure handling*

In line with earlier research of conflicting objectives (Rasmussen, 1997, Reason, 1997, Hollnagel, 2009), the seafarers in this study routinely handle pressures of production and protection, with many tasks and little time. Last section showed examples of how the financial situation and competition in transport are present in the seafarers' daily work. Cost pressure is related to time pressure and demands of efficiency. As core tasks are plenty, the added bureaucracy is not welcomed by the seafarers. Administration can lead to fatigue and increase risk (Silos et al., 2012, Österman and Hult, 2016). Loading and discharging situations are described as work intensive, including increased bureaucracy for each port, and no possibility for rest or going off duty in these situations. Most of the interviewed personnel, on smaller or large vessels, can rest on longer voyages. Vessels with frequent port calls—in coastal or international operations—describe a situation that is most difficult to handle, because of fatiguing pressure. Only when business is going slow, such seafarers have time to follow all safety procedures. Earlier research also has discussed how schedule and workload heavily influence the possibilities for safe work and rest (Størkersen, 2017, Sampson et al., 2014). In the present study, too, it is difficult to isolate which conditions are related to for example regulation or market.

All the interviewed seafarers describe how they handle pressures of production and protection with taking "short cuts", working a lot and resting little. This corresponds with seafarer traditions (Antonsen, 2009a, Knudsen, 2009, Bhattacharya, 2012, Aalberg and Bye, 2017). The norms onboard are strictly followed, as research of maritime safety culture report of (Antonsen, 2009b).

Our results show that conflicting goals of production and protection are constituted by a mix of conditions. These conditions stem from employers, market, and seafarers themselves. Pressures related to costs, time and work are evident for all seafarers in our study, but some aspects come out differently across the groups of interviewees.

5.2 *Maritime gemeinschaft and gesellschaft*

Two categories of seafarers seem to be divided between internal and external production pressure. Most seafarers on large vessels experience a pressure mainly from management, while seafarers on smaller vessels experience a pressure within themselves. Their different organizational conditions are related to Tönnies' types *gesellschaft* and *gemeinschaft*.

Many seafarers describe organizational relations corresponding with *gesellschaft*, with impersonal relations and strategic decisions (Falk, 2000). The seafarers describing their context like this, usually work at large vessels with crews and companies of size. Here, hierarchy is firm, and one are to do as told by superiors. Such relations between onshore management and vessel personnel are also described by Xue et al. (2016), Xue et al. (2015), Bhattacharya (2012). A common feature is that the seafarers have single contracts expiring when they leave the ship, and thus have to act strategic to be hired for the next voyage. Such seafarers experience explicit pressures from onshore management, and sometimes onboard management, and describe that they will not keep the job if they do not act upon the pressures. These seafarers' situation

is also related to a traditional *workers' collective* (Lysgaard, 1961), where subordinates oppose against work pressure through working as smooth and relaxing as possible (Rasmussen, 1997).

Other seafarers elaborate on an internal pressure, where they want to be efficient because they are responsible for their company's survival. Their relations with shipmates and management correspond with *gemeinshaft*'s close relations based on feelings (Falk, 2000). These seafarers typically work in small companies, and smaller vessels on the Norwegian coast (but not only Norwegian registered). In the interviews, they elaborate that they work fast and skip procedures in order to maintain earnings for their employers. They experience to be supported and trusted by the management. They value their autonomy and thus take a lot of responsibility, maybe beyond what management explicitly has stated or expected. This is also described in Norwegian coastal passenger transport (Aalberg and Bye, 2017, Størkersen and Johansen, 2014) and cargo transport and the aquaculture industry (Størkersen, 2012). According to earlier research, management's safety commitment is important for the safety on the vessels (Lappalainen, 2016, Bhattacharya, 2012). In the present study's interviews, the safety commitment of the management in these small companies are not elaborated on. It is possible that the managers are aware of the seafarers' internal pressure, and strategically let them prioritize production over protection.

Another uncertain factor in these results is whether the gesellschaft and gemeinschaft seafarers are different because of their organizations' or crews' sizes—or other conditions. For example, the seafarers in gesellschaft are all from vessels operating in and around Greece, while the gemeinschaft seafarers operate in Norway. There is need for more research to elaborate on the categories suggested in this study.

6 CONCLUDING REMARKS

This study adds to research results about a connection between safety and organizational relations. It also shows that traditional sociological literature of gemeinshaft/gesellshaft is valuable in safety research, since it gives a clear understanding of how different relations result in different safety practices.

All the interviewed seafarers describe how they handle pressures of production and protection with taking "short cuts", working much and resting less. The vital difference between the seafarers on large and smaller vessels is that on the large *gesellschaft* vessels formal structures and management explicitly favor production, while in *gesellschaft* seafarers experience to have support for protective measures, but still choose to favor production.

Teamwork competence required across operational states: Findings from nuclear power plant operation

Ann Britt Skjerve & Lars Holmgren
Institute for Energy Technology, Norway

ABSTRACT: The tasks of Nuclear Power Plant (NPP) operators are highly interconnected, and operators need to engage in teamwork to ensure plant safety. Traditionally, teamwork-competence taxonomies for NPP operators do not distinguish among operational states. This study explored if differences exist among teamwork-competence requirements across the three main operational states in a NPP: normal operation, outage and emergencies. Data was collected from a north European NPP using observations, semi-structured interviews, and a questionnaire survey, and analyzed using a thematic-analysis approach. The study suggested that the teamwork competencies needed by NPP operators are similar, but not identical across the three operational states. The variations were suggested to be caused by a combination task differences and different impacts of three performance-shaping factors: time pressure, task complexity, and proactive attitude to safety. Based on the results, it was suggested that refresher training should be adjusted to increase resilience in teamwork in NPP operation.

1 INTRODUCTION

Nuclear Power Plants (NPPs) are key means for producing electricity in a range of countries today. NPPs are dynamic and highly complex production systems, and training of operational staff is one of the cornerstones for ensuring safe and efficient operation.

Competence can be defined as the "... ability to apply skills, knowledge and attitudes in order to perform an activity or a job to specified standards in an effective and efficient manner" (IAEA, 2002). Training of NPP operators addresses both technical and teamwork competencies (IAEA, 1996): The operators need technical competence to understand the design and functioning of the process system, and they need teamwork competence to be able to work in a team setting, due to the inter-dependability of their tasks. The technical competencies required of NPP operators is well established (e.g. U.S. NRC, 1998; 2007), and training of these is under continuous development within NPPs. The teamwork competencies required is less well-specified. This paper aims at contributing to the understanding of what teamwork competencies NPP operators need.

Teamwork can be defined as "... a distinguishable set of two or more people who interact dynamically, interdependently and adaptively toward a common goal" (Blickensderfer, Cannon-Bowers & Salas 1997, 250). There is general agreement that teamwork is a multi-dimensional concept, but there is no final agreement about the specific dimensions the concept encompasses.

In an NPP, teamwork is highly regulated by procedures and routines. Still, the level of details with which teamwork is regulated varies substantially. For example, in some cases it is specified exactly what information and operator should contribute, where as in other cases, it is merely stated that operators should contribute *all relevant* information. In addition, operators need teamwork competence to adapt performance to emerging situational characteristics, e.g., to the competence possessed by individual colleagues, the colleagues' level of workload, personal concerns, etc.

A teamwork-competence taxonomy is important to support the development of teamwork-training programs. A taxonomy facilitates identification of training needs, as well as documentation of what competencies a training program covers. Within the domain of NPP operation, various teamwork-competence taxonomies exist (e.g. Broberg, 2009; Crichton and Flin, 2004; IAEA, 1996; IAEA, 2001; O'Connor, O'Dea, Flin, and Belton, 2008; Skjerve, Kaarstad and Holmgren, 2013).

Traditionally, the teamwork-competence taxonomies are general in nature, covering the entire span of teamwork competencies needed by NPP operators to perform their tasks safety and efficiently. Still, based on the observation that the NPP operators' tasks are not identical across operational states, it was hypothesized that the teamwork-competence requirements might also not

be identical. If this hypothesis is true, traditional re-fresher training might not fully address all the teamwork competencies required by NPP operators, as it tends to focus on emergency scenarios.

The purpose of this study was to explore if differences exist between teamwork-competence requirements to NPP operators across the three main operational states in a NPP: normal operation, outage and emergencies.[1]

In this paper, the concept NPP operators, include the following roles on a shift: Shift Manager (SM), Reactor Operator (RO), Assistant Reactor Operator (ARO), Turbine Operator (TO), and Field Operator (FO). O'Connor et al. (2008) and Broberg (2009) both report that no differences were found between the teamwork-competence requirements to the two main groups of NPP operators: control-room operators and field operators. For this reason, there will be not distinctions between these two types of roles.

2 NUCLEAR POWER PLANT OPERATION

The main task of a NPP operator team is to ensure that plant safety is upheld. Overall, NPP operation can be decomposed into three operational states: normal operation, outages, and emergencies. The three operational states are defined below based on the tasks that are prototypically associated with each state.

Normal operation is the period when an NPP is producing electricity according to plan and is operated based on the requirements in the standard operating procedures, the technical specifications of the plant, the plant orders and/or other directives provided by the Operational Department. Normal operation may also be referred to as power operation. The overall task of an operator team is to ensure that the operational activities progress according to plan. The team's activities are largely based on routines, and involve monitoring plant parameters and intervening with planned adjustments and with immediate adjustment if necessary. When a shift begins, the first task is to engage in shift-handover: First, each position will have a semi-structured dialogue with his or her opposite on the departing shift to learn about ongoing and planned tasks and deviations (if any). Then all operators on the team will meet to jointly build a common understanding of the situation at hand, and decide how to proceed. Often, the SM will be away from the control-room for longer periods of time, leaving the RO in charge of the team. During normal operation, operator teams are required to perform a set of administrative activities, in addition to the operational activities. These involve, e.g., logging, preparing for upcoming tag-outs, refreshing knowledge, updating descriptions of plant systems, and job appraisal talks.

Outage is the period from when an NPP is brought to shut down for preventive maintenance, upgrades, and refueling until it has been started up again and is ready for production. During an outage, a plant is operated based on the standard operating procedures for shut-down and start-up, the technical specifications of the plant, the Outage Plan, and the outage direction documentation and plant orders. The overall task of an operator team is to ensure that the planned tasks are executed in accordance with the specifications in the Outage Plan and associated documentation to the extent this is possible. Team members' tasks are usually proceduralised, but often non-routine. Their taskload is high, and they need to engage in teamwork with staff members, whom they may not know well in advance (e.g. staff from the maintenance departments) and with external parties (e.g. various types of consultants). Also throughout an outage, time management is an issue of key concern. The conditions in the control-room will be non-normal during an outage compared to power operation: A high number of alarms will go on-and-off in unusual ways due to the various tests performed in the plant, and there tend to be more people present in the control-room. The RO and the TO each with their associated field operators may come to create what looks like two islands in the control-room, and it is important that the SM, who is offloaded at day time by an administrative support, contributes to ensure internal coordination in the operator team.

Emergency operation is the period in which an NPP is in a state described by the Safety Analysis Report (SAR) or in the plant specific Probabilistic Risk Assessment (PRA). In these situations, a plant is operated based on the emergency operation procedures, functional restoration guidelines and in extreme cases severe accident mitigation guidelines. The incidents and standard operation procedures may also be applied. The overall task of the operator team is to ensure that the plant is brought to a safe state. When an event occurs that has been addressed in SAR or PRAs (e.g. a rupture of a tube in the steam generator), task performance is heavily guided by procedures. When multiple failures (events) have occurred, the crew members will to a larger degree need to adapt the procedures to the characteristics of the situation. During emergencies, RO and ARO will typically be working together to execute the actions required

1. The paper is based on and a further elaboration of results reported in a 'limited distribution' work report by Skjerve & Holmgren (2016).

on the reactor side, whereas TO will execute the actions on the turbines, power and I&C supplies. The FOs will assist in the control-room or out in the plant. The SM will take a stand back position and survey the plant's behavior, including the critical safety functions, and coordinate the crew members' activity and plan ahead.

3 METHOD

The study was based on data collected in a PWR unit of a north European nuclear power plant. Data collection included 108 hours of observation in the control-room during normal operation and outages, distributed between two operator teams by the authors. Observations were further carried out across refresher training (i.e. regular training after the operators has been licensed to refresh and update competencies, comprising simulator and classroom sessions), including eight days of simulator runs addressing emergencies. In addition, data were obtained from 14 semi-structured interviews lasting in average 1.5 hours with plant personnel, and a questionnaire survey administered to 33 NPP operators. Method triangulation (Denzin, 1978) was applied to seek to increase the validity of the findings by cancelling out the limitations associated with each of the three methods.

Data was analyzed using a thematic analysis approach, i.e. a qualitative method that makes use of labelling and iterative restructuring of data, to identify patterns—or themes in the dataset. The analysis process was developed based on Braun and Clarke (2006). It contained four phases.

Phase 1: Familiarization with the dataset. This implied reading through notes from observations, the interview responses, and the responses to the questionnaire survey to obtain an overview of the content.

Phase 2: Generating initial codes: All data obtained, i.e. from observations, interviews, and questionnaire survey, was decomposed into segments. A segment was defined as an entity that described one aspect of the teamwork competence required by NPP operators as it emerged from the data collected. In all 136 segments were identified. Examples on segments include: "Insights into how adults learn" (Learning and Coaching); "Communicating via more information channels to increase the likelihood that a message is understood" (Communication), and "Team-orientation—expanded to unit, plant, and other entities of relevance for ensuring safe and efficient plant performance" (Attitudes).

Phase 3: Searching for themes: Establishing a taxonomy comprising a set of teamwork competence dimensions: First, each segment was assigned to one of the five categories in the taxonomy defined by O'Connor et al. (2008) based on whether the content of a segment. If a segment was judged not to fit into any of the categories, a new category was introduced and/or the definition of one of the existing categories was modified to accommodate a broader range of content. If possible, the segments were allocated one or more of the three operational states: normal operation, outages and/or emergency operation. If not, the segments were defined as common to all states.

Phase 4: The segments associated with each of the three operational states were then grouped across the teamwork-competence dimensions to identify if patterns emerged, which should help clarify the reason for potential differences.

4 RESULTS AND DISCUSSION

The teamwork-competence taxonomy established in analysis phase 3 comprised nine dimensions: Attitudes, communication, coordination, decision making, interpersonal competence, intrapersonal competence, leadership, learning and coaching, and situation awareness.

The distribution of segments across the nine dimensions can be seen in Table 1. The inter-rater reliability between the two authors showed a correspondence of 81%.

The teamwork-competence dimensions identified did not differ substantially from the dimensions identified in earlier studies addressing teamwork competencies in NPP operation. This was interpreted to support the validity of the taxonomy (see Table 2).

4.1 *Teamwork requirements across the teamwork-competence dimensions*

The results suggested that teamwork-competence requirements for NPP operators overall were highly similar: Competence associated with each dimension of teamwork was required in all three operational states. Still, a more detailed analysis showed that except for the teamwork-competence dimension *attitudes*, the specific competence aspects NPP operators were required to master showed some degree of variation across the operational states. Below the main findings are associated with each of the nine teamwork-competence dimensions are summarized:

4.1.1 *Situation awareness*

The task of building situation awareness is done based on somewhat different sources of

Table 1. Distribution of segments across the nine teamwork-competence dimensions.

Teamwork-competence dimensions	Total no. of segments	Segments common to normal operation outages and emergencies	Segments specific to normal operation outages or emergencies	Normal operation	Outages	Outages & Emergencies	Emergencies
Attitudes	8	8	0	0	0	0	0
Communication	13	8	5	0	2	0	3

information and under various workload levels across the operational states. For example, during normal operation the ability to establish accurate situation awareness involves teamwork-competence aspects associated with obtaining information from shift-handovers (i.e. semi-structured dialogues with colleagues), from various logs, etc. and to systematically assess these with colleagues to build a shared understanding. During outages and emergencies, NPP operators needs teamwork-competence aspects associated with obtaining information from colleagues about a dynamic situation on-the-fly, as well as competence aspects related to distinguishing between critical information and other types of information and addressing critical information in crew updates in a way all colleagues understand.

4.1.2 *Decision-making*

A range of teamwork-competence aspects associated with decision-making was shared across the operational states. This included, proactively determining how to verify the consequences of a decision and acknowledging and proactively addressing uncertainties together with team members. The differences found were mainly associated with the overall workload level, but also to some extent with concerns for ensuring the continuous learning of in the operator team. For example, during normal operation competence aspects associated with contributing to (depending on role) a more participatory decision-making process ensuring all understand the basis on which the decision should be made, aimed at jointly developing 'optimal solutions' were required. Whereas during emergencies, competence aspects associated with execution of a more authoritarian decision-making approach aimed at finding 'good enough' solutions were needed.

4.1.3 *Communication*

The communication tasks were basically the same across the three operational states. They involved, e.g., the use of "Three-way communication", adapting communication to the receiver(s)' competencies and active listening. Still, across the operational states the frequency with which communication tasks had to be executed varied, and thus the overall level of time pressure associated with task performance. This implied that the operators needed to master the communication competencies with substantially more *fluency* during outages and emergencies than during normal operation: the number of communication tasks was higher in these operational states, and the time available to identify and correct misunderstandings was more limited. Some communication tasks were further associated mainly with one operational state. During outages, e.g. the operators need to be prepared to communicate with consultants in English (a non-native language to the operators). Also during emergencies, there is a distinct need to uphold continuous communication among team mates during complex and/or stressful situations to promote collective sense-making processes and the provision of mutual support.

4.1.4 *Coordination*

The requirement to coordination competencies is essentially similar across operational states, in the sense that it covers a wide range of activities from performance-adaptation on-the-fly, engaging in backup behavior, to planning aimed at ensure coordination of future activity, which may be needed across the operational states. Still, the requirements to teamwork-competence aspects associated with coordination vary more than e.g. was the case for communication. The reason is that the content of coordination tasks prototypically associated with each operational state is more varied, and involves different teamwork-competence aspects. For example: During normal operation, it is necessary to continually to coordinate performance of operational tasks versus performance of administrative type of tasks; During outages, the need for carrying out Pre-Job Briefings is more pronounced than during normal operation, and will involve more staff, including external specialists; During emergencies coordinating activities to ensuring clear, precise and not least timely is a task of key importance.

4.1.5 *Interpersonal competence*

The inter-personal teamwork-competence aspects were to a large degree similar across the operational states, except they in general had to be mastered with greater *fluency* from normal operation, over outages, to emergencies. They comprised, e.g., building trust, mastering interactions, and recognizing the achievements of colleagues. The interpersonal teamwork-competence aspects were, however, suggested to serve different purposes during normal operation and emergencies: During normal operation, the overall purpose was to transform operators into a team and/or to strengthen the team spirit, whereas during emergencies the purpose was to uphold the operators' ability to function efficiently as a team under highly challenging conditions.

4.1.6 *Leadership*

This competence dimension was assessed to be useful for all operators, regardless of their particular role in the team, because all (with different degrees of likelihood) may end up in a situation, where they need to lead teammates. The teamwork-competence aspects required across the operational states varied, e.g., concerning the leadership style the operator should master: During normal operation, competencies associated with executing a more democratic type of leadership were needed, e.g. promoting team mates' motivation by involving them in decision-making processes and promoting learning processes. During outages, and especially during the acute part of emergencies, competence aspects associated with executing a more authoritarian type of leadership were needed, e.g. giving and meticulously following-up on orders.

4.1.7 *Attitudes*

Attitude requirements included, e.g., safety concerns pervade all thinking and decision-making processes, and conscientious and commitment to quality. For this dimension no variation was found. The attitudes identified were of key importance across all operational states.

4.1.8 *Intrapersonal competence*

This dimension contained a set of teamwork-competence aspects of generic importance for sustaining sound teamwork, such as the competence to monitor own ability to operate the plant safely and efficiently, and courage to speak-up when needing assistance to achieve these goals. Since intrapersonal competence was used to fulfill different purposes across the operational states, the teamwork-competence aspects associated with each state varied somewhat. For example, to uphold attention towards the plant processes during normal operation where 'little happened' over longer periods of time, teamwork-competence aspects associated with reducing the risk for complacency were needed. To uphold attention during outages and emergencies during prolonged periods with high workload and/or safety-critical situations, on the other hand, teamwork-competence aspects associated with preventing negative impacts of fatigue and/or of stressors on the task-performance process were required.

4.1.9 *Learning and coaching*

Learning and coaching activates may be carried out as an integrated part of task performance or as a dedicated activity. The teamwork-competence aspects implied include, e.g., coaching competence, the ability to give/receive and constructively use feedback, and techniques for self-improvement alone or with or assisted by other people.

Dedicated activities to promote learning are prototypically associated with lower workload periods during normal operation. The likelihood that such activities will take place seems to increase, if the operators find that continues competence improvement is important for the team.

During outages and emergencies, competence development may to a certain degree be an integrated part in the task-performance processes, involving teamwork-competence aspects associated with coaching.

However, dedicated learning activity in relation to outages and emergencies will usually be postponed to after the shift period is over and/or after the outage or event has been handled. At this time, a required teamwork-competencies aspect is the ability to address occurrence/events constructively in team setting, i.e. avoiding that the parties involved will be defensive and refuse to share and discuss actions, which may contain important lessons learned from the entire team.

4.2 *Why teamwork-competence requirements are not identical across operational states*

Exploratory analysis of the variations found in the requirements to teamwork-competence aspects across the three operational states, suggested that the dissimilarities might be caused by a combination of two influences: (1) differences among the operational tasks across the operational states, and (2) differences among the impact of performance-shaping factors on otherwise similar operational tasks across the operational states. These two potential causes for dissimilarity will be discussed below.

4.2.1 *Task differences*

The operational tasks that are prototypically associated with each of the operational states, as described in section 2, are not identical.

Shift-handover is a task that is prototypically associated with normal operation. This is, e.g., reflected in traditional refresher training where the hand-over process is substituted by a training instructor simply describe the plant state to the operator team. From an NPP operator's perspective, the shift-handover session in the beginning of a shift include, a semi-structured dialogue with the opposite on the departing team to obtain an accurate understanding of the plant state, including issues that need attention. Learning how to interact with the opposite to obtain the needed information is an important competence. It includes abilities to identify and constructively address potential omissions, misunderstandings and uncertainties in the information provided to build situation awareness. This type of competence is not addressed in dedicated training session following licensing.

The requirement to work with people from different professions and/or with whom the NPP operator is less familiar or unfamiliar is prototypically associated with outages. During outages extended workgroups may arise, which in addition to the NPP operator team consist of colleagues from other operator teams, maintenance personnel, contractor staff from external companies, etc.

In this setting, a key teamwork-competence aspect required is associated with promoting common ground between the diverse members of an extended workgroup. This includes the ability to present information in ways that are understandable to people with different professional background, and ensuring that the concerns of all parties are adequately brought forward and addressed. This type of teamwork-competence aspect is not addressed during training.

Handling of emergencies is highly proceduralised activity, especially in the first part of an event, which is traditionally the part that has been addressed in refresher training. In cases of multiple failures, the requirement to making situation assessment to understand how to proceed will increase. A teamwork-competence aspect that is particularly needed in this situation is the ability to uphold communication throughout periods of

uncertainty when operators tend to keep quiet and focus keep on making sense of the situation on their own. Emphasizing communication is important to promote the team's ability to build situation awareness and making sound decisions. Unless refresher training progresses into this type of situation, these skills may not be upheld.

4.2.2 *Performance-shaping factors*

The study points to three Performance-Shaping Factors (PSF) impacting the requirements to teamwork-competence aspects across the operational states: *time pressure, task complexity* and *proactive attitude to safety.* The influence of these PSFs implies that the performance of otherwise similar teamwork tasks will come to require partly different teamwork-competence aspects.

Time pressure implies that a task needs to be completed within a given time window. The time window is typically defined by constraints in the plant, e.g., the amount of break flow in a storage tank can secure. The impact of time pressure on task performance generally increases from normal operation over outages to emergencies. When time pressure is high, teamwork tasks should be mastered with a greater *fluency*. The ability to communicate concern to a team mate should, e.g., preferably be mastered effortlessly, as the time available for re-stating information and correcting misunderstandings is reduced.

As the level *of task complexity* increases, the more factors (parameters) and interdependencies an operator needs to address when performing a task. For this reason, task performance should preferably be thorough, highly systematic, and be ideally carried out without any time pressure. In situations with high task complexity, teamwork-competence aspects associated with the ability to lead and coordinate teamwork is particularly required, to help ensure that all parties involved in the task performance process will obtain accurate situation awareness, and thus a sound common basis for making decision about the course of actions needed. As for time pressure, task complexity tends to increase from normal operation, over outage to emergencies, providing the latter contain multiple failures. In situations with both *time pressure* and *task complexity*, there will be a need for mastering the teamwork-competence aspects associated with handling task complexity with more fluently.

The PSF *proactive attitude to safety* implies the conviction that it is important to establish the best possible basis for sound teamwork in future settings. This may be done by promoting learning processes, by coaching or encouraging team mates to engage in self-studies, e.g., by studying the background materials for given procedures, etc. If the proactive attitude to safety is deeply rooted in the operators, it will help overcome a tendency to perceive coaching and dedicated learning sessions as an "add on" to the normal wok practices. It will encourage the operator to perceive competence-promoting initiatives as an integrated and important aspect in task performance processes.

The impact of this PSF is most visible during normal operation, where operators may or may not priorities to engage in learning processes. It seems also to be visible in the extent to which operators are able to uphold a 'questioning attitude' while carrying out their work, e.g. reflected in the extent to which they critically review current work practices to protect against drifting.

4.2.3 *Are capturing variations in teamwork-competence requirements necessary?*

Even if the teamwork-competence requirements are not identical across the three operational states, they are highly similar. Has it any real impact on a training program if is based on a generic set of teamwork-competence aspect, rather than a set, which is decomposed across operational states? From a practical perspective, any of the three operational states may contain characteristics that from time to time may be warranted in one of the other operational states: During an outage, there may be intervals resembling operation, such as longer periods of time where 'little happens', and during normal operation, situations may arise where NPP operators need to collaborate with unfamiliar people with a difference professional background, etc. Since a certain level of overlap exists between the tasks that may arise across the three operational states, it should in principle be possible to uncover all teamwork-competence aspects required of NPP operators by studying any of the three operational states exclusively. However, this approach would be substantially less effective than studying the characteristics of each of the three operational states, as the situational characteristics, which traditionally are associated with any of the other two operational states, might likely be manifest only with highly irregular intervals in the given operational state.

Another way of answering the question is to explore the level of teamwork-competence aspects missed if leaving out one of the operational states from an analysis. This can be done based on the distribution of segments reported in Table 1. The exploratory analysis indicates that if data from normal operation is left out of an analysis, 23 teamwork-competence aspects required by NPP operators may be at risk for remaining hidden, because the need for these competence aspects is rare during outages and emergencies. This corresponds to 17% of the entire set of teamwork-competence

requirements identified in the present study. If an analysis does not include data from the outages, 14% of the teamwork-competence aspects (i.e. 19 segments) may be at risk for remaining hidden. If emergencies are left out of an analysis the corresponding figure is 19% (i.e. 26 segments). In addition, outages and emergency situations share a unique set of teamwork-competence aspects segments which together amounts to 11% (i.e. 15 segments) of the teamwork-competence aspects required.

Overall, the results indicate that it is useful to analyses each operational state when establishing requirements to teamwork competence for NPP operators.

4.3 *Implications for teamwork training*

The IAEA (1996) recommends that the Systematic Approach to Training (SAT) is used as a basis for developing training programs.

When preparing for teamwork training for NPP operators, it overall important to promote their ability to adapt performance to situational characteristics, including characteristics of team members, such as their role, current tasks and the type and level of competencies. Mutual performance adaption among team members, in combination with a clear understanding of the team's goals, will promote teamwork processes. Because of the multitude of requirement posed to teamwork-competence aspects in an NPP, it can be expected that operators, who master a wider repertoire of teamwork competencies will be better able to adapt teamwork processes, than operators, who have a more limited repertoire of teamwork competencies.

One potential use of identifying aspects of teamwork competence that are prototypically associated with particular operational states is to provide a mean for deepening operators' level of teamwork competencies. Expanding the scope of teamwork competencies addressed in refresher training will support the operators in developing and upholding an expanded repertoire of teamwork 'techniques' which can be flexibly applied depending on situational characteristics, reducing the risks for break-downs in teamwork (Skjerve, Holmgren & Widheden, 2015).

A teamwork-competence aspect it may be useful to address as a part of the classroom part of refresher training, despite it being prototypical associated with normal operation, is *team-building competence*, in particular teamwork-competence aspects associated with maintaining team members' ability to work together as a team, including upholding team spirit. A feeling of team efficacy and team spirit may promote the operators' ability to overcome challenges to teamwork, and thus contribute to resilient performance.

Similarly, another teamwork-competence aspect it may be useful to address as a part of the classroom part of refresher training or exercises, despite it being prototypically associated with outages, is *the ability to engage in teamwork with less familiar or unfamiliar parties with different professional backgrounds*. This type of training may be included as an element in emergencies exercises, comprising NPP operator teams and key positions in the technical-support center. It may be done, e.g., by asking participants to state their expectations to one another, describe why they have these expectations, and account for their concerns. This would contribute to resilience in the extended team by further strengthening team mates' ability to select information of relevance to team members and to communicate this information accurately, etc. This will promote building and maintaining situation awareness in the extended team.

Expanding the scope of refresher training by teamwork-competence aspects prototypically associated with normal operation and outages may further contribute to promote 'teamwork mode' awareness.

Being aware of the current 'teamwork mode' may increase the likelihood that they will consciously apply teamwork-competence aspects are prototypically associated with the given mode—despite the operational state they are currently in. For example, during a non-acute phase of an emergency with limited workload, an NPP operator may need to talk to various people from the maintenance to refine the teams' understanding of the situation. If the operator recognized the parallels these dialogues may have with the dialogues involved in a shift-hand over process, it could prompt the operator to remember applying similar 'techniques' (such as focus at distinguishing facts from interpretations, specifying what needs to be further examined after completing the dialogue to get a clear picture of the situation, etc.).

An operator's increased focus on how teamwork-competence aspects interplays, may promote meta-cognition about teamwork competencies. Meta-cognition may enable the operator to more readily identifying and developing solutions to teamwork challenges. Transfer of a message between two persons may, e.g., unsuccessful for a variety of reasons: A message may not be stated clearly, if may not formulated in a way the receiver understands, may be transferred at a time the receiver is unable to pay full attention to the message, the receiver may misinterpret the content due to lack of common ground, etc. Awareness that a message may not be transferred to the receiver for a variety of reasons, will allow the operator to

'troubleshoot' potential teamwork break-downs from a range of different angles, and thus increase the likelihood that a means to preventing teamwork break-down will be found.

Both the ability to transfer teamwork-competence aspects across operational states and to engage in meta-cognition about teamwork, may, thus, further contribute to resilience in teamwork.

5 CONCLUSION

The outcome of the study suggested that the teamwork competencies needed by NPP operators across the three operational states are similar, but not identical. The results indicated that unless requirements to teamwork competence are obtained from all operational states, there is a risk that important teamwork competencies will remain hidden. With respect to refresher training, this would imply that these competencies are not addressed and thus potentially that NPP operators will not maintain these competencies to the required standard.

Based on the results, it was suggested that resilience in teamwork could be strengthened if refresher training expanded its traditional focus on teamwork-competence aspects associated emergencies, to include aspects that are prototypically associated with normal operation and outages.

Verification of HTC Vive deployment capabilities for ergonomic evaluations in virtual reality environments

Z. Tůma, L. Kotek, J. Kroupa, P. Blecha & F. Bradáč
Faculty of Mechanical Engineering, Brno University of Technology, Brno, Czech Republic

ABSTRACT: Musculoskeletal assessment of possible risks in the workplace of the future is difficult, because it is not possible to simply evaluate and predict the attitudes of workers. The virtual reality environment offers an initial insight into the future workplace. For better immersion in the environment. HTC Vive were selected. The ergonomic method selected for assessment is called RULA. Because of work in a virtual reality environment, it is necessary to measure in the real laboratory environment. As a reference device, the MS Kinect solution against occlusion has been selected. Measurements were performed in the laboratory according to a recently published article on RULA assessment using MS Kinect. The results show that HTC Vive can serve as an integral tool to assess a musculoskeletal risk in designing new workplaces.

1 INTRODUCTION

In every real production process there are risks that have the potential to endanger the operator or equipment. It is clear that the selected risks associated with the underlying process (e.g. the use of hazardous chemical substances) cannot be completely eliminated, but most of these risks can be significantly reduced. The human factor is one of the most important elements influencing the resulting safety. It is also a component that is often neglected under the prevailing emphasis on technical reliability. The results of major accident investigations consistently show that the human factor plays a very significant role in their development. Therefore, it is important to identify potential human errors and reduce the likelihood of failure of the human factor. The way how to deal with this problem is through an analysis of human factor reliability.

One of the elements of analysis of human factor reliability is also the analysis of the work load. This is both financially and time-consuming; the objective of the present article is to design an automated evaluation process using the virtual reality of HTC Vive and the Kinect system.

HTC vive and HMD are beginning to be widely used in a broad range of applications; such as in medicine (Pelargo et al. 2017) where it is used for education. In this case, it is deployed because of a large number of repetitive demonstrative operations in education and their adverse impact on the patient. It also emphasizes the predicative value in the cases of e.g. blood vessels. It is also deployed in treatment of various therapies. For example, in stress situations to determine if the patient does not suffer from height phobia (Bun et al. 2016). In the field of culture, for example, virtual tours of galleries (Choi et al. 2017) can be addressed. Also, in the field of fine art, primary applications have been made for fine arts and, from the point of view of artists involved in digital fine art, this technology is highly desirable. In engineering applications, we can see examples of the use of HMD technology such as the use of HMD in ship design (Pérez et al. 2015) or in the field of robotics students' education (Crespo et al. 2015). What all these articles have in common is the emphasis on the added value of virtual reality applications. In this case, a benefit is a greater clarity and thus a deeper understanding of the subject.

The present article focuses on ergonomics and a human factor in manufacturing systems and at production sites. There are many simulation programs available for modeling—Siemens Process Simulate, Siemens Classic Jack (Jack and Process Simulate Human 2017), Plant Simulation (Process Simulate 2017), IC: IDO (ESI Applications 2017) dealing with the ergonomic aspects of manual work in the early stages of design and planning of product manufacture. Jack and Process Simulate Human will allow for improvement of safety, performance and comfort of working environment with the use of digital human models. Work environments can be analyzed via virtual human models, while using a database of human body builds typical of the specified population. In our proposals, we can test a variety of human factors, including the

risk of injury, user comfort, accessibility, lines of the views, energy expenditure, fatigue limits and other important parameters. These products offer recommendations for more user-friendly designs throughout the entire design process to help save costs and time.

Key options include:
- Flexible human body builds that are anthropometrically and biomechanically accurate
- Supporting ergonomic analysis of total workforce using country-specific databases of workers and advanced anthropometric parameters
- A comprehensive set of ergonomic analytical tools
- An advanced positioning algorithm that can also analyze how the body responds to the force exerted in a particular direction
- Managing a wide range of workplace options that include work at different heights, stairs and ramps
- Views and analysis of field of view
- Envelope curves radius for fast workplace configuration
- Wide support for virtual motion capture technology including Microsoft Kinect® for Windows
- Support for virtual reality

A new platform in this field seems to be the use of the HTC Vive game console because it allows an observer to achieve a fully immersive insight into the virtual environment compared to the previous imaging headset systems. The HTC Vive console has the following parameters (Oculus Rift vs. HTC Vive: Prices are lower, but our favorite remains the same, 2017:

- Two displays panels with a resolution of 1,080 × 1,200 pixels
- Streaming video with 90 Hz refresh rate.
- Laser position sensors – 32 headset sensors and 48 sensors on the controls
- Microelectromechanical systems—gyroscope, accelerometer
- Minimum space for movement is 1.5 m × 1.5 m, with maximum of 4.5 m × 4.5 m.

It is also possible to use controls to interact with the virtual environment; in the case of HTC Vive, these are two controls captured using two infrared sensors.

The previous article (Plantard et al. 2017) dealt with the case of deploying MS Kinect in the assessment of the real workplace in both laboratory and real conditions. In this case, it would be obvious to use HTC Vive for further research for the above reasons.

It was interesting to assess how one is influenced by the deployment of the game console and whether it is possible to deploy this technology in the industry. For the assessment as in the previous article, a laboratory test should be performed by lifting a box of defined dimensions. This time, game console controls should be used to simulate the operator's hands, and the raised box should be virtual. The model case would fit into the overall concept of using virtual reality, i.e. to use the 3D model of the workplace prior to assembly. Using this technology, it would be possible to verify workplaces from an ergonomic point of view and a human factor without additional costs associated with building up of a dummy workplace, e.g. of cardboard engineering.

2 METHODS

As in the previous article, MS Kinect was used for validation of this method.

The test itself also took place under the RULA and REBA method, with 10 operators being involved in the measurement.

2.1 *Method RULA (Rapid Upper Limb Assessment)*

The RULA (RULA—Rapid Upper Limb Assessment 2017) method (Figure 1) was developed by ergonomists from the University of Nottingham and serves for a rapid and systematic assessment of the risk of damage to the musculoskeletal apparatus with respect to the upper limbs. In abroad, this method was used mainly for the assessment of upper limb disorders arising in the workplace and for the assessment of working postures.

2.2 *REBA method ("Rapid Entire Body Assessment")*

This method systematically evaluates musculoskeletal apparatus and is based on the RULA

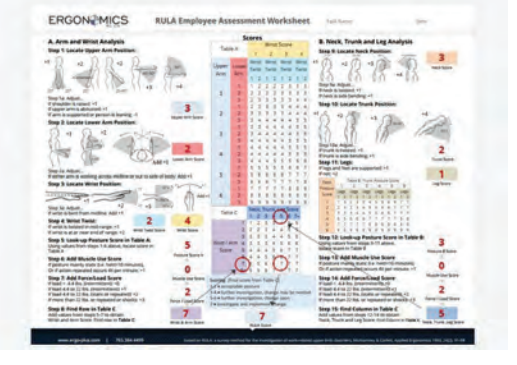

Figure 1. RULA method.

methodology. In abroad, the REBA method was used to assess ergonomic risks when working with imaging units and for risk assessment of healthcare staff. Both of these methods are a tool for postural analysis to evaluate biomechanical and postural loads of individual body parts. The body is divided into segments for individual scoring in relation to movement planes. Identifying of risk postures is very important for evaluation. These may be working postures that are physiologically unfavorable or occupied by the worker for most of the work shift. For RULA and REBA methods, the postures of individual parts of the body (arms, forearms, brace, neck, trunk and lower limbs) are scored with respect to the divergence from the neutral posture (Simulace výrobních procesů 2017). For each part of the body, the so-called basic postures are described to obtain a base score. It is a different range of flexions and extensions that are getting ascending points with increasing divergence from the neutral posture. There are also descriptions of postures to obtain additional points of the so-called variable score (e.g. rotation and bends sideways). The final assessment also includes the weight of the manipulated load (load-strength score) and the influence of the static postures at work (muscle score, activity score). In addition, REBA takes into account the impact of gripping techniques when handling the load (grip score) (Modern methods for the evaluation of ergonomic risks, 2017).

2.3 *Experimental procedure in laboratory conditions*

This section presents an experiment in simulated conditions. For this purpose, an experiment with 10 participants (age: 30 ± 6 years, height 1.78 ± 0.1 m, weight: 70 ± 10 kg) was performed. Each participant of experiment was equipped with the HTC Vive headset and handhelds for interaction simulating the hands. The movement of each participant was sensed (Figure 2), using two MS Kinect devices.

The reason for using the two MS Kinect devices to sense the participants was an insufficient sensing in singular postures when manipulating the virtual object, and also due to occlusion. The correction method described in (Planard et al. 2017) and (Diego-Mas et al. 2014) was also used to increase robustness.

The experiment itself consisted, as in (Plantard et al. 2017) in shiffting a 40 × 30 × 17 cm box between the starting and target positions (Figure 3). As in (Plantard et al. 2016), two target positions were defined as seen in Figure 4. The first placement of the target point was 1.7 m high and 0.35 m to the left and 0.5 m at the front. The second target position was 1.7 m high and 0.55 m to the left.

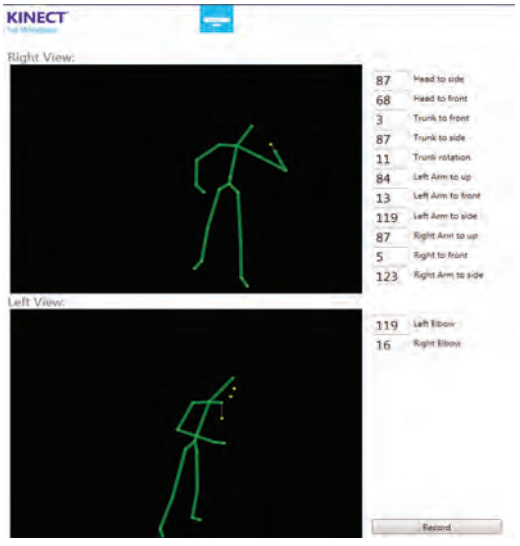

Figure 2. Record from cameras from two MS Kinect devices.

Figure 3. Course of experiment in laboratory conditions.

Figure 4. Positioning of target points in Unity3D environment with avatar.

Unlike in (Plantard et al. 2016), a virtual box of the same defined dimensions was used. The Unity 3D software was used to create the experimental environment.

2.4 *Data analysis*

In the laboratory experiment, we assessed the values of the joint angles calculated from the measured data from the Kinect device (using parallel scanning of two cameras) and compared them with the data evaluated by the expert estimate using the RULA principle.

3 RESULTS

Calculated RULA values and the values obtained by the expert estimate according to the RULA method:

The present article only evaluated the movement when lifting the object. The measured data was subjected to the Kolmogorov-Smirnov test for normality of the distribution of values. The data analysis has not shown normality.

Subsequently, the RMSE coefficient was calculated (Table 2) for each condition. Then we compared the resulting RULA score obtained from measurements with parallel use of two Kinect systems with a reference value obtained by expert estimate.

The results of the analysis show that the proposed RULA method of automatic measurement of RULA indicators provides relatively accurate results. Only the results for the Upper Arm score (left and right) are loaded with a major error; this could be reduced by changing the magnitude of field of view of the cameras. Other issues of measurement are a large number of singular points. These points could be eliminated using two MS Kinect devices scanning a moving person. However, this approach also has its disadvantages. An issue of measurement was the overshadowing of the limbs through the body. At this point, only one sensor was active. Therefore, in this case, measurements and data from the second sensor were not used, since it would put a significant error in the whole measurement.

Table 1. RULA score.

RULA	RULA—calculated	RULA—expert estimate
Upper arm score	2.35	2
Lower arm score	1.83	2
Score A Left (upper body)	2.79	3
RULA Grand Score Left	2.74	3
Upper arm score	2.31	2
Lower arm score	1.9	2
Score A Right (upper body)	2.78	3
RULA Grand Score Right	3.15	3
Neck score	2.51	3
Trunk score	2.24	2
Score B (neck, trunk and legs)	2.97	3

Table 2. Calculated RMSE values for each RULA indicator.

Score	RMSE
Upper arm score	1.05
Lower arm score	0.38
Score A Left (upper body)	0.83
RULA Grand Score Left	0.45
Upper arm score	0.98
Lower arm score	0.3
Score A Right (upper body)	0.7
RULA Grand Score Right	0.46
Neck score	0.75
Trunk score	0.44
Score B (neck, trunk and legs)	0.66

The advantage of this approach is to significantly reduce the cost of evaluation. Accuracy of the results is sufficient for practical measurements; however, for laboratory evaluation, it would be necessary to carry out further adjustments of the measuring procedure.

4 CONCLUSION

This article dealt with the idea of using the HTC Vive gaming console to analyze workloads. Comparison of the angles of movement is based to RULA method, within each body part, each angular assessment is divided into three sections and is tested for monotype actions. This method of automatic analysis has demonstrated its validity using assessment in a virtual environment.

Despite these constraints arising from performed measurement, HTC Vive can be considered as a promising tool for assessing workload analyses. Another indisputable advantage of the entire system is a very easy deployment in the industry, as it does not place high demands on software readiness of potential users. Another important role is also played by a good price value of the entire system. Another challenge will be to test the prepared solutions in assessing of the real production. The data from real-time measurement in traffic and the feedback from industry partners will provide us with a comprehensive picture of the use of these technologies. For a comprehensive examination of

the overall image of the production site design, further measurements including fine motor skills are required. This approach requires the deployment of other virtual reality technologies as well as other methods of assessing these movements.

ABSTRACT: A lack of empirical data is often been presented as a large challenge for HRA, which begs the question: why is this so difficult? HRA methods were not developed as objective quantitative test methods, but more as qualitative evaluation methods because objective data did not exist. Since HRA methods include substantial qualitative evaluation of the meaning of the elements in HRA methods, such as definitions of the performance shaping factors as well as their strength, these elements cannot be objective measured. This paper also discusses other challenges with collection data from event reports, literature reviews, experiments and databases. The conclusion in this paper is that a decision should be made about how we should look at HRA methods: as qualitative evaluation methods or objective quantitative test methods. Quantitative and qualitative methods have different approaches to evaluate the quality of the methods making it difficult to be something in between.

1 INTRODUCTION

Most of the Human Reliability Analysis (HRA) methods and techniques have been developed to estimate human reliability for tasks within Probabilistic Risk Analysis (PRA) in nuclear power plants. Human reliability analysis (HRA) was developed because of the lack of empirical data on human error probability. If data on the likelihood of human error on specific tasks existed, we would not need an HRA method. Williams (1992, p.20) said: "Therefore in cases where an assessor may have access to more specific and accurate task failure data, these should be used in preference to the HEART generic data-set." So if we had the data, the data should be used and not a HRA method.

HRA methods like; THERP (Swain & Guttmann, 1983), HEART (Williams, 1992), SPAR-H (Gertman,et al. 2005; Whaley, et al. 2011) and ATHEANA (Forester, et al. 2007), were developed as methods to support more qualitative expert judgements. The expert judgement provides gross estimates of failure probabilities for tasks defined by the PRA, when better data was missing. In the HEART manual (Williams, 1992, p. 4) states: "When considering system safety and reliability, engineers are generally concerned with gross changes in the probability of failure within system e.g. factors of 10, the proverbial order of magnitude. To be of value, therefore human reliability assessment techniques should be concerned with those factors, which are likely to produce probability of failure modification in excess of a factor of 3, and which, when cumulated, could produce significant changes in performance, and possible threaten system safety, operability and reliability."

Also HRA methods are often said to be simplified methods since it is often not enough resources in performing a comprehensive analysis which mean that the analyst is analyzing the most important influences on human reliability with limited time to read and understand guidelines and to perform the analysis.

Even though HRA analysis results in a quantitative likelihood for failure or success, HRA methods were not developed as positivistic quantitative test methods. HRA methods seem to be closer to a post positivistic research view. In positivism one assume that an objective reality exists, that this reality can be objective measured by scientific methods and that it is possible to develop scientific laws that can be generalized across settings (Guba & Lincoln, 1994). Within this approach, only quantitative research methods are used. In post positivism one assumes that an objective reality exists. However, this reality is complex and that

it can only be imperfectly apprehended and that we can never be sure that a true reality has actually been found (Guba & Lincoln, 1994). Within this approach, both qualitative and quantitative methods are used.

In spite of these characteristics of HRA methods described above, many authors claim that the biggest challenge in HRA is the lack of objective empirical data (for example; Boring et al. 2012; Hallbert et al. 2004; Kim, et al. 2015; Swain,1990; Williams, 1985). A question raised here is a question that was first presented in Laumann (in review) about what an HRA method actually is: Is an HRA method a qualitative evaluation method that leaves a lot up to the analyst qualitative evaluation and where mainly expert judgement was used to develop HRA? Or is an HRA method a quantitative test method where empirical tests where used to develop and test the methods? HRA today, is much more a qualitative evaluation method than a quantitative test method. Probably the words used about HRA methods such as "analysis" and "techniques" reflect the qualitative basis of HRA, rather than a quantitative.

In this paper, we will present challenges for HRA methods to be quantitative test methods and challenges with collecting quantitative HRA data. First, we will define challenges that exist for obtaining quantitative data for HRA that are the same challenges found with all kinds of quantitative methods. Then we will present challenges to obtain HRA data that exist with more specific methods such as; literature reviews, experiments designed to collect HRA data, event reports and databases. For simplicity, we have chosen to present example from SPAR-H (Gertman, et al. 2005; Whaley, et al. 2011) and HEART (Williams, 1992). However, the challenges for collecting empirical data presented exist for all HRA methods. SPAR-H and HEART were also chosen because these are methods where quantitative data collection have been much discussed.

2 DISCUSSION

2.1 *Challenges that exists for all kinds of data collections in HRA*

There are some demands for all kinds of quantitative test methods; they should be valid and reliable. HRA methods have a strong similarity to psychological test methods where human behavior is predicted from different "psychological" construct. HRA is also about predicting human behavior from constructs, since the elements in the methods such as Performance Shaping Factors (PSFs) or Error Producing Conditions (EPCs) are constructs, which are assumed to affect human behavior. In psychological test methods, validity is divided into different facets; content validity, construct validity, concurrent and predictive validity (Murphy & Davidshoffer, 2014). These demands will not be described here since they are well known and can be found in many textbooks as for example Murphy and Davidshoffer (2014).

A large challenge for HRA is content validity. Content validity is achieved by a) judgments and descriptions of the constructs and of the structure within these concepts and b) definitions and development of measurement scales to measure the constructs and their structure. If the content of the constructs, their structure, and how they should be measured (measurement scales) have not been clearly defined, then it is not possible to test the other aspects of validity such as construct validity, concurrent validity and predictive validity or reliability. Next, we will give some examples of content validity issues in two HRA methods SPAR-H and HEART. Laumann and Rasmussen have also presented challenges with content validity in SPAR-H in several papers (Laumann & Rasmussen, 2016; Rasmussen, Sandal & Laumann, 2015; Rasmussen & Laumann, in review).

The elements in SPAR-H (Gertman, et al. 2005; Whaley, et al. 2011) are: two nominal tasks with two nominal failure rates and eight performance shaping factors. The two nominal tasks in SPAR-H (Gertman,et al. 2005; Whaley, et al. 2011) are diagnosis and action. A task should be classified as diagnosis if it involves cognitive processing. An action involves limited cognitions. The separation between cognition and action within SPAR-H is very peculiar since probably nothing an operator does within an accident scenario is purely action without cognition. The diagnosis/action separation gives room for a much interpretations of what this actually means.

In the SPAR-H manual (Gertman et al. 2005), there are no specifications about what is meant by a task or at what task level the analysis should be performed. How a task is defined have a large effect on the result of the analysis or the probability for errors (for a discussion see Rasmussen & Laumann, 2017). SPAR-H leaves it up to the analyst to define at what task level SPAR-H should be applied and this gives much room for analyst choice and interpretation.

The elements in the HEART (Williams, 1992) method described in the user manual are 14 generic task types with a nominal human unreliability value and their suggested uncertainty bounds and 38 EPCs. For the EPCs the analyst should also assess the proportion of affects. Williams and Bell (2017) have recently reviewed HEART with a large literature review. Based on this review 32 out of the 38 original EPCs were kept, six of the EPCs were revised slightly and two new ones was incorporated in HEART.

It is difficult to find a definition of what a generic task actually is in HEART. It is said about generic tasks in HEART (Williams, 1992, p.8): "The first is the assumption that basic human reliability is dependent upon the generic nature of the task to be performed, i.e. for each task in life there is a basic probability of failure." So a generic task has something to do with the generic nature of the task which is not a very specific definition. Error producing conditions in HEART are defined as (Williams, 1992, p.1): 'Error producing conditions are factors that can affect human performance, making it less reliable than it would otherwise be.' The separation between what is a GTT and what is an EPC is not obvious in HEART, and some of the GTTs include elements that are very similar to the EPCs. This gives room for different interpretation by different analysts.

HEART defines that a task should be analyzed at the level that fits the GTT. How to analyze the proportion of affects or the strengths of the EPCs are not well defined in HEART, which gives much room for interpretation by the analyst.

To show an example of the difficulties with content validity, SPAR-H and HEARTs definitions of the PSF available time (SPAR-H) and time shortage (HEART) will be presented.

SPAR-H [Gertman et al. 2005, page 20] defines one of its PSFs available time as: "Available time refers to the amount of time that an operator or a crew has to diagnose and act upon an abnormal event. A shortage of time can affect the operator's ability to think clearly and consider alternatives. It may also affect the operator's ability to perform. Multipliers differ somewhat, depending on whether the activity is a diagnosis activity or an action."

The SPAR-H Step-by-Step (Whaley et al. 2014, page 2–4) give the following definitions of the levels for available time in SPAR-H:

Inadequate time—the time margin is negative because less time is available than is required.

Barely Adequate Time—the time margin is zero because the time available equals the time required

Nominal Time—there is a small time margin because the time available is slightly greater than the time required.

Extra Time—the time margin is greater than zero but less than the time required; the time available is greater than the time required

Expansive Time—the time margin exceeds the time required; the time available is much greater than the time required.

With these definitions, subjective evaluation depending on the characteristics of the tasks and the contexts are necessary to decide on a level for available time for a particular task. There is no way to objective define the level since there is no objective description of how much time one should assume to define the different levels. In addition, it is a question, what is the unit of analysis in SPAR-H. It has been claimed by the authors of SPAR-H that it is an analysis of the average operator. However, if there is barely adequate time for the average operator one might expect that there is too little time for the slower than average operators. How much failure one expects becomes circular with the definition of the unit and the unit of analysis is not well defined in SPAR-H.

HEART has a similar EPC, which is described as: "A shortage of time available for error detection and correction". HEART gives no advice on, how the analyst should go about analyzing this EPC. As shown under the discussion of SPAR-H, a lot of information needs to be clarified to analyze this EPC and since it is not available in the method, it is up to each analyst subjective judgement. Something that is peculiar with HEART is that the analyst is not instructed on how he/she should go about collecting information about the GTTs and the EPCs. The EPCs are defined by one sentence and then it is up to the analyst to interpret how this sentence fit their contexts/tasks, or what the sentence actually means, as for example—how much shortage of time should exist before the maximum predicted nominal amount should be chosen.

These characteristics with HRA methods (as SPAR-H and HEART) show that they are more qualitative evaluation methods than objective quantitative test methods and that they are far from being objective quantitative test methods. It is a question if we should expect methods that include so little definitions and descriptions (content validity) as SPAR-H and HEART to show interrater reliability. To obtain interrater reliability the concepts need to be precisely, defined. However, with a qualitative evaluation method view of the method, we will focus more on the analyst ability to predict correct error rates based on qualitative evaluations with use of a HRA method. With this approach, we might not expect high interrater reliability, but rather look at the quality of the data and the evaluations that the prediction is based on.

We claim that if HRA is going to be tested with quantitative methods they need to be improved and that the place to start is to develop good definitions of the content of the concepts included into the method. If good definitions exist, it might be possible to develop measurement scales for the PSFs/EPCs. If we have these measurement scales of the PSFs/EFCs it might be possible to predict how different levels of PSFs, such as for example complexity, affects performance.

However, it is a question, if this is possible. It could be that with the different elements included into HRA, it is impossible to be so well defined that quantitative measurements can be developed. For example, for time available, it could also be that the

tasks and contexts that are evaluated in HRA are so different that it is not possible to develop the exact meaning of the PSFs and the PSFs levels/strengths that counts for all kinds of contexts and tasks. If this is the case, the qualitative evaluation view of HRA methods might be better, but then also the qualitative part of the analysis need to be further developed.

2.2 *Challenges with data from psychological and human factors studies (literature reviews)*

HEART was developed based on human factor literature (Williams, 1992). Williams (1992) and Williams & Bell (2017) has done literature reviews to investigate studies that include EPCs and their maximum multipliers and nominal error rates on GTTs in experimental designs. Also, Laumann, Sandal & Rasmussen (Laumann & Rasmussen, 2016; Rasmussen, Sandal & Laumann, 2015; Rasmussen & Laumann, in review) have done literature reviews to investigate the meanings of the PSFs and how large effect the PSFs have on affecting human errors on tasks.

One challenge with using literature reviews on psychological and human factors studies to collect information for HRA is that these studies were not designed with the purpose of testing HRA methods and therefore it is difficult to transform the data to fit the HRA method. For example, literature studies usually only included one negative level for a PSF and this level is difficult to match with the level description for example in SPAR-H. It is also difficult to match the description of PSFs to the one manipulated PSFs in this kind of studies.

It is not obvious how the literature review to collect information on EPCs in HEART was done. Williams and Bell (2017) say that they have looked for the maximum multipliers of the EPCs. However, the human factors studies do usually not intent to manipulate the maximum multipliers of the EPCs. They usually just manipulate one level and it is often not described or discussed what this level actually is. In addition, the experiments usually intend to study why the PSFs/EPCs have an influence on performance rather than how much it affects performance. In the human factors literature there is also not developed measurement scales for the PSFs/EFCs. We have looked at some of the studies that are referred to by Williams & Bell (2017) and it is difficult to see that the maximum multiplier, in the meaning of 'the highest possible negative multipliers' for the PSFs/EFCs,' were the manipulations in these studies.

We are hopeful that Williams & Bell (2017) will present more from their literature review and discuss the evidence for the EPCs' maximum multipliers and nominal failure rates on the GTTs. In this way, other researchers can better understand the authors' arguments, and perhaps add to and relate this evidence to other methods. We do not think one should look at this data as objective evidence for an EPC/PSF but rather an evaluation done on the available evidence. Since it is an evaluation, it is important to understand the authors' arguments on for example, including or excluding experiments and the authors' argument about how similar the experimental manipulations found in these experiments are to the concepts in HEART.

2.3 *Challenges with performing new experiments to collect data that is relevant for HRA*

The unspecific definitions of the concepts in the HRA methods are also a large challenge for developing experiments since it is difficult to develop manipulations and measurements that fit with the HRA methods. An example of this is an experiment performed by Liu and Li (2014) where experimental data were compared to the multipliers in SPAR-H. In this experiment, one can see the difficulties the authors have in matching the definitions of the PSFs and the levels in their experiment to SPAR-H definitions and levels. For example, experience and training were defined as the 20 first trials as the negative level and the later 20 trials as the nominal level. This manipulation does not fit with the negative level description of experience and training given in SPAR-H, which is less than 6 months of relevant experience and training. It was difficult to develop an experiment manipulation that fits with this level description in SPAR-H. In this experiment, also complexity was manipulated, but the measurement of complexity measured the complexity of the procedures, and then it is a question if this should have been looked at as complexity or procedures. There were also questions on, how to match the manipulated levels to SPAR-H levels also for complexity and available time.

For the HEART EPCs, one should in experiments only manipulate the maximum strength of the EPCs, since these are the elements included into the method. However, usually, the maximum strength of an EPC, does not seem to be a meaningful experimental manipulation, if the "maximum multiplier" is interpret literary. For example, in an experiment on EPC 1 (Williams, 1992, p.22): 'Unfamiliarity with a situation which is potentially important but which only occurs infrequently or which is novel' one would give the participants no training on a completely new task. In this situation, one would have expected a human error probability for failure close to 1, and we might not need to test this because the result is too obvious.

For some of the GTTs in HEART and the nominal tasks in SPAR-H an obvious challenge for new experiments is the number of subjects needed, when errors is expected to occur in 1 of 100, 2 of 100 or 1 of 1000 subject.

There are many challenges with performing experiments that are relevant for HRA. One frequently mentioned challenge is that if these experiments should be done with actual operators in a simulated control room, the cost of the experiments are high and little data would be collected (Boring, 2012).

Another challenge that exists when performing experiments on PSFs (with both operators and other participants such as students) is that PSFs are difficult to completely control and without that control, it is difficult to measure the independent effect of the different nominal tasks and/or the PSFs/EPCs. We have seen in experiments that other PSFs than those manipulated often affect the results. For example, poor teamwork is a variable that is difficult to control, since this might exist within the crews before they come to the experiment, or develop during the experimental run. Other examples of PSFs that are difficult to control are; operators that are ill, hungry, stressed, fatigued or demotivated. The crews themselves might also increase the complexity of a scenario by some erroneous actions or by forgetting a procedural step. Then the manipulation for some crews might be different from the one the experimenter planned.

PSFs have a tendency to exist from before the experiments or occur during the experiments, they cannot be completely controlled, and some you might observe (e.g. poor teamwork) and other might be more hidden for the experimenter (e.g. fatigue, stress and illness).

As an example of this, the first author experienced that in an experiment at the Halden Reactor Project where we intended to manipulate available time and information load, but for some of the crews we also observed that poor teamwork also occurred. The poor teamwork and short available time combined had a very negative effect on performance for some of the crews (Laumann, Braarud & Svengren, 2005).

In addition, another challenge with simulator experiments with operators is that these simulators such as the simulator at the Halden Reactor Project, often are computer based simulators rather than analog simulators that the operators use at their own plant, making it difficult to know how much "the new interface for the operator" PSF interacts with the manipulated PSFs and how this affect error rates.

2.4 *Challenges with event report as a basis for HRA data*

One possible source of data in HRA is event reports. One problem with using event reports as a basis for HRA data is that the event reports only investigate and report when an error occurred and then we do not know if the PSFs are usually present when this task is done or if there were some particular PSFs that were present when the error occurred (Kim et al. 2015).

Another issue is that event reports are often written by operators that probably do not have much knowledge about PSFs/EFCs and how to investigate the presence of PSFs/EFCs. The event reports that we have seen have not been very specific about how they collected the data on the PSFs and how the data were interpreted. In addition, the strengths or levels of the PSFs are not defined in the event reports and much interpretation have to be done to decide on a specific level or strength.

Another problem with event reports might also be that the events occur so infrequently that they do not give much data for HRA (Boring et al. 2012).

It is also a problem for HRA that usually in the event report more than one PSF has occurred in the event, which makes it difficult to estimate the effects on orthogonal PSFs/EFCs, which is included in the HRA methods.

It is also a problem with event report that many organizations prefer to not be open about such matter as human errors and why they occur since this is regarded as sensitive information.

2.5 *Challenges with databases*

There have been several attempts to develop databases for HRA data, which included data from event reports, literature reviews, and/or from experiments or simulations. Examples of such databases are NUCLARR (Gertman et al, 1990). HERA (Halbert et al, and COREDATA (Gibson, Basra & Kirwan, 1999).

The challenges described for event reports, literature reviews and event reports are also challenges for databases because this is the information that is entered into the databases.

The general reason for a database is to organize data in some predefined ways. Also for databases, the unclear definitions in HRA are a large issue because when a data bases structure is developed the definitions, for example of PSFs/EPCs and PSFs/EPCs levels/strengths from one or more method, have to be used as template and the data then has to be interpreted based on these definitions in the database. Data from databases are never going to be better than the data included in the first place. To include quality data into a database, a good and precise structure and definitions, which were also used during the data-collection from either event reports or experiments is required.

Since the HRA methods, include so diverse definitions of the elements in the methods one structure in the databases for each method is necessary, which is very resource demanding.

In HRA, the structure and purpose of the databases are often not clearly specified and the

argument for them seems to be that one day, some analyst (a very smart analyst) could find a good way to analyze this data in a way that fits HRA. However if the developers of the database do not know more exactly how the database should be used and what is the purpose of it, the work invested in it might be useless. One might wonder if all the resources to develop HRA databases have been a good investment based on the amount of data relevant for HRA that has been provided so far.

3 CONCLUSION

HRA methods have been criticized for the lack of predictive data and validation of their results. However, is seems like HRA methods are criticized for not being something they never intended to be: quantitative test methods. It is not enough to say that HRA methods, are methods to estimate human reliability on tasks. Within HRA one should make a choice, whether we should look at HRA methods as a qualitative evaluation methods that gives gross and crude differences based on expert judgement or if HRA methods should be developed to be quantitative test methods. The inventors of SPAR-H and HEART seems sometimes to present their method as much more objective quantitative test methods than they actually are. Of course, this likely because they were developed to support probabilistic risk assessment where a quantitative result is required. ATHEANA went in another direction and defined an HRA method that is mainly a qualitative method, with an expert based quantification technique added at the back end. We think that also SPAR-H and HEART are mainly qualitative methods, requiring substantial analysts' judgement in order to produce the quantitative result.

To be a quantitative test method we need content validity and very good and specific definitions of the concepts the method includes, definitions of measurement scales for the concepts, definitions of who is the unit of the analysis, and definitions of how should a task be defined for that method. An important question is: Are these definitions possible within HRA? Maybe concepts such as PSFs and EPCs might be too difficult to be precisely defined, because the concepts include too much, and because they vary too much from context to context or from task to task. It might not be possible to develop definitions and measurement scales that can apply for all of the contexts and tasks where the HRA methods are used.

However, if we define HRA methods as qualitative evaluation methods, criteria for a good qualitative analysis should be developed and discussed. Qualitative research methods have other methods to evaluate the quality of the research than quantitative research methods. One paper by Laumann (in review) presents criteria for good qualitative analysis and discusses how these could be applied for HRA.

It might be that the definitions when a qualitative method is used do not need to be that specific and are more allowed to vary between contexts. However, even with a qualitative evaluation method view, as good as possible definitions and advice about how to perform the analyses, should be available.

This question about how we should look at HRA methods should be answered based on what we think about our data. Is it possible to precisely define the different elements in a HRA method that can be used across different contexts and tasks? If this is not possible, we have to collect HRA data with a qualitative approach.

After working for many years with HRA methods, definitions of PSFs and their levels and performing experiments within HRA, we doubt that it is possible to define and specify the PSFs/EFCs and measurement scales of the PSFs/EFCs enough that a quantitative approach is possible. An alternative for HRA then is to more focus on developing good qualitative methods for evaluation of PSFs/EPCs, PSF levels/EPC strengths, and error rates.

As HRA methods are today it would be a best to just admit that they are qualitative expert judgement methods trying to predict crude differences in performance, and that they are far from being objective test methods that can be empirical validated with quantitative methods. However, HRA methods are not good and systematic qualitative methods either and improvement in descriptions of how the qualitative analyses should be performed, are also needed. A qualitative method approach might demand lesser specification than a quantitative test approach.

One could argue, if HRA methods are not objective test methods why should they predict performance? There have been some studies to test the validity of HRA methods such as The international empirical study (Forester, et al. 2014) and the U.S HRA empirical study (Forester et al. 2014). These studies do not give an overall conclusion on how well HRA methods predict human errors. They give many and varied answer depending on the task, the HRA method and the analyst. However, in these studies one might wonder, what is actually tested? Is it the analysts' ability to use the HRA method to predict the likelihood of errors or is it the HRA method in itself that is validated? If one assume that the method was tested, the researcher should assure that the HRA method guideline was reliable followed by the analysts. This is not possible since some of the methods like SPAR-H and

HEART do not include complete and prescriptive descriptions of the qualitative parts of the analysis. In these studies, it seem to be the analysts' qualitative evaluation with use/help of the HRA method that was tested and not the method in itself.

HRA methods should not continue to be something in between qualitative and quantitative research methods, since then they are based neither on good qualitative research methods nor on good quantitative research methods. Qualitative and quantitative research methods have different assumptions about quality and have different ways to investigate the quality of the method or the quality of the research. A choice should be made within each method and the choice has to be made by the authors of the methods.

Usability and user experience: Adaption and application for a railway related environment

Marc Burkhardt & Birgit Milius
Siemens AG Braunschweig, Germany

ABSTRACT: When developing consumer products, for a long time already usability is an issue and an integral part of the development process. For railway systems, usability is still a rather new area with new requirements. In our paper, we will discuss what makes usability and the newer research area of user experience for railways special and how certain features of the railway system, e.g. high requirements regarding safety will influence how usability can be included in the development process.

1 INTRODUCTION

For most industries, usability is a concept which is applied for years. In railways, at least in Germany, the application of usability methods and tools is still rather new. In our paper we give an overview about the general objectives of usability and user experience. We present an example for how usability methods are applied in the railway sector. In the later chapter, we discuss an aspect which makes usability in railways special. Railway applications have often safety requirements which need to be taken into account. This can lead to solutions which do not have a very good usability. We discuss this paradigm and its implications for the inclusion of usability in a railway systems development process.

2 USER EXPERIENCE AND USABILITY

Usability is defined in ISO 9241-11 as "*The extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use*." This means that the technical systems should be designed in a way that a user can concentrate completely on the task at hand and is not distracted by the interface design. This means that a good usability can only be achieved when the resources and conditions of a human's perception and cognition are taken into account.

However, usability only looks at specific aspects of the human-machine-interaction. Especially in the last years the more holistic concept of user experience was developed and is researched. ISO 9241-210 defines user experience as "*a person's perceptions and responses that result from the use or* anticipated use of a product, system or service". User experience includes all the users' emotions, beliefs, preferences, perceptions, physical and psychological responses, behaviors and accomplishments that occur before, during and after use. Even more so than usability, user experience is the result of the product, the user and the context/ environment.

To make a successful product, it is important to take both aspects into account. It would be a mistake to assume that because a product has a good usability the user experience is good. And also the other way around is not true. Just because a product is beautiful or aesthetically pleasing does not meant that it can be easily or intuitively used.

While it is obvious why a product which is used for pleasure, e.g. a game or a mobile phone should have a good usability and excellent user experience, some might argue that an emotional connection with a product is not necessary in a business setting. However, on a qualitative side, an emotional connection to a product or a system makes a person more relaxed and fosters a better immersion into work (Hassenzahl 2003, Vorderer 2005). Also on a quantitative side it can be shown that user experience is important. In Wright et al. (2007) is proven that personal well-being correlates with the performance in the job. Further research is needed but it can be concluded that especially in safety related industries this correlation can mean that satisfied and content users work more reliable.

Despite all the argumentation above, in practice the general ideas of usability are more often applied than those of user experience when developing new products. One of the reasons might be that we have a well founded set of methods and procedures to measure usability, whereas the same extended catalog of tools is missing for user experience.

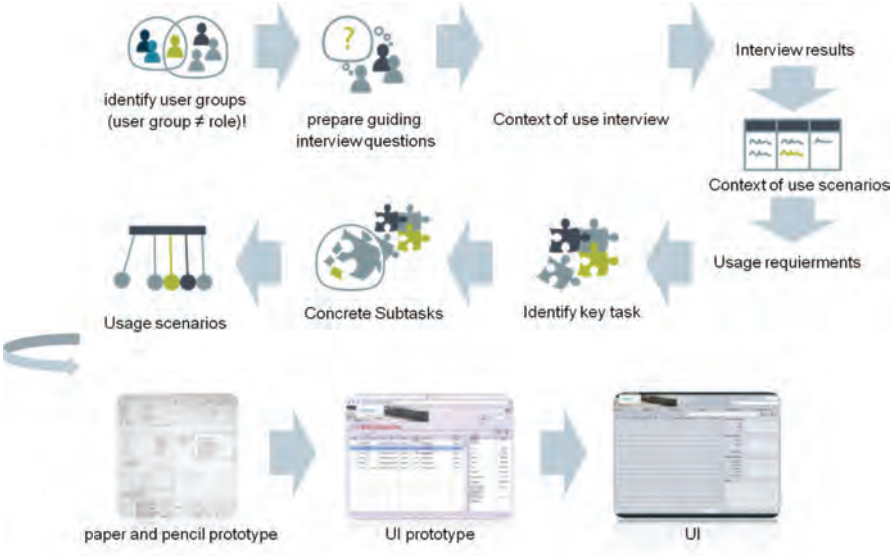

Figure 1. Usability design process at Siemens AG.

3 USABILITY IN RAILWAYS: AN EXAMPLE

In this chapter, we present an approach for designing a railway specific system.

Signaling systems in railways are very complex structures which need to be closely monitored to avoid major malfunctions which can lead to the disruption of railway traffic. Traditionally, the maintenance supervision of each system or system group was done separately, however, with the raising complexity and taking into account new and existing dependencies between such systems it became necessary to transfer all supervisory maintenance related tasks into one system. Such a system allows not only monitoring several systems, but also in cases of disruptions to coordinate all efforts regarding these systems with the aim of minimizing disruptions.

Traditionally, when developing such a user interface, functional requirements were the leading elements. Due to the new complexity, combined with usually less people being responsible, it becomes urgent to focus as much on functional aspects as it used to be but additionally to take human factors aspects into account to enable the user to fulfill the necessary tasks at a high quality. Also, the high reliability of new railway systems leads to very few failures. This has the effect that the procedures to recover from these failures are not as readily available as it would be if a person is confronted with them often. Therefore, a supervisory maintenance system needs to be able to provide detailed processes and a vast amount of information to enable and guide the user when solving problems and repairing systems.

At the beginning of most development processes in railways stands a detailed list of requirements. The complete list of requirements is describing the scope of the project and is used afterwards for verification and validation. The following list gives examples for how usability requirements were described.

- Req1: Identify, which user groups are interacting with the system and how they can be distinguished
- Req2: Identify on different level of detail, which information are need by which user/user group
- Req3: Identify, in which situations and in which environments/contexts will the system be used
- Req4: Identify, which systems with similar tasks/ in similar environments are used and known by the future user and which aspects of legacy systems[1] have to be taken into account
- Req5: Identify functions/tasks with safety relevance as these need special attention

The process as shown in Figure 1 was used to get a maximum of information from the users and

1. Legacy systems play a huge role in railways as signaling systems usually (at least in the past) had a very long life span. Even today, there are still mechanical interlockings in operation which date back to early last century.

to develop a User Interface (UI) with a very high usability. However, due to the fact how contracts in the area work, the application is not as straightforward as it looks.

Typically, the first step when deriving the user requirements is to identify the relevant user groups and develop the key questions which are necessary to derive all necessary information. However, especially when you develop a completely new system, the identification of the user groups is difficult. The (future) organizational structures and with this the functions and hierarchies are not necessarily known so assumptions have to be made. Experience has shown that for this, it is better for the development process to start with a more general description of the user groups and go into detail later than start with a too limited description. If the identified group of potential users is too small, danger is that important aspects are forgotten and consequently the User Interface (UI) cannot be used from all users with the same ease. Sometimes, it helps to think outside the box. In some projects, the user groups at the operators' side are generally known but the supplier has not the opportunity to talk to these people. Here it can help to interview people with indirect knowledge, e.g. from trainings to get a better understanding of the requirements.

During the interviews it is extremely important not to ask for specific functionalities but have people describe their daily tasks and how they are performed in the current setting. It is not the aim to listen to a general process description but rather to really understand the motivations behind actions and the needs to perform a task. This means that also short cuts or informal, typical processes should become known and are an important input in the development process. The approach becomes more difficult when safety related, process based tasks are to be discussed. If a usability study is done for, e.g. a traffic controller, the tasks of his jobs are described in detail in the rule book and in general it is not allowed to deviate from them. There is a danger that interviews will only show the officially allowed processes but potentially safety relevant changes are not talked about. Here, a longer field study is very helpful.

Like in most other IT industries the railway development process follows specific regulations. In railways e.g. the CENELEC norms DIN EN 50159 and DIN EN 50129 have very specific safety related requirements which in UI design have to be taken into account. In so called "context interviews" it is very important to understand all kind of input from of these regulations and their influence on the daily work. We recommend recording these interviews in audio and/or video. The experience shows that even if you have several well trained interviewers you could miss very important answers during the interview compared to a later "offline" analysis of audio or video recordings.

Figure 2. Iterative process when designing a UI as described in ISO 9241-210.

The next step in the process is to develop the real needs or demands from the system from the user's perspective. From this developed needs and demands the so called usage requirements will be generated. These set of usage requirements are the input to identify the key task and subtask of the users' daily work with the new system.

The goal of this separation of tasks is to find the concrete subtask a user wants or has to do and then develop usage scenarios out of these set of concrete sub tasks. This procedure is time consuming but definite worth it to do.

If you have your setup of usage scenarios it is time to start the first UI prototype design which then needs to be tested exceedingly. It is very much recommended to start the UI prototype design with a wire framework paper and pencil attempt. Start in simple black and white and concentrate on the content and not on the design. Use "placeholder" for parts which should be described in more detail later and concentrate on the current concrete subtask. Improve this paper and pencil design from subtask to subtask.

Even though we described the development process as straightforward, in reality it is iterative and will need several iterations until a final version of a UI is developed. The iterative process is visualized in Figure 2.

If you reach a first detailed design of your system start using design tools to develop a first digital version of your system design and improve this design from iteration step to iteration step. Colors and specific design elements should come up in the later iteration steps.

4 USABILITY FOR SAFETY-RELATED PRODUCTS: DIALOGUE CRITERIA

In the previous chapter we described the usability process as applied by the Siemens AG to a supervisory maintenance system. This process is of general

nature and only takes the special organizational requirements of the railway industry into account. Even though the process might not change significantly when safety aspects are to be taken into account, the contents of, e.g. interviews becomes more sensible. Also, at the latest when prototyping starts it will become necessary to balance good usability with the described safety-related processes.

As in any other industry, in safety related industries a good usability is necessary to help the personnel to work motivated and reliable. E.g., there is lots of research going on in the field of health engineering to provide safe, usable systems for health care. However, some of the aspects which are considered as making a product usable cannot be incorporated in a safety critical system. As an example, in this chapter, we have a look at the *seven dialogue criteria* from ISO and discuss, if and under which conditions these criteria can be used when assessing a safety relevant dialogue. As a railway example, we look specifically at the user interfaces for traffic operators.

Traffic operators usually work centralized and get all necessary information via screen. Typically, at least the tracks are shown, one can see which parts of the track are occupied and how the signals are set. Many more information is shown directly or via menus. The manipulation of the signals is done automatically, but they can also be handled manually. In these cases, the tasks of a traffic controller can be directly safety-critical. Besides information from the screens, traffic operators get or deliver information, e.g. by phone.

In the following paragraphs we discuss if the seven dialogue criteria can be used to evaluate the usability of a display.

The dialogue criteria are:

- Suitability for the task
- Conformity with user expectations
- Suitability for learning
- Suitability for individualization
- Self descriptiveness
- Controllability
- Error tolerance

An interactive system is suitable for a task, when it helps the user to complete the task. This means that functionality and dialogue are based on the task to be done. This is an aspect which should be applicable to safety systems. However, when dialogues are designed in rules and processes, this might not always be the case.

A dialogue conforms to user expectations when it behaves just as other dialogues in the given system. E.g. if a dialogue has to be confirmed, it should be confirmed every time in the same way (e.g. "confirm" and not sometimes "OK"). Also, it implies that the system behaves as the user expects it to do (SAP 2017a). This criterion can also be applied in a safety-related setting. As railways is an area where many aspects are standardised and it is an area which only develops very slowly, most people working in the area, e.g. most traffic controller, have the same professional background and their expectations to use the given systems are in general defined by the same technical systems. This might make it actually easier to define a new system, as the user group is very homogenous. This criterion can and should be applied when designing a display for a traffic controller.

A dialogue is suitable for learning when it helps the user to learn and understand the system. This aspect is less important when applied in safety-related settings, especially in railways. To work in a control centre, users had to undergo a rigid training. They are supposed to know the system very well and learning significant amounts of new aspects in the system would mean that the training is not good enough. In other areas, e.g. maintenance of systems, this aspect might be very sensible and can help to design systems which are actually making a task easier to achieve.

A dialogue is suitable for individualization when a user can adapt the man-machine-interaction and/or the display of information to his/her own preferences. Up to now, adaption of the man-machine-interface is not an option for traffic controllers. The reasons for this might be that the tradition exists to have the displays all looking the same. But there are also scenarios possible in which it is necessary that everyone gets the important information quickly, easily and reliably from the screen. This is the case, e.g. when in a difficult situation a second opinion is necessary. Today, it is not be possible to apply this criterion. For the future, research into the positive effect of individualization or changing general rules of cooperation in a train control center could result in the fact that the criterion is actually applicable.

Self descriptiveness means that it is obvious for a user at what point of the process he/she is working right now, what tasks are to be done and what options he/she has. In SAP (2017) it is explained that self-descriptiveness provides simplicity by reducing users' memory load. Users can retain their capacity for their tasks instead of bothering with the system. They can work more efficiently. For future developments this might actually be a game changer. The area controlled by just one controller gets larger all the time. There is the necessity to provide the controller with more and well structured information to always provide him/her with a well defined picture of the current situation. Also, railway displays contain many information, often in abbreviations. Applying the rule regarding self descriptiveness, this should be changed or the user should be well supported.

Controllability means that a user is able to start a dialogue as well as control its direction and

speed. In a safety related system sometimes it is almost always critical that dialogues are started and controlled by the system to provide on time information. The means, that the options for a traffic controller to influence the dialogue are limited. This might feel uncomfortable to the controller.

Error tolerance means that a user can make errors and can undo these with acceptable effort. Here, we have to distinguish between errors in operation in normal and degraded mode. In normal mode, errors can either not be made because the technical system prevents them or they are operational, then they can be redone as long as it is safe. There are situations, which are safe but lead to operational disturbances, e.g. when a train is led on a wrong track. In general, all measures to redo an operational error are governed by operational rules. In degraded mode, when technical systems are not or not fully available, an error can have directly safety critical effects. The display might show a critical situation but might not recognize it. Undoing such a safety-critical error is possible but in general time critical. Due to having accidents because of traffic operator errors (BadAibling 2016), it would be a very valuable research area to look at how a typical traffic controller display or complete system set up can be changed to at least help to recognize errors.

After having discussed the criteria one after the other, we will now look at a concrete example. A typical example in railways where the designed process does not fully comply with usability standards for dialogues is how safety critical actions are safeguarded. In these cases the so called "KF Bedienung (command release task)" has to be provided. After pushing the necessary buttons to, e.g. allow a train to pass a red signals, a window will pop up and ask the user if the planned action is correct and sensible. This has to be acknowledged after a givien time. In this time the user should take his time to be again aware of the complete situation on the tracks. The idea behind this is to make sure that such actions are not done lightly and by mistake. The authors are well aware that from a human factors point of view this process is flawed. However, for the sake of this paper, we only look at the design of the dialogue.

- Suitability for the task: To discuss the suitability of this dialogue for this task is an ongoing research questions. Due to several human factors, it can be argued the goal of this approach will not be reached. By designing the dialogue more intelligent as it is now, and taking into account how the brain usually works, the dialogue can be changed to be suitable for the task.
- Conformity with user expectations: As the traffic controllers are trained on these systems and the general processes are defined in rules and regulations the dialogue definitely confirms with the standards of the system and the expectations of the users.
- Suitability for learning: The dialogue not actually promotes a better learning or understanding of the system but focuses on repletion. The second dialogue can be confirmed (and probably often will be) without a deeper examination of the situation.
- Suitability for individualization: There is no individualization possible, as this type of dialogue is designed in the system.
- Self descriptiveness: The dialogue makes it clear what actions are expected from the controller.
- Controllability: The user does not have the chance to manipulate the dialogue, but he can stop the command.
- Error tolerance: There is little error tolerance. If the user actually made a mistake and is realising it, he/she cannot undo the wrongly given commando. Alternative processes are designed for these cases.

Overall, the general assessment of the usability of the dialogue regarding command release task is not very good. As it is known that there is a correlation between good usability and reliability/safety, the results of this assessment can be used to start a general discussion about how to design such processes in the future. The design process should take into account the basics of usability and combine them with the requirements of safety related, rule-based actions.

5 USABILITY AND THE SYSTEM LIFE CYCLE PROCESS

Another issue is the intervening of usability needs with the needs of the system life cycle. The system lifecycle is strictly structured in different phases in, e.g. several standards. In an ideal world the usability process for safety-critical systems will have an interaction with many of these system lifecycle phases. This was explained for general human factors issues in Milius (2017). However, as we do not have a very formalised process for human factors integration, it is easier to imagine an intervening of human factors and risk assessment. For usability, a very structured process already exists as was shown in chapter X of this paper. Combining both approaches is necessary for better products but also a difficult task.

6 CONCLUSION

In the previous chapter we stated the discussion regarding the integration of usability issues into the railway system development processes. We were focussing on usability rather than user experience

because the latter is still to new and provide several challenges before it can become a part of a formalized process. The given example has shown how usability is treated by Siemens Ag when a new, not directly safety related system is developed. Due to the fact that all tasks with a connection to safety operations are strongly regulated, even in the area of maintenance we have special aspects which distinguish railway usability from e.g. usability for a consumer product.

Another level of difficulty arrives when usability is applied to the design of safety-related systems. To show the possible effects, the generally acknowledged dialogue criteria were discussed and it was assessed if they can be applied to safety relevant functions. It is obvious that several of the criteria cannot be applied fully and/or directly. This was also shown using the command release tasks for safety-critical actions as an example. Here, lots of research needs to be done.

Usability is just a part of human factors. As was discussed in earlier papers (Milius 2017), recent incidents in railways show that even in highly automated systems humans still have to make safety-critical decisions. While the development in the past was focused heavily of replacing the human, newer research talks about effectively integrating the human in all necessary processes. The challenge will be that we start from a very different set-up as it used to be. As humans are more and more just supervisors, we have to make sure, that they still understand what's going on and we have to use modern technology to keep them informed and to provide help where necessary. This means that we have to integrate new functions in our new and existing systems. But it also means that we have to update existing processes to take the human, and usability, into account. Regarding general human factors integration, some ideas were already discussed in Milius (2017), but we need to focus on usability and life cycle as well. Last but not least, providing clear processes ho to integrate usability analysis in the general development process will lead to better acceptance.

ABSTRACT: Airplanes, ships, nuclear power plants and chemical production plants (including oil & gas facilities) are examples of industries that depend upon the interaction between operators and machines. Consequently, to assess the risks of those systems, not only the reliability of the technological components has to be accounted for, but also the 'human model'. For this reason, engineers have been working together with psychologists and sociologists to understand cognitive functions and how the organisational context influences individual actions.

Human Reliability Analysis (HRA) identifies and analyses the causes, consequences and contributions of human performance (including failures) in complex sociotechnical systems. Generally, HRA research is concentrated in modelling workers' performance in the "sharp-end", assessing the ones directly involved in handling the system, especially operators. However, in theory, a reliability analysis can be applied to any kind of human action, including those from designers and managers.

This research will evaluate a way of conducting HRA in the design process, as previous research has demonstrated that design failure is the predominant contributor to human errors (Moura et al., 2016).

Bayesian Network (BN) – a systematic way of learning from experience and incorporating new evidence (deterministic or probabilistic) – is proposed to model the complex relationships within cognitive functions, organisational and technological factors. Conditional probability tables have been obtained from a dataset of major accidents from different industry sectors (Moura et al. 2017), using a classification scheme developed by Hollnagel (1998) for an HRA method called CREAM – Cognitive Reliability and Error Analysis Method.

The model allows to infer which factors most influence human performance in different scenarios. Also, we will discuss if the model can be applied to any human actions through the project life cycle—since the design phase to the operational phase, including their management.

1 INTRODUCTION

1.1 *Human Reliability Analysis (HRA)*

Human reliability analysis can have three objectives: identify human performance (as failures and their consequences), quantify the likelihood of failure (and error recovery) and to reduce or remediate those errors in the system (Kirwan, 1997).

The expected results of such study can be either qualitative or quantitative, depending on the industry sector best practice, data availability and regulatory requirements.

Quantitative results for HRA means giving the human performance a number, a probability of occurrence—the so-called Human Error Probability (HEP). This gives decision-makers the

opportunity to decrease the HEP to as low as practicable by tackling the factors that impact it, or to check if a certain risk criteria is met.

HRA research, practice and regulatory requirements are currently focused on operation and maintenance workers—called 'sharp-end' workers—those who actually interact with the processes (Reason, 1990; Hollnagel, 1998).

1.2 *HRA in design phase*

Can human reliability analysis be applied in other phases of an industrial project, such as design, construction, commissioning and decommissioning?

Theoretically speaking, it is possible: where there is human action, there is the possibility to model, analyse and measure performance (Hollnagel, 1998).

This research will focus on the design phase and design changes during other phases, as there is evidence from previous studies that design failure is the organisational factor that most triggers human failure actions (Moura et al., 2016).

One of the constraints of this approach is that human (engineers and managers) performance in the design stage has limited public data, preventing detailed task analyses.

However, it is also known that design failures identified in latter stages of the lifecycle (i.e. operational phase) are much more expensive to correct, compared to those detected during the design stage (Kohler and Moffatt, 2003).

Thus, it is believed that understanding engineers and managers performance during the design phase would have the potential to motivate improvements in organisational design procedures, based on overall accident patterns.

It is a trade-off between having perfect data but not sufficient resources to make design changes in the operational phase and having imperfect data but sufficient resources to improve the design in earlier stages of the lifecycle.

1.3 *Can human performance influence design?*

Design failure is often considered an organisational factor in HRAs, as the methods and assessors take into account that it influences human performance and not the opposite.

In contrast, there are studies, outside the safety and engineering community, showing that organisations are not an unmanned box of procedures, but individuals deciding whether using them, based on other factors like regulations, knowledge and resources (Rocha Fernandes et al., 2005). Besides, those individuals, usually middle and front-line managers, have a significant influence in all levels of the organisation, dictating and implementing the organisational strategy (Wooldridge et al., 2008; Purcell, 2007).

Another key aspect of this discussion is recognising the difference between 'managing the design' and 'managing design changes'. First, because they can occur in different phases of a project and thus managed by completely different team profiles.

Second, because decision-making in engineering practice can have two distinct meanings: 'design decisions' are the ones about the design itself (e.g. which equipment to choose in a system), while 'management decisions' are the ones about the team responsible for designing the system or issues that impact this team (Herrmann, 2015).

Each of these different concepts leads to a different kind of performance to analyse.

2 METHODOLOGY

2.1 *Classification scheme used*

The classification scheme is considered the collection of error modes (cognitive functions and human actions) and the Performance Shaping Factors (PSFs) which shapes the context that triggers each error mode.

To achieve the aim of this research, it is essential to use an HRA classification scheme that recognises cognitive functions, as both 'design decisions' and 'management decisions' cannot be evidenced only by actions described in most classification schemes from the first generation of HRAs.

For this reason, a classification scheme of the second generation of HRA was chosen (see Hollnagel, 1998, to understand the differences between the first and the second HRA generation).

From the publicly available ones, there are only two methods from the second generation that are considered useful to the Major Hazard Directorates of HSE, the UK safety regulator (Bell and Holroyd, 2009): CREAM (Hollnagel, 1998) and ATHEANA (Forester et al., 2007).

From these two choices, CREAM's (i.e. the Cognitive Reliability and Error Analysis Method) classification scheme was chosen to conduct this research, as it shows a clear distinction between causes and manifestations. This enables the application of the method in both directions: to analyse major accidents retrospectively and to predict events as a traditional HRA method. Therefore, this feature made it possible to use a pre-existent dataset from major industrial accidents (Moura et al., 2016) in the current work, as explained in the next section.

This classification scheme splits cognitive functions into two categories: analysis (the mental processes used when someone tries to understand a problem) and synthesis (the mental processes used

Table 1. Summary of errors of cognition used in CREAM.

		Wrong reasoning
		Decision error
		Delayed interpretation
		Incorrect prediction
Synthesis	Planning	*Inadequate plan*
		Priority error

to solve the problem). Further, these are also split into subcategories, as summarized in Table 1.

One of the problems that may be argued against this choice is that most HRA performed in practice are the ones from the first generation (Zwirglmaier et al., 2015, Henderson and Embrey, 2012), such as THERP, HEART and SPAR-H. Also, according to CREAM's creator, all the PSFs presented at the classification scheme are still useful, apart from the cognitive reliability, that he considers a 'misleading oversimplification' (Hollnagel, 2012). According to him, "explaining human performance as based on 'cognitive processes' represents a myopic information processing view, and talking about the reliability of such processes is an artefact of the PRA/PSA mindset".

However, the current research is not using CREAM as an HRA method, limiting the discussion to the assessment of the HEPs, as a way to disclose possible improvements.

2.2 *Data used*

To generate Human Error Probabilities (HEP), or to validate HRA methods, different types of data are used. Kirwan (1997) classified them as: (i) real or operationally derived data (i.e. from incidents and near misses), (ii) simulator derived data, (iii) data from the psychological and ergonomics performance literature, (iv) expert judgement, (v) other techniques.

Data from real operation are considered the one with highest quality, but also the more difficult to obtain. That is because to achieve an absolute result for the HEP (number of observed errors by the number of opportunities for error) both the numerator and denominator of the equation should be assessed by the observation of each human action through an industry lifecycle. This is impractical, as one should count even the actions and errors that have not led to incidents.

For this reason, much research is being conducted using operationally derived data as near misses (i.e. events with the potential for undesirable consequences (CCPS, 2007) and accidents occurred in industrial installations.

Preischl and Hellmich (2013) used data from near misses, occurred on German nuclear power plants, to construct their model to estimate HEPs, in order to check validation of THERP handbook estimates. Groth and Mosleh (2012) have used the HERA database, from retrospective analyses of risk-significant events occurred on nuclear power plants, that contain at least one human error.

In the current research, it was decided to use a dataset derived from major accidents from different industrial sectors, not yet tested as model to estimate HEPs: the MATA-D – Multi-attribute Technological Accidents Dataset, built by Moura et al. (2016).

Differently from near misses reports, investigation reports of major accidents have the potential to uncover more PSFs that trigger a human error. This is because major accidents' investigations usually use several man-hours of an expert team (Moura et al. 2016)aiming to achieve an increased depth of analysis, eventually reaching root causes such as organizational issues (CCPS, 2007).

MATA-D has been derived from the analysis of 238 accident reports from different industrial sectors using the same classification scheme, with the intention to optimise the learning from cross-sector accidents. All the reports had evidence on the presence of organisational, technological and person-related factors, the PSFs described in Table 3. Also, nearly half of all the reports had indications about the cognitive functions and actions executed, described in Tables 1 and 2.

The MATA-D dataset is a table of 238 accidents by fifty-three parameters (thirty-nine factors, ten cognitive functions and four erroneous actions), where the number one represents the presence of a parameter in an accident report and the zero its absence.

For the reasons listed above, it has been decided to use the available MATA-D data to feed a model, in order to understand if the results could describe human performance in design and its management, instead of modelling the whole process, developing PSFs, collecting data and creating a new method from scratch.

above were modelled into a Bayesian network (BN). BN is known as a systematic way of learning from experience and to incorporate new evidence (deterministic or probabilistic), and it was chosen due to the possibility of modelling those complex relationships within variables of different nature.

Mkrtchyan et al. (2015) had suggested that using BN, human reliability analysis also benefits from:

i. Its graphical formalism (Figure 1) of conditional probability equations (Equation 1). Using the visual representation of BN is a practical way of discussing the relations between factors, facilitating the communication between the multidisciplinary team that should be involved in an HRA meeting analysis, such as engineers, psychologists and sociologists.

$$P(C=c1 \mid A=a1,B=b1)\ P(C=c2 \mid A=a1,B=b1) = 1-P(C=c1 \mid A=a1,B=b1) \quad (1)$$

ii. A probabilistic representation of uncertainty, making it compatible with Probabilistic Safety Assessment.
iii. Combination of different sources of information: empirical sources as databases of events, theoretical models of human cognition and expert judgement.

The mathematical background of Bayesian networks was described by Tolo et al. (2014) as statistical models used to represent probability distributions, that can provide combined probability distribution associated to an accident, exploiting information about the existing conditional dependencies, e.g. between PSFs and cognitive functions.

BNs are represented by acyclic graphs, where nodes are connected to each other by arcs (Figure 1). Child nodes must have a causality relationship with each parent node.

For example, consider in Figure 2, the child node 'cognitive function'. The probability of its occurrence is conditioned to the occurrence of its parent nodes: organisation, technology and

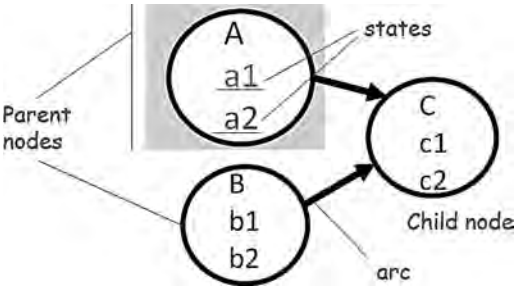

Figure 1. Directed acyclic graphs typical of a Bayesian network.

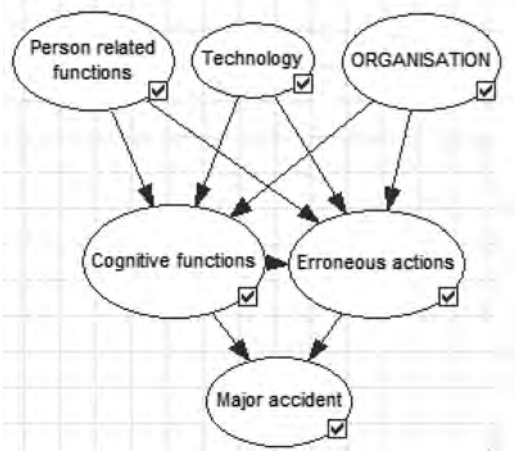

Figure 2. Example of a Bayesian network.

person-related functions. To have a proper causality, one has to know the answer to the question: what is the probability of occurring a cognitive function when the organisation, technology or person related factors occur altogether? What about when none of them occurs? And if only an organisational factor occurs, and no technology and person-related factor? All possible eight combinations from three parent nodes have to be answered, to establish a proper causality.

Generically speaking, the number of combinations a conditional probability table has to represent a child node is two (pair of combinations) to the power of the number of parent nodes (2^parent nodes).

This means a high number of combinations if all the factors of the CREAM methodology are considered. The implications of this issue are discussed in the next section.

3 MODEL

3.1 *Bayesian model of human reliability*

To build and test the human reliability model, it was used the summarised process represented by Figure 3. It was proposed by Mkrtchyan et al. (2015), through their review of HRA methods using BN models.

First, the nodes and their states were defined. Then, the structure, which means the links between the nodes. After the structure, comes the assessment of Conditional Probability Tables (CPT) for each node. Finally, a verification was conducted. The validation process will be conducted in a future work.

3.2 *Nodes and states*

The nodes used in the model are the sub-factors of CREAM classification scheme (Hollnagel, 1998), where the major factors are human, technology and organisation.

The states of the nodes will be 'presence' or 'absence' of the sub-factors observed during the investigation of major accidents.

The result of the MATA-D dataset, presented in the methodology section of this paper, has fed our model as a matrix of zeros and ones of 53 rows × 238 columns. At the dataset, the absence of a parameter (factor, cognitive function or action) is represented by the number zero and the presence of them in an accident represented by the number one.

Only the factors, cognitive functions and actions in *italic* in Tables 1 and 2 were used as nodes for the model. The reason is explained in the next section.

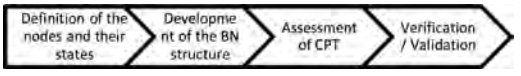

Figure 3. Process to build a BN model to HRA.

3.3 *Structure*

Basically, to create the structure of this BN model, parent nodes (organisational, technological and person-related factors) were linked by arrows to the child nodes (cognitive functions and human erroneous actions).

It would be that simple if there were no limitations from the algorithm used to build the model in Genie software. For the reason explained in section 2.2, the thirty-nine factors provided by the classification scheme would generate 549,755,813,888 combinations (two to the power of thirty-nine) – more that was supported by the BN software used.

The algorithm supports a large number of nodes, but not a large number of connections to one child node. Therefore, it was necessary to make assumptions to simplify the model structure.

To make assumptions about connections between nodes, one must have a clear understanding of the causal relationship that factors transmit to cognitive functions.

That is the reason why the most common way to simplify a model, for human reliability purpose, is using expert judgement, also known as expert elicitation (Mkrtchyan et al. 2015). However, it is also the stage where happens one of the most claimed disadvantages of using Bayesian networks for human reliability analysis: it is argued that experts can bring more uncertainties to a model due to their personal bias.

In an attempt to avoid this kind of uncertainty, the strategy was to let the data 'speak' for itself. This strategy has been already used by Groth and Mosleh's (2012) at their BN model, where they had introduced nodes of 'error context' to align certain combinations of PIFs that are more likely to produce human errors than the individual PSFs acting alone.

At the present work, the 'error context' was represented as the arcs of the BN model instead of the nodes. The context was imported from the treatment applied by Moura et al. (2017) to their dataset, to disclose common patterns and significant features among major accidents. They have used an artificial neural network approach to the dataset, a data mining process that translated the information into a graphical interface, the self-organising maps (SOM). Analysing them, one can perceive that the 238 accidents are allocated into four different regions, shaped by the clustering of accidents with a similar profile and, thus, a similar combination of factors, cognitive functions and actions.

Summing up, the model connections were proposed based on those SOM relations: factors that were in the cluster #1 were linked only to cognitive functions located on the same cluster, and the same process was repeated for all the clusters.

Simplifications to the network structure were applied not only to the connections but also to the number of nodes. Using previous research by Moura et al. (2017), the nodes were restricted to the factors, cognitive functions and actions considered significant for the dataset of major accidents by the self-organising maps algorithm.

Consequently, if a factor had represented negative or very low variations in the formation of one of the SOM clusters, it was interpreted that that factor was not significant to the causation pattern of major accidents and, consequently, it was not included in the Bayesian model presented in this paper. The considered nodes are presented in italic in Tables 1, 2 and 3, and in the nodes represented in Figure 4.

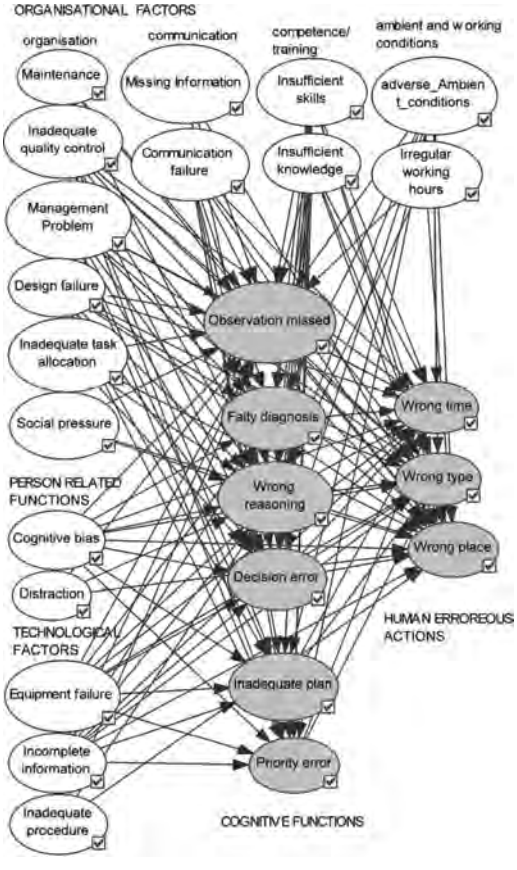

Figure 4. Bayesian model considered.

The model considers that cognitive functions are affected by each factor and that human erroneous actions are affected by the factors and by the cognitive functions. That is because the model assumes that workers have a mental process behind their actions (Hollnagel, 1998).

3.4 *Conditional Probability Tables (CPT)*

Conditional probability tables have been obtained from the dataset of major accidents from different industry sectors (Moura et al. 2017), using the CREAM classification scheme (Hollnagel, 1998).

After the simplification on the network, the higher number of combinations to a child node reached was the node 'wrong place', with nineteen parent nodes combinations, considering the possibility of occurring a 'wrong place action' influenced by sixteen factors and three cognitive functions. That means 524,288 combinations, and thus 524,288 probabilities of an action to occur or not.

The prior probabilities of the model were obtained by calculating how many times a specific combination occurred, divided by the total number of accidents of the dataset.

3.5 *Software used*

The accident dataset developed by Moura et al. (2016) has been originally built as a table of zeros and ones, that was uploaded to the BN software.

If the number of combinations was small, an Excel spreadsheet could be used to find the CPT and export to GeNIe software. However, as presented in the previous section, the dataset generated conditional probability tables of 524,288 probabilities for some child nodes. This row (or vector) of data extrapolates Excel software limits, and thus Matlab had to be used. Also, to optimise the data gathering, it was necessary some coding skills to create the Conditional Probability Tables—as 'filtering' the combinations in Excel would consume too much time.

The BN model was built in GeNIe Modeler for academic use (BayesFusion, LLC). The clustering algorithm embedded in the software was used to calculate the posterior probabilities, and the node type used was 'chance—general'.

Useful explanations of how to use the GeNIe software can be found in the manual provided by the developer and also by the authors of an evacuation time analysis of ships using BN (Sarshar et al., 2013).

4 RESULTS

After building the model, inserting the prior probabilities of parent and child nodes (through their

conditional probability tables), the marginal probability distributions were calculated using Genie software, as presented in Table 4:

Although a validation was not yet conducted, the order of magnitude of the HEPs (cognitive functions and erroneous actions) is consistent with HRA directives from the Oil & Gas industry (OGP, 2010), and HRA documents obtained at the website of the Environmental Protection Department of The Government of the Hong Kong (2017). A validation is needed to understand if the model is optimistic or pessimistic, according to validation criteria discribed by Kirwan (1997).

4.1 *Verification step*

To verify if the model behaves according to its specifications, some scenarios were created, changing the factors to its extremes. It means that each parent node was assumed to be 0 and 1 separately. In other words, each factor (organisational, personal and technological) was assumed to be absent or present in an industrial scenario.

To achieve that, after changing the factors, the posterior probabilities of the human performance nodes were calculated, updating the Bayesian network.

4.2 *Sensibility of human performance to each factor*

To infer which factors most influence human performance, the results from the verification process have been used.

When a factor node was set as present in a scenario (state 1 of the node), it was assumed that the variation caused to the posterior probability of a human performance node is the sensibility of this parameter to that change. Note that the parameters are represented by small probabilities, so changes in their marginal probability are also expected to be small. Thus, for better visualisation of the sensibility, the variation in percentage has been calculated.

As can be noticed in Table 5, there is a slight increase in the presence of missed observations when Inadequate Quality Control and Design Failure, both organizational factors, are present in a scenario. Moderated positive variation is also perceived when the technological factors equipment failure and inadequate procedure are present. Interpretation functions (faulty diagnosis, wrong reasoning and decision error) are the most influenced parameters by changes in organisational and technological factors.

Errors in design and equipment failures also increase errors in interpretation functions (mainly in wrong reasoning), but the results show a more accentuated positive variation at interpretation when changes of quality control, task allocation and knowledge (related to training) occurs.

While interpretation has its presence affected by training (knowledge), planning incidence seems to be more related to experience (skills).

Failures in equipment increase the possibility of poor planning in an accident scenario, but not as much as the inadequate quality control and design failure, both organisational factors.

Errors of execution (wrong time, type and place) are triggered by quality control, design failure, task allocation and, with fewer effect, equipment failure.

The results suggest that some factors do not make cognitive functions vary positively, possibly meaning that an error on cognitive functions would not occur with a scenario with errors in factors as maintenance, management, social pressure and irregular working hours.

5 CONCLUSION AND DISCUSSIONS

The Bayesian model proposed was built to serve as a tool to predict human performance in industrial scenarios, i.e. the human failure probability, with the potential to be applied in different sectors such as chemical (including oil & gas processing), nuclear and aviation.

The novelty of the present model is the use of a dataset of major accidents to define the basic aspects of a Bayesian network HRA model: nodes, states, structure and prior probabilities (conditional probability table). The model was developed as one of the objectives to achieve the aim of understanding human performance in the design phase.

Some discussions are developed below in the form of answers to questions proposed for this research.

5.1 *Can this model be used for HRA purposes?*

Not yet. All the steps of the model were executed, apart from the validation. The intention is to

validate the model against data from recent major accident that are not yet covered by the original dataset, to measure if the model describes other real operational data.

In future works, the dataset can be adapted to PSFs of classification schemes from other HRA methods.

5.2 *Is the model able to describe human actions through all the project life cycle?*

Although the verification step suggests the model is capable of inferring which factors most influence human performance, the model still interprets design as a PSF affecting human performance in other stages—and do not consider PSFs affecting designers. In addition, it is believed that some factors may influence design phase in a different way from the prior probability extracted from the dataset of major accidents

Although it is believed that this model cannot describe the design phase, it has the potential to describe changes in design during the operational phase. In fact, that is one of the uncertainties that need to be investigated in the dataset used, as some situations described as a design failure can be attributed to changes in the initial design during latter phases. This can also change part of the prior probabilities considered in this model.

Further development must consider the creation of new PSFs, with new organisational factors that should be considered during design. It seems that expert elicitation will have to be considered phase—as there is few public evidence of this process.

5.3 *Can this model be used to understand decision-makers performance during design?*

The model has the potential to describe front-line and middle managers' routine and emergency performance, during the operational phase. It is expected that it will give a better description of cognitive functions than actions, as a reflection of the decision-makers typical job description.

However, further investigation should be conducted to understand how specific factors affect different people in the organisation, specially for organisational factors for which results suggested that the impact in cognitive function is marginal, such as social pressure and irregular working hours. These factors, for instance, are reported in the literature (Thomas et al., 1999) to affect middle-managers in a different way, compared to sharp-end employees.

The importance of understanding managers' safety performance is part of the present research, as a way of investigating if improving their performance on safety issues has the potential to lead

industries to better organisational factors and fewer accidents. Managers are linked at the same time to top management and operational teams—having the opportunity to sell new ideas to top management and to promote strategic change to employees (Wooldridge et al., 2008; Purcell, 2007).

For this reason, it is recommended that further models consider all factors proposed by CREAM's classification scheme, instead of only using the significant ones according to previous research (Moura et al., 2017). Accounting for factors like 'excessive demand' and 'cognitive style' might give an improved model for managers' roles. With this purpose, different software and algorithms to calculate posterior probabilities have to be tested, to support more links between nodes. Therefore, Cossan (Patelli et al., 2018), a software for Uncertainty Quantification and its Bayesian network toolbox will be tested in the future.

Risk assessment in military transport—human factor in estimation of risk

J. Ryczyński & M. Nowakowska
Tadeusz Kosciuszko Military University of Land Forces, Wroclaw, Poland

ABSTRACT: The article discusses the problems of conducting transport operations in the army. The original contribution of the authors in this field of research lies in the fact, that special attention has been paid to the Human Factor to estimate the risk of transport. Analysis of the impact that Human Factor, has on the risk of the transport depending on cultural aspects. The most important anthropological factors were identified in carrying out a successful military campaign in a culturally different country (Somalia, Iraq, Afghanistan). The authors present the results of pilot studies on the impact of the human factor on risk assessment in the implementation of transport operations in the army. The elements presented in the article are innovative, because the cultural and cultural factors were taken into account, conducting the analysis in the army.

1 INTRODUCTION

The design and implementation of military transport is a multilevel logistic process, aimed at preparing the cargo transport for safe transport along some particular segment of route. Regardless of of the mode of transport used to transport some cargo, opportunities and constraints exist for different modes of transport, so it is necessary to make a detailed analysis of the factors that need to be taken into consideration when planning for safe passage of cargo.

Analyzing the needs of the army, in the field of movement and transportation, specific features of the transport process should be taken into account. The primary feature is its intangible nature, which means that it is not possible to assess the transport process before implementation (Ryczyński and Smal, 2017). Specific features include a simultaneous realization and consumption of the transport service and the variability of quality standards, in particular for the movement of military forces including the mutual interaction between the provider and the recipient. No possibility of transport services congregation forces the user to anticipate the needs of transport in advance for military purposes.

Movement and transportation of troops and weapons systems is an issue arising mainly from the expeditionary nature of the modern armed forces and is associated with the need to movement forces in order to plan for their operational use.

The aim of the displacement of troops is to change the location of personnel, weapons and military equipment and means of supply caused by operational needs, logistics and training (Ryczyński and Smal, 2017).

Part of the military's movement and transportation involves the operation of one of the following subsystems: management, transport and transport networks. Movement and transportation is characterized by unpredictable nature referring to operational needs, the need to preserve the special conditions of caution and the need to prepare the means of transport to carry heavy and oversized and dangerous loads. Military transport is divided into due to its nature and purpose:

Operating, which includes transporting troops and their equipment.

Supply, the carriage of weapons, military equipment, munitions and materials.

Evacuation of unnecessary supply, failures and damaged of weapons as well as military equipment and packaging.

The proper choice of transport means it is one of the most important strategic decisions. This decision, depends on primarily on the operational criteria, the number of personnel provided for transportation, equipment and inventory quantities.

We have to also take into account the geographical location of the destination, distance, redeployment time, the possibility of using point and linear elements of the communication infrastructure and cost.

When planning a military movement and transportation we should be primarily aimed to achieve two functional objectives: ensure the timely

completion of tasks, and minimize costs at an acceptable level of effort.

2 RISK ASSESSMENT IN THE TRANSPORT—LITERATURE REVIEW

Currently, there is no single, unified and commonly used definition of the term of risk (Aven, 2012). We can even say that the basic concepts of risk are difficult to define and even more difficult to estimate (Heckmann et al, 2015).

In recent decades, we have observed that this term is used in many research areas, such as decision theory, management, emergency planning or critical-structure operations, including the efficiency of transport systems (Tubis and Werbińska-Wojciechowska, 2017). Historical trends in the development of the risk concept have been discussed, eg in (Aven, 2012 and Anderson. 1989). An overview of risk perspectives and discussions are provided, e.g. in (Aven, 2012, Aven et al., 2009, Aven and Krohn, 2014, Anderson, 1989). Aven distinguish between two types of approaches to risk analysis: relative frequency based approaches and Bayesian approaches. The first category includes both traditional methods of statistical inference as well as the so-called Frequency probability approach. Depending on the risk analysis method, the purpose of the analysis is different, and the results are presented in different ways.

This type of approach can be characterized as follows (Aven, 2012):

1. Relative frequency-based methods: The risk analysis consists in estimating certain basic probabilities of interpretations or frequencies. Such probabilities express the relative part of the time the event of interest, if the analyzed situation was hypothetically "repeated" an infinite number of times. The basic probabilities are unknown and are estimated in the risk analysis. These estimates are uncertain, because there may be large differences between estimates and valid (real) probabilities.
2. Bayesian methods: Probability is a measure of uncertainty about future events and results (consequences), seen through the eyes of an assessor and based on certain information and knowledge. Probability is a subjective measure of uncertainty.

These concepts are reflected in the literature dealing with the problem of risk estimation in transport processes. To effectively manage any organization (including companies providing transport services), a new concept—Enterprise Risk Management (ERM)—was introduced and promoted. One of the most popular definitions of the concept of corporate risk management (ERM) in literature is the one presented in the COSO II standard. In accordance with the COSO II standard, Enterprise Risk Management is defined as a process carried out by the management staff in order to identify potential events that may affect the reduction of the ability to achieve the entity's goals. According to COSO II, the organization's ERM system should be aimed at achieving the following four objectives:

1. Strategy: high-level goals, aligned with and supporting the organization's mission.
2. Operations: effective and efficient use of the organization's resources.
3. Reporting: reliability of the organization reporting system.
4. Compliance: organizational compliance with applicable laws and regulations.

Proper implementation of the ERM concept also affects the risk assessment processes performed in the selected company. Risk assessment is an indispensable and systematic process that is part of risk management, the purpose of which is to identify, assess risks and plan actions to address risks [34].

Referring to the previously presented definitions and taking into account the perspective of the process, the starting point for the risk assessment should be the identification of hazards that may cause the failure to achieve the goals of providing transport services. The holistic approach assumes that the area of analysis will cover various levels of the implemented process, eg technical elements, Human Factor as well as legal and organizational issues (Tubis and Werbińska-Wojciechowska, 2017). Risk assessment should be preceded by a process analysis that identifies potential adverse events. Risk assessment is usually only carried out at specific time points. Correct identification of the largest number of disturbing factors is the basis for a correct risk assessment.

3 RISK ASSESSMENT IN TRANSPORT DURING MILITARY OPERATIONS

The proposed methodology risk assessment in the transport of oversized loads consists of several stages (Fig. 1). The first step is, to diagnose the potential risk that accompanies transport, e.g. oversized loads. The next step is data collection and risk assessment. The diagnosis is necessary to determine the causes, factors that may cause difficulties in transport (Ryczyński and Smal, 2017). Evaluation of the results helps to choose a strategy for reducing the number of factors affecting the various types of risk and limit its negative impact. One of the most important element risk assess-

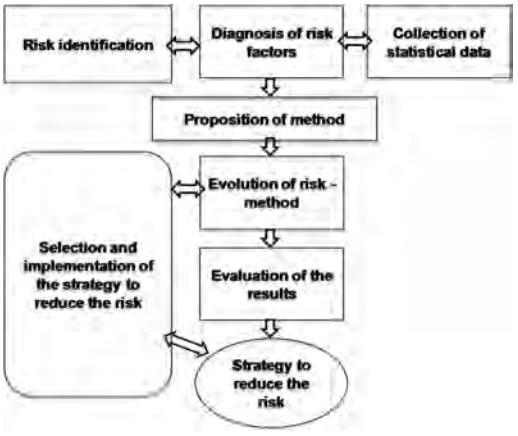

Figure 1. Methodology of risk assessment in military transport.

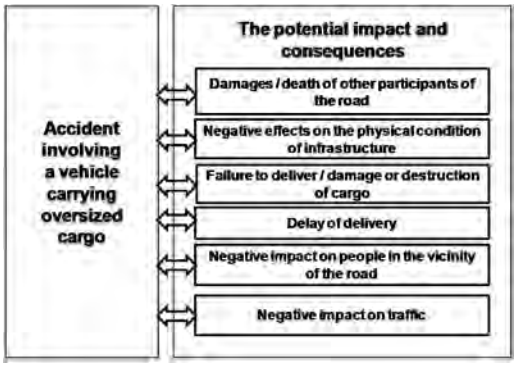

Figure 2. Dependence: accidents – potential consequences.

ment for the transport of oversized loads is the calculation of the probability of an accident.

Transportation of heavy oversized loads may have a negative impact on the infrastructure and the organization of traffic and generate, e.g.: the delay, damage to roads, damaged buildings located on the route of travel and the danger to other road users. To minimize the risk of an accident involving other vehicles to transport non-normative, it may be introduced ban on movement of other traffic on a particular stretch of road or along the entire length of the route. The diagram below shows the possible impact and the consequences of the traffic accident involving a vehicle carrying oversized loads (Fig. 2). The occurrence of an accident on the road can also affect vehicles normative.

Often the cause of the accident is incorrect actions of other road users, not adapted to the conditions prevailing on the road, the wrong choice of means of transport or incorrect load securing.

When modeling the risk for the oversized loads, the following data are used:

1. On the motorway network, including their physical characteristics.
2. On accidents involving heavy vehicles, including the frequency and severity of accidents.
3. On the flow of traffic.
4. On the loads, goods together with their characteristics.

These spatial data can be presented in GIS format. Information on highways, vehicles, accidents, traffic flow are readily available from various transport agencies. However, data on the transported loads, goods make bigger problem. Most of the available data in this area is insufficient to achieve the desired level of accuracy of risk assessment.

In practice, there are methods spreadsheet, which you can use to assess the degree of risk undertaken in the project. The classic model of risk calculation is as follows:

$$R = p \cdot C \tag{1}$$

where:

R – risk,

p – the probability of an accident,

C – the consequences of the accident.

The probability of an accident is dependent on many factors: the volume of traffic, time of transport operation (day or night), load of the vehicle, transport distance, the parameters of roads, road surface conditions, time of year, weather conditions, visibility, etc. The risk assessment process (Fig. 3) may contain more factors and deriving your situation, the consequences of the accident—but this is dependent on the availability of data on accidents.

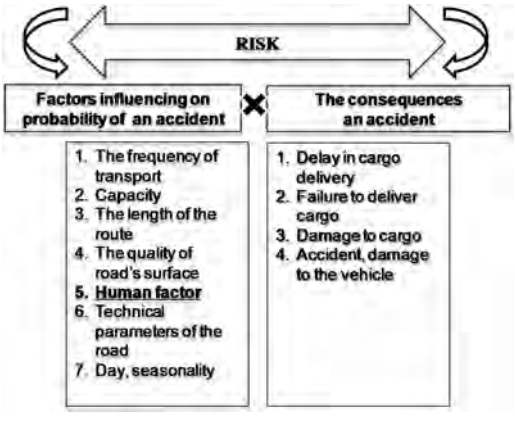

Figure 3. Risk assessment in transport: factors × consequences.

4 HUMAN FACTOR IN RISK ASSESSMENT

As shown in Figure 3, one of the most important element, is the Human Factor which affect the magnitude of risk in military transport. Based on expert research, the authors have determined that the Human Factor is more important during the realization of transport plans than, for example, the technical parameters of the roads during transportation.

A particularly important issue appears in matters of security and risk assessment related to the conduct of military activities. This is confirmed by the words of David Kilcullen (Killucen, 2010), an Australian anthropologist who has been developing new strategies for warfare for many years, including the use of cultural knowledge. Kilcullen claims that "knowing and understanding a foreign culture is a prerequisite for victory over an opponent".

What exactly is the Human Factor and how is it defined? We can define Human Factor as understanding human performance within a given system: trust, fear, decision-making, stress are crucial in so-called "golden hour" (Helsloot et al., 2004).

In industry, the Human Factor (also known as ergonomics) mean the study of how humans behave physically and psychologically in relation to particular environments, products, or services. Many large manufacturing companies have a Human Factors department or hire a consulting firm to study how any major new product would be accepted by the users in its design. A Human Factors specialist typically has an advanced academic degree in psychology or anthropology or has special training. The term usability is now sometimes used as an alternative to Human Factors like human error or human resource.

Today there are 2 different views on Human Factor as a cause of failure. The so-called "old view" means:

– human error is the cause of most accidents;
– the engineered systems in which people work are made to be basically safe;
– progress on safety can be made by protecting these systems from the unreliable human through selection, procedures, automation, training and discipline.

The other "new view" sees human error not as a case but as a symptom of failure:

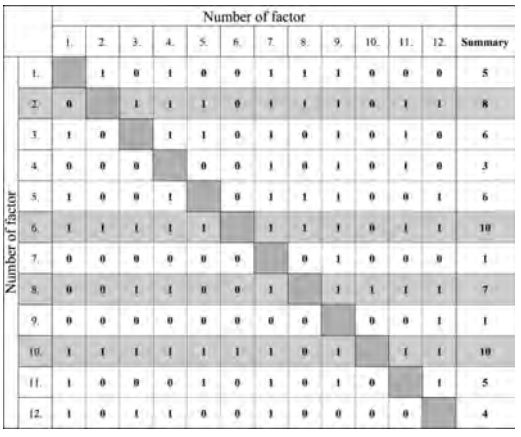
– human error is a symptom of a trouble deeper inside the system;
– safety is not inherent in the systems—people have to create safety;
– human error is systematically connected to features of people tools, tasks and operating environment.

Progress on safety comes from understanding and influencing these connections (Gambetti et al, 2012).

The Human Factor is very difficult to measure. Other component factors will be dominant in the determination of the Human Factor in the army and others in the case of testing according to the same methods in the civilian industry. Based on their own experience and using the knowledge of experts who deal with the problem of transport organization on a daily basis, the authors of the article have listed the 12 most important factors affecting the so-called Human Factor:

1. lack of communication – errors and disruptions in the information flow;
2. routine – certainty resulting from long-term practice combined with the loss of awareness of existing threats, caused by often repetitive activities and tedious work;
3. lack of knowledge – lack of clarity or certainty of understanding something, lack of language skills;
4. distraction – caused by distraction, confusion, mental chaos;
5. lack of cooperation in the team – inconsistent effort of a group of people caused by lack of a sense of community of purpose, fear of pointing management to mistakes made by others, inappropriate style of leadership or inappropriate communication;
6. fatigue – it is ignored, because until it is excessive, people do not realize it;
7. lack of resources – lack of tools, materials, outdated documentation, improper working conditions;
8. pressure – caused by the pressure of superiors or colleagues, lack of time, improper setting of tasks;
9. lack of assertiveness – lack of ability to refuse to perform a task resulting from lack of self-confidence, anxiety or complexes;
10. stress – nervousness caused by eg: time pressure, new methodology, change in the scope of tasks, competition or private factors;
11. carelessness – incorrect assessment of possible consequences of action caused by eg: pressure, lack of experience or lack of knowledge;
12. comfort (deviation) – acceptance by most people of deviations from the instructions as standards facilitating work.

The aim of the research was to indicate those factors that are dominant in the case of success or failure to complete the task. The described 12 factors were presented to a group of 35 military drivers (participants of foreign missions) and were asked to choose the most important factors. The comparison took place in such a way that participants



Number of factor	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.	Summary
1.		1	0	1	0	0	1	1	1	0	0	0	5
2.	0		1	1	1	0	1	1	1	0	1	1	8
3.	1	0		1	1	0	1	0	1	0	1	0	6
4.	0	0	0		0	0	1	0	1	0	1	0	3
5.	1	0	0	1		0	1	1	1	0	0	1	6
6.	1	1	1	1	1		1	1	1	0	1	1	10
7.	0	0	0	0	0	0		0	1	0	0	0	1
8.	0	0	1	1	0	0	1		1	1	1	1	7
9.	0	0	0	0	0	0	0	0		0	0	1	1
10.	1	1	1	1	1	1	1	0	1		1	1	10
11.	1	0	0	0	1	0	1	0	1	0		1	5
12.	1	0	1	1	0	0	1	0	0	0	0		4

Figure 4. Result of research influence of chosen factors for success of complete the task.

compared all 12 factors with each other. The more important factor was rating 1 – a factor less important in a given pair – 0. The maximum value that a single indicator could have obtained was 11 points. Obtained results of tests are presented in Figure 4.

The studies carried out have shown that fatigue (10 points), stress (10 points), routine (8 points) and pressure (7 points) are of the greatest importance for success or failure in the implementation of the task. The least important was the lack of resources and the lack of assertiveness. It has been assumed that the lack of assertiveness will be the least important factor, because the army is a hierarchy institution and the soldiers carry out orders.

It should be noted that the presented results were made on a small research sample—the results of pilot studies. Currently, research is conducted on groups of 200 people, both civilian and military drivers. The completion of the research will allow for a more complete identification of the most important elements of the Human Factor in the process of estimating transport risk.

5 CULTURE ASPECTS OF HUMAN FACTOR

The research conducted by the authors allow to conclude that all available definitions completely omit the influence of cultural aspects on the success of the performance or non-performance of the task. The authors of the article, as participants of military foreign operations, observed this phenomenon during the mission in Iraq and Afghanistan.

The biggest problem in the course of military expeditionary operations in foreign countries is the mentality problems of the local population. The standard of behavior is a deliberate action consisting in violating applicable procedures, instructions, requirements or regulations. There is social acceptance for this type of behavior and they are not treated as an offense.

As one of the most representative example of the cultural aspect on the Human Factor, the Restore Hope operation in Somalia, can be mentioned. It was planned as a military and humanitarian mission under the auspices of the United Nations and was meant to provide transport services—providing food to the starving population of Somalia. One of the biggest problems of the mission in Somalia was a different understanding of the culture of this country by military components of individual countries, and thus different ways to accomplish mission objectives. Lack of understanding of the culture and history of Somalia was also characteristic of the United Nations, which worked on the assumptions of the mission. In particular, the clan system and the decentral nature of traditional political institutions in Somalia were not understood, which was manifested in the pressure on the UN that a particular clan would rule over the entire country. Such behavior, degrading the importance of the leaders of other clans, caused their reluctance to peace forces.

It should be emphasized that cultural problems were not only related to the relations between UNOSOM and Somali troops. Cultural differences influenced the effectiveness of UN force management and control. For example, soldiers of the Italian and French contingents ostentatiously ignored the orders of the Pakistani commander by following only the instructions coming from their own countries.

Based on the experience of foreign missions, the world's largest armies attach great importance to the issue of cultural differences.

Today, the American standard is *Operational Culture for the Warfighter and Applications for Operational Culture. Perspectives from the Field, as well as Through the Lens of Cultural Awareness: a Primer for US Armed Forces Deploying is Arab and Middle East Countries*. In January 2013 was published doctrinal document of the British forces JDN3/11 Decision Making and Problem Solving: Human and Organizational Factors. The document is devoted to the impact of a culturally conditioned Human Factor on the functioning of organizations such as the military, as well as on the ways of thinking and acting during various crises and military operations.

According to the mentioned documents, the culture can be "purchased" and not "biologically inherited" in the process of enculturation. It distinguishes members of one group from another and

is a lens through which members of a given group perceive and understand the world. Documents emphasize the importance of culture and man for the army "culture is part of a wider context in which military operations and everyday relations take place. Ignoring the importance of culture increases the risk of failure of a given company or mission and creates barriers to effective interaction. Developed cultural ability reduces these risks and creates: new opportunities that can contribute to the enemy's failure or success in negotiating with him; a better understanding of local communities and the foundations of a given conflict; fruitful cooperation with allies. (...) Understanding the value of culture in the whole spectrum of operations and military processes will result in increased situational awareness, better preparation of combat forces, better protection of forces and more effective tactical preparation. Culture is particularly important for security and stability where the human dimension is crucial".

In research on the Human Factor, the concept of intercultural awareness often appears—which is supposed to facilitate the functioning of culturally alien areas. An example is, the *Human Terrain System* (*HTS*), a new system of gaining knowledge about people and culture—operations in Iraq and Afghanistan revealed that the US army has no doctrine corresponding to the reality of operations. HTS operates on the basis of Human Terrain Teams, consisting of military, anthropologists, sociologists and linguists. Each team is recruited and trained to work in a specific region, where a military unit works, which the team is supposed to support. The system was criticized at the beginning of the 21st century as unethical from the point of view of anthropological research. However, the words of General David Petraeus are still quoted, saying that "knowledge of the culture of a given area can be just as important, and sometimes even more important, as knowledge of the geography of a given area. This observation is to draw attention to the fact that people's knowledge is, in many respects, a decisive factor, and that we must study the culture of a given area with the same attention we have so far devoted to the geography of the area" (Petraeus, 2006).

6 SUMMARY

When carrying out military transports, in addition to the behavior tests of drivers, it is necessary to create procedures according to which the organization of the entire transport system is to be organized. This system should be adapted to a specific cultural region. It must refer to all aspects of transport in which a human play role: communication, updated technical documentation or organization of teamwork. Components that need to be tested are:

1. defined main participants involved in transport, including the main coordinator responsible for the organization;
2. systematic characterization of the transport system of a given region and the socio-economic situation of the state from the residents' perspective;
3. indication of activities undertaken by residents and entities involved in the procedure;
4. examining the limitations, challenges and human potential in the region's transport system.

The conducted research shows communication problems at the local level, as well as problems with the lack of appropriate tools, lack of knowledge of customs, including stressful and motivating factors. Cultural research is proving necessary to understand the cultural environment of the planned transport operation. They also indicate the necessity of synergic cooperation between the army and the inhabitants, the government administration, and, in the case of missions, also non-governmental organizations. The aim of such action is to minimize and eliminate negative effects

ABSTRACT: Human factors present one of the essential contributors to maritime accidents, and seafarers' emotion is sensitive to working environment and information inaccessibility. The data collected from 11 experienced seafarers' Self-Assessment Manikin (SAM) questionnaires, is analysed to investigate the impact of their emotions during watch-keeping in a bridge simulator. SAM scale rating questionnaires are received separately after two sections, emotion calibration and recognition. The emotion is induced and identified in the calibration section. In the recognition, emotion is self-rated after the crew-qualified test and the Support Vector Machine (SVM) model is used for classification. The results indicate that SVM can effectively identify the emotions with a precision of 72.73%. Seafarers' emotion in maritime operations affects their behaviour and decision-making. The overall positive emotion identified by SAM rating does not mean positive effect on sailing, while negative emotion identified by SAM rating does not lead to negative behaviour.

1 INTRODUCTION

Nowadays, more than three-quarters of the world trade cargoes in terms of volume are accomplished by shipping (Grech et al., 2008). Shipping contributes to the increase of awareness on transport safety in maritime. Surveys (Ren et al., 2008) show that 75–96% of maritime accidents are fully or partially caused by human and organisational errors. There has been an overwhelming understanding since 1993 when the USCG reported that human errors had been the essential cause of approximately 80% of maritime accidents and near misses over the past decades (Grech et al., 2008). Moreover, out of nearly 62% of pollution and maritime accidents over the past years (Er and Celik, 2005), human factors result in 30% of deck officer error, 7% of shore-based personnel error, 2% of engine officer error, 8% of pilot error. It reveals that human factors are not the direct cause of the accident, but they are the beginning of a considerable incident or catastrophe by trigging following chain events.

In this regard, it is meaningful to investigate human factors in ship bridge as it is closer to the root causes of maritime accidents. One of the earliest initiatives was fired up by accidents caused by a typical radar-assisted collision (Grech et al., 2008). In 1956, the collision between the two passenger ships Andrea Doria and the Stockholm was one example. The root causes of the accident were related to the ship bridge. It is demonstrated that much attention should be paid to human factors and the bridge. Consequently, it causes some interest in the area of bridge design and cognition, both in Europe and the United States. Nowadays, the bridge has become more automated. Automation is often highlighted because it has been overwhelmingly understood that it would reduce the involvement of crew, so far as to reduce human workload and human errors, and increase efficiency. However, as demonstrated by the grounding of Royal Majesty (the Panamanian passenger ship grounded on Rose and Crown Shoal about 10 miles east of Nantucket Island, Massachusetts on June 10, 1995) as well as evidenced by other research results (Lutzhoft and Dekker, 2002), automation has a prospecting expectation of human work and safety, which cannot simply replace human work thoroughly. Fewer crew numbers do not lead to less workload. There exists increased mental workload affecting situation awareness (Aguiar et al., 2015). In this regard, automation in the bridge creates new error pathways, especially resulting from human errors, deficiencies in mission shifts, and postpone

chances to correct errors in the system further into the future. It is noteworthy that the bridge plays an essential role in the success and failure of navigation, as well as human errors research.

In the amendments of Seafarers' Training, Certification and Watchkeeping (STCW) Code in 1995, human error was classified in three major taxonomies. They are operational-based, management-based, and the combination of the two. For quantitative assessment of shipping accidents, Celik and Cebi (2009) generated a Human Factors Analysis and Classification System (HFACS) based on a Fuzzy Analytical Hierarchy Process (FAHP), to identify human errors in shipping accidents. In line with the HFACS, as well as Reason's Swiss Cheese Model and Hawkins' SHEL model, Chen et al. (2013) proposed HFACS for a Maritime Accidents (HFACS-MA) model to measure the Human and Organisational Factors (HOFs). Soner et al. (2015) combined Fuzzy Cognitive Mapping (FCM) and HFACS to generate a proactive model in fire prevention modelling onboard ships. Chauvin et al. (2013) found that most collisions were due to decision errors by a modified HFACS model in collisions reported by the Marine Accident and Investigation Branch (UK) and the Transportation Safety Board (Canada). Meanwhile, the accidents were also associated with poor visibility and evidence deficiencies of the socio-technical system (technical environment, the condition of operators, leadership level, and organisational level) (Chauvin et al., 2013). In that way, cognition and error in accidents attract research attention as well.

Quite a number of studies exist on human reliability to define human performance in accidents and estimate human failure probabilities (Yang et al., 2013, Yoshimura et al., 2015, Yang and Wang, 2012). Akyuz and Celik (2015) adopted Cognitive Reliability and Error Analysis Method (CREAM) to assess human reliability along with the cargo loading process, and Akhtar and Utne (2015) used it to study common patterns of interlinked fatigue factors. It was illustrated that "inattention", "inadequate procedures", "observation missed", and "communication failure" were related to fatigue factors that influenced the human cognitive processes in accidents. The bridge team should be trained to recognise fatigue and exercise caution related to the fatigue factors. Moreover, Hetherington et al. (2006) divided human factors into fatigue, stress, health, situation awareness, teamwork, decision-making, communication, automation, and safety cultural diversity.

Among them, the emotion factor of the crew is vulnerable to working space, inaccessible information sources, and communication. Their negative emotions are mainly related to irritability, tension, instability, depression, and burnout with periodic changes. From this perspective, Liu et al. (2016b) proposed an EEG (Electroencephalogram) system in bridge simulation to monitor officers' workload and pressure. It was one of the earliest studies on seafarer's psychological response using bridge simulators. However, the relation with psychological response and seafarers' performance was not demonstrated. For quantification of the crew emotion, this system also took into account monitoring emotion, emotional stress, and environmental stress (Liu et al., 2016a). It identified the emotion of cadets in the bridge simulator supervised by EEG, but not related to human errors neither. Geethanjali et al. (2017) detected and recognised the human emotion using Self-Assessment Manikin (SAM) rating. The statistical analysis revealed the emotion identification differences between several groups. Moreover, other studies on angry driving in road transportation(Yan et al., 2015, Wan et al., 2016, Yan et al., 2014, Zhang et al., 2014) have been conducted to find the emotional connection between humans and the safety. Hence, seafarers' emotion identification should be further studied by better incorporating psychological knowledge.

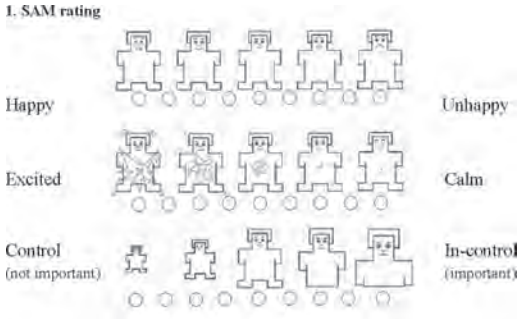
This study is conducted to identify the emotion in the bridge by SAM rating questionnaires, and classify the emotion in a Support Vector Machine model by use of bridge simulators. It would benefit the crew training aiming at navigational safety and improve the watch-keeping while sailing. The remainder of paper is organized as follows: In Section 2, the methodologies of this study are described, including SAM and SVM methods. The experiment design and procedures are illustrated in Section 3. The result and discussion are presented in Section 4. Finally, the conclusion is given in Section 5.

2 METHODOLOGY

2.1 *Self-Assessment Manikin (SAM)*

In this paper, the nine-point scale in Self-Assessment Manikin (SAM) (Bradley and Lang, 1994) (Bradley and Lang, 2007) is used to describe pleasure, arousal, and dominance in response to the stimuli. Figure 1 shows the questionnaire that the test subjects need to complete after the experiments, reflecting on their subjective feelings during the assessment.

The scoring measures the pleasure, arousal, and dominance associated with the stimuli. The first SAM scale is the happy/unhappy scale, which ranges from a smile to a frown. The second scale is the excited/calm scale, which ranges from left to right. The last dimension is the controlled/In-control dimension. The left end of the scale represents



2. Word rating

Joyful	Surprised	Satisfied	Protected
Angry	Fear	Unconcerned	Sad
Or give your own descriptive word:			

Figure 1. The questionnaire of emotion with SAM scale on a nine-point rating (Liu et al., 2016a).

the feeling of completely controlled and influenced. The right end of the scale is the feeling of completely controlling, important, and dominant.

The SAM methodology reveals the specific feature of a test subject's certain emotion, as the emotion is a subjective variable. This method quantifies the emotion in specific time and condition. The experiment is recorded by the audio for each test subject. After the qualified test, comments on the performance of seafarers from the experts is recorded by audio, and the test subjects are given a result of pass or not pass.

2.2 *Support Vector Machine (SVM)*

In this study, there are two sorts of emotion categories: positive emotion and negative emotion. The Support Vector Machine (SVM) is used to identify the emotion category for the tested seafarers. SVM is a supervised learning model with associated learning algorithms that analyse data used for classification and regression analysis. As shown in Figure 2, there are two kinds of sets, type "•" and type "▲". The SVM method finds an optimised hyperplane (e.g. a line defined by "w", "b"), calculating the w and b to maximise the margin while still separating the points (primal form). C is a cost function, which is $C = \max\left(0, 1 - y_i(\vec{w} \cdot \vec{x}_i - b)\right)$ (For data on the wrong side of the margin, C is proportional to the distance from the margin), $i=1,2,\ldots,l$, ξ_i is the smallest non-negative number satisfying $y_i(w \cdot x_i - b) \geq 1 - \xi_i$.

$$\min \frac{1}{l} \sum_{i=1}^{1} \xi_i + C\|w\|^2 \tag{1}$$

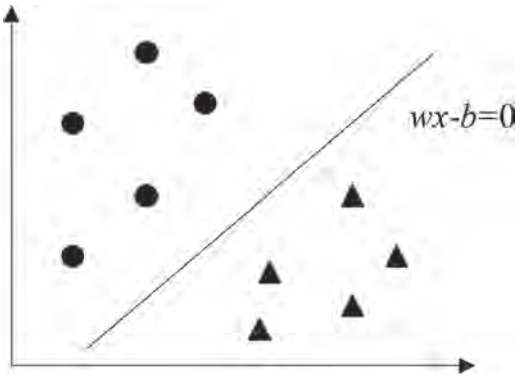


Figure 2. The support vector machine theory.

$$\text{s.t} \begin{cases} y_i(w \cdot x_i - b) \geq 1 - \xi_i \; i = 1,2,\cdots,l \\ \xi_i > 0 \end{cases} \tag{2}$$

In this study, these points are described in three dimensions illustrated in SAM as pleasure, arousal, and dominance. As the emotion is a subjective variable, the SVM uses the feature of a certain emotion in calibration to generate the classifier. Using the classifier training by SVM, emotion in the qualified test of seafarers is identified by the three-dimensional description questionnaire. Specifically, a $33 \cdot 3$ matrix is generated as input, among which "33" represents "$11 \cdot 3$" questionnaires, "3" defines three types of emotion dimensions. In addition, the output is a $33 \cdot 1$ matrix. The group of first 22 samples is the training set while the group of last 11 samples is the test set. After normalisation, the optimal parameters in the SVM is searched by cross-validation. The kernel function of the model is calculated. The result of identification of emotion taxonomy can be calculated.

3 EXPERIMENT

3.1 *Test subject selection*

Seafarers from different companies who were taking the captain and first officer qualification examinations were recruited to be involved in this study. There were 11 exams scheduled in two days. Each exam tested one participant who acted as a captain in a four-person exam group. All subjects were in good health without head injuries. They have 7.7 years of experience at sea on average, as they present a common emotional response during sailing when compared to beginners or cadets. The test subjects range from 26–38 years old, with

the average of 31.9 years old. They are all males. These seafarers attended these experiments as volunteers. The last also demonstrates that they could quit the experiments whenever they changed their minds. Based on this agreement, the calibration part of this study was conducted before the crew-qualified exam, and the test part was carried out after the whole exam. The test subjects were in bridge simulator room, while the staffs were in control room providing scenarios to subjects (Figure 3a, 3b).

3.2 *Stimuli selection*

The role of "captain" in four seafarers during the exam was selected as an independent sample. The rating of their perceived emotion for each stimulus presented uses a SAM scale. In view of this, IADS database was used as the stimulus with two categories (pleasant and unpleasant). It was presented for the first time, and all the test subjects in this study were not aware of the clips prior to the experiment.

(a) Test subjects in simulator room

(b) Staff in control room

Figure 3. The test subjects and staffs in control room.

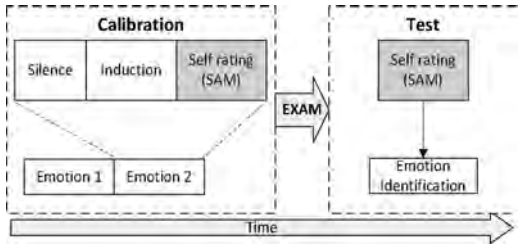

Figure 4. Experimental protocol.

3.3 *Experimental protocol*

The experiment was conducted by SAM scale rating questionnaires received separately after two sections, which are emotion calibration and recognition respectively. In calibration, two types of emotions were induced by the International Affective Digitized Sounds (IADS) methodology, developed by the National Institute of Mental Health Center for the Study of Human Emotion. Every test subject was given by listing to sound clips from IADS with eyes closed in case of blink interrupts. In the calibration part, emotion 1 began with 5 seconds silence to calm down, and 10 seconds for one category of emotion stimulus, and then the SAM rating was carried out. After that, another category of emotion 2 repeated. This section aimed to calibrate emotion for each subject. In other words, the specific feature or standard of personal emotion type was obtained.

In the test part, the subjects filled the questionnaires after at least 30 minutes' exam in the bridge simulator. Figure 4 demonstrates the process of the experiment.

3.4 *Statistical analysis*

As the subjective rating for the emotion questionnaire was not normally distributed, the nonparametric test is conducted. The sound clips of the IADS database are considered as independent variables; the pleasure, arousal, and dominance are considered as dependent variables. The correlation between valance and dominance within subjects is calculated using Spearman's correlation (Geethanjali et al., 2017).

4 RESULT AND DISCUSSION

4.1 *Descriptive statistics*

This study collects 22 (11×2) calibration questionnaires and 11 test questionnaires reflecting 11 seafarers' emotions. Table 1 demonstrates descriptive statistics for seafarers in this research, while Table 2

reveals the statistics in the IADS (2nd edition) database. There is correlation coefficient below in Table 3, and the correlation is significant at the 0.01 level. The clip sounds 105 represents negative emotion, while 220 represents positive emotion in this study. The letter "p", "a", and "d" represent "pleasure", "arousal", "dominance" respectively, and "t" means test emotion. The majority of the mean value of this study is approximately coincidental with the mean value of the IADS, except for the pleasure dimension in negative emotion. The distinction is also revealed in the questionnaires. Notes state that some of them do not make sense of the meaning of the first clip. Therefore, the neutral feeling with rating 5 is given by them.

4.2 *Emotion identification*

After collecting the emotion data from seafarers by SAM questionnaires, SVM is used to identify the emotion category during watch-keeping. Overall, 11 samples consist of 33 × 3 matrix of emotion description, and 33 × 1 matrix of emotion labels. The former 22 pieces are from the calibration part as a training set for SVM, and the later 11 pieces are from the test part as a test set. From these perspectives, the SVM model is proposed to find a hyperplane that divides the test set into two kinds of emotion categories. Figure 5 is the result of the test classification with the accuracy of 72.73%, where "1" represents negative emotion, and "2" means positive emotion. The kernel function of this model is calculated in the way that "$-t = 2$" represents kernel type is radial basis function: $\exp(-\gamma^*|x\text{-}x'|^2)$; "$-c$ = 776.0469" represents cost parameter C; "–g = 0.0068012" represents γ in kernel function.

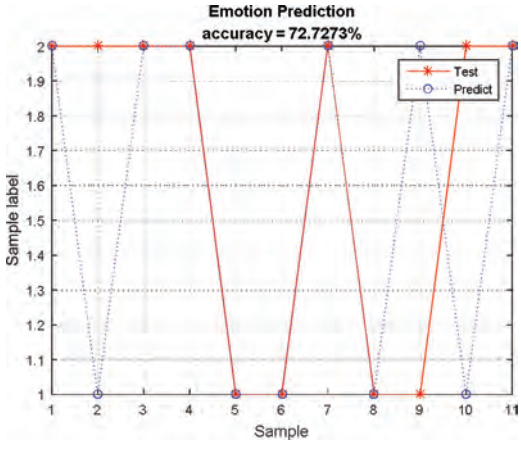

Figure 5. Emotion identification by using the SVM: Accuracy = 95.4545% (21/22) (training); Accuracy = 72.73% (8/11) (test).

Negative	1.000	–0.210	0.043
Positive	1.000	0.321	–0.068
Test	1.000	–0.480	–0.742

The emotion identifications by questionnaire from test subject and the SVM methodology are presented in Table 4, where "P" represents positive and "N" represents negative. More specifically, the self-rating emotions of subject 2 and 10 are positive emotions but were predicted as negative emotions. The self-rating emotion of subject 9 is negative while it was predicted as positive. All the others have the same results between self-rating and SVM.

4.3 *Human performance*

The comments on the examination for each test subject are further analysed to investigate if negative emotion identified by SAM scale questionnaire affects human errors and human performance. Meanwhile, the comments from experts as an inevitable process of the qualified exam are collected by audios. This part took place after the

Table 4. Comments from self-evaluation and third party.

ID	Emotion		Self-evaluation	Third party
	SR	SVM		
1	P	P	Untimely watch keeping in poor visibility Wrong operation sequence	Operate in incorrect sequence when stopping
			Too late to realise poor visibility	Unconcerned watch keeping
2	P	N	Speed control problem Inaccurate report in time	
			Anxious when collision	Not fulfil the Convention on the International
3	P	P	Wrong decision making (collision at ship body instead of bow)	Regulations for Preventing Collisions at Sea (COLREGs)
			Tension during ship encounter	Mistake sail with the current for sail against the current
4	P	P	Response too late Unfamiliar with navigation device	Not fulfil COLREGs Too panic when strand
			Speed control problem	Wrong decision making of the captain
5	N	N	Not enough communication Not stop timely	Manoeuvring inappropriate
6	N	N	Speed control problem Course deviation	Not enough communication Not enough cooperation not enough
			Late report in emergency	Wrong manoeuvring
7	P	P	Unconcerned Inappropriate manoeuvring	Too high speed Course deviation
8	N	N	Not familiar with rudder failure	Slow speed affect steering Failure to meet a contingency
9	N	P	Not switch on navigation lights when starting fog	Not on-time watch keeping Too large deflection angle
			Unfamiliar with navigation environment	Unfamiliar with navigation device
10	P	N	Not report the collision on time	Ignore environment when reporting Failed to fulfil COLREGs
11	P	P	Anxious when getting hurt	Speed control problem Irregular language

whole sessions, beginning with summarised comments from self-evaluation and third party, and ending in experts' comments.

According to the self-evaluation from the subjects and expert comments after the qualification exam, it is common to demonstrate that the human emotion emerging during watch-keeping affects ship manoeuvring, concentration, response to an emergency, and decision-making.

For example, test subject 1 was not able to concentrate on watch-keeping in poor visibility when sailing, which made him incapable of observing the crew onboard falling into the water. Moreover, a further step to eliminate the hazards they encountered was to stop in accurate and timely operation sequence. The test subjects 2 and 7 had the same result as unconcerned when encountering collision scenarios in poor visibility, resulting in a delayed report and operational problem. As a result, subject 2 reported inaccurately in collision scenario and subject 7 had course deviation. There was obvious anxiety when collision occurred as subject 3 demonstrated, causing not fulfilling COLREGs (International Regulations for Preventing Collisions at Sea). Subject 11 just became anxious when the crew got hurt, causing the irregular use of language and inappropriate manoeuvring. Subject 4 had tension emotion when the encounter happened and panic emotion during strand, which caused several mistakes, as shown in Table 4. In addition, subjects 4 and 10 had physiological problems because they were unfamiliar with the device. They were not fulfilling COLREGs.

From the above emotion problems existing in test subjects 1, 2, 3, 4, 7, 10, 11, all of them rated overall positive emotion after the sessions. However, the subjects who rated a negative emotion did not reveal apparent emotion interruption on performance. From this perspective, overall positive emotion identified by SAM rating does not mean positive effect on the sailing, while negative emotion identified by SAM rating does not lead to negative behaviour. Emotion rating through subjective judgement presents the overall feeling after the examination, whereas human errors occur at certain instant point. They are not matched well.

Moreover, the subjects may hide or ignore their true feelings when the mission is well done, and the questionnaires filled after the examination depend more on the result of the scenario completion than the process.

5 CONCLUSION

Seafarers' emotion exists when sailing. It emerges during watch-keeping and could jeopardise the performance and decision-making of seafarers. When an emergency happens, there are requests for the timely report and accurate operation on ships. This study utilised SAM rating scales of 11 test subjects to establish a classification model. The training model is studied by SVM classifier with an accuracy rate at 72.73%. The results concerning officers' emotion in a bridge simulator test reveal that seafarers' emotion in maritime operations affects their behaviour, as well as the possibility of errors in decision-making. In addition, there is no strong correlation between emotion modes identified and behavioural consequences. The overall positive emotion identified by SAM rating does not mean positive effect on sailing, while negative emotion identified by SAM rating does not lead to negative behaviour.

This study does not reveal the accurate in-time response, as the rating is done after the examination. Moreover, some seafarers may hide or ignore their true feelings in the questionnaire after the exam if emergency problems are solved properly in scenarios. Thus, the relations between emotion and human errors are complex, and need to be further analysed according to the real-time physiological responses.

Seafarers tend to be in vulnerable possession when manoeuvring in bridge simulator. Conducting the psychophysiology research in bridge simulator is a meaningful study on human factors or human errors in maritime operations. In addition, the bridge simulation benefits researches on human factors, especially for crew training requirement. From these perspectives, further studies will involve psychophysiological methods to measure seafarers' state and performance in real-time bridge simulation.

ACKNOWLEDGEMENTS

The research was supported by the National Science Foundation of China (NSFC) under grant No. 51609194, the National Key Technologies Research & Development Program (2017YFC080490, 2017 YFC0804904), the Fundamental Research Funds for the Central Universities (WUT: 2017IVA102, 2017IVB049, 2017IVB074), and the EU project RESET (H2020-MSCA-RISE-2016, 730888). The authors would like to thank the University of Florida for sharing the IADS database. The authors also appreciate the support of China MSA, the Bridge Simulator centre in Wuhan University of Technology, and all bridge officers participated in this experiment.

ABSTRACT: Recently, numerous organizations have made progress in developing autonomous ships, motivated by, among other factors, the potential for increased safety. This applies especially to accidents involving human error, as autonomous ships would remove operator role from all or most operations. The reality is that although the human role is reduced, autonomous ships would still rely on operators for supervision, remote control, and involvement in case of a glitch or an unexpected situation. Thus, autonomous ships do not fully eliminate the possibility of human error. In this study, we assess the potential for human error in autonomous ship operations. We analyze an unmanned autonomous ship operation, and through a generic analysis of the interaction between operators working a Shore Control Centre (SCC) and system, we identify possible Human Failure Events (HFE). This provide a starting point for performing human reliability analysis of autonomous ships operation.

1 INTRODUCTION

Important projects have drawn attention to autonomous ships in recent years. The so-called MUNIN (Maritime Unmanned Ships through Intelligence in Network) is currently establishing a concept for an unmanned merchant ship. AAWA (Advanced Autonomous Waterborne Applications Initiative), in turn, investigates challenges in different scientific fields related to autonomous shipping operations (Laurinen, 2016). A third example is the DNV GL ReVolt project, which is a concept developed by DNV GL for an unmanned, zero-emission, shortsea vessel.

One of the motivations for using autonomous ships—common to all autonomous systems in general, concerns the potential for increased safety and reliability. Human error accounts for an important root cause or contributing factor of accidents in a diversity of industries and activities, e.g. 70 to 80% in aviation (Wiegmann and Shappell, 2012), over 80% in chemical and petrochemical industries (Kariuki and Löwe, 2007), over 90% in road traffic accidents (Treat et al., 1979). The maritime activity does not differ from those: the European Maritime Safety Agency points to human error as the triggering factor in 62% of incidents with EU registered ships from 2011 to 2016 (EMSA, 2014). Moreover, statistics on fatal accidents have ascertained that work on deck, for example mooring operations, is 5 to 16 times more dangerous than jobs ashore (Blanke, Henrique and Bang, 2017). Therefore, putting the human operator aside for all (or most part of) operation tasks is believed to avoid accidents (Laurinen, 2016). However, as highlighted by Rødseth and Tjora (2014), human error can still occur in autonomous ships operation.

Current projects on autonomous ships have different views on how they should operate in terms of crew onboard and autonomy level. The Munin project calls for a ship that would be unmanned only on the deep-sea part of the voyage, with a crew onboard for the departure from and approach to port. When unmanned, the ship would be autonomous, but monitored by operators in a Shore Control Center who can take over control of the ship in certain situations. The AAWA project, on the other hand, works with the concept of unmanned ships—i.e., there would be no crew onboard at any time of the voyage, and with dynamic levels of autonomy. This means the autonomy level approach would depend on the state of the vessel and mission being executed. In some cases, such as navigation in the open seas, the ship can be nearly fully autonomous whereas for some parts of the voyage it will require close supervision and decision making, or even full tele-operation from the human operator.

The two concepts above show that, although an autonomous ship would have less interference of a human operator, the human is still part of the operation: they would still rely on a human operator for one of the voyages phases (e.g. departure

and docking) or for taking over control in case there is a situation the autonomous system cannot resolve by itself. Therefore, the autonomous ship operations are not free of the possibility of accidents generated or aggravated by human error. The current literature, however, have not deeply focused on the human element when considering autonomous ships' safety. In fact, as pointed out by Parasuraman, Sheridan and Wickens (2000), for autonomous systems in general there is a voluminous technical literature on automation, but a still small (but growing) research base examining the human capabilities involved in work with automated systems.

The potential for human error in autonomous ships can be assessed through a Human Reliability Analysis (HRA). HRA is a technique to assess both quantitatively and qualitatively the human contribution to accidents. Swain and Guttman (1983) define human reliability as the probability that a person (1) correctly performs an action required by the system in a required time and (2) that this person does not perform any extraneous activity that can degrade the system. HRA is thus, in short, a method by which human reliability is estimated (Swain and Guttman, 1983; Swain, 1990).

To be able to perform an HRA it is essential to understand, first of all, how the operators will interact with the system. If autonomous ships will be a reality in years to come, ensuring they are safe and reliable is imperative, and the possibility of human errors cannot be minimized.

The current literature presents some relevant works on autonomous ships containing discussions on human factors topics, mostly pointing out the factors that could affect the operators' decision and actions (Ottesen, 2014; Rødseth and Tjora, 2014; Laurinen, 2016). A more general discussion on these factors, applied to all autonomous systems, can also be found (Parasuraman, Sheridan and Wickens, 2000; Chen, Haas and Barnes, 2007). In terms of identifying the possible human failure events (HFEs) in autonomous ships operations, however, the literature still falls short—and this paper aims to fill in this gap.

The identification and definition of HFEs is can be considered as the starting point of an HRA (Ekanem, 2013). Boring (2014) differentiates between two approaches for identifying HFEs. A top-down approach would start with the analysis of hardware faults and deducing human contributions to those faults, and is widely used in Probabilistic Risk Assessments in the nuclear industry. A bottom-up approach, on the other hand, would look at opportunities for human errors and then model them in terms of potential for affecting safety outcomes. This paper will adopt a bottom-up approach, performing a screening of the interactions between the operators and the system and the subsequent tasks in order to identify the HFEs. The present paper, hence, aims to analyze the interactions between the operators' and the system in the operation of autonomous ships, and identify the possible human failure events that derive from it.

The discussions of this paper are part of an ongoing research aiming to identify and model the risks arising from autonomous ships operation. The scope of this paper is limited to human actions and human failures during operation, under the assumption that the system would work as expected. Therefore, it does not cover system failures, which will be addressed in forthcoming papers by the authors.

Nonetheless, it is important to acknowledge that the possibility of human error is not restricted to the operation of the ships. Human error associated with autonomous ships can be related to design, construction and installation, testing and verification and maintenance, among other activities carried out by humans prior to the operation. This paper does not cover these tasks, as it focuses on the operation only, i.e., it considers that there would be no failures in all of these tasks previous to operation and navigation. Hence, the question it aims to answer is: given perfect design, maintenance, equipment and instruments behavior, could human actions affect safety during autonomous ships operation?

The paper is organized as follows: Section 2 presents the system description and the assumptions made in this study, Section 3 focuses on describing of the interactions between the operators' and the system and the possible Human Failure Events deriving from these interactions. Section 4 presents some concluding thoughts.

2 SYSTEM DESCRIPTION

As stated in Section 1, the ongoing projects on autonomous ships have different concepts in terms of the ship being manned or on the level of autonomy. Utne et al. (2017) use the following definition of autonomy (adjusted from National Institute of Standards and Technology (NIST) (2008)): "a system's or sub-system's own ability of integrated sensing, perceiving, analyzing, communicating, planning, decision-making, and acting, to achieve its goals as assigned by its human operator(s) through designed Human-Machine Interface (HMI)". From fully manual control to fully autonomous systems there can be distinct levels of autonomy (LoA), and the literature provides different proposals for these levels and its taxonomy. One of the oldest taxonomies is the one

proposed by Sheridan and Verplank (1978), with 10 LoA, where Level 1 corresponds to fully manual control and level 10 to fully autonomous control. A review of all proposals can be seen in Vagia et al. (2016).

From among the autonomous ship concepts indicated in Section 1, the analysis in this paper is based on the AAWA concept—unmanned ships and dynamic level of autonomy. A dynamic level of autonomy means that the autonomy level can change depending on the context of the voyage, e.g., one phase of the voyage is set to be fully autonomous (Level 10 in the Sheridan and Verplank taxonomy) but the operation encounters a small problem and give the operator a "veto" option before solving it autonomously (Level 6 of autonomy). The reason for choosing this concept are: (i) because it is unmanned, it offers the most different case study from ship operations nowadays, and (ii) because it has a dynamic autonomy level, it covers a different range of situations, from totally autonomous operation to tele-operated control.

Being an unmanned ship, the operators would be working onshore, and we assume they would be working in a Shore Control Center (SCC) as the one proposed in the Munin project. The Munin project website[1] offers a range of information and publications on the Shore Control Center. Essentially, the Shore Control Centre acts as a manned supervisory station for monitoring and remote controlling a fleet of autonomous ships. Most of the time the ships would operate autonomously, without the need for intervention from shore. When needed, though, the operators' in the SCC would provide assistance and may take over control of the ship (Porathe, 2013; Porathe, Prison and Man, 2014; MUNIN, 2016).

The voyage can be divided into four phases, in which the operators would have different possible levels of interaction with the system: Voyage Planning, Unmooring and maneuvering out of dock, Open Sea and Port approaching and docking. The following of these phases is based on the information stated in the AAWA whitepaper (Laurinen, 2016) for a general cargo vessel.

The first phase is the Voyage Planning, in which the operators assess/define certain conditions of the voyage. The operators' assessment makes use of systems that should be present in the ship, such as an automatic system for verifying the sea readiness before starting the voyage. Most of the systems can be checked remotely by the operator while in some areas (such as securing cargo) shore based crew can also be used to check that voyage can be started.

One of the conditions that have to be assessed by the operator previously to the voyage is the connectivity—some of the remote control or remote supervision modes might require a latency and bandwidth that exceeds the capability of the satellite systems in adverse weather conditions. The operator will have then to ensure that there is sufficient connectivity for the intended mission. If there is enough connectivity for the mission, the operator has then to define the primary operational strategy for each leg—autonomous or manual, considering the weather and environmental conditions. Note that manual operation, in this case, means remote operation from the SCC. Next, the operator defines the navigational and fallback strategies. Although the AAWA whitepaper does not describe what the operators take into account during "navigational strategies", we believe that in addition to predefined paths and waypoints it would also include considerations with maintenance (to verify when should the next maintenance of determined equipment be versus the length of the voyage), propulsion and fuel consumption. The fallback strategy, on the other hand, is a strategy executed if the ship experiences an unexpected situation that would require operator intervention. The fallback strategy could include: asking operator to take manual control, slow down and proceed to following waypoint, stop the vessel and stay in DP mode, navigate to previous waypoint, navigate back to preset safe location. The commands and their execution sequence is not same in all parts of the voyage. For example trying to maintain its position in the middle of a congested and narrow fairway in harsh weather might not be a feasible strategy.

It is important to bear in mind that, given dynamic autonomy, the definitions made in the voyage planning are not static, i.e., it can be that one leg was defined to be autonomous but due to external circumstances it goes manual. Moreover, the voyage plan as well as the fallback strategies can always be modified during the voyage using the satellite communication link.

The phase after voyage planning would be unmooring and maneuvering out of dock. The mooring systems can be fully or semi-automatic. A fully automatic mooring system would mean that the operation can be remote controlled or automatically executed by the autonomous vessel. A semi-automatic mooring, on the other hand, means that connection to the quay can be made automatically but the crew is needed to secure the docking. When the ship is maneuvered out of the congested harbor area, it can be controlled by the operator or it can use the dynamic positioning control computer and autonomous control system to reach the waypoint. Moreover, in some areas it could go directly to autonomous mode instead of starting with teleoperation or supervisory control.

[1] http://www.unmanned-ship.org/munin/

The third voyage phase, after maneuvering out of dock, is the open sea navigation. In autonomous mode the ship executes the voyage according to the defined plan, and the operator receives relevant status data such as ship's location, heading, speed, ETA to next waypoint (or area of closer supervision) and key information from the situational awareness systems as well as critical ship systems.. For situations where the autonomous navigation system's autonomous decision making threshold is exceeded, the operator is notified and can intervene. Therefore, the autonomy level is dynamically adjusted if the mission execution is not proceeding according to the original plan and the autonomous navigation system sees that adjustments are needed. AAWA differs between two different situations: one is a "veto" situation, in which for example the vessel is deviating from the planned course between the two waypoints but stays within specified margins the autonomous navigation system. In this case the system would notify the operator about planned evasion and give the operator a possibility to veto for a limited time. If modifications are needed, the operator can take the vessel in manual control. It can also be that the vessel would need to change the course in such a way that complete waypoint has to be replanned. In order to ensure that changes to the plan are made in a safe way operator confirmation will be requested. The autonomous navigation system will offer one or more alternatives of how the waypoint could be modified but the operator will finally make the decision how to continue the voyage.

A second case would be a "pan-pan" situation—when there is a complex scenario that the autonomous navigation system path planning and algorithms cannot unambiguously solve. Example of this could be if extremely large number of crafts or other objects are detected and the path planning algorithms are not capable to identify them and thereby the system cannot determine how the navigation should proceed. In this type of scenario the vessel will immediately send a "pan-pan" message to the operator indicating that it is in urgent need of assistance. The ship has a predefined set of fallback strategies (defined at the voyage planning phase) that it will start to execute in the planned order if user response is not received, and depending on the urgency, automatic fallback strategy execution can also be started immediately.

The last phase of the voyage is port approaching and docking. As the other phases, it can be remotely operated or autonomous. This phase together with open sea navigation and unmooring and maneuvering out of dock will be named "navigation phases".

The next section details the interactions between the operators and the system in each of these phases.

3 INTERACTIONS BETWEEN THE OPERATORS AND THE SYSTEM

This section discusses the interactions between operators and the system for each voyage phase of the autonomous ship described in the previous section. It explain the operators' main tasks and the possible decision/action paths they may take when accomplishing these tasks.

The outcomes of the operators' actions will be described in this paper as a "success" or a "failure" of that voyage phase. A successful operation is defined here as an operation that did not encounter any unexpected problem or an operation that did encounter a problem but successfully recovered from it, by operators' actions or autonomous solving. For instance, if during autonomous navigation in the open sea the ship faces a complex situation it cannot solve autonomously and it gives a "pan-pan" alert for the operators, they take over control in time and manage to bring the ship back to a safe status, this is a successful open sea voyage. An unsuccessful operation, on the other hand, is one that encounters a problem and does not recover from it. In the previous example, if the operators fail to respond to the "pan-pan" alert and the ship follows a fallback strategy that is inadequate, this would be a failure in the open sea voyage, leading to an incident.

Note that for voyage planning a failure will not itself cause an accident, but it will increase the probability of having a "veto" or "pan-pan" situations at the following phases. For example, if during voyage planning the operator decides for open sea voyage to be autonomous when the environmental conditions are not safe for the operation, there will be a higher chance that an unexpected situation during the voyage arises and the operator receives a "pan-pan" alert about it. Failures at the following phases, on the other hand, can cause accidents. These may, however, differ in terms of gravity: an accident when still in harbor is less probable to be of catastrophic consequences than during open sea voyage. Yet, the final events treated in this paper will be "success" and "failure", not distinguishing between the severities of this failure, such as collision, grounding, etc. This is illustrated in the general Event Sequence Diagram in Figure 1, where

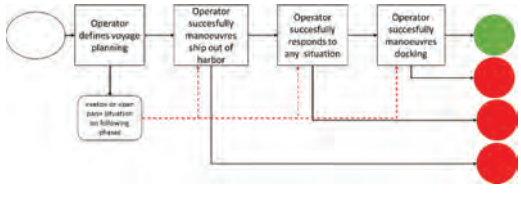

Figure 1. Interaction scheme for voyage planning.

the "success" outcome is represented by the green final event, which is reached if all voyage phases are successful, and the "failures" are represented by the red final events.

For the unmooring and maneuvering out of harbor phase it was considered a fully automatic system, i.e., the operation can be remote controlled or automatically executed by the autonomous vessel, depending on what was defined at the voyage planning phase. Moreover, in spite of the AAWA whitepaper describing the "veto" or "pan-pan" situations only during the open sea voyage, it was considered that they could also happen during unmooring and maneuvering out of harbor and port approaching and docking, when these are in autonomous mode. In this sense, the possible interactions between the operator and the system in the three voyage phases that follows voyage planning are similar: the operation can go manual or autonomous; in case it is autonomous it can i) operate as expected, ii) encounter a small problem and generate a "veto" situation, iii) encounter a more complex problem and generate a "pan-pan" situation. Moreover, the operators' possible responses to these situations are also similar in the three phases. Thus, what will be discussed below for unmooring and maneuvering out of harbor can be extended to the open sea navigation and port approaching and docking.

The operator's interactions with the system in the voyage planning phase are described in subsection 3.1, and for the following phases, exemplified by unmooring and maneuvering out of harbor operation, in sub-section 3.2.

3.1 *Voyage planning*

From the description in Section 2, it is possible to identify the operator's tasks and possible paths in the voyage planning, which are described in the tables below.

3.2 *Unmooring and maneuvering out of harbor*

The operator's tasks and possible paths in Unmooring and maneuvering out of harbor are described below, and can be extended for the open sea voyage and port approaching and docking phases.

I. Autonomous operation

When the operation is autonomous there can be a small problem that the vessel can solve autonomously, in which case the operator receives a "veto" alert (Table 5). If there is a significant problem, the vessel gives a "pan-pan" alert to the operator (Table 6). In that case, if the operator does not take over control the vessel follows the fallback strategy.

Table 1. Possible operator decisions for Task 1.

Task 1 (T1): Ensure there is sufficient connectivity			
I. If there is no sufficient connectivity, the operator can:		**II.** If there is sufficient connectivity, the operator can:	
T1_path 1: be wrong and believe there is sufficient connectivity, and the operation goes on	**T1_path 2:** be right about the connectivity level and cancel the voyage	**T1_path 3:** be wrong and believe the connectivity is not enough, and cancel the voyage	**T1_path 4:** be right and the operation goes on

Table 2. Possible operator decisions for Task 2.

Task 2 (T2): Define primary strategy for each leg (autonomous or manual)		
T2_path 1: Operator decides that the operation for one leg is autonomous when, due to weather and environmental conditions, it should be manual. For each phase:		
i. Unmooring and maneuvering out of harbor goes autonomous when it should be manual	**ii.** Operation in open sea goes autonomous when it should be manual	**iii**. Port approaching and docking goes autonomous when it should be manual
T2_path 2: Operator decides that one leg should be manual when it could be autonomous		
i. Unmooring and maneuvering out of harbor goes manual when it could be autonomous	**ii.** Operation in open sea goes manual when it could be autonomous	**iii.** Port approaching and docking goes manual when it could be autonomous
T2_path 3: Operator correctly decides that the operation for one leg is autonomous. For each phase:		
i. Unmooring and maneuvering out of harbor goes autonomous	**ii.** Operation in open sea goes autonomous	**iii**. Port approaching and docking goes autonomous
T2_path 4: Operator correctly decides that one leg should be manual:		
i. Unmooring and maneuvering out of harbor goes manual	**ii.** Operation in open sea goes manual	**iii.** Port approaching and docking goes manual

Table 3. Possible operator decisions for Task 3.

Task 3 (T3): Define navigational strategies for the autonomous operations	
T3_path 1: The operator defines an incorrect navigational strategy	**T3_path 2:** The operator decides for a good operational strategy

II. Manual unmooring

To aid in the visualization of these tasks and paths, these interactions are modeled through the schemes presented in Figure 2 for voyage planning

and Figure 3 for unmooring and maneuvering out of harbor.

As stated previously, these interactions were modeled not considering system failure yet—e.g. there is a "pan-pan" situation and the alert at the Shore Control Center fails, or the operator takes over manual control and the communication between the SCC and the vessel fails. It isolates, then, the human errors, considering no failure on other aspects of the operation.

From the interaction schemes above it is possible to identify the possible Human Failure Events that could lead or contribute to accidents in autonomous ships operation. Table 8 presents the HFEs involved in the voyage planning phase. Note that these failures would not cause an accident itself, but would contribute for having a "veto" or "pan-pan" situation in the following phases, as illustrated in Figure 1. Table 9 present the HFEs involved in

Table 4. Possible operator decisions for Task 4.

Task 4 (T4): Define fallback strategy for the autonomous operations	
T4_path 1: The operator defines an inadequate fallback strategy	**T4_path 2:** The operator defines an adequate fallback strategy

Table 5. Possible operator decisions for Task 5, after a "veto" alert is received during autonomous operation.

Task 5 (T5): Respond to "veto alert"	
T5_path 1: The operator does no respond to the veto alert	
T5_path 2: The operator responds to the alert and supervise the vessel solve the problem autonomously	
T5_path 2_1: The operator should have "veto" that operation and take over control because the autonomous solutions were not adequate	**T5_path 2_2:** The autonomous solution is adequate
T5_path 3: The operator responds to the alert and take over control of the vessel	
T5_path 3_1: The operator successfully operates the ships	**T5_path 3_2:** The operator fails when operating the ship

Table 6. Possible operator decisions for Task 6, after a "pan-pan" alert is received during autonomous operation.

Task 6 (T6): Respond to "pan-pan" alert	
T6_path 1: The operator does no respond to the "pan-pan" alert	
T6_path 2: The operator responds to the alert and supervise the vessel solve the problem autonomously following the fallback strategy	
T6_path 2_1: The operator should have taken over control of the ship because the fallback strategy is not adequate	**T6_path 2_2:** The fallback strategy is adequate
T6_path 3: The operator responds to the alert and take over control of the vessel	

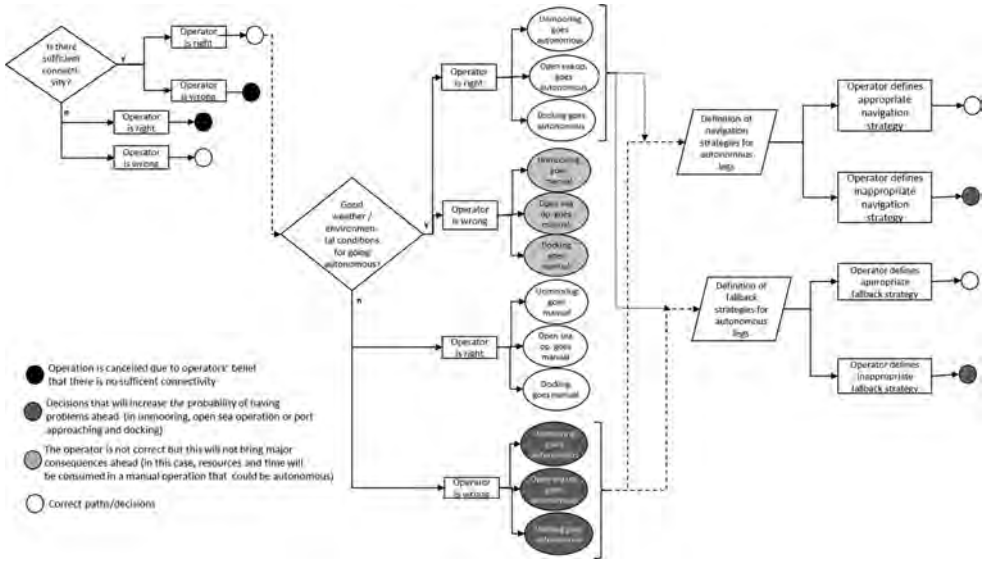

Figure 2. Interaction scheme for voyage planning.

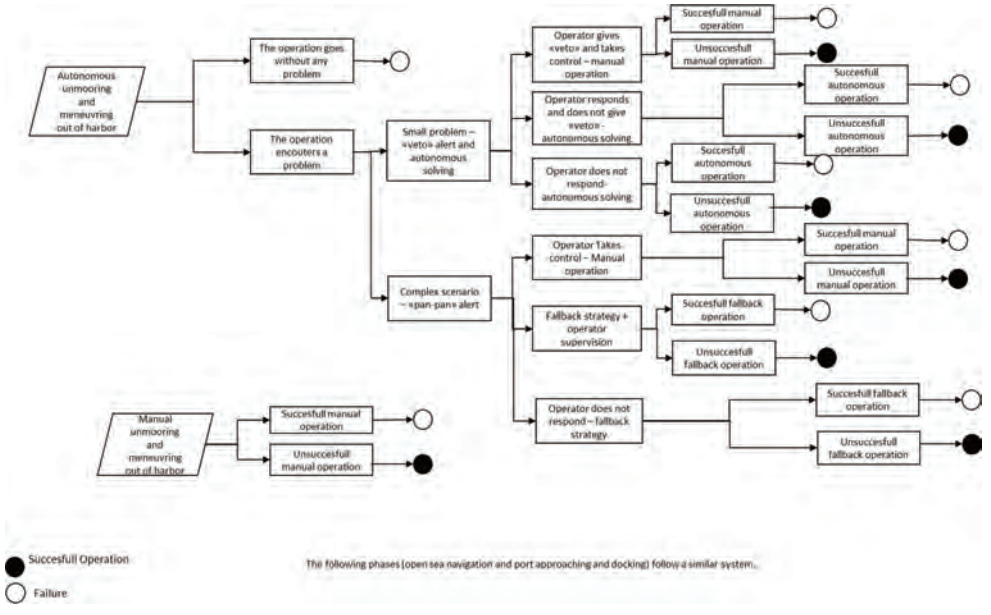

Figure 3. Interaction scheme for unmooring and maneuvering out of harbour.

Table 7. Possible operator decisions for Task 7, in manual operation.

Task 7 (T7): unmooring and maneuvering out of harbor by tele-operation	
T7_path 1: Operator successfully operates the ship	**T7_path 2:** Operator fails to operate the ship

the following phases (navigation phases). These are the HFEs that could lead to the "failure" final events in Figure 1.

The Human Failure Events presented in Table 8 and 9 are defined rather broadly, and can be decomposed, if needed, to identify sub-HFEs. In this sense, they are a general representation of what could go wrong, in terms of human failure, in the autonomous ships operation. They are a starting point that allows to analyze, for each HFE, the crew cognitive processes involved, in order to identify more specific Failure Modes that would lead to each HFE. Furthermore, for each Failure Mode it will be possible to identify and assess the factors that influence the operator's decisions and actions—the Performance Influencing Factors (PIFs).

In this sense, as stated in Section 1, the identification of Human Failure Events is the first step towards a solid Human Reliability Analysis.

The description of the operator-system interactions in autonomous ships and possible HFEs

Table 8. Human failure events in voyage planning phase.

Path	Human Failure Event	Description
T1 path 1	Failure to correctly assess connectivity level	The operator is wrong about the low level of connectivity. The operation goes on, and the low level of connectivity can lead to communication problems between the SCC and the ship.
T2 path 1	Failure to correctly define primary strategy	During definition of the primary strategy for each leg the operator believes the conditions are adequate for autonomous operation when, in that situation, it should be manual (tele-operated)
T3 path 1	Failure to define adequate navigational strategy	The operator defines an inadequate navigation strategy. This will increase the probability of having problems ahead and a "veto" or "pan-pan" situation
T4 path 1	Failure to define adequate fallback strategy	The operator defines an inadequate fallback strategy. In case there is a "pan-pan" situation the fallback strategy will be followed by the ship, if the operator does not take manual control of the ship

Table 9. Human failure events in navigation phases.

Path	Human Failure Event	Description
T5_path 1 **T6_path 1**	Failure to respond to an alert	The operator does no respond to an alert, which may be a "veto" alert or a "pan-pan" alert.
T5_path 3_2 **T6_path 3_2** **T7_path 2**	Failure to remote-operate the ship	The operator is manually operating the ship, which may be after a "veto" or a "pan-pan" alert or may be from the beginning of that operation, in case it was defined to be manual.
T5_path 2_1 **T6_path 2_1**	Failure to take over control of the ship when necessary	The operator trusts the autonomous solution or fallback strategy and does not take over control of the ship in a situation where this is needed

deriving from it demonstrates that there is still room for human failure in its operation. The assessment of human error, therefore, cannot be neglected or minimized when considering autonomous ships' safety and reliability.

4 CONCLUDING THOUGHTS

This paper demonstrates that although compared to conventional ships the human interaction is reduced in autonomous ships, the human still plays a role, with a potential for human error that has to be considered.

One of the concerns regarding autonomous ships' operation is the new risks they can pose, and how to asses them. Being a novel operation, the possible interactions between operator and autonomous ships are not yet clear, but this paper contributes to identifying these interactions and modeling it. The paper also identifies, at a high level, possible Human Failure Events deriving from these interactions.

Three HFEs deserve particular attention, for they can lead/contribute to an accident such as collision, grounding: a failure to respond to an alert, a failure to remotely operate the ship, and a failure to take over control of the ship when necessary. A deeper analysis of these events is needed to identify possible failure modes and the factors that can influence them. That analysis, in the context of an HRA, will make it possible to identify opportunities to reduce the likelihood of critical human failures.

Moreover, it can be a basis for discussing whether autonomy will indeed reduce the likelihood of accidents caused/aggravated by human error—and to determine the appropriate level of autonomy that can lead to a safer operation.

It is important to point that this paper approaches human actions focusing on their contribution to accidents. Actions of operators onboard, however, contribute also to avoiding accidents and/or to reducing the severity of their consequences. This aspect needs to be evaluated as well in further discussions on the shift from onboard to onshore operation.

Human reliability analysis in NPP: A plant-specific sensitivity analysis considering dynamic operator actions versus accident management actions

D. Kancev, S. Heussen, J.U. Kluegel, P. Drinovac & T. Kozlik
NPP Goesgen-Daeniken AG, Daeniken, Switzerland

ABSTRACT: The human reliability analysis is a method by which, in general terms, the human impact to the safety and risk of a nuclear power plant operation can be modelled, quantified and analyzed. It is an indispensable element of the PSA process within the nuclear industry nowadays. The paper herein presents a sensitivity study of the human reliability analysis performed on a realistic nuclear power plant–specific probabilistic safety assessment model. The analysis is performed on a pre-selected set of post-imitator operator actions. The purpose of the study is to investigate the impact of these operator actions on the plant risk by altering their corresponding human error probabilities in a wide spectrum. The results direct the fact that the future effort should be focused on maintaining the current human reliability level, i.e. not letting it worsen, rather than improving it.

1 INTRODUCTION

The human reliability analysis (HRA) is an integral part of the probabilistic safety analysis (PSA) in the nuclear power plants (NPP) throughout the world. While there are those, who contend that it is the single most important element of the entire plant analysis, others contend that any attempt at rigorous evaluation of human reliability is merely an academic exercise in futility. Human beings are unpredictable, they do not obey the laws of physics, and it is impossible to collect relevant statistical evidence to understand or predict human behavior during complex "real world" situations. While it may be true that human behavior is not as statistically predictable as rolling dice, it is also true that the probabilistic framework of PSA acknowledges that all data are uncertain, and it rigorously accounts for these uncertainties. Lack of directly relevant experience and statistical evidence does not preclude a fundamental understanding of the motivations, physical and psychological factors, and external constraints that would most strongly influence human response in a specific situation.

The HRA has a multirole purpose: identifying critical human-system interactions, i.e. human actions; modelling and quantifying the associated human error probability (HEP); HRA optimization. Various preventive and mitigative operator actions (OA) are planned, trained and employed for various accident scenarios that are postulated in the nuclear industry.

There are various methods, models and databanks with estimated HEPs by the help of which qualitative and quantitative analysis of the reliability of OAs in the NPPs can be performed. The inherent variability of the human performance under different conditions and for different functions implies relatively wide uncertainty bounds for the HEP estimates. The uncertainty should be generally smaller for the routine tasks such as test, maintenance, normal control room operations and higher for the OAs as a response to an abnormal event (IAEA 1995, 1996, U.S. NRC 1983 a, b, c). The literature offers a wide spectrum of studies in regards to the various HRA qualitative and quantitative methods (Hannaman & Worledge 1988, Lydell 1992, Moieni et al. 1994, Kim & Seong 2006, Khalaquzzaman et al. 2010, Podofillini & Dang 2013), its coupling with the deterministic safety analysis (Cepin & Prosek 2008), as well as HRA uncertainty and sensitivity studies (Fujimoto et al. 1994, Cepin 2008, Bedford et al. 2013, Baraldi et al. 2015).

In that sense, the presented paper summarizes a HRA sensitivity study performed on a realistic NPP—specific PSA model. The NPP of interest is the Goesgen-Daeniken NPP (KKG) in Switzerland, a 3-loop PWR plant. The plant PSA model is prepared with the RISKMAN® analysis tool (ABS Consulting Ltd. 2008, 2015).

Firstly, all the Type C or post-initiator OAs modelled within the PSA model (ca. 30 different actions with their corresponding split fractions) are subjected to sensitivity analysis such that

their corresponding HEP values are being altered through a wide spectrum of values. Consequently, the quantitative effects on the PSA Level 1 (L1) and Level 2 (L2) risk measures – Core Damage Frequency (CDF) and Large Early Release Frequency (LERF) – as well as the qualitative effects regarding the general risk profile and the changes in the OAs importances are studied.

Secondly, the analysed OAs are then delineated into dynamic, post-initiator OAs on one side and accident management actions on the other side and are subjected to sensitivity analysis given the plant risk as well as their quantitative and qualitative impacts compared and discussed.

2 MODEL

2.1 *Preliminary considerations*

The PSA model herein considers three general groups of OAs:

Type A or pre-initiator system-specific OAs: This type of action involves routine activities such as restoring a component or flow path to normal after the completion of testing, inspection, maintenance, instrument calibration, etc. These system specific activities are typically performed by one or more individuals as part of their normal workday duties. They are not related directly to operator actions or equipment response during the plant transient after an initiating event. However, errors may leave important equipment disabled and require additional dynamic actions to restore it to service during the transient. These routine testing, maintenance, and surveillance actions are identified in each system analysis and are quantified as specific causes for equipment inoperability.

Type B OAs: The second type of human action that may be considered in a PSA is a personnel error that directly causes or contributes to an initiating event. These human errors are not quantified separately for most initiating events in contemporary PSAs because the available initiating event frequency data contain contributions from all causes, including human errors. Most of the initiating event frequencies for the KKG PSA are quantified from a combination of generic and plant-specific data. The initiating event databases do not differentiate among the specific causes for each type of event. Since the frequency of human errors is already included in the initiating event data, these errors are not quantified separately for any initiating events that are derived directly from generic and plant-specific experience.

Type C or post-initiator OAs: The third general type of human action in a PSA is a scenario-specific, directed mission activity. This action is an integral part of plant response to an initiating event. The operators must accomplish well-defined tasks for manual initiation, control, and alignment of plant emergency equipment or selected backup systems. These tasks are generally guided by the plant emergency response procedures. The available time window for successful response, the type of action that must be taken, and other factors that influence operator stress and confusion are determined by the type of event being evaluated and all preceding actions during a specific response scenario. These actions are incorporated as distinct decision points in the KKG PSA event tree models. This type of actions—the post-initiator OAs—are in the focus of the HRA sensitivity study herein. These type C post-initiator actions are being divided in two general groups: the immediate, dynamic OAs as a post-initiator accident OAs and the accident management actions (AMA). They are presented in the following table (Table 1).

In addition to the OAs encompassed by Table 1, the following three actions are also considered: L3 – late fire extinguishing system operation; L4 – fire extinguishing by fire brigade before ignition in adjacent room.

The part of the top event (TE) VU—related to the operator failure to clean debris after season event and thus rendering the main water intake unavailable—is also considered.

2.2 *Analysis and calculations*

The plant PSA model is prepared with the RISKMAN® analysis tool. It is a small fault tree (FT) – large event tree (ET) linking approach software. Each of the OAs summarized in Table 1 is modelled as a separate top event (TE) within the KKG PSA model. Each of these TEs are represented via multiple split fractions (SF), modelling different variants of the corresponding OAs under different boundary conditions. The failure probability of each OA is calculated as a logical OR between the cognitive/diagnosis and the implementation/manipulation failure probability. Failure probability density functions (PDF) – accounting for the HRA uncertainty—are assigned to each of the cognitive and the implementation part.

At this point, it is important to note that the dynamic OAs comprise not only the immediate, post-initiator, preventive measures but also recovery measures within these actions. Namely, one of the advantages of the SF modelling approach is that one can model different variations of the same OA that correspond to different boundary conditions. This, in turn, corresponds to different stages and/or different developments of a given accident.

This paper tends to present a HRA sensitivity study of the values of the L1 and L2 risk measures,

Table 1. Overview of the OAs used in the KKG PSA model.

Type			OA ID	Description
Accident management actions	Dynamic OAs		OALP	Start residual heat removing (RHR) cooling
			OCD	Start active cooldown
			ODP	Depressurize/cooldown
			OEFW	Start emergency feedwater (EFW)
			OPUD	Align demineralized water makeup to feedwater tank
			ORT	Reactor trip
			OSG	Isolate ruptured steam generator (SG)
		Level 1 PSA	OAMFT	Align feedwater tank
			OAMFW	Align fire truck
			OAMIS	Isolate large containment openings
			OAMLI	Isolate letdown line
			OAMPB	Depressurize vie primary pressure relief
			OAMPF	Align fire water to low head (LH) pump path
			OAMRW	Align flood tanks to operating high pressure injection (HPI) pump
			OAMSR	Open SG relief
			OAMTH	Align TH17/37 and VX01/02
			OAMFL	Injection and recirculation via TH17/37 after recovery of bus FL/FM
		Level 2 PSA	OAMIGA	H2 recombiners placed into service prior to vessel breach
			OAMIGB	H2 recombiners placed into service after to vessel breach
			OAMVA	Containment filtered venting system (CFVS) placed into service prior to vessel breach
			OAMVB	CFVS placed into service after to vessel breach
			OAMVC	CFVS scrubbing tank re-filled as necessary
			OAMVD	Isolate CFVS to prevent large release

i.e. CDF and LERF respectively, as a function of the altering values of the HEP for the dynamic OAs and the AMAs. By simple assignment of a scalar parameter (e.g. "*SENHRA*", "*SENHR3*") to the basic event (BE) calculation module where the OA failure probabilities are being calculated, one can alter all the wanted HEPs and hence, perform a sensitivity study. In that sense, the *SENHRA* parameter is part of the data module of the applied KKG PSA model. All the HEP related to all the dynamic OAs as well as AMAs within the KKG model are multiplied by the *SENHRA* parameter. In this way, one can conduct systematic sensitivity analyses by simply altering the value of the *SENHRA* parameter. Within the nominal model, i.e. within the base case, value of 1.0 is assigned to *SENHRA*. Further on, the *SENHRA3* parameter is assigned to the HEP values related only to the dynamic OAs in addition to the already assigned *SENHRA* parameter. In such a way, one can perform HRA sensitivity analysis only to the OA group, without altering the AMA group.

Two main cases within the sensitivity study are analysed:

i. altering the HEP values of all the dynamic OAs as well as all the AMAs together (via altering the parameter "*SENHRA*");
ii. altering the HEP values of the dynamic OAs only, while leaving the AMAs with their nominal HEP values (via altering the parameter "*SENHR3*").

Figure 1 and Figure 2 present the first of the above-mentioned cases—altering the HEP values of both the dynamic OAs as well as the AMAs defined within chapter 2.1. The effects of this sensitivity case show that the potential "worsening" of the HEP values would have much higher consequences on the CDF and LERF in terms of risk increase than the "improvement" of the HEP values might have on reducing this risk. In other words, by increasing the HEP values by a factor of 10, the CDF increases by factor 3 and the LERF by 80%. By worsening, i.e. increasing the HEP values by a factor of 100, the CDF increases by factor 50 and the LERF by factor 20. On the other side, by improving the HEP values by a factor of 10, the CDF reduces by merely 7.5% and the LERF by 7%.

By improving the HEP values by a factor of 100, the CDF reduces by merely 8% and the LERF by 7.6%.

Figure 3 and Figure 4 present the second of the above-mentioned cases—altering the HEP values of the dynamic OAs only, while leaving the AMAs with their nominal HEP values (via altering the parameter *SENHR3*).

The effects of this sensitivity case are qualitatively the same as the ones for the first sensitivity case. Namely, they show that the potential "worsening" of the HEP values would have much higher consequences on the CDF and LERF in terms of risk increase than the "improvement" of the HEP values might have on risk reduction. In addition to this, however, one can also see that if the two cases are compared on quantitative basis as well, they are relatively close to each other. This is especially true in the case of LERF (Figure 6). Figure 5 and Figure 6 address this comparison as separate presentation. Figure 5 presents the calculated CDF for both the above-mentioned cases. Figure 6

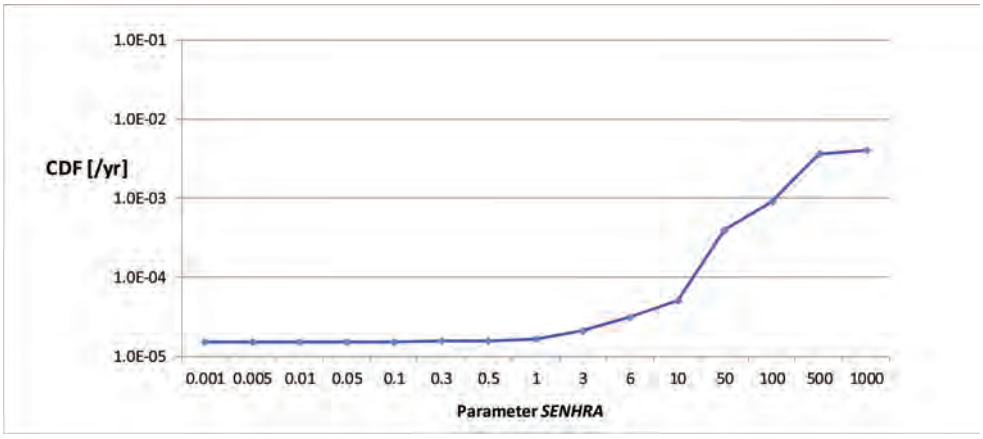

Figure 1. Sensitivity of the CDF as a function of the parameter *SENHRA*.

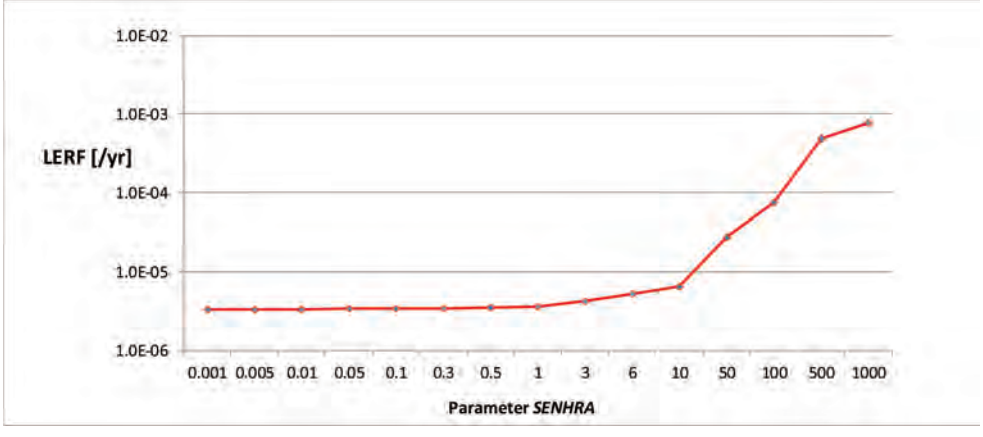

Figure 2. Sensitivity of the LERF as a function of the parameter *SENHRA*.

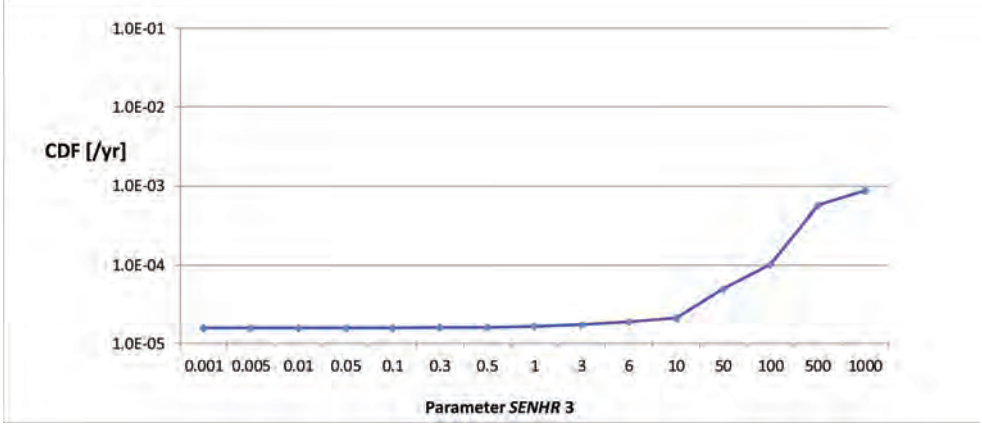

Figure 3. Sensitivity of the CDF as a function of the parameter *SENHR3*.

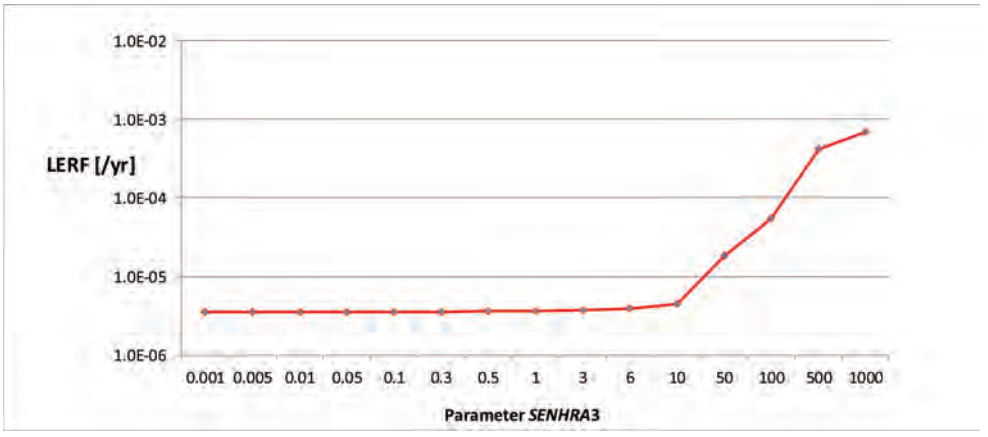

Figure 4. Sensitivity of the LERF as a function of the parameter *SENHR3*.

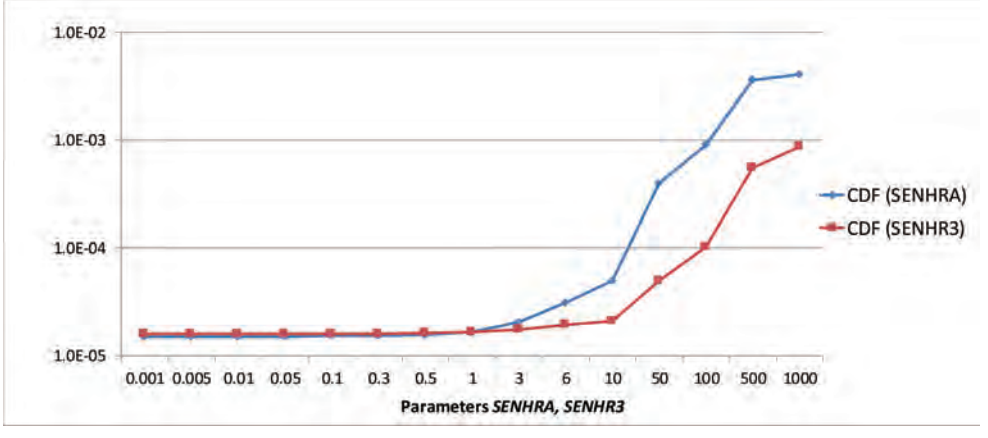

Figure 5. Comparison of the CDF between the two cases: CDF (*SENHRA*) vs. CDF (*SENHR3*).

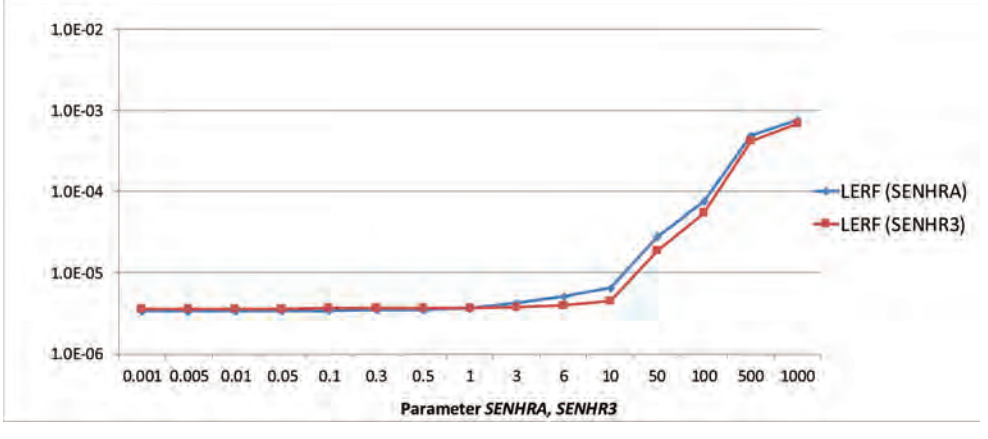

Figure 6. Comparison of the LERF between the two cases: LERF (*SENHRA*) vs. LERF (*SENHR3*).

presents the calculated LERF for both the above-mentioned cases.

In order to inspect the influence of the AMAs solely, a third case is established:

iii. altering the HEP values of the AMAs only, while leaving the dynamic OAs with their nominal HEP values (via altering the parameter "*SENHR1*");

Figure 7 and Figure 8 present this third case—altering the HEP values of the AMAs only, while leaving the dynamic OAs with their nominal HEP values (via altering the parameter *SENHR1*). By worsening the HEP values by a factor of 100, the CDF increases only by factor 2.5 and the LERF only by ca. 25%. By improving the HEP values by a factor of 100, the CDF and LERF reduce by ca. 6–7%. Thus, it is clear that the effect of the AMAs, seen in general as a group of personnel actions, is less than the one of the dynamic OAs presented in case ii.

When comparing Figure 3 with Figure 7 and Figure 4 with Figure 8, it can be concluded that the changes in the plant risk (CDF, LERF) due to altering (increasing) the HEP values are predominantly governed by the changes affecting the dynamic OAs solely when compared to the case where solely the AMA HEP values are being altered (increased).

Of course, the above stated is a general conclusion in a sense of comparing the personnel action

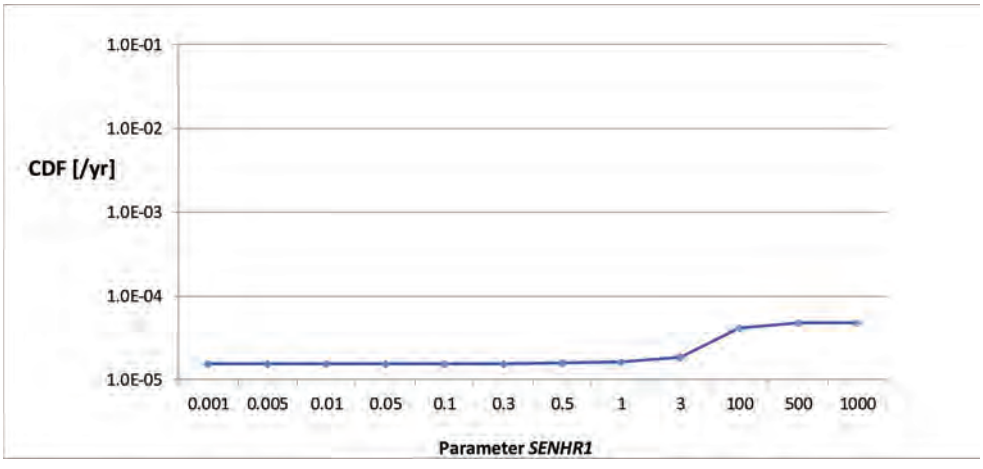

Figure 7. Sensitivity of the CDF as a function of the parameter *SENHR1*.

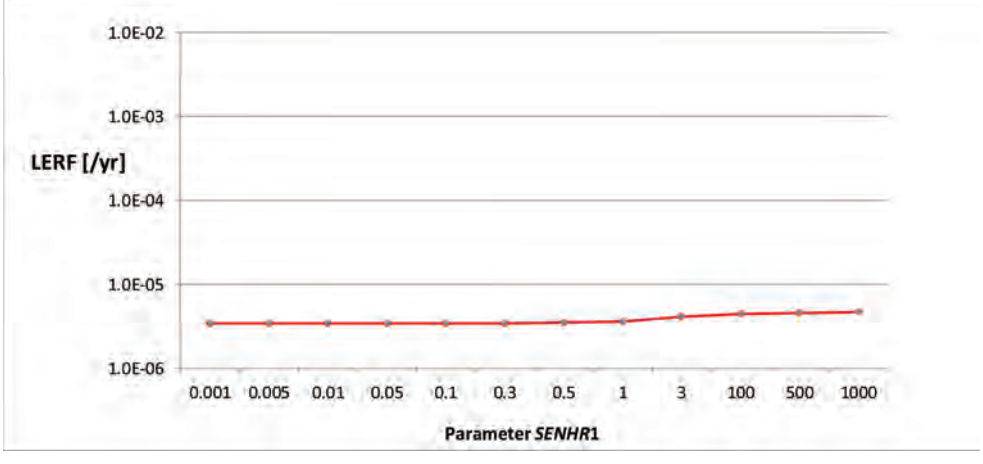

Figure 8. Sensitivity of the LERF as a function of the parameter *SENHR1*.

groups (dynamic OAs vs. AMAs) with each other. There are, of course, AMAs whose risk achievement worth (RAW) is higher than the RAW of some dynamic OAs.

3 DISCUSSION AND CONCLUSIONS

Probabilistic studies of risks show that the human factor can considerably contribute to overall risk. The potential for and mechanisms of human error to affect plant risk and safety is evaluated by the human reliability analysis. The HRA has quantitative and qualitative aspects, aimed at designing operator interfaces that will minimise operator error and provide for error detection and recovery capability. The objectives of HRA therefore, are to assure that potential effects on plant safety and reliability are analysed and that human actions that are important to plant risk are identified so that they can be addressed in both PSA and plant design.

The presented paper summarizes a HRA sensitivity study performed on a realistic NPP–specific PSA model. This sensitivity analysis is performed in order to investigate the role of the HEPs of two groups of OAs to the overall spectrum of plant risk.

Type C or post-initiator OAs are in the focus of the study. These type C post-initiator human actions are being divided in two general groups: the immediate, dynamic OAs as a post-initiator accident OAs and the accident management actions—AMAs. Each of the considered OAs is modelled as a separate TE within the KKG PSA model. Each of these TEs are represented via multiple SFs, modelling different variants of the corresponding OAs under different boundary conditions.

The paper presents a HRA sensitivity study of the values of the L1 and L2 risk measures, CDF and LERF respectively, as a function of the altering values of the HEP for the dynamic OAs and the AMAs.

Three cases were analysed:

i. altering the HEP values of all the dynamic OAs as well as all the AMAs together (via altering the parameter *SENHRA*);
ii. altering the HEP values of the dynamic OAs only, while leaving the AMAs with their nominal HEP values (via altering the parameter *SENHR3*);
iii. altering the HEP values of the AMAs only, while leaving the dynamic OAs with their nominal HEP values (via altering the parameter *SENHR1*).

The effects of the first sensitivity case i. show that the potential "worsening" of the HEP values would have much higher consequences on the CDF and LERF in terms of risk increase than the "improvement" of the HEP values might have on reducing the risk. In other words, by worsening the HEP values by a factor of 10, the CDF increases by factor 3 and the LERF by 80%. By worsening the HEP values by a factor of 100, the CDF increases by factor 50 and the LERF by factor 20. On the other side, by improving the HEP values by a factor of 10, the CDF reduces by merely 7.5% and the LERF by 7%. By improving the HEP values by a factor of 100, the CDF reduces by merely 8% and the LERF by 7.6%.

The effects of the second sensitivity case ii. are qualitatively the same as the ones for the first sensitivity case. In addition to this, however, one can also see that if the first and the second case are compared on quantitative basis as well, they are relatively close to each other. This is especially true in the case of LERF.

In order to inspect the influence of the AMAs solely, the third sensitivity case is run. By increasing, i.e. worsening the HEP values by a factor of 100, the CDF increases only by factor 2.5 and the LERF only by ca. 25%. By improving the HEP values by a factor of 100, the CDF and LERF reduce by ca. 6–7%. Thus, it is clear that the effect of the AMAs, seen in general as a group of personnel actions, is less than the one of the dynamic OAs presented in case ii.

The usability of the herein performed HRA sensitivity analysis is summarized through the conclusions derived below in text. The interplay of the two identified type C human action groups (dynamic OAs and AMAs) and their significance and contribution to plant risk is discussed.

From the results of the sensitivity study can be concluded that the changes in the plant risk (CDF, LERF) due to altering the HEP values are predominantly governed by the changes affecting the dynamic OAs when compared to the case where solely the AMA HEP values are altered. This coincides with the comparison of the RAW factors of the dynamic OAs vis-à-vis the ones for the AMAs. In general, the former group have higher RAW values than the latter.

Of course, the above stated is a general conclusion in a sense of comparing the personnel action groups (dynamic OAs vs. AMAs) with each other. There are, however, AMAs whose RAW is higher than the RAW of some dynamic OAs. Additionally, the effects of both the groups on the plant risk are not additive. Still and as already stated, the plant risk is much more sensitive to the increase of the HEP values of the dynamic OAs considered alone than to the increase of the HEP values of the AMAs considered alone.

Therefore, the general conclusion is that the focus should be put on maintaining the boundary

conditions for diagnosis and execution of the general group of all the personnel type C actions on such a level so that the current reliability of their performance would not be endangered. In other words, future effort should be focused on maintaining the current HEP values, i.e. not letting them get worse, rather than improving these HEP values. Further on and more specifically, when already delineating between the dynamic OAs on one side and the AMAs on the other, the focus should be set foremost to maintaining the HEP values of the dynamic OAs group, since their deteriorating effect on CDF, LERF can be much higher than the one of the AMAs.

The weighting method's impact on the weighting process in decision making problems

A. Tzioutziou & Y. Xenidis
Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT: Assigning values to weights in a multi-criteria decision making problem is critical, since it introduces the decision maker's perception and preference over the importance and value of the decision problem's criteria and alternatives, respectively. This paper investigates theoretically and experimentally the impact of the applied weighting method on the decision maker's determination of weights. The research develops a methodology to evaluate the impact that a weighting method may have on the decision maker's attitude concerning the assignment of weighting values, comprising; a) a psychometric test revealing the decision maker's attitude against risk and ambiguity with a new modeling approach based on a psychometric function and b) an assignment of weighting values by the decision maker with different weighting methods. The results demonstrate that the expression and particularly the ranking of decision maker's attitudinal preference are affected by the weighting method and this impact is measurable through the proposed methodology.

1 INTRODUCTION

The principles of decision analysis set the framework wherein decision makers determine weights through the use of various methods and diverse approaches. According to the current theoretical approaches, decision analysis is characterized by two discrete principles, namely the normative and the descriptive (Barzilai, 2010; Riabacke, Danielson and Ekenberg, 2012; Aliev et al., 2016), whilst there is also the prescriptive principle, which constitutes a combination of them (Jia, Fischer and Dyer, 1998; Riabacke, Danielson and Ekenberg, 2012; Aliev et al., 2016). The decision analysis principles determine the characteristics of the method's input and process, imposing the use of numerical data or the combination of numerical data with verbal expressions.

Recently, great importance has been given to the cognitive process of weight determination, which includes three conceptual phases, namely the extraction of data, their representation and the interpretation (Riabacke, Danielson and Ekenberg, 2012). The two main classes of weight elicitation methods are the precise and the approximate methodological approaches (Jia, Fischer and Dyer, 1998; Bottomley and Doyle, 2001; Barzilai, 2010; Riabacke, Danielson and Ekenberg, 2012; Hafezalkotob, Hafezalkotob and Sayadi, 2016; Wang, Wang and Zhang, 2016; Podinovskaya and Podinovski, 2017). The literature review revealed that new weighting methods are constantly added to the existing ones, integrating contemporary mathematical analysis (Abidin, Rusli and Shariff, 2016), as well as complementary techniques for the determination of weights, like integration of weights and consensus building (Beliakov and James, 2015; Peng et al., 2015; Blagojevic et al., 2016).

The determination of attribute weights is essentially a problem of preference formation in different conditions, with many possible limitations. The concept of preference describes the degree that a subject desires a potential outcome (Hogarth, 2010). Its formation is related with multiple cognitive, emotional and even biological mechanisms, connected with cognition and behavioral traits (Hogarth and Einhorn, 1990; Weller, Levin and Bechara, 2010; Panno, Lauriola and Figner, 2013; Naili et al., 2015). The study of those mechanisms, along with the external conditions of risk and ambiguity from the fields of Psychology and Economic Theory could enhance the comprehension of the preference formation and launch a further challenging investigation; the prediction of preferences (Weller, Levin and Bechara, 2010; Retief et al., 2013; Brand et al., 2014; Roth and Voskort, 2014; Johansen and Rausand, 2015; Csermely and Rabas, 2016; Shao, Taisch and Ortega-Mier, 2016; Thomas, 2016; van Winsen et al., 2016; Jern, Lucas and Kemp, 2017).

Based on the above, there is evidence to connect the behavioral preferences with the process of weight elicitation. The paper investigates the determination of weights as an expression of preference and behavioral attitude, which can be described

and modeled with a psychometric approach and a new methodology. This new psychometric approach is presented in Section 2 and the new methodology for recognition of behavioral attitudes with the use of the psychometric function is discussed in Section 3. The cognitive process leads the decision maker to assign weight assessments, and this research examines experimentally this aspect of the weighting method in Section 4. Section 5 presents the conclusions of this work.

2 A NEW APPROACH FOR REVEALING BEHAVIORAL ATTITUDE

Previous works on the field offer the theoretical background to determine a new approach for the identification and classification of behavioral attitudes, based on the concept of psychometric function. The definition of this concept is presented in subsection 2.1, while the proposed approach for the use of the psychometric function for preference expression under risk or ambiguity is discussed in subsection 2.2.

2.1 *Definition of the psychometric function*

The psychophysic problem describes the formation of the mathematical operation which expresses the behavioral preference (Robert, 1985). The psychometric function that has been introduced in the context of the Signal Detection Theory offers an effective solution to the psychophysic problem, according to which the preferences are sensory responses that depend on a parameter of a specific stimulus for decision making (Gold and Ding, 2013; Hunter, 2017). The psychometric function can be applied in decision making problems with only two alternatives, also known as yes-no problems, in order to demonstrate the preference shift affected by the stimulus intensity (Gold and Ding, 2013) and reveal the behavioral attitude of the subject. The stimulus for making a choice is the probability of an event (Hunter, 2017) and especially for the decision making context, this stimulus becomes the gain probability or else the expected added value.

In practice, the psychometric function allows the simultaneous study of multiple preference variables and characteristics (Gold and Ding, 2013). In the context of the present paper the psychometric function takes the form of the Sigmoid function, which is defined by the formula $\frac{1}{1+e^{-(x-a)/b}}$, as shown in Figure 1 (Hunter, 2017). In the function variable a, determines the shift of the sigmoid and is interpreted as the preference's bias, whilst variable b, determines the steepness of the slope and characterizes the preference's sensitivity (Gold and Ding, 2013; Hunter, 2017).

2.2 *Modeling attitudinal preferences with the psychometric function*

In order to fit the psychometric function in choice problems affected by the phenomenon of risk and ambiguity aversion, it is essential to translate the preference expression into arithmetic terms. The phenomenon of aversion can be defined as a shift of preference, and the subject's response can be translated into values of the interval [0, 1], where a zero value reflects the risk or ambiguity aversion and a value of 1 reflects the risk or ambiguity seeking, respectively. The relevant tasks examine the subject's multiple responses to a specific problem, while the gain probabilities progressively increase and they lead to the shift of the preference, from 0 to 1, which can be represented both arithmetically and graphically. When there are several values of such responses from multiple tasks, the average of all the responses is extracted for every 10 hundredths of gain probability rise, so as to extract the average response pattern and produce the graph of Figure 2. This sensory response pattern represents graphically the shift of attitude for all the relevant expressions and also determines the appropriate

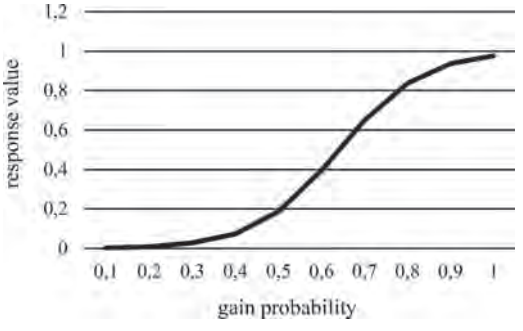

Figure 1. The graph of the psychometric function with $a = 0.642$ and $b = 0.096$, which reflects the attitude towards risk.

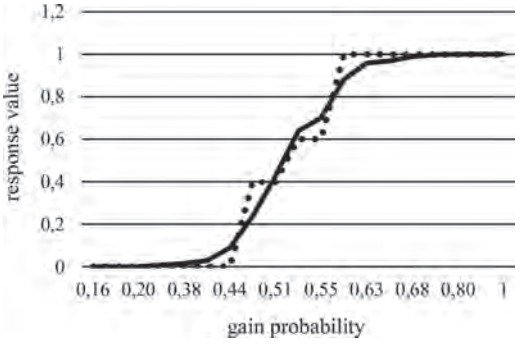

Figure 2. Fitting of the sigmoid function under ambiguity.

psychometric function which best reflects the subject's behavioral attitude. In particular, the sigmoid function is determined by the gain probability variable x and the output $f(x)$ is the value of the subject's response for the given probability, whilst the function fitting is estimated with non-linear regression and the least squares' method. Practically, the variables a and b are estimated accurately with the use of Solver Tool in Microsoft Excel 2013 and the psychometric function is defined, as shown in the graph of Figure 2.

3 A METHODOLOGY FOR BEHAVIORAL ATTITUDE IDENTIFICATION

The new approach for revealing the subjects' behavioral traits and attitudes was presented in Section 2. This research explores experimentally the utility and the significance of this approach with the methodology described in this Section, and particularly in the subsections 3.1, 3.2 and 3.3. The methodology includes the procedure of identifying attitudes under the conditions of risk and ambiguity, respectively, as presented in the subsections 3.4 and 3.5.

3.1 *The experiment*

The objective of the specific research is the investigation of the individual attitudinal preferences and their potential influence on the determination of weights in decision making. To meet this objective an experiment was realized in two phases. The initial phase included a personality test with control questions for the evaluation of the subjects' comprehension and consistency and a weighting test. The personality tests that were used included checklists of multiple values to two different problems of alternatives evaluations, i.e. a problem of a ballot choice and a problem of the best bet among a set of offered bets. The answers to these tests reflect the subject's respective psychometric function, which is either risk prone or risk averse (Holt and Laury, 2002; Csermely and Rabas, 2016; He, Veronesi and Engel 2017).

The evaluation of the responses led to the identification of the subjects who responded properly to the control questions and so their responses could be considered valid. These specific subjects were selected to participate in the second phase of the experiment, which included some explanatory questions about the subjects' personality and preferences in the conditions of risk and ambiguity, respectively, in order to validate and confirm their behavioral preferences and attitudes. The content of the second-phase tests was the same with the respective tests of the first phase.

3.2 *The sample*

The present research was addressed to 50 engineers with professional experience in decision making in the field of construction industry; 37 of them participated to the experiment providing a satisfactory response rate of 74%. The sample included engineers of different specialties, such as civil engineers, mechanical engineers, architects and surveyors, with various levels of working experience from two to 30 years, representing both the private and the public sector, and including individuals with diverse personalities, behaviors and cultures (Charness, Gneezy and Kuhn, 2013). Based on these features, the sample can be evaluated as satisfactory in the context of this research.

3.3 *Identification of behavioral attitudes*

The initial test was completed successfully by 37 subjects and after the evaluation of the results, 10 of the completed tests, which represent the 37.04% of the initial responses, were excluded from further processing because of incorrect responses to the control questions. Consequently, the number of valid responses in this phase is 27, which is sufficient for the estimation of the subject's preferences in risk and ambiguity and also allows the extraction of weighting tasks' results.

The first analyses of the personality test results lead to the determination and the optimization of each subject's psychometric functions for the shift of preferences in the conditions of risk and ambiguity, respectively. The determination of the sigmoid function requires the estimation of the characteristic values of variables a and b, which reveal the preference's switching point and also allow the identification and the categorization of the subject's behavioral attitudes. Moreover, the sigmoid function and its variables are uniquely determined for every subject in the environment of risk, as well as in the environment of ambiguity. The estimated values of these variables for the risk attitude, and also the corresponding values for the ambiguity attitude are presented in Table 1.

3.4 *Identification of risk attitudes*

The determination of risk attitude with the use of the psychometric function is based on the assumption that the switching point of the subject's preference can describe the behavioral attitude. According to this assumption, the critical switching point is observed when the gain probability is 60% (Holt and Laury, 2002; Csermely and Rabas, 2016; He et al., 2017).

In practice, this means that when the subject changes preference from risk avoidance to risk taking

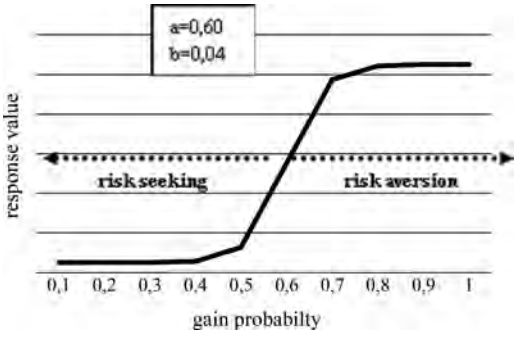

Figure 3. An example of the psychometric function with the critical switching point representing subject's risk attitude.

before the gain probability of 60%, this attitude is characterized as risk seeking. Accordingly, if this shift of preference occurs when the gain probability is greater than 60%, this attitude would be risk averse. In the psychometric function approach, the switching point can be directly identified because it is determined as the value of the characteristic variable *a*, as represented in Figure 3. The results of this analysis demonstrated that in the sample of 27 subjects, 19 of them, representing the 70.37%, are characterized as risk averse, while only 8 subjects, representing the 29.63% are characterized as risk prone.

In addition, it is important to examine the value of variable *b*, which expresses the sensitivity of subject's choice under risk. As the value of variable *b* increases, the sensitivity of the choices also increases and consequently, it is more likely to observe inconsistent responses. The value of variable *b* determines the different levels of sensitivity in the sample as shown in Figure 4 and particularly, in the total of 27, 11 subjects are characterized by *b* value smaller than 0,050 and therefore great consistency in their preferences, whilst 16 subjects demonstrate greater *b* value and three of them demonstrate remarkably great values, which indicate great sensitivity in preference expression.

3.5 *Identification of ambiguity attitudes*

The same analysis was conducted in order to extract results for subjects' attitudes in the condition of ambiguity. The responses' values are modelled with the psychometric function and the variables *a* and *b* are estimated. Based on the Ellsberg Paradox's assumptions about the inherent ambiguity aversion, the critical switching point of preference is set at 60% gain probability (Lauriola and Levin, 2001; Schneider and Nunez, 2015). In the sigmoid function approach, this fact can be translated to variable $a = 0.60$ and the subjects' behavioral attitudes can easily be identified as ambiguity averse or prone, as presented in Figure 5.

The majority of the sample, 25 subjects in total, confirms Ellsberg's assumptions about an inherent ambiguity avoidance, as they demonstrate *a* values between 0.50 and 0.60, while there are only two cases where the value of variable *a* is greater than 0.60, a fact that indicates an ambiguity seeking attitude, as shown in Figure 6. Moreover, the sensitivity of these preferences, as determined by the values of variable *b*, remains small with minor differentiations. The *b* values vary between 0.05 and 0.01, showing that the subjects express their preferences with high consistency and stability.

4 FINDINGS ABOUT THE WEIGHTING METHOD'S IMPACT

The research aims to evaluate the impact that a weighting method may have on the decision maker's attitude concerning the assignment of weighting values. For this purpose, the proposed methodology employs three different weighting methods which are presented in subsection 4.1. The procedure of the analysis and the results are presented in detail in subsection 4.2.

4.1 *The examined weighting methods*

It is a fact that different weight elicitation methods lead to different weighting and consequently different decision results, a phenomenon which is mainly connected to the methodological approach and the cognitive process of weighting, rather than random response errors (Jia, Fischer and Dyer, 1998). The three basic weighting methods selected for this examination are the direct rating, the distance estimation and the pairwise comparison.

One of the most popular weighting methods is the direct rating, which depends on the decision makers' quantitative estimation of their preference. The method leads to a rank order of the alternatives in descending order, and also permits the formation of linear models for capturing that preference (Bottomley and Doyle, 2001). The direct weighting is implemented with the direct evaluation of the criteria or the alternatives with the application of a specific weighting scale. The cognitive approach of this method entails a preliminary examination of all the criteria, so that the subject discerns the significance of each element, and then proceeds to the final evaluation.

In an effort of disengagement from the direct and precise determination of weights, the method of distance estimation is used. According to this weighting process, the decision maker firstly determines the ideal situation and then uses this as reference base for the determination of weights. Every criterion or alternative is compared with the ideal situation, so as to determine the distance between the two situations, with a sense of proportion for all the rest situations. It has been observed by Jia, Fischer and Dyer (1998) that this method's results present significant differentiation which depends on the given distance scale.

The method of pairwise comparison offers a completely different approach for the elicitation of weights. This particular method depends on the concept of trade-off (Jia, Fischer and Dyer, 1998) and also offers the expression of reciprocal preference relations (Xu et al., 2015). In this case, the criteria are not examined generally, but in separate pairs and so the decision maker tends to rely more on intuition, rather than correlation.

4.2 *The examination of the weighting methods*

Initially, the purpose of this research is the examination of the consistency and reliability of each weighting method, as a correlation of the decision makers' behavioral attitudes. Each weighting task includes discrete sub-tasks, which are used to compare the assigned weights and extract the correlations, as a measure of each method's effectiveness. The correlation between direct rating, distance estimation and pairwise comparison has to depend on an approach that is not affected by each method's characteristics. For this reason, the present approach is based on the rank order of the alternatives and so the ranking correlation coefficient, well-known as the Spearman coefficient, is extracted. Additionally, the ranking correlations and methods' consistencies are related to the decision makers' behavioral attitude, so as to investigate any connection between them.

The first weighting test is formed with the method of direct rating. The specific weighting method demonstrates high correlation between its results, as Table 2 shows. The overall correlation coefficient is the average of the correlations of the quantitative and qualitative weightings, which is estimated at 0.922, with a minor variance 0.002. This high coefficient also shows the high consistency of the responses, expressed with the method of direct rating.

Table 2. The correlation coefficients and the compatibility degrees of the three weighting methods.

Averages		**0.921915**	**0.917263**	**0.66727**

Generally, referring to the subjects' attitudinal characteristics, both risk averse and risk prone subjects demonstrate high consistency degree for their weightings with this particular method. Specifically, the risk averse subjects demonstrate the same high consistency 0.922 and smaller variance 0.001, whilst the risk prone subjects are characterized by a slightly lower consistency coefficient 0.911 with variance 0.002. The consistency of weights and its relation with the decision makers' attitude is presented graphically in Figure 7.

The second method examined in this experiment is the distance estimation. In this weighting method, the correlation coefficient average and therefore the consistency of the responses is also high, at the level of 0.917, with slightly increased variance 0.009, compared to the previous method, as demonstrated in Table 2. The method of distance estimation helps the decision makers to determine weights with high consistency. The risk

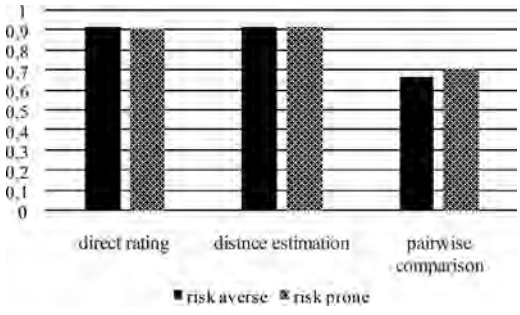

Figure 7. The consistency of responses for the three weighting methods.

averse decision makers express high consistency 0.919 and variance 0.006, while the risk prone decision makers seem equally consistent with consistency average 0.918 and variance 0.003.

These results partially confirm the observation of Jia, Fischer and Dyer (1998) for the increased effectiveness of distance estimation compared to the direct rating, only for the risk prone subjects, whose consistency increased slightly from 0.911 to 0.918, as presented in Figure 7.

The third weighting method examined is the pairwise comparison, where the decision maker's responses have the form of bits of a binary system, instead of a rank order of the alternatives. This is the reason for the determination of a different method for the correlation extraction. Every response with this weighting method was compared to the corresponding response and ranking with each one of the other two examined methods, in order to extract conclusions for the consistency of the method. When the response that is expressed with the pairwise comparison coincides with the response determined with one of the other two weighting methods, then this response is considered true and takes the value 1, whereas in any different case, with no indication of such coincidence, the response takes the value 0. For instance, when a decision maker assigns greater weight to the alternative with 70% gain probability, compared to the alternative with 50% gain probability, in a comparison between these specific alternatives, it is normally expected to select the alternative with 70% gain probability. This case can be described as compatibility between the responses of the direct rating and the pairwise comparison. In any different case, the coincidence cannot be achieved. With this procedure, all the responses of the pairwise comparison are tested for their coincidence with the other applied methods and finally, the average of the response compatibilities is estimated as the compatibility degree of Table 2, that reveals on the one hand the method's reliability, and on the other hand, the subject's consistency with this weighting method.

The compatibility degree average, hence, determines the consistency of weights, and simultaneously reflects the correlation with the two other weighting methods. It is obvious in Table 2 and in Figure 7 that the responses of the pairwise comparison demonstrate a severe lack of consistency, because with the specific weighting method more inconsistent answers occur, which entail, for most of the subjects, an unexpected risk and ambiguity seeking.

The correlation degree average for this method is significantly lower and estimated at 0.677, with high variance 0.031. The risk averse subjects seem to follow this trend, as they demonstrate a correlation average of 0.672 and variance 0.022. However, it is worth to mention that in this case, unlike previous observations, the risk prone decision makers seem slightly more consistent compared to the risk averse subjects, as they have a correlation average of 0.709 and variance 0.009.

5 CONCLUSIONS

This research focuses in the decision makers' determination of weights and features the cognitive process of weighting from the perspective of behavioral preference and attitude. Therefore, a new approach for revealing and classifying behavioral attitudes is proposed, based on the decision maker's preference expression with the use of the psychometric function. The proposed methodology allows the modeling, the recognition, and the classification of individual attitudinal preferences and the parallel examination of other crucial parameters, like sensitivity.

Moreover, the paper investigates the impact of the applied weighting method on the weighting process and consequently, on the determination of weights. A methodology is developed to evaluate the consistency and reliability of the weighting method, as well as the impact that it may have on the decision maker's attitude concerning the assignment of weighting values. The results demonstrate that the weighting methods affect the expression and the ranking of decision maker's attitudinal preference. In particular, the methods of direct rating and distance estimation demonstrate high consistency of responses, compared to the method of pairwise comparison that has significantly lower consistency. Additionally, risk averse subjects seem to respond more consistently with the two first methods, as opposed to the risk prone subjects, who respond better with the method of pairwise comparison. This evidence can be very helpful to the assignment of managers and decision analysts on projects and to the selection of the proper weighting method to apply to decision making problems.

School of Food Science and Environmental Health, Dublin Institute of Technology (DIT), Dublin, Ireland

ABSTRACT: Nowadays the majority of organizations operating in manufacturing field recognize the importance of including the Human Factor contribution in the industrial process optimization (Hong et al. 2007). Technical measures and work organization procedures have been optimized in order to reduce the defects and waste generation but the Human Performance prediction still represents for Managers a difficult task to deal with.The prediction of the human performances of all workers involved in a production system would help Managers in better allocating the human resources. In order to reach this objective, a model to quantify the human capability of managing a complex task in a working context characterized by a set of physical, organizational and cognitive factors was designed.This paper presents the preliminary results of a three years industry/academia partnership project to assess the human performance in manufacturing plant. A multi-discipline approach involving both technical and individual factors was adopted.

1 INTRODUCTION

In manufacturing sector, the process optimization plays an important role to improve the production efficiency and economical profits.

Production is influenced by several factors such as: technology, organization, energy and workers performance.

In many cases, process optimization has been primary focused on technical measures and work organization procedures.

The Human Factor, despite the level of automatization in manufacturing industry is considerably increased and the standardization of working-procedures drives the working activity, still plays an important role on the efficiency of production system (Baines et al., 2005).

Human Factor has a strong influence on the occupational accident occurrence and defects generation.

Human Factor represents for Managers a difficult task to deal with even if most of organizations operating in manufacturing field recognize the importance of including the Human Factor (HF) contribution in the industrial process optimization (Hong 2007).

The Human Factor analysis has been approached differently in several areas.

Safety and Quality managers focused their attention to the deviation of human behavior from procedures. Miller (1987) analyzed a set of environmental, organizational and individual factors in relation to error-related outcomes. The ex-post events analysis approach has been used (Comberti et al., 2015) to identify causes of occupational accidents and defects with the aim of reducing their repetition.

Work Organization managers related the HF analysis to the ergonomic with the aim of calibrating and optimizing the task-time and reducing the operative risk task-related (Lin et al., 2001).

Many studies on Human Performance modeling suggest that the HF has to be approached as a complex system, where behavior, cognition, physiology and working condition deeply interact (Leva, 2016).

The knowledge of the relation between the human nature and the working condition of all workers involved in a production system would be crucial for the industrial Management.

Better allocating the human resources forward the different tasks will probably reduce the defects generation and the unsafe actions frequency.

In order to reach this objective it is necessary to model a system able to quantify and predict the human capability of managing a complex task in a context characterized by a set of physical, organizational and cognitive factors (Groth, 2012) in other words a model able to define and assess the Human Performance (HP).

Relevant researchs in this topic suggested which variables can be used to define the HP.

Baine & Benedettini (2007) suggested a multidisciplinary approach based on Sociology, Phycology and Engineering disciplines to be consistent on human nature representation. Eklund (1997) showed that Ergonomic has to be related to quality performances.

This paper presents the preliminary results of an industrial and academic project to develop a Human Performance assessment method for safety and quality optimization.

The aim of this work is to approach the HP modeling to facilitate the management of HF into the industrial improvement process.

The proposed model was developed on the basis of Straeter (2000) results.

It is based on the fundamental assumption that the HP can be represented as directly dependent from two macro-factors:

- Task Complexity (TC): that summarizes all factors contributing to the physical and mental requests to execute a given operative task, including work environmental factor.
- Human Capability (HC): that resumes the resources of workers under the real working condition. This factor represents both physical, mental and cognitive ability of the worker.

Section 2 of this paper presents the Conceptual Model of this project meanwhile section 3 shows the Operative Model deducted from the case study.

Section 3 gives an illustration of the project future development with a focus on the model validation. Conclusions will end the paper.

2 HP PROJECT DESIGN

This project has been managed in 4 steps as Figure 1 shows.

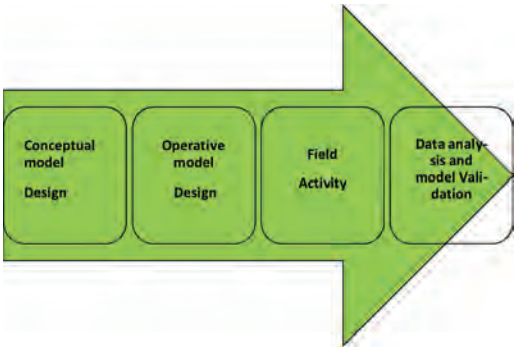

Figure 1. Project structure.

First step was focused on the "Conceptual Model" designing process.

Conceptual Model defines the variables and relations considered to the HP assessment.

Second step was characterized by the Operative model-design that represents the projection of Conceptual model into the industrial real life.

In other words each variables introduced into the Conceptual model have to be replaced by a measurable quantity into the Operative model.

Third step will be focused on HC and TC assessment with an intensive data field collection. This step will involves directly the workers of the plant with skill tests performed during the working activity.

In addition to this the descriptive parameters of TC will be collected with a deep analysis of working places.This step will be completed by a systematic interview of all workers involved. The interview will be structured on a set of questions related to individual motivation, risk-perception, working complexity perception.The information acquired with the survey will be used as a feedback for safety, work organization and quality improvements. On the basis of the results a validation or modification of the model will be done. This paper presents results related to the first and second steps of the project.

2.1 *Conceptual model*

The HP model represents the interaction between two macro factors: the Human Capability (HC) and the Task Complexity (TC).

Both factors can be analyzed with a wealth of methods for different purposes, such as data collection, task analysis (including cognitive task analysis), workload measurement, assessing situation awareness performance assessment (including team performance assessment), human error identification and interface evaluation methods (Stanton, 2004 and 2006).

In this work the proposed conceptual model of Human Performance is showed in Figure 2.

TC, as mentioned in the previous section, represents the total demand of resources asked to perform correctly a given task under certain work environmental condition.

TC is the result of the contribution of two main factors: Mental Workload (MW) and Physical Workload (PW), both associated to a single operative task.

PW factor is easily relatable to the physical, motion and postural efforts required to complete a given task.

Bad ergonomics combined with time pressure (coping with pace) have been estimated to cause about 50% of all quality deviations (Lin, 2001).

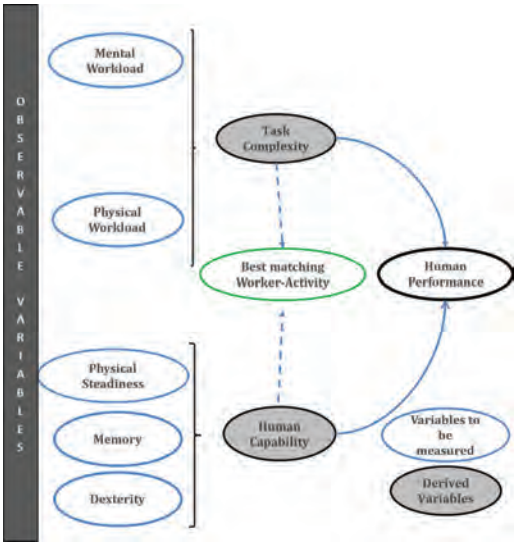

Figure 2. HP conceptual model.

Several studies demonstrates that high physical workload such as unkind postures can decrease the performance for discomfort (Erdinç, 2011).

A low variation, such as repetitive motions and static workload, was observed as additional cause for muscle fatigue (Punnett, 2000).

Other factors that may be included on PW modelling can be identified in the degree of rotation between high and low demanding tasks (Horton, 2012) and into the gender effects for the differences concerning discomfort and muscle fatigue in repetitive and static workload (Hunter, 2012).

In addition to the above mentioned factors, that are related to a specific operative task, other variables able to affect the PW are represented by environmental workload effects (Jung, 2001) which include: improper temperature, lighting, noise, vibration and exposure to chemical agents and physical agents as dust.

The physiological effects of these environmental factors, under industrial conditions, can contribute to an increase of the stress level and consequently to a loss of human performance (Grandejan, 1985).

MW was defined by Kahneman (1979) as "a factor directly related to the proportion of the mental capacity of an operator spends on task performance".

The MW assessment has been conducted in various research fields with both objectives and subjective measures such as: physiological activity under simple task normative condition (Kramer, 1991), cognitive performances, subjective analysis (Didomenico, 2008) and combined approach (Miyake, 2001).

All these studies have been performed in normative condition, with simple standardized tasks and under controlled environmental condition. This configuration is far away from industrial situation.

A relation between MW of assembly tasks and quality deviations was recently founded by Falck (2014). This work suggests that MW can be estimated trough the evaluation of the complexity of the task.

Operating in an industry plant it would be more suitable assessing the MW factor with a combination of subjective measurement and indirect task-related variable quantification, instead of approaching it with physiological measurement and cognitive normative test.

As a results of literature review and plant analysis a set of variables to TC definition was identified.

Figure 3 summarizes all variables selected to TC definition.

Human Capability (HC), as mentioned in the previous section, represents the total amount of resources that a worker is able to give for execute a given task under environmental working condition.

The HC factor is given by the contribution of several human skills that are all engaged in performing an operative task.

In particular the main Human skills that have been considered in relation to an assembly task are:

- Ability: skills like Precision, Manual Handling, Coordination are solicited continuously during a front line assembly work.
- Memory: remembering the sequence of operations and parts to complete correctly a given task can differ considerably.
- Physical: the ability of maintaining a constant performance during the shift and the ability of coping with pace.

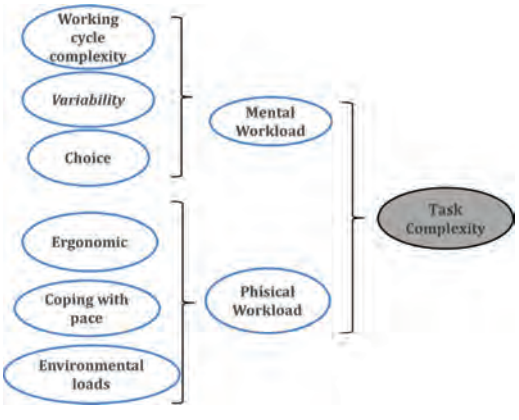

Figure 3. TC conceptual model.

2.2 *Operative model*

The Conceptual model defined in the previous section represent also the trace for the Operative model definition.

Operative model contains for each factor taken into account into the Conceptual model a set of observable and measurable variables.

The variables were selected after a field analysis performed in the beginning stages of the project with a participatory approach that involved both academic and industry professionals operating in the various management areas involved: Safety, Work Analysis, Quality, Work Organization.

The observable variables selected will be measured both in numerical and qualitative scales.

In order to allow the confrontation between variables with different nature and scale, all the variables will be harmonized in a common numerical scale.

TC factor will be estimated trough the assessment of observable variables that are showed in Figure 4 (Mental Work Load) and in Figure 5 (Task Complexity).

In the proposed representation of Figures 4 and 5 some variables are not used directly into the HP model but are compared with the results of the workers interviews previously mentioned.

HC factors will be estimated trough a set of measures, showed in Figure 6.

These measures will be obtained as a results of skill tests performed by workers during the real working activity.

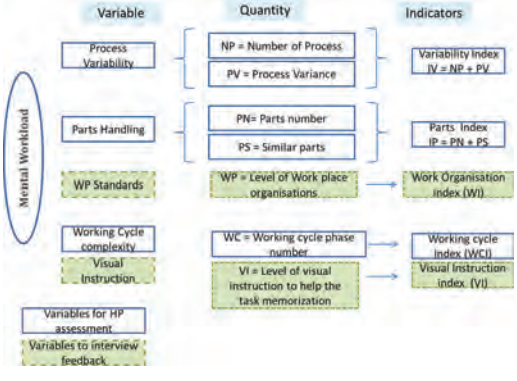

Figure 4. MW operative model.

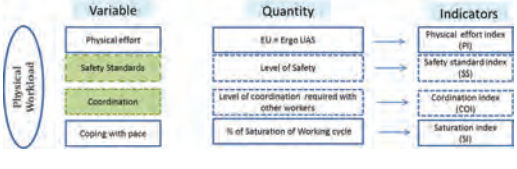

Figure 5. PW conceptual model.

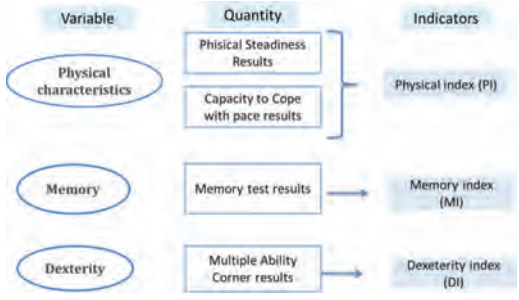

Figure 6. HC Operative model.

As an example the "Memory skill" will be tested recording the time spent by a worker to replicate a symbol sequence shortly showed.

Dexterity variable will be measured with 3 "ability tests" that simulate some typical operation asked into an assembly line.

The HC of each single workers will be assessed recording the time spent to complete all tests and recording the number of errors done.

In addition to these human skills, to model the Human Capability, it must be noticed that an important psycological aspects that can be described as "Motivation" can interact constructively or disprutively with this factor.

Motivation includes several psychological factors:

- Perception of task-risk;
- Perception of task complexity;
- Personal awarness;
- Job satisfaction\dissatisfaction

It is conceptually easy to consider that a severe mismatch between Task complexity and Perceived Task Complexity can facilitate the human error or unsafe act generation.

Information acquired with the interview will be used to estimate the level of motivation and perception of each workers.

3 PROJECT DEVELOPMENT AND MODEL VALIDATION

Nowadays the project ended the second step. On the basis of the Operative model in the next 6 months a field data collection will be done. This activity will involves 150 workers operating in 4 assembly lines.

The total number of working places can be approximately estimated in 70 units. The application of this model will imply the calculation of 170 Human Capability profiles and 70 Task Complexity profiles. The HP calculation will be done according the scheme showed in Figure 7.

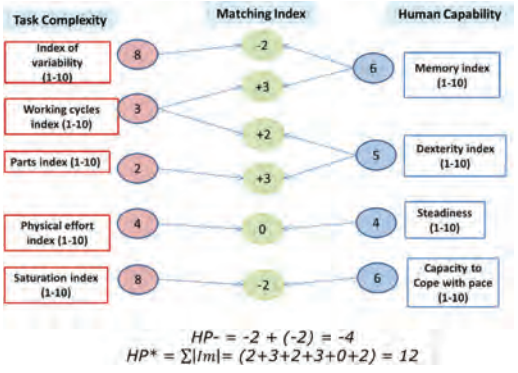

Figure 7. HP assessment.

Figure 7 summarize the generic scheme of calculation of HP between the TC of a working place characterized by 5 index (Variability, Working Cycles, Parts, Physical Efforts, Saturation) and the HC of a worker characterized by 4 index (Memory, Dexterity, Steadiness, Coping with pace).

This scheme of calculation is based on the operation "HC-index – TC-index" and leads to the definition of 6 matching indexs.

On the basis of the matching-index two Human Performance index are defined:

- HP-: represents the sum of all negatives matching index.
- HP*: represents the sum of all absolute values of matching index.

The assessment for each assembly line of HP— and HP* will allows a quantitative calculation of the potential Human Performance related to the matching workers-working places.

Changing the distribution of the workers will leads to a different HP estimation.

Minimizing HP-and HP* will implies the optimization of the distribution of the workers forward the working places on the basis of each individual human capability and each task complexity.

To validate this model a collaborative processes involving Quality and Production Managers in mutual learning processes will be adopted as suggested by Action Research method (Greenwood, 2006).

A set of 25 working places with relevant problems of quality will be selected.

HP results will be used to identify the best matching workers-working places and on the basis of that a new configuration of the line will be done.

A period of 3 months will be used to monitor the results of the new configuration workers-tasks and quality indicators will be collected.

The comparison of quality data ante and post configuration will allows the evaluation of the impact of the method.

This operation would leads to a reduction of human error related to a wrong matching worker-working place.

The HP assessment would be used as a sort of objective guideline to optimize the workers distribution into assembly lines.

The number of workers involved (more than 150) and working places analyzes will allows a statistical validation of the model.

4 CONCLUSION

Conclusively, the strengths of the proposed empirical approach with respect to the Human Performance assessment can be summarized as it follows:

- a model to HP definition as the ultimate product of the balance between the TC (driven by all the factors from the environment) and the operator characteristics (HC) was developed.
- The empirical based analysis will enhance the knowledge of the specific process operations at Managerial level, possibly highlighting latent drivers of Human Performance.
- This model was developed and will be tested in real operative condition and with a large number of workers directly involved. That represents a rare case of cooperation between academia and manufacturing. Results of the model application will be directly applied by industrial management with a measurable impact in term of process optimization.

Symptom-based approach for dynamic HRA and accident management

G.I. Petkov
Independent Consultant, Sofia, Bulgaria

ABSTRACT: The paper presents symptom-based approach for dynamic Human Reliability Assessment (HRA) and accident management through holistic context evaluation by the Performance Evaluation of Teamwork (PET) method. The macroscopic context evaluation procedure of the PET method gives opportunity for correct definitions of emerging issues, challenges, and possible solutions in the field of HRA for errors of commission, dependency analysis, multi-unit considerations, long time window scenarios, digitalized main control room, etc. In addition, the measuring the durations for recognition and disregard of symptoms, depending on various Performance Shaping Factors (PSFs), by utilization of well-developed stimulus-response models on the microscopic level, and extended use of simulator data could improve the quality of HRA, accident analysis and Probabilistic Safety Analysis (PSA) respectively.

1 INTRODUCTION

Human reliability assessment (HRA) is an applied science on the frontier between Probabilistic Safety Analysis (PSA), reliability theory, Deterministic Safety Analysis (DSA), complex system simulation, Human Factors (HF), Cognitive Systems Engineering (CSE), psychology and neuroscience. It is trying to apply what is known from sciences to reflect human interferences within Socio-Technical System (STS)[1] assess probability of Human Failure Events (HFEs), design and construct fault-tolerant and resilient system interactions between human, technology, organizations and environment.

With the increase in reliability of equipment in technical systems, the human who designs, manages and maintains them becomes a critical element. His/her reliability has to be explored and increased to match that of the machine. HRA has been emerging in the 60 s as a product of the development of the complex technical systems and technologies in the military, space and nuclear industry.

Human reliability is an irreplaceable element for the efficient and safe use of STS. The understanding and evaluation of safety is related to probabilistic risk assessment (PRA). Risk is characterized and includes at least two quantities:

- *magnitude (severity)* of the possible adverse consequence(s), and
- *probability of occurrence* of each consequence.

The development of nuclear technology is a priori related to ensuring its safety. Therefore, in the first systematic and comprehensive risk study, WASH-1400 (1975); HRA was included as an indisputable and important element.

There, HRA used the Technique for error-rate prediction (THERP) method (Swain & Guttman, 1983), developed by Alan Swain, and based on existing statistics and HF knowledge of that time, theoretical assumptions, and expert judgment. This method gives the *"thesis"* or the aim of "first generation" HRA methods—to obtain a Human Error Probability (HEP) of identified HFE by guessing, reasoning and weighting of internal and external factors influencing HEP. Thus, the scenario's severity is taking into account by expert judgment through multiplication of performance shaping factors (PSFs).

In every human action (HA), one may distinguish two sequential stages—Cognitive (Diagnosis or Decision-making) stage and Executive (Response or Manual) stage. For the second stage some reliable statistics does exist (e.g. THERP) or can be obtained. However, for the first cognitive stage refuted and recanted holographic-like[2] models are not available. This is due to the "unfinished business related to" HRA, which includes identification, specification and fitting of human cognition model to define the error potential and context of human action" (Dougherty, 1993). Hollnagel (1993) also emphasized that HFEs take

[1]STS consists of human, organization, technology and environment.

[2]Holographic-like behavior of STS is a system without any communication among separated processes (Townsend, 1984).

place in a cognitive system. He also argued that the detailed knowledge of HA objective context and its subjective image which exists in human mind is a basis for understanding of human performance: *"... any description of human actions must recognize that they occur in context" and in dynamics "on a second-by-second basis" and must take into account multidimensional dynamic context and "how the context influences actions" and a whole cognitive process* (Hollnagel, 1998).

When considering human performance reliability in accident conditions, the first dimension is time. This *temporal approach* used in THERP, e.g. Swain's Time Reliability Curves or its 'improved' version called the Human Cognitive Reliability (HCR) Correlation (Hannaman & Spurgin, 1984) is "virtually impervious to context". It should be complemented by *influential* or *contextual approach* to avoid "bareness in modeling" (Dougherty, 1993). He came up with the idea the change the "first generation" included HRA models such as THERP and HCR with the "second generation" HRA models (Dougherty, 1990). The *"antithesis"* or the aim of "second generation" HRA models was to take into account HA context with its specifics, severity, multidimensional dynamics and holistics for any individual, group mental or manual process.

However, the most of "first generation" HRA methods made a formalistic substitution of "influential factors", the THERP's holistic PSFs or their modifications, with contextual factors and it does not substantially alter HRA's outcomes. Moreover, difficulties arising from significant uncertainties in the quantification of each factor for HEP due to lack of data and an appropriate method to address uncertainties and dependencies between PSFs. This substitution exemplifies the Dougherty's observation and insight of that "the influential and contextual approaches may find themselves indistinguishable at the quantification stage because of the paucity of actual data" (Dougherty, 1993).

Since then the HRA community is discussing and substantiating some contentions and challenges of HRA, which caused much debate and launched the so-called "second generation" HRA. Some of HRA basics are already indisputable; others are the result of inertia in group thinking, misleading interpretation, judgment biases, business dependences and interests.

The following list shows HRA features that are valuable[3] for the accident analysis and whether they are implemented or not in the discussed second generation HRA methods (the features are in italic):

- *The response-related model is necessary*—not implemented in *Méthode d'Evaluation de la Réalisation des Missions Operateur* (MERMOS);
- *"…any description of human actions must recognize that they occur in context"*—implemented in *Cognitive Reliability and Error Analysis Method* (CREAM);
- *'extremely contextual'*—implemented in MERMOS;
- *situational and knowledge/mental models*—implemented in *A Technique for Human Event Analysis* (ATHEANA);
- *shift the problem from quantification of the operator behavior to the quantification of the error-forcing context*—implemented in CREAM, MERMOS, ATHEANA;
- *'error' identification*—implemented in CREAM, MERMOS, ATHEANA;
- *'error' quantification*—implemented in CREAM, MERMOS, ATHEANA;
- *'error' reduction*—implemented in CREAM;
- *accident context is a function of time "on a second-by-second basis"*—not implemented in CREAM;
- *individual dynamics of situation*—not implemented in MERMOS;
- *variability of performance is more important than how actions can fail*—not implemented in CREAM;
- *some combination between performance-related effects*—implemented in MERMOS;
- *context as a collection of weighted PSFs*—implemented in SLIM by domain expert judgments;
- *human performance limiting values*—implemented in MERMOS;
- *context could be different for each crew member*—not implemented in MERMOS;
- *systematic search process by series of lists of possible Human Failure Events, Unsafe Acts and error-forcing conditions (EFCs)*—implemented in ATHEANA;
- *identification of erroneous actions based on the accident* context and not to "subsume the errors identified with the event sequence mostly by historical means"—implemented in ATHEANA.

To overcome the above mentioned problems with subjective judgment of PSFs, holistic and dynamic human performance in STS, HFE identification, quantification, reduction, data-mining and measuring, a more realistic *symptom-based approach* for the statistical description of the STS context was proposed (Petkov and Furuta, 1998). The STS context quantification procedure is a first step of a *Performance Evaluation of Teamwork (PET)* HRA method that can implement the above features valuable for both HRA and accident analysis It relies on combinations of recognizable

[3] This means that the HRA method can assess the severity of the context, its potential for human error and thereby reduce the risk or optimize the action of an operator.

symptoms[4] for description of the variability of STS performance and gives controllable macro structures of main mental processes as cognition and communication (Petkov, 2000).

And finally, the HRA *"synthesis"*: to obtain a HEP of identified HFE in the STS context based on its holistic specific symptoms' recognition, severity & dynamics for any individual, group mental/manual response. A symptom's impact is reasoned, measured and weighted by internal and external "glocal" *(global & local)* PSFs for it.

2 SYSTEM APPROACH TO HUMAN PERFORMANCE

The HRA experience showed that often the approach to the study of human actions and failures is unilateral and biased, for example from the point of view of psychologists and engineers.

For example, the engineering modeling of human reliability, in similar way as equipment reliability, encounter grounded arguments by psychologists that it does not account for its activity and variability, and that man is cognitive, emotional, volitional, and not an item. On the other hand, the concerns of some of psychologists are unfounded that man cannot be simplified as one of the system components or cannot be evaluated as a number, i.e. neuroscience or HRA should not apply the universal ways for modeling and sharing scientific knowledge.

There are two approaches to human errors – "the person approach and the system approach." The first approach "focuses on the contribution of human errors on the system, their own psychological justification, accusations of forgetfulness, inattention, or moral weakness" (Reason, 2000). For example, "Over time, the role and importance of human contributions has grown for early PRAs, the contribution of humans has been set at about 15%, now the contribution has grown to 60% to 80%" (Spurgin, 2009).

The second approach focuses on the conditions, situations and context in which a person deliberately and conscientiously performs his/her actions to effectively manage the system and limit the consequences of the risk of its operation. The extreme statement is that "Human error is never the root cause."

Human performance needs to be considered as a variability of a whole STS where human interacts with technology, other humans, organizations and environment. The system approach is the more preferable and practical for context-based HRA. It is not important "who blundered, but how and why the defences failed" (Reason, 2000).

[4] A symptom is a measurable plant parameter that is available to the operator in the control room (IAEA, 2006).

3 SYMPTOM-BASED APPROACH TO STS STATISTICAL DESCRIPTION

The system approach means more components, more states, more interactions and information that have to be taken into account. How to analyze the system performance is the most important issue.

The enormous amounts of information and the use of digital technology, for information processing, have been changed individual (human) and group (social) mental processes and people behavior. The use of structural or functional decomposition, customary to PSA and CSE modeling, in HRA does not work because they break the most important dynamic interactions in the system and cannot explain its holistic behavior. The real-world decision-making processes need to be modeled in the context of the complex multi-agent and multi-level socio-technical system. The 'context' concept is the crucial in order to really make a difference in such multi-disciplinary models to control and coordinate the balance between enormous information and limited human cognitive capacities.

3.1 *Symptom-based approach in nuclear accident management*

The symptom-based approach is now usual for nuclear accident management. The IAEA NS-R-2 (2000) establishes the following requirements on accident management: "The training of operating personnel shall ensure their familiarity with the symptoms of accidents beyond the design basis and with the procedures for accident management." Later in IAEA SRS No. 48 (2006) "symptom/state based procedures" were justified and in IAEA NS-G-2.15 (2009) a "symptom-based approach" was also recommended: "2.14. The approach in accident management should be based on directly measurable plant parameters or parameters derived from these by simple calculations."

3.2 *Statistical entropy description of socio-technical system*

The STS dynamic interactions are manifested by interference of symptoms (*stimuli with meaning for human*) and the system context could be presented by them on the macro level. Of course, if we want to understand the root causes of human errors, we should searched in depth at micro level. But the macroscopic statistical description of the STS context would help to identify the dynamic and holistic nature of the system's behavior (Petkov et al., 2001).

The basic idea of the distinction between macro- and microscopic levels is to change the set of microscopic accessible states with equivalent

subsets of macroscopic states. A certain macroscopic state can be found in many microscopic accessible states. This idea follows the Shannon theorem (1948) regarding the entropy as the measure of information, and was the basis for the used, in the PET method, *an analogy of energy and information*. The mental process in the STS is described at each moment by its *microstate*. This is a specific *quantum state* that represents the most detailed possible STS description.

3.3 *Practicality of symptom-based STS description*

As the context characterization and analysis in the HRA is implemented with the assistance of the personnel, then it is more practical and natural, firstly, to describe STS context in symptoms used by personnel. Recognizing each symptom by operator is a mental process involving individual cognition, communication between the group of operators, decision-making, checking and recovery. Each symptom has its specific symptom-influencing factors (SIFs) that essentially coincide with the used holistic PSFs in HRA. But if all the symptoms into a given scenario are described with a common PSF then it leads to blur the specific influence of a PSF on a given symptom, masks the dependencies between the PSFs and increases the uncertainty of the results.

3.4 *Theoretical issues and limitations from unexplored mental processes*

In addition to the above, there are other deeper theoretical reasons for using the symptom-based approach, these are the unexplored mental processes.

Townsend (1984) emphasizes the need for a theory for connection of *holographic-like behavior* and separation of selective and non-selective influence:

- "*Systems based entirely on holographic-like behavior* without any communication among separated processes, are omitted."
- "The selective influence postulate is critical." The "empirical tests of selective influence will likely be tied closely to separation of selective from non-selective systems."
- *"Factors that influence* not only durations but also *outputs of processes* have not been investigated."
- "*The expectation* (the mean) *of a sum of random variables* (in this case, serial processing times) *is equal to the sum of the expectations, which is true for any set of random variables whether or not they are independent*."

If systems with holographic-like behavior are omitted from exploration of mental processes then the holistic PSFs-based approach for STS context quantification is very questionable! In symptom-based approach every symptom is recognized separately and context quantification is based on enumeration of STS accessible states.

Duration of symptom recognition is measured as a degree to which an operator's perception of the STS is compatible with the required action.

A model to establish a mathematical function that describes the relation f between the symptom x and the expected duration of the recognition ΔT is necessary: $\Delta T = f(t)$. A common simplification assumed for such functions is linear, thus we expect to see a relationship like:

$$\Delta \boldsymbol{T}_i = \Delta \boldsymbol{T}_{i,min} + \boldsymbol{t}.\boldsymbol{\beta}_{ij} \quad (1)$$

where β_{ij} is j-factor, $SIF_j\ (PSF_j)$, for i-symptom.

Since Townsend & Schweickert (1989) also emphasized "Although we view the test for additivity as one important strategy in an overall systematic approach to uncovering psychological processes, *we do not identify processes with additivity*," then this means that the influence of n factors could not have been considered simple by the expression as $\beta_i = \Sigma\beta_{ij}$, where $j = 1...n$. However, $\Delta T_{i,max}$ could be measured for given human performance context (STS accessible state), and the uncertainty of the results for HEP could also be reduced.

4 PET EXTENDED DEFINITIONS, HUMAN FAILURE EVENTS TAXONOMY, EVALUATION PROCEDURE AND MODELS

4.1 *Extended definition of dynamic STS context*

Petkov & Furuta (1998) have proposed a heuristic concept of Context Factors and Conditions (CFCs) as quantitative factors to indicate *"how symptoms (CFCs) influence context"* in order to study their effects on human performance—*"how context influences actions"* during the accident. As well as they consider the context to be a function of time and second argument of the HEP function, while first argument of the HEP is time, i.e. $HEP = f(t, context)$.

Petkov & Groudev (1999) proposed an indirect similarity between material ('transition temperature shifts') and mental processes ('human performance shifts') to measure dynamic deviations of symptoms (CFCs). The common ground of this study is the emergency context. The similarity is seen between the "reference" temperature for the pressurized thermal shock in materials and the "reference" context probability for the HFE. The latter is regarded as generalized evaluation of the context influence on HA. The basic assumption of

this study is that the stress both of materials and human is due to symptom deviations or parameter gradients (between reality and expected values) which determine their characteristics and behavior.

The interactions or *"STS performance shifts"* represent the dynamic STS context or processes in human-technology-organization-environment. Matching the object in situation is an approximation that could be identified and described as an *"image"* or as a *"signature"* of the object in the situation. The concept *"image"* is the imprint of the consciousness and sub-consciousness of the *"human performance shifts"* that affect the person's physical, physiological, psychological and psychosocial ability to make sense, perceive the *object (STS)* and to perform action in the STS context.

Generally, context is defined by psychologists as "a state of mind' or 'a set of internal or mental representations and operations rather than a set of external elements". In (Petkov, 2004) the context definition was extended as *"a common state of universe, mind and situation in their relation"—object-image-situation*. In (Petkov, 1999), the term *"context probability" (CP)* was coined as a measure for severity magnitude of error-forcing context. But this general definition of context is not so practical to be a measure. The practical definition of context is: *a statistical measure of the degree of the STS state randomness defined by the number of accessible states taking place in the STSs' ensemble*.

Since the man analyses and operates the machine most frequently by discrete actions, the combination (number, value and tendency) of symptoms (stimuli with meanings), which she/he manages to distinguish, is of greatest importance to him. As a measure for symptoms' influence the relative deviation of symptom image is proposed: $\Delta\phi/\phi_o = |\phi_o - \phi_s|/\phi_o$, where the indices denote the two types of values under interest (o – objective; s – subjective; ϕ–image).

4.2 *Extended definition of STS violated image of symptom*

Petkov & Petkov (2000) presented the Combinatorial Context Model (CCM) for context quantification of cognitive process based on deviations of the symptom image from object in situation. The CCM uses the following symptoms for context quantification: *event (E), parameter (P), action (A), resource (R), function (F), transition (T) & goal (G)*.

In order to demonstrate the crucial impact of violations (term "circumventions" is used in USA) on the post-accident context, a *Violation of Objective Kerbs* (VOK) method was also proposed there to account for the probability of aberrant circumstances (prior to or during the initiating event) in cognitive process. Following the Reason's qualitative definitions (1994) the quantitative definitions were proposed for the context quantification purposes:

Errors is probable when the differences between objective & subjective images of context symptom is not zero, $\phi_{sn}(t) \neq \phi_{on}(t)$, where zero-context is $|\phi_{on}(t) - \phi_{sn}(t)| \rightarrow 0/\min$.

Violation of Image of Symptom (VIS) occurs when the objective image of context symptom ϕ_n is changed from $\phi^1_{on}(t)$ to $\phi^2_{on}(t)$ due to any reason.

It should be emphasized that the quantitative definitions of *error* and *violation* thus formulated are dealt with not only in human performance context, but in the context of the whole STS. Therefore, they have not only a wider, but also more different meaning than these of Reason. For example, Reason (2000) defines "procedural violations" as an active failures that "have a direct and usually short-lived impact on the integrity of defenses."

In Reason (2000), the strategic decisions are "made by designers, builders, procedure writers, and top level management" refer to latent conditions that "can create longlasting holes or weaknesses in the defenses" and "may lie dormant within the system for many years before they combine with active failures and local triggers to create an accident opportunity."

In the PET method, the VIS is considered as a strategic decision and introduces of "inevitable 'resident pathogens' within the system," resulting in a resonant increase in severity of error-forcing context, i.e. the CP & HEP.

Taking into account the relativity of time when the strategic decision was made, seconds or years ago, we can conclude that the difference of the PET VIS is that it may be in apparent or latent conditions, but these conditions must lead to a sharp/resonant increase in the *severity of context, i.e. CP(t)*.

If we take into account the consequences of the PET VIS, it can be said that they are similar to those of *Error of Commission (EOC)*. However, such consequences can occur not only after actions but also in disturbing the objective image of other symptoms, i.e. EOCs are subset of the set of VISs.

For example, some VIS≠EOC during the Fukushima Daiichi NPP #1 accident are the following: VIS-E: *SBO – loss of AC power*; VIS-T: *Loss of DC power*; VIS-F: *Containment Failure*. These VIS aren't EOC, because the violated symptoms are E, T & F, but they dramatically increased the accident severity & C(t).

For example, some VIS≡EOC during Chernobyl NPP #4 accident are the following: VIS-A: *System for Emergency cooling system has turned off from the previous shift;* VIS-A: *The scram is disabled when two turbo-generators are turned off;* VIS-A: *Several manually operated rods are pulled out to increase power, they remain less than 8 of 15 required rods in the reactor core;* VIS-A: *The opera-*

tional reserve of reactivity reaches a value requiring the reactor shutdown, but it is not done on time.

4.3 *PET HFE taxonomy*

The explained concepts, approaches and definition extensions used by PET method are presented on the HFE taxonomy shown on Figure 1.

4.4 *Recursion of context and recognition*

Context probability (CP) is determined by the existing deviations of symptom images in human cognition and team communication processes.

Matching the object in situation is approximation of a subjective image to the objective one by comparison of certain symptoms (signals, symbols and signs) that could be identified and described as an image of the object in the situation. These symptoms are Event, Parameter, Action, Resource, Function, Transition, Goal and VIS.

Symptom recognition and cognitive context are iterative & recursive functions. In order to calculate CP, the durations of recognition for any symptom (as CFC) & cognitive disregard durations of VIS are needed. At the next step of iteration of cognitive process, we may use the new duration of symptom recognition based on previous calculation.

Duration of symptom recognition could be based on measurement or expert judgment about the type of the recognized symptom (skill-based, rule-based, and knowledge-based). The times for completion of cognitive process for 'skill-based', 'rule-based' & 'knowledge-based' symptoms would be in correlation 1:5:30 (Petkov, 2017).

A symptom (CFC), after its recognition, could be kept or removed from the operator's context model and his memory depending on the situation. Some unimportant symptoms could be disregarded after their recognition by analogy with hypothesis that Rodin (1987) labeled 'cognitive disregard'.

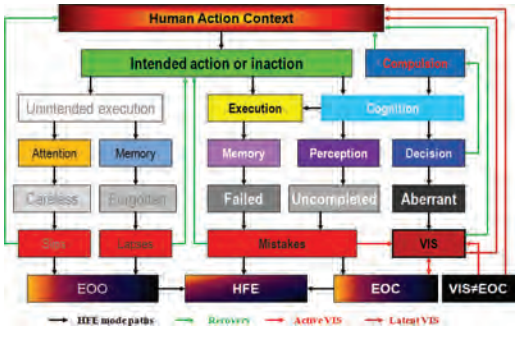

Figure 1. Human action context and HFE taxonomy.

The PET procedure for evaluation of context, cognition, communication and decision-making probabilities consists of eight steps (Petkov, 2018).

5 PET DIAGRAMS OF HRA PROCESS IN PSA

5.1 *PET scenario's timeline description, symptoms and violations of symptom's image qualification*

The PET scenario's timeline description of symptoms and violations of image of symptom qualification is presented on Figure 2. The following abbreviations are used: SAMG (Severe Accident Management Guideline); EOP (Emergency Operating Procedure); OED (Operational Experience Data); PIE (Postulated Initiating Event); TH (Thermo-Hydraulic Simulation); CS (Computer Simulator); FSS (Full Scope Simulator); normP, abnormP (Normal/Abnormal Procedure); OP/MP (Operational/Maintenance Procedure); PSA; DSA; HRA; VIS; S (Symptom/Stimulus): P, R, E, T, G, HA and F.

5.2 *PET screening, holistic and atomistic quantitative assessment and integration in PSA*

The PET screening, holistic & atomistic quantification and integration in PSA are presented on Figure 3. The following abbreviations are used: CP; EP (Error Probability); HEP; HA (Human Action/Task); HFE; RI (Risk Importance).

5.3 *Holistic dynamic profiles of CPs and EPs*

The PET diagram for obtaining holistic dynamic profiles of context and error probabilities is

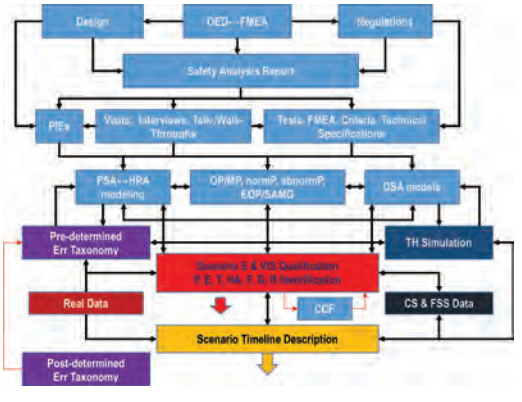

Figure 2. PET scenario's timeline description, symptoms and violations of symptom's image qualification.

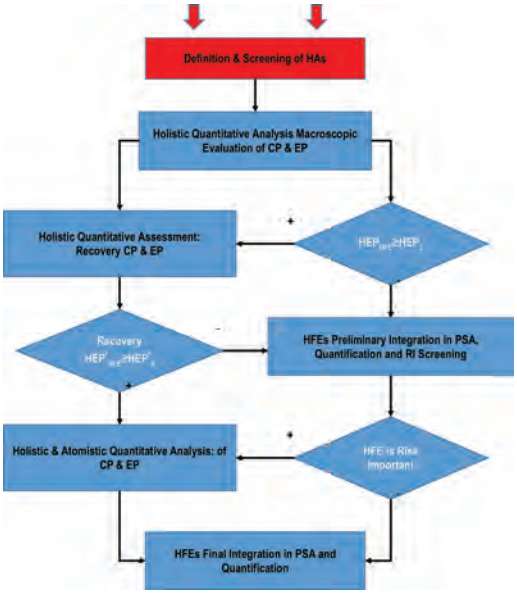

Figure 3. PET screening, holistic and atomistic quantitative assessment and integration in PSA.

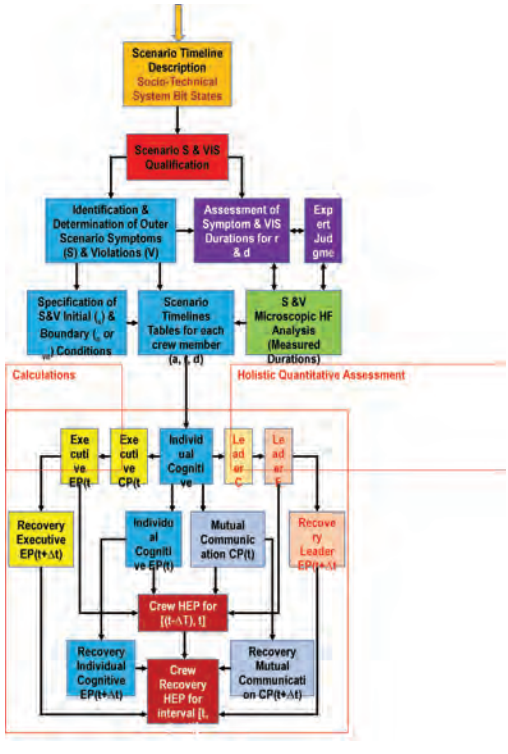

Figure 4. PET diagram for obtaining holistic dynamic profiles of context and error probabilities.

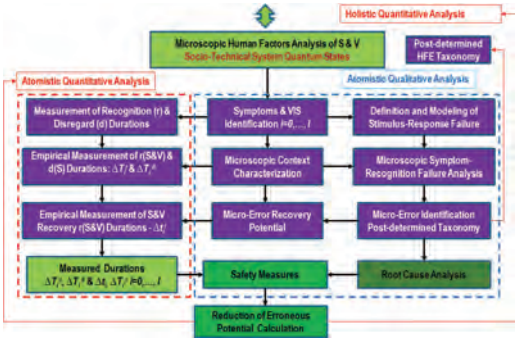

Figure 5. PET diagram for obtaining atomistic potential reduction and root causes.

presented on Figure 4. The following abbreviations are used: CP; EP (Error Probability); HEP; HA (Human Action or Task); HFE; a (appearing); r (recognition); d (disregard); ry (recovery); o (objective); S (subjective); vo (violated o).

5.4 *Atomistic error potential reduction and causes*

The PET diagram for obtaining atomistic potential reduction and root causes is presented on Figure 5.

6 HRA ADVANCED PRACTICE BY PET METHOD

HFEs are unexpected events in STS leading to unwanted outcomes. Therefore, the HEP has been changing in time before, during and after any HFE, and severity of STS context should be dynamic variable of error-producing potential. In nuclear accident conditions this dynamic and holistic measure could be defined as context probability, where for the most severity context—the probability is 1.

HRA methods try to predict a HEP in the "prevailing" context that means in a statistical average context of an average crew performance but only for some short time interval "prevailing" could exist during the accident. A static value (anchor) of HEP based on a judged average context of crew for identified task is calculated. The HEP is adjusted by multiplication of guessed values of PSFs taking into account the variability of all system components. Fuzzy logic of each HRA technique, tabulated and justified by its database is used to introduce PSFs into the HEP variation. Usually, a cited database is 'know-how' of the HRA method. It is verified and validated by the owner and concerned national regulator. But the structures and parameters of models and obtained data are not accessible for other users in order to check them and to repeat data-mining.

The benchmarking of the HRA methods is based on results for similar identified tasks, but not on models and experimental data.

Implicit, static and pseudo-holistic determination of context based on an anchor HEP and fuzzy PSFs values judged by expert, makes HRA methods superficial and insensitive to the STS models (structures and parameters), HFE symptoms and causes, and human performance processes.

The main reason for the HRA insensitiveness is the lack of models and data for a holographic-like behavior of the human interactions in a complex situation and multifactorial context. These models are substituted with expert judgments and multiplication of concurrent PSFs considered for specific task. This subjective way of HEP evaluation does not allow a systematic and multi-layered study of human and STS performance. Practical PET applications for retrospective and prospective HRA and accident analyses are shown in (Petkov, 2017).

7 CONTRIBUTIONS TO EXISTING HRA

The PET method allows dynamic evaluation of the individual CP and communication context probability (CCP) over time as gauge parameters.

Based on the dynamic individual CP and CCP, HEP and its constituents can be evaluated—cognitive, executive, recovery and decision-making by a group of people or organizations.

Average HEP that is usually evaluated by ther HRA methods is easy calculated as a mean over the time interval during which the human action is most likely to be performed.

The PET method provides an opportunity to generate HRA database based on simulations using thermo-hydraulic codes, computer-based, engineering or full-scope simulators.

It also allows to evaluate and optimize the individual and group performance of the main control room operators during real events or training.

The perspective to go in-depth and to move from a macroscopic to a microscopic context evaluation with the PET method would allow not only to scan and monitor the human error potential, but also to assess the importance of each symptom and PSFs influencing its recognition.

8 CONCLUSIONS

The PET, as a HRA method, applies a realistic procedure for dynamic symptom-based context evaluation of cognition and communication, and context-sensitive digraph models of cognition, communication and decision-making.

The intermediate use of symptoms for dynamic context evaluation gives better opportunities for the systematic identification, qualitative and quantitative interpretation of time-dependent HFEs during the accident and for improving of emergency response planning and/or severe accident management.

The PSA modeller is responsible for appropriate determination of the initiating event progression and needed actions based on accident reports, thermal-hydraulic simulations or full-scope simulator training exercises.

The detailed and qualitative data of accident reports are the best source for validation and verification of HRA methods.

The data use of thermal-hydraulic calculations & full-scope simulator are a valuable option for optimization of time to implement emergency measures and actions to ensure safety during the DBA and DEC/BDBA based on joint deterministic and probabilistic criteria.

The qualitative description and analysis of the accident scenario should be improved in order to improve the quantitative assessment of the context and the HFE probability. If important elements of description are missed then distortions occur in the evaluation. The HRA modeller is responsible for correct definition of symptoms, violated images of symptoms and determination of the durations of their manifestation, recognition and disregard, action and recovery implementation. It is preferably to measure them but guess or judgment could be acceptable as a first approximation.

The correct distribution of roles in modelling, limitation of expert guesses and possibility for experimental verification & validation supposes that PET could be applied with higher degree of confidence.

Insufficient exchange of information between designers, DSA, PSA and technologists may lead to violated context and increased risk.

The PET is a prospective emerging HRA method for dynamic, context-based, retrospective and prospective analysis and data-mining that could provide the PSA studies with HEPs for any specific action/task based on state-of-art simulations in order to avoid expert guesses.

ABSTRACT: Decommissioning of offshore facilities involve changing risk profiles at different decommissioning phases. Bayesian Belief networks (BBNs) are used as part of the proposed risk assessment method to capture the multiple interactions of a decommissioning activity. The Bayesian Belief network is structured from the data learning of an accident database and a modification of the BBN nodes to incorporate human factors and barrier performance modelling. The analysis covers one case study of one area of decommissioning operations by extrapolating well workover data to well plugging and abandonment. Initial analysis from well workover data, of a 5-node BBN provided insights on two different levels of severity of an accident, the "Accident" and "Incident" level, and on its respective profiles of the initiating events and the investigation-reported human causes. The initial results demonstrate that the data learnt from the database can be used to structure the BBN, and give insights on how human factors pertaining to well activities can be modelled, and that the relative frequencies can act as initial data input for the proposed nodes. It is also proposed that the integrated treatment of various sources of information (database and expert judgement) through a BBN model can support the risk assessment of a dynamic situation such as offshore decommissioning.

1 INTRODUCTION

Decommissioning of offshore facilities takes place in different phases which can include the warm suspension phase, the cold suspension phases and the removal phase. Some examples of the warm suspension phase activities are pipeline decontamination and sectional removal or well plugging and abandonment. Well plugging and abandonment involves multiple tasks at the same time, and the assessment of location specific risks such as reservoir profile, and presence of gas deposits from its drilling history. Location-specific historical information can be used to model risks more specifically. Bayesian Belief Network (BBN) is defined as an acyclic graphical network that is capable of representing qualitative and quantitative relationships between factors of interest defined in it. The nature of the relationships can be defined by whether there exists a (i) causal (ii) functional or (iii) statistical relationship. The BBN model structure can be derived by experts' judgement or statistically, or through a combination of both. The proposed model in this paper is structured from the data learning of an accident database and the BBN nodes are modified to incorporate human

factors and barrier performance modelling. The analysis considers one case study of well workover data extrapolated to well plugging and abandonment activities. The information fed into the BBN consists of relative frequencies from data learning from the database and expert-elicited where there are data gaps. The desired output of the model is a probabilistic risk profile of the potential consequences of a particular decommissioning activity, and one that has considered and can trace different sources of information—generic historical data, location-specific information and expert-judgement, instead of only historical data in most existing methods.

2 PROPOSED STATISTICAL MODEL FOR STRUCTURE LEARNING

2.1 *Data types*

The most comprehensive offshore safety database is the World Offshore Accident Database (WOAD) (DNV GL, 2017) that has been collecting data since 1976 by the Norwegian company DNV GL. The WOAD database provides principle information such as accident causes and its chain of consecutive events (for e.g. a dropped object resulting in fire and oil spill), location of accident facility, year of accident etc. The WOAD database has also been built on merging information from existing databases such as the Offshore Blowout Database (SINTEF, Norway), MAIB accident database (UK Marine Accident Investigation Branch) and the COIN/ORION database (UK HSE—offshore Safety Division).

The data in WOAD appears as a discrete, 'count' nature, each time there is an accident reported, it is updated. Also, some factors have order in its states, such as the severity of events, where "Accident" is more severe than a "Near Miss".

2.2 *Statistical model—generalised linear models*

The proposed model should be able to accept the updating of information and would be able to present the risk picture as per the most updated snapshot. The Beta and Dirichlet density function allows the quantification of the prior data (belief) and updating new information (beliefs). For analysis where only binary variables are involved, such as in a Fault Tree/ Event Tree where there are only 'True' or 'False' status, or the location of vessels such as 'In the port' or 'At sea', the Beta density function can be used. The beta density function f with parameters a, b, $N = a + b$, where a and b are real numbers > 0, is (Neapolitan, 2004, p. 306):

$$\begin{aligned} p(f) &= \frac{\Gamma(N)}{\Gamma(a)\Gamma(b)} f^{a-1}(1-f)^{b-1} \\ &= beta(f;a,b),\ 0 \le f \le 1 \end{aligned} \tag{1}$$

With updated information, t and $M = s + t$, and considering d as the dataset, the updated beta density function, with respect to obtaining the probability of having dataset d can be written as (Neapolitan, 2004, p. 306):

$$\begin{aligned} P(d) &= \frac{f^s(1-f)^t\, p(f)}{E(F^s((1-F)^t)} \\ &= \frac{\Gamma(N+M)}{\Gamma(a+s)\Gamma(b+t)} f^{a+s-1}(1-f)^{b+t-1} \end{aligned} \tag{2}$$

For analysis of multinomial variables, the Dirichlet density function can be used to provide equal counts for all statuses to be studied. For example, the severity of a consequence can be 'Near miss', 'Injury/Accident' or 'Fatality'. The Beta density function is, in fact, a special case of the more generic Dirichlet density function. Similarly, considering d as the dataset, the probability of having the dataset d by assuming all statuses are Dirichlet-distributed is shown below (Neapolitan, 2004, p. 306,386):

$$\begin{aligned} P(d) &= E\left(\prod_{k=1}^{r} F_k^{S_k}\right) \\ &= \frac{\Gamma(N)}{\Gamma(N+M)} \prod_{k=1}^{r} \frac{\Gamma(a_k+s_k)}{\Gamma(a_k)} \end{aligned} \tag{3}$$

Offshore safety data is based mainly on response and explanatory variables of non-metric, discrete forms, such as operation sections on a platform (Drilling and/or Production area) or initiating events of accidents (Falling Load, Leak etc). A common response variable would refer to consequence status differing in levels of severity, and in this case, the order of the status is important, such as 'Fatality' having more severe considerations than a 'Near Miss'. A statistical model suitable for offshore safety data should be required to be able to handle multivariate data or non-metric format, and hence the classical regression models are unsuitable. The proposed statistical model able to handle ordered, categorical data is a log-linear model that falls under the classification of a Generalised Linear Model (GLM) (Agresti, 2002, p. 125). A GLM extend ordinary regression models to encompass non-normal response distributions and modelling functions of the mean and has three components (similar to classical regression models)

consisting of a random component (response variable), a systematic component (explanatory variables) and a link function that transforms the mean to the natural parameter. The categorical data is arranged in a table form with its frequency information, and the log-linear modelling involves fitting models to the cell count in the cross-tabulation of categorical variables to derive the association and interaction patterns among variables.

For a table of response variable y and explanatory variable x (or two categorical responses), in a table with row i and column j, the cell probabilities are π_{ij} and the expected frequencies are $\mu_{ij} = n\pi_{ij}$.

$$log\mu_{ij} = \lambda + \lambda_i^X + \lambda_j^Y \tag{4}$$

where λ_i^X refers to the row effect and λ_j^Y refers to the column effect.

Assuming there are interaction effects, then a saturated model with statistically dependent variables would be (Agresti, 2002, p. 316):

$$log\mu_{ij} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_{ij}^{XY} \tag{5}$$

where λ_{ij}^{XY} refers to deviations from independence.

When extrapolating the assessment from a two factor to a three factor contingency table, the following summarised log-linear models (see Table 1) illustrate the combination of potential interactions.

The modelling process begins with a saturated model, i.e. with the highest order interaction between the variables, before systematically and sequentially removing a higher-order interaction term so that model complexity is reduced without any significant loss in accuracy. The removal stops at a point where any removal leads to a poor fit of the data. The threshold of removal is considered by comparing the test model against the saturated model based on the difference of its deviances.

Table 1. Loglinear models for three-dimensional tables.

Loglinear Model	Symbol
$log\mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z$	(X,Y,Z)
$log\mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ij}^{XY}$	(XY,Z)
$log\mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ij}^{XY} + \lambda_{jk}^{YZ}$	(XY,YZ)
$log\mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ij}^{XY} + \lambda_{jk}^{YZ} + \lambda_{ik}^{XZ}$	(XY,YZ,XZ)
$log\mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ij}^{XY} + \lambda_{jk}^{YZ} + \lambda_{ik}^{XZ} + \lambda_{ijk}^{XYZ}$	(XYZ)

Deviance is the likelihood-ratio statistics for testing the null hypothesis that the simplified model would hold against the saturated model. For a particular GLM for observations $y = (y_1, \ldots, y_N)$, let $L(\mu; y)$ denote the log-likelihood function expressed in terms of the means $\mu = (\mu_1, \ldots, \mu_N)$. Let $L(\hat{\mu}; y)$ denote the maximum of the log-likelihood for the model, i.e. a saturated model, which can provide a baseline for comparison with other model fits. In this saturated model, $\hat{\mu} = y$, and the deviance, D, of a Poisson GLM is defined to be (Agresti, 2002, p. 119):

$$\begin{aligned} &D(y; \hat{\mu}) \\ &= -2log\frac{\max likelihood\ for\ model}{\max likelihood\ for\ saturated\ model} \\ &= -2\left[L(\hat{\mu}; y) - L(y; y) \right] \end{aligned} \tag{6}$$

Consider two models, M_0 with fitted values $\hat{\mu}_o$ and a saturated model M_1 with fitted values $\hat{\mu}_1$. Since M_0 has lesser interactions considered than M_1, a smaller set of parameter values satisfies M_0 as compared to M_1. Maximizing the log likelihood over a smaller space cannot yield a larger maximum, thus $\left[L(\hat{\mu}_o; y) \le L(\hat{\mu}_1; y) \right]$. Continuing from equation (6) (Agresti, 2002, p. 141), and assuming that model M_1 holds, the likelihood-ratio test of the hypothesis that M_0 holds uses the test statistic (Agresti, 2002, p. 141):

$$\begin{aligned} &D(y; \hat{\mu}_o) - D(y; \hat{\mu}_1) \\ &= -2\left[L(\hat{\mu}_o; y) - L(y; y) \right] - \{-2\left[L(\hat{\mu}_1; y) - L(y; y) \right] \\ &= -2\left[L(\hat{\mu}_o; y) - L(\hat{\mu}_1; y) \right] \end{aligned} \tag{7}$$

Under regularity conditions, this difference has approximately a chi-squared null distribution with degrees of freedom equal to the difference between the numbers of parameters in the two models in comparison. The difference of the models' deviances follows a χ^2 null distribution (Agresti, 2002, p. 142).

Before determining the factors with the loglinear model, it is proposed to use a two variables dependency test based on the Pearson χ^2 model in order to shortlist the factors for consideration of a 3-variable analysis. The Pearson's χ^2 test compares the frequencies observed in certain categories to the frequencies that might be expected in the same categories by chance, with respect to the degrees of freedom given by the (number of rows -1) multiplied by (number of columns -1)(Field, Miles, & Field, 2012, pp. 802–803).

Similar to regression, the residual is simply the error between what the model predicts (the

expected frequency) and the data actually observed (the observed frequency):

$$standardised\ residual = \frac{observed_{ij} - model_{ij}}{\sqrt{model_{ij}}} \quad (8)$$

Through determining statistical dependencies between factors, the nodes of the BBNs are then established, and from which the base structure of a BBN can be defined.

3 CASE STUDY—WELL WORKOVER TO WELL P&A

3.1 *Well workover*

Well workover data from the UKHSE database refers to operations in which a well is re-entered for any purpose, for example, maintenance related activities' of replacing retrievable downhole safety valves, or malfunctioned electrical submersible pumps or worn out tubings. Before any well workover, the well must be killed, which requires the removal of the well head, flowline, packers and lifting the tubing hanger from the casing head, before putting a column of heavy fluid into a well bore to prevent the flow of reservoir fluids without the need for pressure control equipment at the surface (which have been removed, a part of the well kill process). Such an operation usually requires a drilling rig to be involved.

While this data is strictly not well abandonment and plugging work required for a decommissioning process, well plugging and abandonment work includes removing casing and other downhole equipment, thus suggesting the similarities with wireline operation. The risks of well killing can also be comparable to a well plugging and abandonment procedure which involves cement being injected to plug the well, while in the well kill event; heavy fluid is injected into the well.

The factors in WOAD database, relating to Well Workover activities are: (i) Schedule quarter (ii) Human causes (iii) Initiating event (iv) Evacuation and (v) Severity of accident.

Thus the five factors from Table 2 will be analysed to understand its dependency relationships.

Table 2. Table of factors to be analysed in the Bayesian belief networks (DNV GL, 2017).

Factors	Description
Schedule Quarter	Each work schedule is divided into 12 hours, and the quarters are 3 hour session each.
Human Causes	In investigation reports that have concluded the cause of the incident to be human related, four major causes have been identified based on the incident reports: (i) unsafe act carried out without any procedures, (ii) procedures deemed to be unsafe (iii) improper design and (iv) unsafe act carried out against procedures.
Initiating Event	The initiating events were pre-defined in the WOAD database and are identified as follows: (i) falling load or dropped object (ii) release of fluid or gas (iii) well problem without blow out (iv) blow out (v) out of position (vi) fire
Evacuation	Indicates whether the emergency procedures of leaving the facility is (i) not required (ii) required and successful (iii) required and not successful
Severity of Accident	There are four levels of severity and are classified below: • Accident (A) has recorded fatalities and severe injuries. • Incident (I) refers to low degree of damage, but repairs/replacements are required or for events causing minor injuries to personnel or health injuries. • Near-Miss (N) refers to events that might have developed into an accidental situation. No damage and no repairs required. • Unsignificant (U), refers to events with minor consequences. No damage, no repairs required. Other inclusions are small spills of crude oil and chemicals, and very minor personnel injuries, i.e. "lost time incidents".

3.2 *Results of well workover data analysis from two-variable and three-variable dependency analysis*

Dependency analysis between two variables is performed for all possible combinations in order to generate an initial list of dependency relationships. The analysis is based on the Pearson's χ^2 test which was elaborated in Section 2.2. With the chi-squared value, and the corresponding number of degree of freedoms, the P-value can be obtained. The confidence interval then plays an important role on the significance test on the hypothesis of independence. The most commonly set confidence interval is at 95%, i.e. a P-value exceeding 0.05. For this data set (see Table 3), the confidence interval is set at 95%, and if the obtained P-value from the dependency analysis is less than 0.05, this implies a dependency between the two factors being investigated.

Table 3. Snapshot of 'cleaned' data to be processed in the software R for the dependency analysis between 5 factors: (i) Schedule quarter (ii) Human causes (iii) Initiating event (iv) Evacuation and (v) Severity of accident (not all factors are shown in below).

No.	Schedule_ qtr	Accident_ Category	Human_Cause
1	3	Incident	Unsafe act/No Procedure
2	4	Near_miss	Improper design
…	…	…	…
99	5	Incident	Unsafe Procedure
100	2	Incident	Unsafe Procedure

Within the five factors, a 2×2 frequency table and its ten combinations of the pair-wise comparison of the five factors, has been extrapolated from the data source, and the Pearson's χ^2 test ran on R to calculate the P-value. The results tabulated in Table 4 only reflect the results where the P-Value has been found to be less than 0.05 and indicates a "dependent' relationship. Other independent results have been omitted since they do not have an impact on how the BBN can be structured. The pairs of variables thus provide the background for the three variable independency analyses.

The modelling of a three variable dependency begins with a saturated model for (A,B,C) which consist the individual effects from each factor alone, and the secondary interactions AB, BC, AC as well as the highest order which is the effects of ABC. Backwards eliminated is initiated from the saturated model, by removing the highest order interaction. The model with the highest order removed, is compared with the saturated model by considering the differences in the 'likelihood', 'degrees of freedom', and in the 'P-value'. The 'P-value' demonstrates the difference between the models, and if the value < 0.001, it represents a highly significant 'P-value difference' and that removing the higher order interaction has made a significantly worse fit to the data (Field et al., 2012). In other words, the higher order interaction is a significant factor to ensuring a good fit of the model.

If the removal of the three-way interaction shows a 'P-value delta' greater than 0.001, then the combination of the two-way interaction is compared against the next highest saturated model—which would refer to the three-way interaction.

Based on the results from the two-way dependency analysis, the following three-way dependency analyses have been grouped (see Table 5).

From the analysis from R (R Core Team, 2017) and summarised in Table 6, it can be observed that the model considering the interactions (Human Causes: Initiating Event + Initiating Event: Evacuation)

Table 4. Dependency relationships between two variables.

Combinations	X^2 value	DoF*	P-Value
Accident Severity, Initiating Event	47.98	21	0.000692
Accident Severity, Evacuation	18.748	6	0.00461
Initiating Event, Human Causes	41.47	21	0.004903
Initiating Event, Evacuation	42.131	14	0.0001178

Table 6. Summary table of conditional independency analysis.

Model	DoF	Likelihood Ratio	Deviance (diff)	Diff in DoF	P-Value (diff)
Human_ Cause (H) * Initiating_ Event (IE)* Evacuation (E)	0	–	–	–	–
H:IE + H:E + IE:E	42	0.332754	0.332754	42	**1**
H:IE + H:E	56	24.68428	24.35152	14	0.0415
H:IE + IE:E	48	1.549424	1.216669	6	**0.9760**
H:E + IE:E	63	21.71695	21.38419	21	0.4357
H + IE + E	83	67.52035	67.18759	41	0.0060

has a P-value delta of 0.9760 which is much higher than the P-value delta of the remaining models. The dropping of the interaction (Human Causes: Evacuation) still produces a good-enough fit for the model based on the P-value delta difference of 0.9760 compared to the P-value difference of the saturated model (Human Causes: Initiating Event + Human Causes: Evacuation + Initiating Event: Evacuation. The interaction (Human Causes: Initiating Event + Initiating Event: Evacuation) thus suggests a conditionally independent relationship between Human Causes and Evacuation given the occurrence of the Initiating Event, which can be noted as **I**(Human Causes, Evacuation | Initiating Event).

Similar operations have been performed for the remaining three-way combinations numbered from 2 to 5 in Table 4. As an example, the second three-way combination in Table 4 identified as (Initiating Event – IE, Human Causes – H, Schedule Quarter – S) is also investigated in the same manner, in that it considers the saturated model of H*I*S which consists of the following interactions of (H + IE + S + H:IE + H:S + IE:S + H:IE:S), followed by comparing the performance of the (H:IE + H:S + IE:S) model with the higher order interaction term H:IE:S removed, and subsequently proceeding towards the simplest independent model of just H + IE + S. The best fitting model, not necessarily the most complex, is then chosen based on the P-value differences in a similar process as documented in Table 6, which referred to the three-way dependency analysis of the factors (Human Causes: Initiating Event + Initiating Event: Evacuation). Having investigated the relationships between the factors and in creating the nodes, the next step is to put together the node network (see Figure 1), and its corresponding joint probability distribution through Bayesian Belief Networks (BBNs).

In order to analyse the data in a BBN, the data obtained from the database needs to be transformed into probabilities and/or conditional probabilities. For any node, the probabilities can be represented by the Dirichlet Density Function, which can be looked at as a ratio of a status, against the total number of statuses for that event. If an event has a parent event, then the conditional probability distribution should be used. The resulting BBN can then represent the relative frequencies of the occurrence of events as in Figure 2.

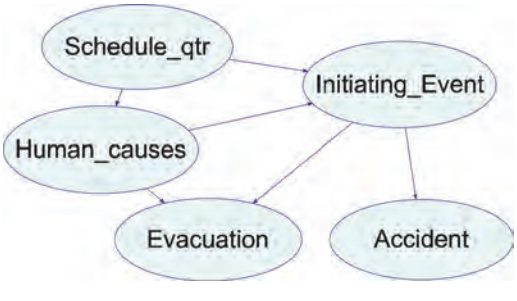

Figure 1. Snapshot of proposed BBN structure using GeNie (BayesFusion, 2018).

4 EXPERT ELICITATION TO BBN STRUCTURE AND CONDITIONAL PROBABILITY DATA

4.1 *Risk profile categorised by severity of accidents*

The BBN also allows for a sensitivity analysis to identify the types of initiating events associating with the 'Incident' level of severity of event (see Figure 3): which reflects that 'Falling Load/ Dropped Objects" make up the majority of the initiating event, with the "Release of fluids/gas" the next most common initiating event, and that the "Well problems leading to no blow outs" is the least common initiating event. It is also interesting to

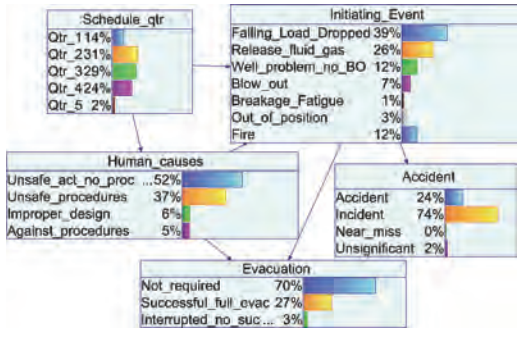

Figure 2. Snapshot of BBN with distribution of respective factors based on the data from WOAD.

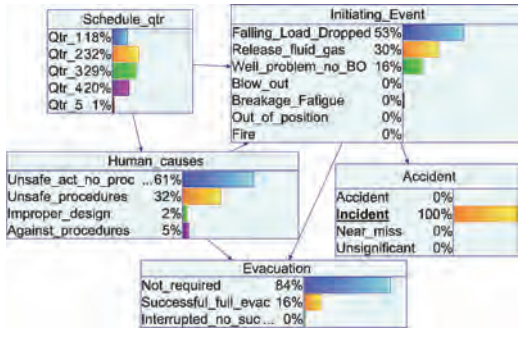

Figure 3. Risk profile when "Incident" in the Severity node is reflected as 100% (observed to have happened).

identify that unsafe act carried out stemming from the lack of procedures is the most common documented human cause in the investigation reports.

In terms of "Accident" level of the severity of incidents (see Figure 4), "Fire" as a triggering event makes up the majority of the initiating event. The next most common is a "Blow-out" followed by "out of position" and lastly the "Release of fluid or gas". It is also interesting to identify that unsafe procedures is the most common documented human cause in the investigation reports. It can be noted that the documented human cause between different levels of severities of an incident reflects the trends in the procedural level, at the "Incident" level, most of the time no procedures were in place, while in the "Accident level", procedures were in place but needed to be improved. In both cases, human action against procedures makes up a small percentage.

4.2 *Combining human factors, location specific risks and equipment reliability in the model*

The Petro-HRA guidelines published in 2017 (Taylor, 2017) adopted the SPAR-H methodology for assessing human error probabilities in the petroleum industry based on a nominal HEP that is adjusted by performance shaping factors. The diversity of the activities in a petroleum facility makes it difficult to list the performance shaping factors, or define what constitutes a "missing/misleading" human machine interface design, especially since decommissioning activities constitute a wide range from well P&A to structural removal. Strand et al (Strand & Lundteigen, 2016) further defined the crucial or "good" factors in a human-machine interface for drilling operations, such as having the ability to interpret wellbore flowrates, in situ pressures along the wellbores etc, and with each factor bearing different weights, indicating that some factors have a greater effect than

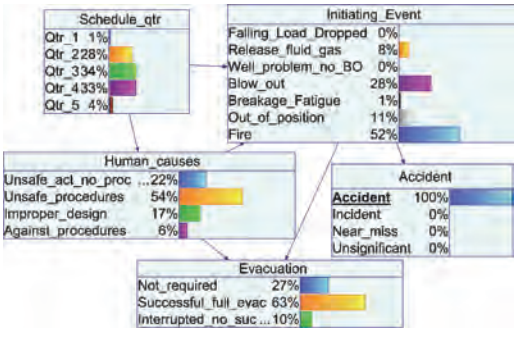

Figure 4. Risk profile when "Accident" in the Severity node is reflected as 100% (observed to have happened).

others. This exact ranking and its respective weight ratios proposed by Strand et al is also a reflection of an expert judgement as a source of information, where it is the other mechanism proposed in this paper; the first method being to obtain information from the database. It is proposed that the relationships learnt and the relative frequencies obtained from the database can be used to supplement the HRA model by Strand et al (Strand & Lundteigen, 2016).

The proposed BBN (Figure 5) consist of several parts: the nodes in light blue are information extracted from the data learning part as in Section 3.2. The "Severity of Accident" node has been expanded to include more consequences, including the state of safe operations, which is not originally in the accident database as it only recorded accidents. The green-shade of the node "Kick Frequency during drilling operations" represent learning from information as well, but not from an accident database, rather, from the record keeping of the operating history of the facility. The motivation behind such an information node is to incorporate location-specific risks. A plugging and abandonment activity will also be susceptible to kicks from the well, and often it is due to the reservoir profile of a well, hence in this case, location specific historical data would help to assess the risks more dynamically.

The relative frequencies for the "Human Cause" node has been removed and replaced with a "Procedures_PSF", in which PSF stands for Performance Shaping Factors, and the data learning part indicated that the relative frequencies for 'Not_ Available" or "Incomplete" would 0.52 and 0.37, and this could be the information for the initial conditional probability.

The next part of the BBN structure is indicated in yellow, which are safety barriers in relation to the identified, and shortlisted Initiating Event (a well kick), which are "Kick Detection" or the action to "Kill Well". These information can be obtained from the failure probability data from reliability databases, as in the approach for Bhandhari et al (Bhandari, Abbassi, Garaniya, & Khan, 2015) where "Kick Detection" failure probability was 0.01, and Well Kill operations had a failure probability of 0.25.

The third part of the BBN structure is indicated in pink, and refer to human factors that may influence how well a kick can be detected, or how the killing of a well can be conducted with success. The human factors were identified as specific to a well drilling operation by Strand et al (Strand & Lundteigen, 2016), such as how the presence of certain features would assign the Human Machine Interface PSF to be nominal or good. In Strand et al's human factor framework, they had based it on the

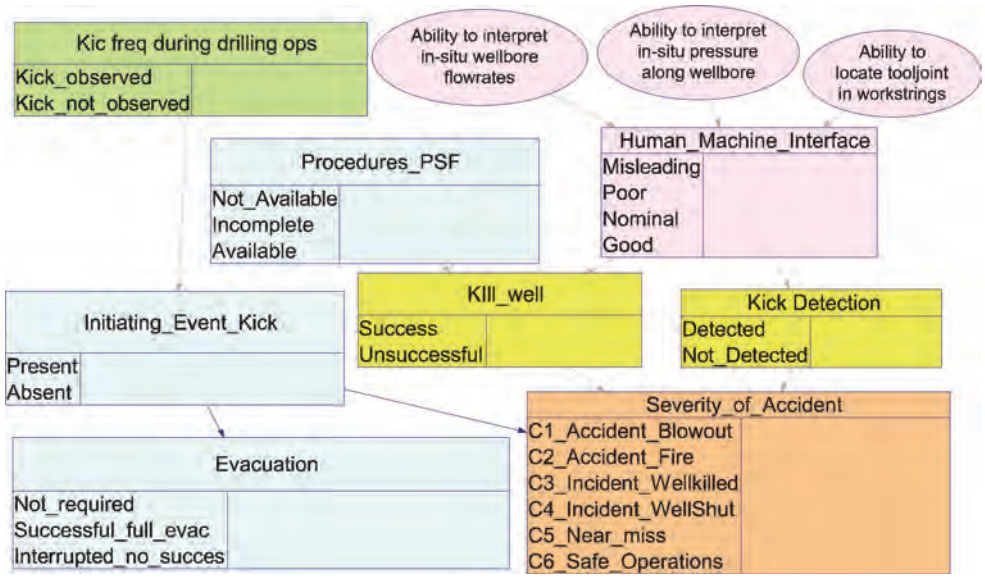

Figure 5. Proposed BBN with structure/information learned from database, and expert judgement input.

BORA-Release methodology (Sklet, Vinnem, & Aven, 2006) where weights have been assigned to each contributing item to a PSF. The weights in nodes leading to the HMI PSF (the BORA-Release methodology) are derived from expert judgement. The discussion of expert judgement input for the pink nodes, and arguably the data gaps for the orange node for the output node of interest could allow the risk to be computed from a combination of historical data (with updating mechanism, each time the database is updated), expert judgement in the human factors part of the model, or to fill in data gaps in other parts of the model.

4.3 *Expert judgment and elicitation of information in nodes of BBN*

A literature review conducted by Mkrtchyan et al (Mkrtchyan, Podofillini, & Dang, 2016) identified eleven methods of the assessment of conditional probability information, in which the methods vary in terms of whether a probability elicitation is direct or indirect, or whether it allowed multiple expert aggregation.

No expert judgment and elicitation have been carried out on the proposed BBN model yet, however, the method proposed should be one that is used to model human reliability as one of the nodes is a human factor node, and as pointed out by Podofillini et al (Mkrtchyan, Podofillini, & Dang, 2015), the conditional probability information building methodology needs to meet two criteria of allowing combination effects such as error-forcing effects where two factors in consideration are working on the same polarity, or the opposite end of the combination effect such as a compensation effect from a poor factor in combination with a good factor.

5 CONCLUSION

From the initial modelling of the BBNs derived from accident data, the results show potential in using industry data for accidents having an overall risk profile of the industry. The model provided insights on the "Accident" and "Incident" level of a severity of an accident, and its corresponding profile of the initiating events and the investigation-reported human causes. This forms the base structure of adapting the initial BBN model to include also barrier performance, such as the performance of kick detection, and potentially include human factors analysis for high operator involvement work, such as well plugging and abandonment and heavy lifting. This analysis also meets one aspect of the QRA framework requirements in demonstrating how the performance of barriers changes with different conditions. The model indicates the source of historical data and expert judgement, and is able to keep track of how data used in the model affects the results. Existing risk assessment methods are often based on generic failure statistics alone, which may not be reflective of an existing risk picture of a location. The model combining generic failure statistic, location-specific historical

data, and expert judgement of a particular work task could provide a more updated risk picture.

6 FUTURE WORK

The scope for future work is to expand the model to include the effects of expert judgment in the model, sensitivity analysis of how robust the model is, information learning from other databases or information sources, and subsequently expanding the analysis to other decommissioning activities.

Urban avalanche search and rescue operations in Longyearbyen: A study of public-private cooperation

S.M. Tengesdal
Civil Protection, County Governor of Sogn og Fjordane, Leikanger, Norway

B.I. Kruke
Centre for Risk Management and Societal Safety, University of Stavanger, Stavanger, Norway

ABSTRACT: The two urban avalanches in Longyearbyen, Svalbard, in 2015 and 2017 were unexpected and fast developing, with trying conditions and consequences both for people buried by the snow, and for people coming to their rescue. The fatality rate increases rapidly as the minutes pass if people are buried by the snow. Thus, successful rescue if buried by an avalanche depends on a prompt response. The aim of this paper is to discuss the role of the local population in urban avalanche search and rescue. Empirical data was collected from 8 months of fieldwork in Longyearbyen, including interviews with representatives of public and private organisations and the local population, as well as literature surveys on the population's involvement in acute crises, reports and newspaper articles. People are often present when crises strike. Many of them have the knowledge, training and equipment to be a valuable resource in avalanche search and rescue.

1 INTRODUCTION

19 December 2015 an avalanche hit urban areas in Longyearbyen, a small town situated on the Norwegian archipelago of Svalbard in the Arctic. The avalanche resulted in two fatalities and destroyed eleven houses below the mountain Sukkertoppen. Survivors and neighbours immediately commenced search and rescue activities. Over 150 unorganized volunteers stood shoulder to shoulder with the professional emergency responders in a joint effort to search for fellow citizens buried by the snow. Seven people were excavated and rescued (Indreiten and Svarstad 2016). Another urban avalanche hit Longyearbyen 21 February 2017, in almost the same area. This time there were no fatalities. However, the snow masses resulted in major damages to an apartment building. The people who lived there assisted each other in the evacuation. Once again, a large number of unorganized volunteers stood in line ready to come to the rescue of possible friends and neighbours buried by the snow. The local police, in close cooperation with the local Red Cross Society, quickly clarified that none were buried by the snow. Thus, further assistance from the unorganized volunteers was not required this time (Tengesdal 2017).

In this paper we aim to discuss the role of the population in urban avalanche search and rescue. We will use the term «population» synonymously with the term «unorganized volunteers». This includes the efforts of survivors and people who are randomly present or nearby the avalanche area. Organized volunteers, such as members of the Red Cross Society, are not included in these groups of volunteers.

We will start with a brief introduction to some important avalanche characteristics. Then we will present the conceptual frameworks, with an emphasis on crisis characteristics, crisis management and the population's behaviour and capacities in crises. After a brief methodological presentation we will present our empirical findings from the two urban avalanches. The findings will be discussed in relation to the conceptual frameworks before we conclude with some remarks on the population's contribution in search and rescue in urban avalanches.

2 AN INTRODUCTION TO AVALANCHES

In a historical perspective, the risk of avalanches was mainly a problem for people in settlements and along roads and railways located in avalanche prone terrain. This picture started to change in the 1970s, as a result of a growing interest in outdoor activities in steep terrain. Nowadays, the majority of the fatalities due to avalanches are related to winter recreation activities (McClung and Schaerer 2006). However, avalanches in countries like Norway, Iceland, USA, Switzerland, Austria

and France clearly demonstrate that we have to take into consideration that avalanches may represent a major risk also for people, buildings and infrastructure in urban areas.

To get caught in an avalanche is associated with great danger. The probability of survival are approximately 90 per cent if a victim, completely buried by the snow, is excavated within 15 minutes, unless the victim is not already dead due to trauma (killed by debris in the snow). After 15–45 minutes, the chances of survival decrease rapidly due to oxygen deficiency. After 45 minutes some 75 per cent of those excavated die, mostly due to hypothermia. The level of moisture in the snow and the victim's clothing are both crucial factors for survival after 90 minutes. A victim excavated at this point in time may die due to the reflow syndrome, a fatal condition caused by hypothermia and cold blood flowing from the extremities to the heart (Landrø 2007).

It is quite common to distinguish between two main types of avalanches; loose snow avalanches and slab avalanches. A loose snow avalanche is a chain reaction initiated at a specific point, and expands both in width and depth as it continues downwards (Landrø 2007). The initiating point in a loose snow avalanche consists of a small layer of surface snow that loosens, while it is a thin and weak layer of snow at a deeper level that fails in a slab avalanche. A slab avalanche is further characterized by a large and coherent mass of snow that loosens and splits into blocks as it moves downwards (McClung and Schaerer 2006). This type of avalanche reaches high speed in a short period of time, and the width can be several hundred meters, within seconds (Landrø 2007). A loose snow avalanche has a pear shaped pattern, while a slab avalanche usually has a rectangular shape (McClung and Schaerer 2006). 99 per cent of the avalanche accidents occur due to slab avalanches (Landrø 2007). The 2015 and 2017 urban avalanches in Longyearbyen were slab avalanches.

As we have already discussed, the chances of survival after 15 minutes are relatively poor if a victim is completely buried by the snow in an avalanche. Therefore, the best avalanche rescue strategy is to avoid to get caught in an avalanche in the first place (Fredston and Fesler 1986). In most situations, successful avalanche rescue depends on a prompt response from people nearby (Kruke 2016). Statistically, professional emergency responders arrive *too* late in the avalanche area to save lives. The mobilisation and deployment of professional emergency responders might take hours. Consequently, people moving in avalanche prone terrain should have the basic knowledge and training, both to avoid getting caught in an avalanche, and to perform buddy search and rescue if needed (Brattlien 2017, Landrø 2007, McClung and Schaerer 2006). Basic avalanche equipment, such as avalanche beacons, probes and shovels, is crucial to perform a speedy and reliable search and rescue operation (Brattlien 2017).

3 CONCEPTUAL FRAMEWORKS

After this brief introduction to some central avalanche characteristics, we now turn to the conceptual frameworks, with an emphasis on crisis characteristics, crisis management and the population's behaviour and capacities in crises.

3.1 *Crisis characteristics*

Rosenthal and colleagues define a crisis as «a serious threat to the basic structures or the fundamental values and norms of a system, which under time and pressure and highly uncertain circumstances necessitates making critical decisions» (1989: 10). This definition highlights crisis characteristics such as threat, uncertainty, time pressure and the need for critical decision-making. In addition to these crisis features, we need to look further into some defining characteristics of crises. 't Hart and Boin (2001) and Gundel (2005) present two different approaches to the classification of crises. 't Hart and Boin (2001) classify crises based on their speed of development and termination patterns, while Gundel (2005) differentiates between crises based on the degree to which they are predictable and influenceable. It is fair to assume that unexpected and fast developing crisis will be particularly difficult for professional responders to manage in the initial phase. Thus, the population present will often be left to manage the initial acute phase of these crises themselves.

It is quite common to distinguish between different phases of a crisis. A number of researchers

Table 1. Some fundamental differences between the military model and the problem-solving model (Dynes 1993).

The military model	The problem-solving model
The initial response in the incident area is characterized by chaos	The initial response in the incident area is characterized by a degree of continuity
Command systems are needed to re-establish control	The response must be coordinated to reach an overall degree of cooperation between the actors present
Existing social structures have limited capacities	Existing social structures perform crisis management
Centralized approach	Decentralized approach

have suggested ways of doing this, e.g. (Turner 1976, Kruke 2015, Olson 2000). The model below outlines three basic phases, which are usually inherent in most phase descriptions in the crisis literature (Kruke 2015).

We will put emphasis on the acute phase of the crisis in this paper. This is the phase where lives might be at stake and responders come to the aid of people in acute need. This phase, when the population is conducting the response, prior to the arrival of the professional emergency responders, is also termed the *golden hour* (Helsloot and Ruitenberg, 2004). It is important to notice that the response, or the acute crisis management, and to what extent it succeeds, has a strong connection with the prevention and preparedness activities in the pre-crisis phase (Engen, Kruke et al. 2016; Kruke 2015).

3.2 *Crisis management*

Dynes (1993) argues that the dominant approach to crisis planning and management is based on a centralized command and control model, derived from military analogies. He claims that this model is based on inadequate assumptions about social behaviour in crises (ibidem). The military model is built on the notion that crises create social chaos. Hence, command and control must be established by professional emergency responders to eliminate such chaos (Dynes 1993). In this perspective, it is assumed that much of the civilian population become passive, helpless and incapable of making reasonable decisions in crises (Dynes 1994a). Dynes (1993) also suggests a decentralized problem-solving model as an alternative approach, derived from research on social behaviour in crises. The problem-solving model suggests that the focus should be on continuity rather than chaos, coordination rather than command and cooperation rather than control. The model takes the stand that civilians are fully capable of making reasonable decisions in a crisis, and that they will not be stunned, passive or irresponsible (Dynes 1994a). The model assumes that a crisis represents a set of problems that also have to be dealt with by the resources that are already present in the local community (Dynes 1993). Problem-solving capacities are inherent in all individuals and social structures. Thus, such capacities must be utilized in an effective manner when a crisis strikes us (Dynes 1994a).

These models are based on a totally different view of the population's behaviour and capacities in crises.

3.3 *The population's behaviour and capacities*

Panic and helplessness are two viable myths about people's behaviour in acute crises. What is panic? The tabloid newspapers, and the public discourse, often label the reactions of victims as panic. Many researchers have contributed to our understanding of the degree to which we panic in crisis situations, for example (Fritz and Marks 1954, Quarantelli 1954, Helsloot and Ruitenberg 2004, Ripley 2008, Kruke 2015). However, there is no complete consensus about what panic really is. The term is used to describe many human reactions in stressful situations, such as an excessive alertness and/or uncontrolled fear that leads to unwise action, or loss of judgment. A common use of the term is that panic is a very excited emotional state of acute fear, and that it results in uncontrolled escape (Quarantelli 1953). Panic can also be characterized as a form of irrational behaviour (Fritz and Marks 1954, Quarantelli 1999). There are some conditions that may lead to panic behaviour (Fritz and Marks 1954, Perry and Lindell 2003):

- Understanding of an immediate and serious threat
- Flight options are limited and disappearing.

Even though there are examples of panic in acute and life-threatening situations, there are also examples of such situations were panic do not occur (Quarantelli 1954, Dynes 1993, Helsloot and Ruitenberg 2004, Ripley 2008, Kruke 2015). This research concludes that citizens provide a lot of assistance, even in situations where they put their own life at stake, trying to rescue fellow citizens.

Some people become helpless in acute crises, mainly due to shock leading to paralysis and passivity (Helsloot and Ruitenberg 2004, Kruke 2015) or a disaster or crisis syndrome (Perry and Lindell 1978, Tierney, Lindell et al. 2001), described as a dull state of being. Passivity may also result in a collective disclaimer, called the «bystander effect» (spectator effect) (Darley and Latanté 1968), where no one takes responsibility immediately after an

event because everyone thinks someone else will do it.

Another string of research is related to altruism, a stand that helpless and panic behaviour are myths, and that most people both want to and also contribute to saving lives in the midst of a crisis. Altruism may be understood as a moral commitment people have to serve others and to put the interests of others in front of their own (Comte 1973), as a form of solidarity during crises (Tierney, Lindell et al. 2001). Altruism can be manifested as an individual, collective or situational commitment (Dynes 1994b). The society's collective and institutional resources may in some crises be inadequate for a prompt and reliable response (ibidem). To cope with these unexpected, acute and uncertain circumstances, individual altruism may result in responses supplementing traditional response structures (ibidem).

4 METHODS

This paper mainly draws on empirical findings from 8 months of fieldwork in Longyearbyen, from mid-September 2016 to end of May 2017. The primary data collection methods were semi-structured interviews, field conversations, observations and participant observations. Semi-structured interviews were conducted with the local population and response actors in Longyearbyen, including: The Police, Longyearbyen Red Cross Society, Longyearbyen Hospital, Lufttransport AS[1], Longyearbyen Fire and Rescue Agency, and the Longyearbyen Community Council. Additionally, 40 field conversations were conducted with the local population. Empirical data was further collected from three public meetings in conjunction with urban avalanches in Longyearbyen. Furthermore, one of the authors took part in the local population's response to the urban avalanche 21 February 2017. Empirical data was also collected from document analysis, primarily public documents, newspaper articles, and avalanche literature and statistics.

5 EMPIRICAL FINDINGS

5.1 *The urban avalanche in 2015 and the local population's reactions in the acute phase*

A slab avalanche hit urban areas in Longyearbyen Saturday 19 December 2015 at 10.23 am (DSB 2016). According to an informant from the Red Cross Society survivors and neighbours immediately commenced search and rescue activities. Professional emergency responders were also in the avalanche area within minutes. Shortly after the avalanche, a private citizen posted a message on a local community Facebook group to encourage people to pick up their shovels and meet in the avalanche area. The Longyearbyen Community Council posted a similar message on their public Facebook page. In a short period of time a huge mass of unorganized volunteers lined up to participate in the excavation efforts. There are many examples of this initial response.

Five people sat in their kitchen eating breakfast when the avalanche hit their house. All of them were buried by the snow. One of them managed to get out of the snow masses by himself. He then managed to locate and excavate his wife and his eight-week-old daughter. He continued to search after the two missing persons, and dug in the snow masses with a wok pan, while he wore a sweater, sweatpants and socks. This was one of the first impressions meeting the police officers upon their arrival in the avalanche area.

Another informant lived close by the houses that were hit by the avalanche. He noticed that the lights indoors and outdoors started to flicker. Suddenly, everything went dark. He immediately understood what had happened when his wife shouted that several houses had collapsed. He grabbed his headlight and shovel, and ran out. Meanwhile, his wife called the police and went from house to house to alert the neighbours. She also brought the children in the area to safety. The informant came home with two survivors and provided them with warm clothes, blankets and food. As soon as medical personnel arrived, he went out again to continue search and rescue efforts.

Yet another informant was on his way to work when he noticed blue lights and sirens nearby the town centre. He met some people outside the shopping mall who told him about the avalanche, and that they were on their way to offer their assistance. He instantly joined them in the excavation efforts.

None of the informants from the professional emergency responders observed people affected by panic or shock. However, a small number of the informants noticed a few passive spectators. A doctor working at the hospital told about a man who stood nearby when the avalanche hit. He had some trouble coping with the situation and seemed to be rather confused. One of the informants from the local population described an acquaintance who allegedly was struck by panic. As she stood on the stairs outside her home smoking a cigarette a house started to move and hit the house next to her. According to the informant, the woman then

[1]Lufttransport AS is a private company operating the Governor of Svalbard's two search and rescue helicopters.

panicked and ran away, and was taken care of by others later on.

A number of informants told about people who felt helpless as a consequence of not being able to participate in the search and rescue operations in the acute phase of the crisis. One informant said that he suffered for months because of not being involved in the response. He had no choice but to stay at work when the avalanche hit. Another informant told about some friends unable to get out of their house, due to the snow masses. Tt made them feel extremely indignant, as they had a strong desire to help their fellow citizens in the avalanche area.

5.2 *The urban avalanche in 2017*

In the morning hours Tuesday 21 February 2017 the Longyearbyen Community Council informed the public on their website about an increased avalanche hazard. The message reassured that the settlement was not considered to be at risk. A couple of hours later, a slab avalanche hit the settlement and destroyed an apartment building (Tengesdal 2017). The people at home managed to assist each other in the evacuation out through the windows. Since also this avalanche hit nearby the town centre, the professional emergency responders were not far away. The police quickly confirmed that none of the people living in the area were missing nor seriously injured. They still decided to maintain the search, in case other citizens had been in the area (Malmo 2017).

5.3 *The professional emergency responders' perspectives on the local population contribution*

All of the informants interviewed characterized the urban avalanche in 2015 as a totally unexpected event. However, a couple discussed the bad weather conditions the previous night and the resulting huge snowdrifts on Sukkertoppen, just uphill from their house. While looking up the hill through the window, they agreed that this could not possibly be good. Soon after, the avalanche hit their house (Palm 2016). Both of them survived the avalanche.

The informants described the avalanche area as rather chaotic. Many referred to houses that were moved and destroyed. However, the informants underlined that the avalanche area was quiet and that the level of stress was low. A professional rescue worker from Lufttransport AS said: «What you see is chaos, but there is no panic». All of the informants expressed that the local population was a crucial resource in the search and rescue operation. An informant from the Red Cross Society said that «the help we got from the unorganized volunteers made it possible to quickly locate and excavate the victims». A police officer further explained why the local population was an important resource in this response operation: «Time is of the essence when it comes to avalanches. The chances of survival decrease rapidly. The important thing in this situation was to gather a lot of people who could dig».

An informant from the Red Cross Society explained that intelligence is of the utmost importance to be able to locate victims, both in backcountry and urban avalanches. In line with him, Genswein and Harvey (2002) point out that intelligence in a backcountry avalanche is gathered by looking for tracks into the avalanche area, an initial primary search for people or their belongings, and a more thorough systematic search in the avalanche area. In an urban avalanche, the snow masses are so polluted with debris that the conventional search strategies are no longer effective. Instead, intelligence is gathered by talking to survivors and neighbours. The professional rescue workers from Lufttransport AS underlined that they were totally dependent on the local population during the initial search and rescue phase. They especially pointed to the population's efforts in intelligence gathering and excavation of people buried by the snow. One of them claimed that «without the information and knowledge provided by the local population, it would have been like searching for the needle in the famous haystack». The local population also delivered different kinds of rescue equipment to the rescuers in the avalanche area, such as shovels, probes, jerven bags[2], chainsaws etc. In addition, people offered warm clothes, food and drinks to the rescue workers. None of this assistance was ever requested, according to an informant from the Longyearbyen Fire and Rescue Agency.

One of the informants from the Red Cross Society said that the professional emergency responders in Longyearbyen do not have the capacity to manage a crisis of this scale on their own. Several informants also mentioned that rapid assistance from mainland Norway in the acute phase of a fast developing crisis is not likely, due to the geographical distance. Tough weather conditions may delay assistance from outside even longer. This makes the local population a crucial resource in a crisis like the urban avalanche in 2015. Almost all of the informants described that the local population has proved to be a valuable resource in countless backcountry avalanches near Longyearbyen. People often come to the rescue on their snowmobiles, loaded with avalanche equipment. Depending on the situation, they initiate search and rescue operations

[2]A jerven bag is a protective poncho and tarpaulin.

themselves, or offer their assistance to the professional responders.

The vast majority of the informants from the professional emergency organisations expect the local population to be a resource in avalanche search and rescue. They pointed out that many of the citizens have the knowledge, training and equipment to be a resource. They also pointed to the fact that most of the local population is young and employable, and that they typically have a great interest in outdoor activities. The children in one of the kindergartens actually conduct search training when they play with avalanche beacons searching for candy buried together with an avalanche transmitter.

Some informants added that Longyearbyen is a rather small town where people know their neighbours, which makes all affected when an urban avalanche strikes the town. One of the rescue workers from Lufttransport AS referred to the message on Facebook posted by a citizen (mentioned earlier), and added that «the local population know their role in an event like this. Most of us have avalanche beacons, probes and shovels. Meet up»! A doctor working at the hospital said that «history has shown that the local population represents a difference when crises strike in Svalbard. It is a resource we can count on».

The authorities did not request any assistance from the local population after the avalanche in 2017. Nevertheless, a large number of unorganized volunteers, men and women, youths and adults, stood in line nearby the avalanche area with avalanche beacons, probes and shovels, ready to assist if needed. Everyone behaved calmly and focused, and there was no sign of irrational behaviour. After a relatively short period of time, the police informed people waiting to stand down, as none were missing and the risk of a second avalanche was considered to be high (Tengesdal 2017).

6 DISCUSSION

6.1 *Unexpected and fast developing crises*

The urban avalanches took most citizens and authorities in Longyearbyen completely by surprise, even though some of the citizens were worried due to the snow drifts uphill on Sukkertoppen in 2015. Also in 2017 some people were worried. But, they were reassured by the Longyearbyen Community Council that urban areas were safe. However, it is important to notice that the exact location and time of an avalanche cannot be predicted (Brattlien 2017). When the avalanches were triggered (natural causes), it was only a matter of seconds before they hit urban areas in Longyearbyen. Thus, with reference to the crisis typologies presented by 't Hart and Boin (2001) and Gundel (2005), it can be argued that the urban avalanches in Longyearbyen in 2015 and 2017 were unexpected and fast developing crises. It may also be noted that the avalanche in 2015 has some legal aftereffects influencing the termination of the event[3].

6.2 *The local population's response*

There are some factors that point to the need for the local population's response in avalanches. First of all, time is of the essence in such crises. The statistics tell us that the chances of survival following an avalanche decrease rapidly after just 15 minutes, if a victim is completely buried by the snow (Landrø 2007). Consequently, the time and pressure that Rosenthal et al. (1989) stress in their crisis definition are extreme. In general, it will often take some time before the professional emergency responders arrive at the scene in an acute crisis (Kruke 2012, 2015). Statistically, they arrive *too* late to save lives (McClung and Schaerer 2006, Landrø 2007). This means that the victims themselves, and the people who are randomly present, are the ones who need to take the first shift pending the arrival of the professional emergency responders, in the *golden hour* (Helsloot and Ruitenberg 2004). This golden hour is crucial when the difference between life and death is a race against time. As we have discussed, it was the victims and the people randomly present who initiated search and rescue in the urban avalanche in 2015. Also, in the urban avalanche in 2017, the victims themselves helped each other to safety. In other words, it was the victims and the people randomly present who took the responsibility to manage the initial acute phase of these crises. Therefore, they can be considered as *first responders* (Kruke 2015).

Another factor is related to the professional emergency responders' lack of capacities. The *golden hour* in these crises do not last more than a few minutes. The urban avalanche in 2015 clearly demonstrated that the professional emergency responders in Longyearbyen lack the capacity to manage a crisis of this magnitude on their own. Therefore, altruistic behaviour is necessary in such situations as a supplement to the traditional response structures (Dynes 1994b). The professional emergency responders were totally dependent on the continuity in operations (Dynes 1993) provided by the local population in the acute phase of the avalanches. The inclusion of the population

[3]The parents of a little girl dying in the avalanche may go to court to get compensation due to accusations of inadequate urban planning.

made it possible to quickly evacuate people, and to locate and rescue people buried by the snow. The local population has proved to be an important resource in many search and rescue operations following avalanches in Longyearbyen and surrounding areas. They often initiate search and rescue activities themselves, or offer their assistance to the professional emergency responders. The local authorities did not encourage the population to participate in the urban avalanche in 2017, as was the case in 2015. Still, approximately 150 unorganized volunteers met up next to the avalanche area (Tengesdal 2017). The fact that they actually met up unrequested, strengthen the view that the local population is an asset in avalanche search and rescue.

6.3 *The local population's behaviour*

An informant from the local population told about a woman who allegedly panicked and ran away when a house crashed into the house next to her. Can this behaviour actually be characterized as panic? Quarantelli (1953) describes panic as an excessive alertness or fear that leads to an unwise action. Panic can further be regarded as a form of irrational behaviour (Fritz and Marks 1954, Quarantelli 1999). In this specific situation, it is fair to assume that her decision to run away from houses *in motion* is a rather wise and rational modus operandi. She brought herself to safety. Generally, it is possible that panic occurs in acute crises, but we know that this form of irrational behaviour is rare (Helsloot and Ruitenberg 2004). The rest of the informants did not witness any examples of panic among the local population following the urban avalanches in 2015 and 2017. The doctor's story about the man who stood nearby when the avalanche hit in 2015 is a possible example of shock. He had some difficulties coping with the situation and seemed to be rather confused. It is not unlikely that he was paralysed (Helsloot and Ruitenberg 2004, Kruke 2015) as a result of watching the enormous slab avalanche hitting the settlement.

There are several examples of people who actually felt helpless, as a consequence of *not* being able to participate in the search and rescue operation in 2015. The fact that people felt helpless as a result of *not* being able to participate in the acute response, can be regarded as a considerable contrast to the widespread assumption that we turn into helpless human beings when crises strike. This study clearly shows that the population has a strong desire to help others in need. This may be rooted in a moral commitment (Comte 1973) and a form of solidarity (Tierney, Lindell et al. 2001). The spectator effect (Darley and Latanté 1968) was minimal in the urban avalanches in 2015 and 2017. The informants have very few examples of passive spectators in the avalanche area in 2015. There were also very few passive spectators observed in 2017 (Tengesdal 2017).

6.4 *The military model versus the problem-solving model*

The responses to the 2015 avalanche indicate that many of the citizens in Longyearbyen possess both the knowledge and training to be a valuable resource in avalanche search and rescue. The empirical findings also show that the professional emergency responders are aware of the local population's capacities, and that they actually count on the local population to be a resource in avalanches rescue when needed. This is largely in line with the problem-solving model presented by Dynes (1993) stressing the need for effective utilization of existing problem-solving capacities in the community (Dynes 1994a). The population quickly initiated search and rescue operations following the avalanche in 2015, displaying a sort of continuity (Dynes 1993) witnessed by the professional emergency responders upon their arrival in the avalanche area. The local authorities actively encouraged the population to participate in the excavation efforts in the urban avalanche in 2015 and coordinated the joint efforts between the actors present. Clearly, the authorities and the professional emergency responders didn't expect social chaos, which is an inherent assumption in the military model (Dynes 1993). Instead, they expected the population to be a resource, as the problem-solving model strongly suggests (ibidem).

Instead of establishing command and control structures, the authorities and the professional emergency responders focused on coordination and cooperation among public and private response structures in the avalanche area in 2015. It is fair to assume that the public-private cooperation was decisive for the outcome of the avalanche in 2015. Victims and neighbours immediately initiated search and rescue, and a large number of unorganized volunteers came to assist the professional responders. As a result, the victims were quickly located and excavated.

6.5 *Characteristics of the local population*

Can we expect the population to be a resource in urban avalanche search and rescue elsewhere, or is there something unique about Longyearbyen? Many social researchers take the stand that most citizens are rational actors who often provide lifesaving assistance in acute crises and demanding situations where lives are at stake (Quarantelli 1954, Dynes 1993, Helsloot and Ruitenberg 2004, Ripley 2008, Kruke 2015). Therefore, it is fair to assume that also citizens elsewhere would have

done their best to rescue their neighbours. Even so, there seem to be some aspects that particularly make the population in Longyearbyen a resource in avalanche search and rescue.

Firstly, the ones who come to the rescue possess the essential equipment that is needed to perform a speedy and reliable avalanche search and rescue operation. Secondly, many of them have both the knowledge and training to be a valuable resource. Thirdly, the population is young and employable. Fourthly, many citizens in Longyearbyen have a great interest in outdoor activities. Consequently, many of the citizens are also physically fit for an avalanche search and rescue operation. This represents a set of characteristics that presumably is quite unique for the population in Longyearbyen. In addition to this, it is likely that the rural location is influencing the population's expectations to help each other. Rescue resources from outside the archipelago cannot be expected in the acute phase of an avalanche. The citizens know that *they* are the ones who must provide the assistance. The sense of unity among citizens is strong, making the whole community affected when an urban avalanche strikes. Although these characteristics of the population in Longyearbyen make them a valuable response resource in an unexpected and fast developing urban avalanche, it can hardly be argued that they apply exclusively for the population in Longyearbyen.

7 CONCLUSIONS

The aim of this paper has been to discuss the role of the local population in urban avalanche search and rescue. The cooperation between the professional emergency responders and the local population was decisive for the outcome of the unexpected and fast developing urban avalanche in 2015. The urban avalanches in 2015 and 2017 show that the local population are the ones who are present when crises strike, and they perform search and rescue in the acute phase. The immediate response from survivors and neighbours, and the inclusion of unorganized volunteers that came to the rescue, made it possible to locate and rescue seven victims buried by the snow. This was possible due to an altruistic behaviour of the local population, that the citizens possessed the required equipment, knowledge and training, and that the local authorities and the professional emergency responders understood the value of including the population in the search and rescue operation. The responses to the avalanches in 2015 and 2017 show that the widespread assumptions about panic and helpless behaviour are mostly myths. The local population are first responders and have a strong desire to help their fellow citizens in need.

At least as safe as manned shipping? Autonomous shipping, safety and "human error"

T. Porathe & Å. Hoem

ABSTRACT: A paradigm shift is presently underway in the shipping industry promising safer, greener and more efficient ship traffic with unmanned, autonomous vessels. In this article, we will look at some of these promises. The expression "autonomous" and "unmanned" are often used interchangeably. We will therefore start out by suggesting a taxonomy of automation and manning of these ships. We will then go on examining the promise of safety. An hypotheses of increased safety is often brought forward and we know from various studies that the number of maritime accidents that involves what is called "human error" ranges from some 70–90 percent. If we replace the human with automation, can we then reduce the number of accidents? And is there a potential for new types of accidents to appear? Risk assessment will be a valuable tool, but will only reach as long as to the "known unknowns".

1 INTRODUCTION

The shipping industry are about to enter a new epoch. The story started in the 1800 when mechanized power was introduced and the vessels moved from propulsion by sail to propulsion by steam. The next stage came in the early 1900's when the diesel engine enabled more efficient and reliable ship services, analogous to the introduction of mass production on shore. In the 1970's the computerized control of ships was introduced. Now we are about to go a step further where cyber physical systems and autonomy, as part of "Shipping 4.0" (Rødseth 2017), will form a new gravity.

1.1 *The first autonomous ship accident*

We will start this article by a fictive illustration: It was an unusually warm to be in the end of October. The water in the strait was completely calm and mirrored the sky and the setting afternoon sun. In the Vessel Traffic Service (VTS) tower under the bridge the operator followed a lone kayak with his binoculars. It seemed like the kayaker was a child and not very proficient in his or her paddling and the kayak only slowly worked its way across the sound. The timing for crossing was not the best, the operator thought. He had an outbound oil tanker due in a few minutes and the autonomous *Yara* shuttle was to pass in the other direction soon after. The tanker was already approaching from the far side of the bridge sounding her horn to let the kayaker know she was approaching the 200 meters wide strait, something that probably did not make the situation better for the child in the kayak, the VTS operator thought. From the other side the autonomous shuttle was visible inbound on a westerly course with her 6 knots. He expected her to slow down any minute as her sensors detected the kayak in the sound.

Suddenly two water scooters appeared from nowhere, criss-crossing over the strait and around the kayak at some thirty or forty knots. The VTS operator could hear the roar from their engines all the way into the VTS tower. The surplus water shot up like a fountain from the back of the scooters and their wakes brought the water into turmoil around the kayak. In his binoculars, the VTS operator saw the child in the kayak letting go of his paddle and waving his arms to signal the scooters. Suddenly the kayak flipped over and the boy disappeared into the water. The scooters shot off towards the far side and the operator could see the head of the boy reappear on the surface beside the overturned kayak. He was right in the way of the tanker. The operator quickly grabbed the VHF receiver and called the tanker.

"*Tarnfjord, Tarnfjord* this is Brevik VTS on channel 16. Have you seen the overturned kayak ahead of you?"

"Brevik VTS, this is *Tarnfjord.* Rodger that. We are slowing down and holding to port. We should manage to avoid the kayak. But we cannot reverse. And we will have close call with *Yara.*"

"OK, *Tarnfjord*, thank you for that," the VTS operator replied, and continued immediately to call the shuttle, "Yara remote control, Yara remote control, are you following what is happening in the Brevik strait?"

He turned and looked at the shuttle and could see that she had not slowed down as he had expected. Both of the ships were now only a few hundred meters from the overturned kayak under the bridge.

"*Yara* remote control, *Yara* remote control, this is Brevik VTS on channel 16. Please respond *Yara*."

He took up his binoculars and saw that the tanker was slowly turning. The shuttle was now only some 100 meters from the overturned kayak and the turning tanker and still showed no sign of slowing down.

The radio crackled. "Brevik VTS, this is *Yara*. Did you call me? I had a coffee break."

"Thank, you, *Yara*," the operator quickly replied. "Stop immediately; can't you see the kayak in front of you?"

"No, the sun is completely blinding both my cameras and on the radar I only see the bridge" the remote operator answered, and then he shouted "What the hell is the tanker doing!"

We will not know how this incident ended as it is pure fiction and the Yara shuttle will not start to traffic the Brevik strait in southern Norway until 2021 (she will be manned in 2019, remote controlled in 2020, before attempting to go autonomous 2021). Nevertheless, the situation could be plausible. Kayaks, scooters and other leisure crafts will be close companions to autonomous ships in Scandinavian waters summertime. Cameras and radars can be deceive, as was shown in the Tesla car accident in 2017 (Lambert 2017; NTSB 2017). Bridges may obscure radar detection of objects underneath. Objects coming and leaving like the two scooters may confuse the artificial intelligence of collision avoidance systems, and LIDAR (Light Imaging, Detection, And Ranging) is only useful at close range, closer than the stopping distance. Finally, the human backup may have gone for a cup of coffee.

The fictional incident above is, maybe unfairly, attributed to the planned autonomous Yara-Birkeland container feeder (Kongsberg Maritime 2017). This unmanned, autonomous vessel, taking 120 containers on a fully electric propulsion system, will replace some 20 000 trucks taking the same amount of containers on the road today. There is an economic as well as environmental gain to be made. Doing this autonomously and unmanned will be a challenge. So let us start by looking at that.

1.2 *Ambiguity in definitions*

The concepts of unmanned and autonomous when used on ships are ambiguous. The ship bridge may be unmanned, perhaps in periods, but crew may still be on board, ready to take control when needed. A ship can also be remotely controlled from a shore station via highly redundant and high capacity communication links. Is this ship unmanned or autonomous? A dynamic positioning (DP) system on a ship will automatically control the position and perhaps the heading of the ship, but most DP systems will rely on an operator to handle any errors, e.g. in sensors, that occur during the operation. Is the DP automatic or autonomous?

Furthermore, to what ship functions do unmanned or autonomous apply? In (Rødseth & Tjora 2017), eight main functional groups are identified, including, e.g. navigation, engine control, cargo monitoring and onboard safety functions. In the following text, we will refer to typical bridge functions, but in a truly autonomous ship, all shipboard functions must be automated to some degree and the degree of autonomy may be different for each function.

Finally, the degree of autonomy will be different during the ship's voyage. Tighter supervision and perhaps continuous remote control will be necessary during berthing while a high degree of autonomy is normally desired during the deep-sea passage.

This ambiguity is reflected in many existing definitions of "autonomy levels". In (Vagia et al. 2016), 12 different "levels of autonomy" are examined and even more have become available as autonomy levels have been extended to ships (Rødseth & Nordahl 2017). One reason for the numerous definitions is that autonomy must be defined along several axes and with a strong focus on the operational profile at hand. The idea of autonomy is very context dependent.

1.3 *Three axes of autonomy*

For ships, we propose to characterize autonomy along three axes (Rødseth & Nordahl 2017).

One axis is the *complexity* of the intended operation. Is the ship operating in sheltered or open seas, what are the likely weather or visibility impacts, how much other traffic is there, how complex is the sailing routes in terms of shallows, turns and obstacles, and so on. We propose to capture the complexity in the operational design domain (ODD) as explained in the next section.

Table 1. List of autonomous ship operation types.

	Continuously manned bridge	Unmanned bridge, crew on board	Unmanned bridge, no crew on board
Operator controlled	Direct control	Remote control	Remote control
Automatic	Automatic control	Automatic control	Automatic control
Partly autonomous	Partly autonomous	Partly autonomous	Partly autonomous
Constrained autonomy		Constrained autonomy	Constrained autonomy
Full autonomy			Full autonomy

The second axis is the *manning level*. The ship can have a continuously manned bridge, but still have a high degree of autonomy in automated object detection and collision avoidance. One can foresee ships with enough autonomy to allow the crew to go to bed at night, when sailing in open waters and fair weather. Ships can also be remotely controlled, with hardly any "real" autonomy at all. On the other end of the axis, one may see ships with no crew and no remote monitoring at all: they are fully autonomous. The manning level is dealt with in Table 1.

The third axis is the operational autonomy, how the necessary operations to satisfy requirements of the ODD are divided between human and machines. We propose to capture this aspect by diving the Dynamic Navigation Tasks (DNT) into two parts: One part that requires human intervention to be executed (Operator Exclusive DNT) and one that can be handled by the automation systems (Control System DNT).

1.4 *A proposed taxonomy*

To simplify the definition of autonomous and unmanned, we will start with a concept borrowed from the US car industry and its definition of terminology for autonomous cars (SAE 2016). This is called the "Operational Design Domain" (ODD) which is the operational conditions that limits when and where a specific autonomous car can be used. The corresponding capabilities of the car and its control systems is the "Dynamic Driving Task" (DDT). The concept also includes the "DDT Fallback" which is procedures and safety guards that are built into the vehicle and control systems for handling situations when the ODD is exceeded. The DDT Fallback will bring the system to a "minimal risk condition" (SAE 2016). For a ship, we suggest renaming DDT to the "Dynamic Navigation Task" (DNT).

Most autonomous or unmanned ships are expected to have a "backup" operator somewhere on board or on shore, so that situations that cannot be handled by automatic functions can be safely handed over to the operator. This can be illustrated by dividing the DNT into two regions:

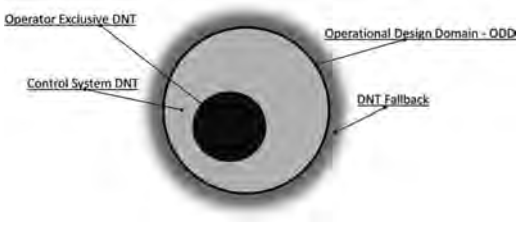

Figure 1. The operational design domain and dynamic navigation task.

The "Operator Exclusive DNT" where the operator is needed to resolve problems that the automation cannot handle and the "Control System DNT" which represents the unassisted capabilities of the automatic systems. The complete concept is illustrated in Figure 1.

A proposed set of definitions for autonomous merchant ships (Rødseth, Nordahl 2017) indicates that four distinct levels of autonomy may be needed and are probably sufficient. These levels are defined independently of the human operator being located on board the ship or in a remote location:

1. *Operator controlled (AL0-1):* The DNT is fully handled by the operator. Systems may provide decision support or very limited automatic control, e.g. as in an auto pilot or track pilot. This is the current situation on today's ships.
2. *Automatic (AL2):* The ship systems can operate without human intervention for a very specific function, typically as a DP system works today. An operator is required to handle all deviations from expected operational parameters. This autonomy level is probably appropriate for automatic berthing or other situations where very accurate control is needed and where less deterministic and autonomous problem handling is unwanted.
3. *Partly autonomous (AL3):* The ship can perform certain tasks in the DNT autonomously, e.g. transiting open sea in fair weather. This can, e.g. be used to have a periodically unmanned bridge.
4. *Constrained autonomous (AL 4):* The ship can operate autonomously within most or all of the

DNT, but it has clear limits to what actions it can take by itself, e.g. maximum speed and track deviations. If the ship needs to exceed these limits, e.g. due to anti-collision manoeuvres, the operator has to be called to change limits or to remotely control it until constrained operations can resume.

5. *Fully autonomous:* The ship systems can perform all its DNT tasks without human intervention. There are no operational limits beyond those defined by the OOD.

Constrained autonomy is the most likely type of autonomy for fully unmanned ships with shore supervision. It enables the ship to solve all "standard" problems by itself while reducing system complexity by having an operator available for the more complex situations. It also gives a high degree of operational determinism due to the operational envelope it cannot exceed without human acceptance. Fully autonomous is the necessary level for autonomous ships that have no remote supervisor. This will in many cases require very complex control systems and is not very likely level for ships in the near future.

The levels can be characterized by having different ratios between the operator exclusive DNT (black) and the control system DNT (grey), as illustrated in Figure 2. One may validly argue that the levels between automatic and constrained autonomy should be the same class as they both have operator and control system DNTs. However, it is useful to differentiate between them since they are likely to be used in different context during the voyage.

Dependent on autonomy level and the operator being available on the ship or on shore, one can de-fine the matrix in Table 1. The shaded cells represent operations where one will require a manned shore control center to handle deviations from operator DNT fast enough. The empty cells represent types that are not very relevant, although possible.

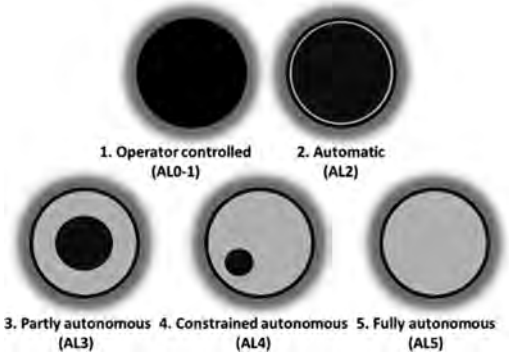

Figure 2. Five levels of autonomy.

The level of autonomy will vary over the ship's different functions such as engine control, cargo monitoring and navigation functions. It will also vary during the ship's voyage. This may be result of, e.g. using an unmanned bridge during night and open sea passage or by having different modes in different phases of the voyage, e.g. using remote control during port approach and automatic control during berthing.

2 AUTOMATION

Going back to the concept of ODD and DNT, one may argue that most incidents occurring with automated systems may be of the following types:

1. *Errors in control system DNT (CS-DNT):* These are purely technical errors that occur in the automation systems and associated sensors. It may be caused by technical system malfunctions or by design errors in system designs or configurations.
2. *Errors in operator exclusive DNT (OE-DNT):* These are human operational errors that may have been caused by, e.g. fatigue or low situation awareness which, in turn, may have been caused by bad technical systems. However, the incident is directly attributed to a human operational error.
3. *Transition from CS-DNT to OE-DNT:* This is a critical issue as the transition both has a timing aspect and must be fast enough and a situation awareness aspect as the human must understand the background for the transition to make the correct decisions.
4. *Operator intervention in CS-DNT:* There are also examples of incidents that have been caused by operators intervening in automated processes when they should have left the automation system alone.
5. *Transition from OE-DNT to CS-DNT:* This is probably a less common type, but it may be challenging to make sure that the automatic control system is activated at the right time and with the right parameters settings.
6. *Transition to DNT Fallback:* When to activate the DNT Fallback is also a critical issue. The DNT Fallback is not necessarily a "fail to safe" control as ships do not have a generally safe state. It is a "minimal risk condition" (SAE 2016). Thus, there is an inherent risk in going from OE-DNT or CS-DNT to DNT Fallback and it is a challenge to define the proper conditions for doing so, particularly when a human is in the control loop.

While this classification seems most relevant for autonomous ships, it is also applicable to manned ships with automation or decision support components. In particular, the transitions between automatic and human control in current automated systems will be a good indication of how this problem will develop when more autonomy is added in the system.

In the following, we will discuss known benefits and shortcomings of today's manned operation with automation and see how that can be applied to autonomous ships.

3 SAFETY, HUMANS AND AUTOMATION

If autonomous unmanned ships are to become a success they have to prove successful in several areas, and safety is one of them. Thus, the first thing we might ask is how safe is then manned shipping?

3.1 *At least as safe as manned shipping*

In a study by Oxford University on British data from 1976 to 1995, the seafaring job is ranked as the second most dangerous occupation in Britain—after being a fisher (Roberts 2002). This is however not usually because ships are sinking, but because of occupational hazards like slips, trips, and falls on a moving platform full of heavy gear and a hazardous environment. In this sense, we might conclude that already removing humans from this hazardous environment has a safety benefit.

However, if we by safety think of the safety of the ship we can say that shipping is very safe and is becoming even safer every year. Just to provide a background we can note that in the three years between 1833 and 1835, on average 563 ships per year were reported wrecked or lost in United Kingdom alone (Crosbie 2006). Today the total number of tankers, bulk carriers, containerships and multipurpose ships (over 100 Gross Tons) in the world fleet has risen from about 12,000 in 1996 to some 33,000 in 2016 (Clarkson 2017). During the same time, the number of ships totally lost per year (ships over 500 Gross Tons) declined from 225 in the year 1980, to 150 in 1996 and 33 in 2016 (total losses as reported in Lloyds List – IUMI 2016) – and this worldwide.

If we look at ship accidents broken down into different causes, we can see that between 2012 and 2016 50% of ships totally lost did this because of weather. Some 20% grounded, 10% was lost because of fire or explosion, 5% by collision, and 10% by machine failure. (Total Losses, all vessel types over 500 Gross Tons – IUMI 2017)

As we can note from the above, there is no mentioning of any losses due to "human error". This is because the statistics often chose a single, simple cause of the accident, but if we drill down looking for a root cause we often find "human error" on one level or another in almost all cases. Dhillon (2007) compiled the following statistics:

A study of 6091 major accident claims associated with all classes of commercial ships, revealed that 62% of the claims were attributable to "human error".

"Human error" contributes to 84–88% of tanker accidents.

"Human error" contributes to 79% of towing vessel groundings.

Over 80% of marine accidents are caused or influenced by human and organization factors.

"Human error" contributes to 89–96% of ship collisions.

A Dutch study of 100 marine casualties found that "human error" contributed to 96 of the 100 accidents. (For detailed references see Dhillon 2007, p. 2)

Let us illustrate how "human error" can be a part of almost all accidents. Let us briefly look at the recent collision accident between the general cargo ship *Daroja* and the oil bunker barge *Erin Wood* that took place in Scottish waters in 2015 (MAIB 2016). In August 2015 the two vessels collided off the east coast of Scotland. It was a nice summer afternoon with light wind and no sea state. The two vessels were both north bound but with crossing courses which brought them closer and closer together for almost two hours without any one of the two bridge officers apparently noticing the other ship until too late. Visibility was excellent, radar and AIS tracking was available on both bridges. The UK Maritime Accident Investigation Board concluded that "*Daroja* and *Erin Wood* collided because a proper lookout was not being kept on either vessel." (MAIB 2016, p. 40) This accident would appear in the aforementioned statistics as a "collision", but the underlying root cause was "improper lookout", which would classify it as "human error".

A variety of taxonomies for "human error" has been proposed. One example is the simple dichotomy between "errors of omission" and "errors of commission" (Wickens et al., 2013). "Errors of omission" mean: not doing anything when something should have been done, as the watch keepers above. "Error of commission", on the other hand, means: doing the wrong thing.

A more elaborated taxonomy developed by Norman (1988) and Reason (1990) involves "mistakes," "slips" and "lapses."

"Mistakes," are when the operator has not fully understood the situation and acts intentionally.

"Slips," on the other hand, are when the intention is right but the action is carried out wrong.

Maybe the wrong button is pressed although the intention was to press the right one. Because humans monitor their own actions, slips are often noticed and corrected before any harm has been done.

"Lapses," finally, are a failure of making any action at all, i.e. an error of omission. Often they are lapses of memory, forgetfulness. Humans forget, we become distracted or think about other things. This is all part of the human condition. Maybe the two watch keepers in the accident above was thinking about other things and forgot to monitor their systems and look out of the window? "Lapses" are sometimes easy to prevent by technical solutions like automation.

One may ask how come there was no warning issued to make the two watch officers aware of the pending danger. Radar systems on both ships as well as the AIS tracks in the electronic chart systems could theoretically extrapolate the courses of the vessels to a collision point. In addition, systems on land that gather AIS data could have made the same calculation. Why is it that available data is not used to the benefit of safety when possible? Why was there no warning and why did not the systems automatically make a small course or speed change to stay out of the close quarter situation? It is because automation is a controversial issue. Warnings are often turned off by operators, because of many false alarms.

3.2 *Why automation can make ships safer*

A large part of the robustness of the shipping industry demonstrated by the constant decline in shipping accidents has to do with automation. The error prone and difficult position fixing, previously done by manual methods like dead reckoning, or sun heights and bearings to landmarks, when sun, stars and land was in sight, has now been replaced by satellite based navigation systems with very high reliability. Manual steering which in old days caused large course errors has been replaced by auto pilots or even track pilots which can follow a pre-programmed path with an accuracy of a few meters- or even centimetres when augmentation systems are used. Just to mention a few areas of marine automation.

The reason automation is safer is that they address human shortcomings like:

Fatigue: Humans are day animals. We are designed to be active by day and sleep by night. Our whole cognitive system is designed for work by day. Even if augmented by technical means, our decision making is crippled during night, even if we are accustomed to shift work by night. A larger degree of accidents happen during night. (e.g. Wagstaff & Sigstad Lie 2011)

Attention span: The ability to focus and sustain attention on a task is crucial for the achievement of one's goals. Although *attention span* is a complex concept and measures depend on a lot of different thing, most researchers agree that the time span humans need to concentrate to handle tasks without being distracted is limited, e.g. 10–20 minutes in healthy teenagers and adults (Wilson & Korn 2017).

Information overload: Overload can be of many kinds. Too much to do, and too little time to do it. Too much information that needs to be considered presented in an unintegrated way at the same time. It boils down to limits of the human *working memory*. Miller in 1956 famously stated that humans at the most could handle 5–9 information chunks at one time. But, *underload* can also be a problem. During a conference in 2014 a British maritime accident investigator mentioned a new type of *boredom-induced accidents*. Evidence of the so-called Yerkes-Dodson law (first proved on mice in 1908) show that human performance describes an inverted U-shaped curve when plotted against arousal (or stress) so as low arousal also may lead to low performance and elevated arousal lead to higher performance to a certain point when performance declines with higher stress (cognitive tunnelling).

Normality bias: This is a form of denial 70% humans revert to when facing events of disaster, as a result of which they underestimate the possibility of the disaster actually happening and its potential results (Omer & Alon 1994).

We could go on stating human shortcomings in this way for many pages, however we think the point is made: automation can make ships safer.

3.3 *Why automation can make ships less safe*

In the everlasting strive to make life easier, humans have automated tasks that are tedious, dangerous, dirty, boring, etc. However, a paradox in automation is that it has often been the easiest tasks that has been possible to automate. In complex and ambiguous situation, the human has had to step in to resolve the ambiguity and finish the task.

Automation needs to be programmed and can therefore only solve simple or *complicated* problems. By "complicated", we here mean that there is a finite solution space that can be parsed by computers. In reality, many real world problems are *complex* in the sense that they have an infinite solution space due to many unknown factors and interrelationships. For such problems, it is not even theoretically possible to program to solve all possible situations (possibly leaving machine or deep learning aside).

The dynamic maritime environment with sea and current, weather, topography, manned and autonomous ships is such a complex environment and will for a very long time need a human to step in and resolve problems out of the range of automation. As we have seen above, there is relatively good statistics on "human error", however there are almost no statistics on "human recoveries", where humans has stepped in and saved a situation caused by e.g. technical malfunction.

An illustration of such a recovery can be fetched from an incident in1991.

In this incident a product tanker loaded with 20 000 metric tons of gasoil was under way through the narrows of a winding Scandinavian archipelago. In a bend in the fairway she had a routine meeting with one of the large ferries trafficking the area. The ferry had almost 1000 passengers and crew onboard. As the tanker applied starboard rudder to negotiate the bend in the fairway, the captain noticed that the rudder instead turned to port and a port turn was commenced a few hundred meters in front of the oncoming ferry. The captain immediately reversed the engine, but realizing that he would not be able to prevent the turn, he called the ferry on the VHF saying they had a breakdown on the steering engine and asked for "green-to-green" (starboard side to starboard side) meeting. The ferry responded promptly, but by making a starboard 360 degree turn and the ships passed each other on parallel courses with 20–30 meter between. The accident investigation board calculated that if the action from the ferry had been delayed 30–60 seconds a collision with the ferry running into the amidships section of the tanker in a right angle would have been impossible to avoid (SHK 1992). The consequences can only be imagined.

The accident investigation concludes that it was the decisive actions by the captains of the two ships that avoided a possible catastrophe. One may wonder what would have happened if one or both of the ships had been autonomous. Remember also the pilot of the airliner that landed on Hudson River in 2009, and who, by acting against protocol and procedures, miraculously saved the lives of passengers onboard (NTSB 2010).So, on one hand we have incidents due to human error that can be avoided with automation, on the other hand we have incidents that is now avoided with humans, but will happen when no humans are onboard. But new technology also opens for new types of accidents.

These relationships are described in Figure 3.

Automation of human processes (middle circle, Figure 3) are expected to significantly reduce the number of incidents happening in shipping today, but one must also assume that a number of

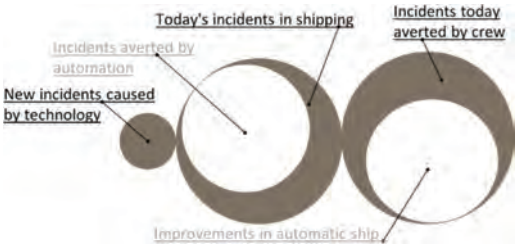

Figure 3. Remaining incidents in the autonomous ship after automating human processes.

potential incidents are averted by the crew's actions and it is not clear if improved automation can match these numbers. Finally, one must also assume that some new types of incidents will occur as a result of the introduction of new technology (far left). The net result is the remaining grey areas and the question is if this will be low enough for societal acceptance of the new ship types.

Thus, while the assumption is that the net result of automation will be lesser accidents and incidents, this remains to be shown. Within commercial air industry, automation has improved safety, (e.g. Billings 1997; Pritchett 2009; Wiener 1988). Can we assume that the same is true for the shipping domain? One way of dealing with this is through *risk analysis*.

3.4 *Risk analysis*

Risk analysis can be "broadly defined to include risk assessment, risk characterization, risk communication, risk management, and policy relating to risk, and risks of concern to individuals, to public- and private-sector organizations, and to society at a local, regional, national, or global level" (SRA 2012). In this paper's context, we look at risk analysis as risk assessment where risk is defined as the combination of the frequency and the severity of the outcome of an accident (IMO 2002).

The expected frequency of accidents must often be derived from an assumed accident probability, as statistical significant data on frequencies are impossible to find. Obviously, this particularly applies to new technology or ship types as in autonomous ships. The probabilities are difficult to determine in themselves and, in addition, the strength of knowledge used to establish the probabilities need to be addressed. In autonomous systems the strength of knowledge is generally low due to lack of experience and the complexity of the autonomous marine system.

The prevalent strategy to the increased (socio-technical) complexity, lack of coherence, and speed of change in contemporary systems, science and

the discipline of risk management, is to incorporate uncertainty, ambiguity, and the knowledge dimension per se in the risk measure (Paltrinieri et al. 2016). This is done through risk analysis of potential accident scenarios that we eventually are aware off and can manage. This is emergent research and there is not much hard knowledge in the area, although some papers have been published, e.g. (Utne et al. 2017) and (Rødseth & Tjora 2014).

The second paper is mainly a preliminary hazard identification (HazId) study based on use cases and ship function breakdowns. It suggests a framework for doing HazId in the unknown environment of the autonomous ship based on assumptions on what can happen and how this influences on the different functions the ship systems have to provide. The first paper argues for a more holistic approach to risk management, including dynamic risk assessments during the autonomous voyage.

This paper will not go further into this area, but it is important to point out that determining the complete risk level for the autonomous ship will be very challenging. As was illustrated in Figure 3, there are more new issues that have to be taken into consideration and for at least two of these we do not have any statistics that can be used in estimates of probabilities. Although, e.g. HazId may be able to identify the hazards and accident consequences, we are still left with very uncertain probabilities and the limitation to the known knowns and known unknowns.

Within safety science, the concept of "human error" are seldom used after 1990's since it has been seen that "human error" is not a cause but a result of other factors such as poor design, poor planning, poor procedures, etc. (Dekker 2006). Instead the concept of "human variabity" from Resilience Theory is often used (Hollnagel, Woods & Leveson 2006). Human variability that sometimes might lead to "human errors" but maybe more often to "miraculous recovery". Positive actions and successful recoveries are usually not recorded, as mentioned in Leveson (1995, p. 94); where an U.S. Air Force study showed 659 crew recoveries in 681 inflight emergencies; with only 10 pilot errors.

4 CONCLUSION

It seems to be generally accepted that automation has the potential to decrease accidents that are due to human variability.

However, automation has the potential of creating accidents in itself, e.g. through transitions between automatic and manual control and the human having to rapidly assess the situation and make the right decisions.

Automation also sometimes creates problems by reducing the work load of the human, inducing boredom and by that further increasing the time needed to do a correct assessment.

With constrained autonomy being the most likely form of ship autonomy, one needs to investigate if these issues actually can increase the probability of some accident types compared to conventional manned ships.

Also, autonomy will create new types of accidents, as suggested by the illustration in the beginning of the paper This is partly due to accidents that was before averted by the human crew and partly due to introduction of new technology and corresponding new accident types. These types of accidents are very challenging to include in the risk analysis as we lack statistical evidence for their probability.

To address the new risk picture, one probably need new types and extensive use of human centred risk analysis. Also, one needs to consider the development and use of dynamic risk assessment systems during autonomous voyages, as well as other real time tools that can be used on the ship or in the shore control centre.

A computerized procedure system framework for U.S. utilities

R. Lew
University of Idaho, Idaho, USA

R.L. Boring & T.A. Ulrich
Idaho National Laboratory, Idaho, USA

ABSTRACT: The United States has a fleet of light water reactors that continue to operate using paper-based procedures. Here we review existing implementations of computerized procedure systems, the potential benefits, as well as their caveats. We also review U.S. regulatory requirements for computerized procedure systems in an effort to identify barriers to adoption. We conjecture that process control procedures, especially the formalized procedures used by U.S. utilities, can be viewed as E-Type Systems from a software engineering evolution perspective. After presenting this argument, we discuss corollaries from treating procedures as E-Type Systems. Based on these analyses, a strategy was formulated to aid utilities in transitioning to computerized procedure systems. And lastly, missing tooling to aid utilities in cost-effective, timely transitions is discussed.

1 INTRODUCTION

The U.S. Department of Energy's (DOE) Gateway for Accelerated Innovation in Nuclear (GAIN) program partners nuclear technology industry partners with DOE expertise and resources. As part of GAIN, Idaho National Laboratory is teaming with the simulator vendor GSE Systems to develop a Computer Based Procedure (CBP) Engine for Nuclear Power Plant (NPP) Main Control Room (MCR) operations. This platform would enable critical research related to CBPs with full-scope simulators specifically to support paper to digital procedure transitions for U.S. utilities seeking to realize the benefits of CBPs.

The aging U.S. fleet of light water nuclear power plants (NPPs) is of paramount importance to the nation's overall base energy production capabilities. Each nuclear power plant has been operating for multiple decades and has already undergone numerous engineering changes. Approximately 74 operating plants have filed license extensions to operate beyond their original 40 year operating license. To operate beyond 40 years, many plants are undergoing modernization efforts of ensure the plants can be operated in a safe and cost effective manner. These changes result in frequent amendments to procedures. The procedures have evolved substantially from when the plant was first commissioned. The U.S. nuclear industry, in addition to being highly proceduralized with operations and maintenance in and out of the control room, is also one of the most stringently regulated energy industries.

Plants were originally commissioned with paper procedures and, despite their shortcomings, have stood the test of time and are still in use today. It is well documented and often cited that human reliability and error are the leading cause for plant events. When the contributors of human error are examined, a U.S. Nuclear Regulatory Commission report (1995) reveals that procedure problems have been cited as contributing to 69% of event reports. Following paper procedures is challenging because:

- Operators must identify the correct procedure and have the most up-to-date version of the procedure. The use of paper procedures can result in an excess number of procedures, often with poor classification schemes (O'Hara et al., 2000).
- Operators must determine the correct path through the procedure and complete the procedure without skipping steps or following steps out of order. Operators must manually keep their place in procedures (Fink et al., 2009).
- Procedure following imposes high memory demands on operators because of the need to track multiple pieces of information tied to disparate pieces of equipment.
- In emergency events, each operator might be performing multiple nested procedures simultaneously. It is in these stressful environments that humans have a high potential for decision making errors, such as making incorrect conclusions (Converse, 1995; Kim, et al. 2011).
- Operators must determine plant state from control board indications or approved (qualified) plant computer systems. This requires frequent searching for information or requests for information from reactor operators (ROs). ROs must determine

the correct instrumentation and control (I&C), and correctly perceive and report the correct value. Senior reactor operators (SROs) often are completely reliant on the RO for critical pieces of information.
- Procedures also require continuous actions to monitor plant variables, and operators must take action if a specified threshold is reached. These continuous actions divide the operator's attention across the board.
- Decisions must be based on the current plant state. The plant state changes as operators progress through a procedure. Normal operating conditions can be different depending on the plant state.
- Procedure following requires engaging in critical actions within specified time intervals. Operators often must keep track of several time intervals simultaneously.

Computer-based systems for nuclear power are precedented with over 30 years of research and multiple use cases. Several systems have shown that computerized procedures can aid operators with many of these challenges as illustrated in the following section.

2 RESEARCH AND IMPLEMENTATIONS OF COMPUTERIZED PROCEDURE SYSTEMS

2.1 *Korea advanced reactors*

KOPEC Nuclear Power operations for Shin Kori Units 3 and 4, which are APR1400 units (Unit 4 is not yet online), rely heavily on computerized procedure systems in a completely different paradigm from conventional operations (Hong, Lee, and Hwang, 2009). With conventional (U.S.) operations the operator follows a paper procedure and references the boards to assess the current state of the plant. Computerized procedures allow the relevant information to be provided within the context of the procedure. However, with individual workstations displaying CBPs, operators communicate less with each other, leading to poorer team situation awareness (Kim, et al. 2011). Operations becomes much more centric to the computerized procedure system, and many of the inefficiencies associated with seeking information and verbally communicating between operators are removed.

With traditional procedures, information is coupled primarily through the reactor operators. With CBPs the communication between operators is loosely coupled.

The Korea Electric Power Research Institute has developed a computerized procedure system that in addition to displaying and executing procedures has functionality for writing and editing procedures, and assessing the validity of logic and plant parameters through a testing framework that integrates with an engineering framework (Hong, Lee, and Hwang, 2009).

2.2 *The OECD Halden reactor project*

The Halden Man-Machine Laboratory (HAMMLAB) of the OECD Halden Reactor Project (HRP) has conducted pioneering research related to computerized systems for nuclear control. In 1985, work on developing computerized procedures began, which culminated in the Computerized Procedure Manual (COPMA) and later COPMA-II. A 1995 experimental study (Converse) found that operators committed half as many errors with COPMA-II compared to using paper procedures. This is even more significant when considering that the participants had only a few hours of training and experience using COPMA-II, although it should be noted that crews responded faster with paper procedures. In 2000, the third iteration of COPMA, based on web technologies, was released (IFE, 2017).

While OECD Halden Reactor Project is perhaps most well-known for ecological interface design and information rich displays, much effort has focused on how task-based displays can be designed to convey the most important procedure relevant information, as well as identifying how task-based displays can integrate procedures with process displays (Braseth, et al., 2009). This philosophy is advantageous because the layout of the information is kept in a standard format and the procedure is simultaneously visible to all operators, resulting in an improved shared situation awareness.

2.3 *Westinghouse*

Westinghouse Electric Corporation began developing CBPs for commercial applications in the early 1990s. Their COMPRO system was highlighted as having a graphical user interface and using relational database technologies. COMPRO has been deployed in Beznau, Switzerland, and Temelin, Czech Republic. Westinghouse's AP1000 will incorporate a computerized procedure system that will also provide a diverse set of procedure views including graphical flowcharts, a textual view and a dynamic logical view (Lipner, Mundy, Franusich, 2006) while retaining much of the COMPRO "DNA" in philosophy.

In the early 1990s Westinghouse collaborated with Army/NASA Ames Research Center to apply the Man-machine Integrated Design and Analysis System (MIDAS), a tool for computerizing the cockpits of advanced commercial and military aircraft, to a computer-based procedure system for main control room operations. This collaboration resulted in an impressive proof-of-concept demonstration of how CBPs could substantially reduce operator memory demands and improve situational awareness (Hoecker, et al. 1994). The caveat being that incorporating MIDAS to translate PBPs to CBPs is a fairly significant refactoring requiring detailed and extensive collaboration between operations and human factors practitioners.

2.4 *EdF N4 series reactors*

The Électricité de France (EdF) N4 series of reactors in France use CBPs. Dien, Montmayeul, and Beltranda (1991) describe the philosophy of developing the N4's original computerized procedures from a human factors perspective. They are careful to note the computerized procedures are not intended to guide the operator actions and the operators should always have the final decision on the actions that are performed in the plant. In operations, they recognized the necessity for operators to compensate for inadequacies in procedures, as well as handling conflicting or ambiguous conflicts between procedures. Procedures can also result in operators looping through a procedure multiple times before finding the correct indication; the EdF approach recognizes that human operators may be able to implement more economical or practical control strategies than those prescribed by procedures.

3 U.S. ADOPTION OF COMPUTERIZED PROCEDURES

Thus far, we have reviewed existing implementations of computer-based procedures and procedural systems. Despite several decades of commercial implementations and several new systems in modernized plants, adoption of CBPs in U.S. main control rooms is almost non-existent in spite of the fact procedure related problems have been implicated in 69% of event reports.

Le Blanc, Oxstand, and Waicosky (2012) surveyed U.S. nuclear utilities about their plans for implementing CBPs in the field, and the perceived barriers of implementation. Utilities are hesitant to be first. Being first in the industry usually entails higher costs. Utilities also need to justify the capital investment, and to do so CBPs need to be demonstrably better than paper-based counterparts.

While there are mixed results, the available evidence suggests that tangible benefits exist:

- Lin et al. (2016) found with a full-scope advanced Main Control Room simulator that operators with CBPs had significantly better task monitoring awareness, and higher task performance while operators completed emergency response procedures. Their results suggest that reduced communication between team members is a side effect of having higher situation awareness. Team members were observed to make verbal inquiries when their situation awareness was low.
- CBPs offload some of the complexity of procedure following, leading to fewer procedure deviations.
- CBPs can be organized by task so that switching between procedures is seamless (Le Blanc, Oxstrand, and Joe, 2015).
- Some of the work performed by operators can be offloaded to a CBP system, e.g. continuous monitoring of a plant parameter.
- Recovery from human error is faster with CBPs compared to paper (O'Hara, 2000).
- CBPs are even more beneficial with multiple failures.
- Dynamic presentation of information is possible. The information does not need to adhere to the standard *one sensor, one-indicator* format. Data can be tailored by clustering and aggregation, through summaries, and graphical presentations (Dien, Montmayeul, and Beltranda, 2009).
- Tasks that would normally require multiple procedures can be combined and ordered in a logical sequence.
- Visual representations of procedural flow paths can result in better awareness of the plant's current state and were the procedure is headed (NRC, 1995).

Why then, is there not greater adoption of CBPs, and how can adoption be encouraged? This question is difficult to answer with the available information, but we can provide some conjecture on the issue. Procedures, to state the obvious, tie to every sub-system of the plant. Undertaking an adoption of a CBP system is a large commitment from an organizational perspective. The benefits of a successful transition from paper to CBPs is clear, but plants also run the risk of disrupting the functional aspects of current procedures and procedural systems. The existing methodologies require completely disassembling and refactoring existing procedures into computerized procedure systems. This might work for new plants and new reactor designs, but could be seen as risky for the currently operating Generation II plants. Procedures are living documents that have been continually maintained over their multi-decade lifespans. Plants are modernizing control systems, and procedures must be amended to stay accurate with plant systems. They contain human years of operating experience and implicit functional characteristics that could be lost if haphazardly transferred to computer-based procedure systems.

4 SYSTEMS OF PROCEDURES

Here we suggest that process control procedures can be viewed from a software engineering perspective. The logic of a procedure is analogous to computer code. Instead of the code being compiled by a computer program, the code is interpreted and executed by a human. Lehman (1980) wrote a seminal article on software engineering evolution. Lehman describes three classes of software programs. *S-Type Systems* are programs whose function is defined by a specification. Programs in this category are provably correct if they meet the specification. The logic

blocks within a conventional distributed control system (DCS) is a prime example of S-Type Systems.

The second class of programs are *P-Type Systems* focusing on real world Problem solutions. P-Type Systems incorporate feedback loops comparing the measured state of the world to desired outcomes. Control systems are P-Type Systems. A controller may monitor a single or multiple parameters and produce one or more control signals to change the state of the system. A vendor will provide a detailed specification of a DCS's inputs and outputs along with descriptions of how the inputs should map to the outputs. The functionality of the DCS can be verified over the range of anticipated operating conditions. However, system control and safety outside of normal operating conditions is intractable. Efforts can be made to make systems more robust through strict quality control, redundancy, incorporation of passive safety, and more resilient through advanced control schemes and artificial intelligence, but ultimately closed form solutions for every possible contingency will not exist. Arguably this is why it is still a good idea to have highly trained and knowledgeable human operators in the control room and human eyes and ears about the plant. Humans can be resilient when hardware and control systems are not.

Lastly, Lehman describes *E-Type Systems* or embedded programs. Embedded programs are named so because they are part of the overall system. E-Type Systems are described as mechanizing a human or societal activity. Human decision making inherently involves some level of prediction as well as uncertainty, intuition, opinion, and judgement. The validity of E-Type Systems is in the human domain, on whether human assessments of its effectiveness for the intended application.

Here we suggest that the procedures used to control nuclear power plant processes are E-Type Systems and as such should be treated distinctly from the S and P countertypes. First, the human operators, maintenance workers, and engineers are the embedded aspect of energy production process. A plant on its own would be incapable of producing power and as such comprises a sociotechnical system. Even if the plant configuration remained static, the constraints, demands, and requirements are constantly evolving. For example, plants incur high downtime costs and are always striving for increasing their capacity factor. Second, the proliferation of renewables presents load shaping requirements for plants. Third, an aging workforce presents challenges to preserving worker knowledge and skills needed to maintain legacy systems. Fourth, consider events like Fukushima Daiichi, or Ukrainian cyber-events and the influence they have on operations, upgrades, and maintenance.

The distinction between S/P-Type Systems and E-Type Systems is important because they convey distinct requirements for their respective life-cycles. A control block that meets its functional specification can operate for decades with virtually no maintenance. E-Type Systems on the other hand are inherently change prone. Operations and procedures change because of the drivers that from a pure control systems perspective are purely exogenous. Procedures need to be adaptable and computer procedure systems need to support the authoring and continued maintenance of procedures as much as the actual running of procedures. If they do not change, Lehman suggests, their utility diminishes over time because their environment is evolving. To remain useful, they must change and have a tendency to become more complex, and Lehman postulates a law of "Continuing Change" to describe this phenomena.

Unfortunately, continual change is also associated with increased complexity (2nd law). Anecdotally, paper based procedures are becoming more complex to fill administrative gaps and remain technically accurate as systems change. Lehman's 6th law of continuing growth describes how the functional content of an E-type system must continually increase to maintain user satisfaction. As an example, procedures have become embedded with notable user experience, which is a function never originally intended for procedures. While the increased complexity captures relevant process related information it also increases the cognitive difficulty of carrying out procedures.

From this perceptive, computer-based procedures could be vital in managing the increasing complexity associated with E-Type Systems. Lehman's 7th law predicts declining quality if an E-Type system is not rigorously maintained and adapted to changing operational environments.

If procedures are more akin to E-Type systems than P-Type systems, then maintaining the ability of procedures to *evolve,* to adapt and continuously modify procedures is of paramount importance. By the conclusion of this document we formulate a strategy to aid utilities in transitioning from paper to CBP systems. The previous survey of computerized procedures suggests that the technology exists, and it is likely that the hurdles to adoption are not technologically based. In the context of modernization, computerized procedure systems are likely not expensive relative to costs associated with modernizing instrumentation and controls. If not technical or financial, then perhaps regulatory considerations are the barrier to entry. In the next section we briefly review regulatory considerations for CBPs.

5 U.S. NUCLEAR REGULATORY COMMISION GUIDANCE

Early work by the U.S. Nuclear Regulatory Commission (NRC) concluded that CBPs were a desirable

goal but the implementation and adoption needed to justify the use of CBPs over paper procedures (O'Hara et al., 2000).

NUREG/CR-6634 provides a detailed technical basis for CBP systems. The technical basis was developed by deconstructing the hierarchical influence of human behavior on plant performance in order to identify how human errors cause unsafe circumstances. NUREG/CR-6634 expresses some valid concern regarding whether CBPs could lead to operators becoming disoriented amongst tabs, or losing situation awareness due to keyhole attention affects, or out-of-the-loop loss of situation awareness. Automation of control actions can also be detrimental because it increases task complexity and can add confusion to diagnosing the root cause of a disturbance (Andresen, et al. 2003). CBPs can use plant process data to guide operators; however, if these systems are disrupted, the CBP may not function, or even provide incorrect assessments and guidance. Operators may become too trusting of the guidance provided by a CBP and induce complacently to follow CBP directions.

The Electric Power Research Institute (EPRI) has guidance for developing Utility Requirements Documents. According to O'Hara (2000), the guidance is based on EdF's CBP experience. EPRI's high level guidance covers human factors criteria describing the allowable presentation formats for procedures, as well as stipulating operators should have final authority in regard to control actions. It also has technical requirements for CBPs to verify operator decisions, provide logging capabilities, and redundancy in the case of loss of CBPs. The EPRI requirements include a validation of each operating procedure using the plant's simulator and performance model. Plants would also need to make sure that alternative procedures are available in the event of loss of CBPs. Utility requirement documents would need to validate and verify CBPs with plant simulations.

The NRC does not consider paper procedures to be a Human System Interface (HSI); however, computerized procedures would be displayed through an HSI would need to meet the human factors requirements of NUREG-0700 as well as the NUREG/CR–6634. For first adopters, the CBP would be considered an *unproven* HSI technology until there has been at least three years of documented satisfactory service in a light water reactor (O'Hara 2000).

6 CATEGORIES OF COMPUTER BASED PROCEDURES

IEEE Standard 1789–2011 describes three types of CBPs along a continuum of increased automation. The least automated are Type 1 and are sometimes referred to as E-procedures in the literature. These are electronic versions of standard PBPs. They provide the ability to view the procedure in an electronic format and provide navigation links between procedures. The second category is Type 2 procedures. These link to plant data in real time to provide process relevant information embedded in the procedure, perform logical assertions based on the procedure and available data, and provide links to process displays and soft-controls that reside in separate systems. Lastly, Type 3 procedures have embedded soft controls and procedure-based automation that carries out a full procedure or several sub-steps of a procedure.

7 STRATEGY FOR TRANSITIONING PAPER PROCEDURES TO COMPUTERIZED PROCEDURE SYSTEMS

Based on the identified constraints and evolving nature of procedures it may be strategically advantageous to transition to a computer based format that is similar in organization and layout to existing procedures. The goal is to provide a process to transition the existing corpus of PBPs into a computerized support system without substantively changing the organization, or format and layout of the procedures. The strategy is to avoid major refactoring that is costly, time consuming, and also has the potential of losing critical information contained within existing PBPs. Plants have finite human resources to put towards the numerous modernization efforts. Modernization schedules can easily run a decade or more into the future. The industry has a need for innovative solutions that can help change occur faster, and our thinking is centered on what can be done in a time effective manner, while offering a high value proposition, and satisfying or exceeding regulatory constraints. Such a strategy would avoid having to completely dissemble, reorganize, and refactor existing procedures, as well as ease the process of transcribing to computerized representations. Maintaining resemblances to paper countertypes also eases training and verification and validation activities necessary for regulation. Therefore, a solution should maintain a textual presentation in the conventional two column format.

Metaphorically this approach would be described as not shooting for the moon, but rather planning a course towards the moon. Based on our proposition that procedures are E-Type Systems it is vitally important that utilities maintain the ability to quickly and adeptly author and edit procedures without continued support from a vendor.

Strategically translating procedures should be thought of as an editing process instead of a complete refactoring of how procedures are performed and constructed. The editing process would likely be iterative, and would contain the following steps:

1. Multidisciplinary review of the existing procedures to identify and remedy shortcomings in the original procedure to prevent them from getting carried forward to a computerized format
2. Provide Type 2 computerized procedure enhancements like live plant parameters, monitoring continuous actions (Choi and Park, 2012), decision support aids for integrating multiple variables, and real-time trends for predefined sets of parameters.
3. Software engineering routinely uses code quality metrics to assess portions of code that may be ambiguous or difficult to interpret. Once a plant's procedures are represented in a form interpretable by a computerized procedure system it becomes possible to develop automated routines for finding indictors of poor quality procedures based on step complexity (Park, Kim, and Ha, 2003) or human reliability analysis performance shaping factors and unique failure modes relevant to computerized procedures (Boring et al., 2011).
4. Technical review of information in the procedure.
5. Plant simulator validation of the procedure.

None of the procedure authoring systems are intended to ease the translation from existing paper implementations. Here we have identified a gap in existing technology capabilities that we aim to fill. We envision a what-you-see-is-what-you-mean (WYSIWYM) authoring system based on Markdown and Jinja templating. Jinja templating allows for context processors to be added to a backend that would, at rendering, insert of live values or handle plant dependencies logically, branching when they are rendered on the display. Most importantly, the representation in the procedure (template) would have simple syntax expressions.

We are currently developing a prototype computerized procedure system intended to conduct the full-scope simulator research needed to validate the engine and the strategy. The goal would be to transition the research framework to a commercial platform for computerized procedures.

Task level errors for human error prediction in GOMS-HRA

R.L. Boring & T.A. Ulrich
Idaho National Laboratory, Idaho, USA

M. Rasmussen
NTNU Social Research, Trondheim, Norway

ABSTRACT: Goals-Operators-Methods-Selection rules (GOMS) was originally developed as a task analytic tool for modeling behavioral primitives in human users of human-computer interfaces. GOMS was recently adapted for Human Reliability Analysis (HRA), producing the GOMS-HRA method. The GOMS-HRA method provides a taxonomy of task level primitives in human activities that correspond to human error probabilities and task timing. The GOMS-HRA method has been used in computation-based HRA (CoBHRA), due to its calibration to the subtask level of human performance, the optimal decomposition level for dynamic risk modeling. GOMS-HRA has also been linked to procedures, and it is possible to map procedure steps (called procedure level primitives) to task level primitives. This paper introduces another important development to the GOMS-HRA framework—the task level errors, which represent the use of the GOMS-HRA taxonomy for predicting human error types. While many HRA methods map task types or task primitives to error rates, the prediction of error is often a generic error type. In reality, each task level primitive has predilections to certain types of errors. To model human error dynamically requires the determination of the types of errors that can occur.

1 A FRAMEWORK FOR DYNAMIC HUMAN RELIABILITY ANALYSIS

1.1 *Human Unimodel for Nuclear Technology to Enhance Reliability (HUNTER)*

Researchers at Idaho National Laboratory set out to create a simplified implementation of dynamic Human Reliability Analysis (HRA), also known as computation-based HRA (CoBHRA) due to consideration of modeling beyond temporal dynamics. The goal of this effort is to demonstrate proofs of concept of modeling HRA dynamically by adapting existing static HRA approaches to make them dynamic, rather than develop an entirely new dynamic HRA method. Because of the complexity of modeling human behavior and cognition, creating a new dynamic HRA method could quickly approach the complexity of artificial intelligence production systems. Thus, this simplified CoBHRA approach should borrow from current simplified, worksheet-based approaches to HRA, seeking to find ways to automate the analysis tasks. Further, the approach should integrate with other modeling tools like thermal hydraulic codes that are used for nuclear power plant simulations. This new HRA framework came to be called the Human Unimodel for Nuclear Technology to Enhance Reliability (HUNTER; Boring et al., 2016). While the initial implementation of HUNTER is focused on adapting static approaches to HRA, the framework is flexible and can in the future readily incorporate other models including dynamic HRA methods that have been developed in parallel at other institutions.

Central to the first implementation of HUNTER is quantification of the human error probability (HEP). Quantification in many HRA methods occurs in three stages (Swain and Guttman, 1983):

- *Nominal HEP*—the generic or default error rate for particular task types
- *Basic HEP*—the nominal HEP modified by contextual factors that increase or decrease errors
- *Conditional HEP*—the basic HEP modified to account for dependence and recovery

Some HRA methods like the Technique for Human Error Rate Prediction (THERP; Swain and Guttman, 1983) or Human Error Assessment and Reduction Technique (HEART; Williams and Bell, 2017) possess a large number of generic task types with a wide range of nominal HEPs, while simplified methods like the Standardized Plant Analysis Risk-Human (SPAR-H; Gertman et al., 2005) contain only two nominal task types. In most HRA methods, the basic HEP is calculated using performance shaping factors (PSFs), which simply

serve as multipliers on the nominal HEP. Finally, for the conditional HEP, dependence suggests that error begets error, and a sequence of human tasks may have increased overall error rates once an initial human error occurs. In contrast, recovery restores the success path and serves to decrease the HEP.

1.2 *Stages of HUNTER Quantification*

1.2.1 *Nominal human error probability*

To address nominal HEPs, HUNTER presently uses an approach called GOMS-HRA (Boring and Rasmussen, 2016). GOMS stands for Goals-Operators-Method-Selection rules, and serves as a task analytic approach to evaluate human-system interactions (Card et al., 1983). Despite many implementations of GOMS for user interface applications, GOMS has not historically been used for purposes of HRA. GOMS-HRA aligns its "operators" (i.e., operations or tasks) to an extended version of the Systematic Human Error Reduction and Prediction Approach (SHERPA) taxonomy (Stanton et al., 2013; Boring and Rasmussen, 2016), as depicted in Table 1. Here the GOMS operators are called *Task Level Primitives* (TLPs), and encompass the spectrum of operations in and beyond the control room. The TLPs are calibrated to scenarios in THERP to produce nominal HEPs as shown in Table 2.

Note that the GOMS-HRA TLPs have recently been mapped to *Procedure Level Primitives* (PLPs; Boring et al., 2017; Ulrich et al., 2017). PLPs represent simple procedure steps derived from a standardized list of operator commands. A common procedure step like CHECK VALVE readily maps to C_C, a single TLP. Other procedure steps may require mapping to multiple TLPs. The PLPs provide a lookup table of common procedure steps to their respective TLPs. This lookup table allows easy analysis reuse of commonly occurring operator actions. Moreover, it allows quick extraction of operator actions into an HRA model format, provided there is good procedure following by the crews.

Table 1. GOMS operators used to define task level primitives.

Primitive	Description
A_C	Performing required physical actions on the control boards
A_F	Performing required physical actions in the field
C_C	Looking for required information on the control boards
C_F	Looking for required information in the field
R_C	Obtaining required information on the control boards
R_F	Obtaining required information in the field
I_P	Producing verbal or written instructions
I_R	Receiving verbal or written instructions
S_S	Selecting or setting a value on the control boards
S_F	Selecting or setting a value in the field
D_P	Making a decision based on procedures
D_W	Making a decision without available procedures
W	Waiting

Table 2. HEPs associated with each task level primitive.

Operator	Nominal HEP	THERP Source*
A_C	0.001	20–12 (3)
A_F	0.008	20–13 (4)
C_C	0.001	20–9 (3)
C_F	0.01	20–14 (4)
R_C	0.001	20–9 (3)
R_F	0.01	20–14 (4)
I_P	0.003	20–5 (1)
I_R	0.001	20–8 (1)
S_C	0.001	20–12 (9)
S_F	0.008	20–13 (4)
D_P	0.001	20–3 (4)
D_W	0.01	20–1 (4)
W	n/a	n/a

*Corresponds to THERP Table values from Chapter 20.

1.2.2 *Basic human error probability*

SPAR-H (Gertman et al., 2005) is a simplified HRA method that features eight PSFs that serve as multipliers on the nominal HEP. The eight PSFs have different influence levels and corresponding multipliers that are selected by the analyst according to whether the PSF has a positive effect (i.e., decreasing the HEP) or negative effect (i.e., increasing the HEP). In the HUNTER implementation, SPAR-H PSFs are auto-calculated (Rasmussen and Boring, 2016; Boring et al., 2017) where possible from available plant parameters. This process works for so-called *external PSFs*, which are situational factors that influence the operators' performance. Internal PSFs—factors intrinsic to the operators—must still be assigned by the analyst or coded to change in particular contexts (e.g., the PSF for *Fitness for Duty*, which represents fatigue, may degrade after a long-duration event but not usually in response to particular plant parameters). The auto-calculated SPAR-H PSFs modify the basic HEPs from GOMS-HRA in the current implementation of HUNTER.

1.2.3 *Conditional human error probability*

HUNTER does not yet include an explicit model for conditional HEPs beyond the dependence

model that THERP and SPAR-H share in common. It is important to note that dynamic HRA modeling occurs at the subtask level. The human failure events (HFEs) used in static HRA represent hardware or process failures that may be influenced by human actions or inactions. These HFEs are often defined at the hardware component or system level, which does not meaningfully specify the spectrum of human activities associated with that hardware. Thus, an HFE may encompass a single step of a procedure or may require a whole procedure. The HFE level of modeling may require considerable task aggregation and expertise by analysts. In creating a virtual operator model in HUNTER, the focus necessarily falls not on the hardware but on the tasks the virtual operator must undertake, which will potentially have an effect on hardware process performance. In HUNTER and other dynamic HRA implementations, human activities are modeled at the subtask level, corresponding to activities surrounding each procedure step or equivalent for those activities that don't feature formal written procedures. This level of analysis is common in task analysis approaches used in human factors engineering, because it represents the most fundamental conscious level of action or cognition of the human (Rasmussen and Laumann, 2017).

Dependence in HRA is the notion that error begets error—that once an error has been committed, it may prime subsequent errors unless there is a clear break in activities. Contemporary thinking frames dependence in terms of mindset (Whaley et al., 2007), which is to say once a human error occurs (e.g., misdiagnosis of a plant upset), that error will propagate until something breaks the chain of operations (e.g., realization of the misdiagnosis). Dependence occurs because the HEP of downstream human activities is related to the first human error and will generally be larger than the calculated basic HEP. Most human error dependence modeling occurs at the task level—between HFEs—which may not readily translate into how dependence should be treated for subtasks—within HFEs. Work is ongoing in HUNTER (e.g., Boring, 2015) to develop better subtask dependence modeling.

2 A COGNITIVE MODEL OF TASK LEVEL PRIMITIVES

The GOMS-HRA TLPs represent a continuum of human cognition. Classical cognitive psychology, heavily influenced by information processing theory associated with computer technology, stressed three phases of cognition (Proctor and Vu, 2006):

Input → *process* → *output*,

which corresponds roughly to the following human activities:

Sensation/perception → *cognition* → *behavior*.

This framework to understand human cognitive functioning is echoed in several contemporary models. For example, Endsley's (2005) situation awareness (SA) model delineates the input and cognition phase into three separate phases: perception (Level 1 SA), comprehension (Level 2 SA), and Projection (Level 3) SA: which culminate in a decision and corresponding action:

perception → *comprehension* → *projection* → *decision* → *action*.

It should be noted that the modality of information and action can incorporate communication, whereby communication is a perceptual input or expressed action.

Cacciabue and Hollnagel (1995) make a distinction between *microcognition* and *macrocognition*. This distinction originally referred to the degree of context involved in decisions. Simplified cognition—microcognition—in carefully controlled laboratory experiments is removed of the context required in real-world complex cognition—macrocognition. While this distinction remains useful for framing the validity of human factors research, the concept of macrocognition has been generalized to represent high-level cognition like decision making in a real-world context. The distinction is helpful in understanding the focus of the GOMS-HRA task-level and procedure-level primitives. TLPs are microcognitive in that they represent the most basic level of human activities. PLPs are aggregated at a higher level to represent a series of cognitive functions and actions corresponding to a procedure step. It might be argued that the HFEs used as the unit of analysis in most HRAs represent a further macrocognitive grouping of multiple steps.

Recent work (Whaley et al., 2016) funded by the U.S. Nuclear Regulatory Commission (NRC) has identified several macrocognitive functions as the basis of the Integrated Decision-tree Human Event Analysis System (IDHEAS) HRA method (Xing et al., 2016). These macrocognitive functions are derived from research by Patterson and Hoffman (2012) and build on earlier functions identified by Klein et al. (2003). The IDHEAS macrocognitive functions include:

detection and noticing → *understanding and sensemaking* → *decision making* → *action* → *teamwork*,

whereby *teamwork* may be seen as an overarching function rather than as a discrete tail-end activity.

Table 3. Failures according to macrocognitive functions in Whaley et al. (2016).

Detecting/ Noticing	Understanding/ Sensemaking	Decision Making	Action	Teamwork
• Cues/information not attended to	• Incorrect data	• Incorrect goals or priorities	• Failure to execute desired action	• Failure of team communication
• Cues/information not perceived	• Incorrect frame	• Incorrect pattern matching	• Execute desired action incorrectly	• Failure in leadership/ supervision
• Cues/information misperceived	• Incorrect integration of data, frames, or data with a frame	• Incorrect mental simulation or evaluation of options		

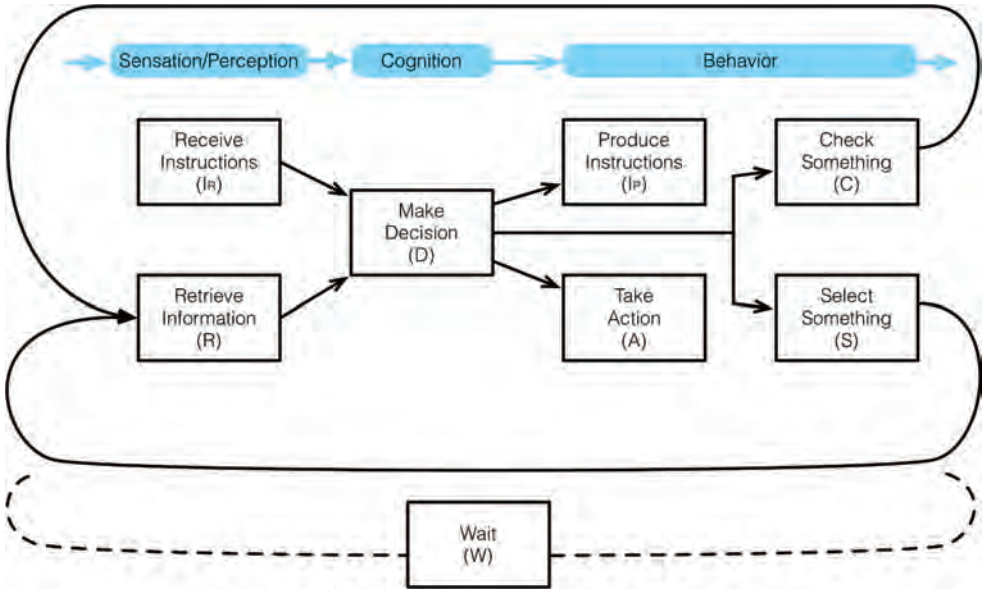

Figure 1. Cognitive model of GOMS-HRA task level primitives.

The IDHEAS macrocognitive functions are linked to proximate causes, which are error manifestations. The IDHEAS proximate causes are listed in Table 3.

Each of these proximate causes may be triggered for different reasons or cognitive mechanisms. For example, under the *detecting/noticing* macrocognitive function, if cues or information are not perceived, this could be caused by low salience of the cues or information, inability to maintain vigilance, inattention, mismatches between expected and actual cues (including biases toward particular information), or overloads of working memory. In turn, these cognitive mechanisms are influenced by PSFs (called performance influencing factors in IDHEAS).

The TLPs in GOMS-HRA as depicted in Table 1 are not ordered in a particular cognitive flow. Figure 1 represents a cognitive model of the TLPs. The distinction between control room and field operations (as depicted with subscripted *C* and *F* in Table 1) is not included in Figure 1, because the location of operations affects the context and corresponding error rates but not the function of the underlying cognition. The basic cognitive framework of GOMS-HRA mirrors a simple information processing model, with core functions related to sensation and perception (represented by *R*), cognitive (represented by *D*), and Action (represented by *A*) activities. As a pragmatic model based on observable operational functions, GOMS-HRA precludes a detailed delineation between *detecting/noticing* and *understanding/sensemaking*. In fact, the original SHERPA taxonomy (Stanton et al., 2013), upon which the TLPs are based, does not include the relatively unobservable decision making (*D*) operator.

Table 4. Crosswalk of IDHEAS macrocognitive functions with GOMS-HRA task level primitives.

IDHEAS macrocognitive function	GOMS-HRA A	GOMS-HRA C	GOMS-HRA R	GOMS-HRA I	GOMS-HRA S	GOMS-HRA D	GOMS-HRA W
Detecting/ Noticing		✓	✓	✓ (I_R)			
Understanding/ Sensemaking		✓	✓	✓ (I_R)	✓		
Decision-Making						✓	
Action	✓	✓		✓ (I_P)	✓		
Teamwork				✓ (I_P)			

GOMS-HRA includes several common operational functions that impact sensation and perception on the input side and actions on the output side. Communication in the form of verbal or written instructions (*I*) is both a cognitive input (I_R) and output (I_P). Checking information (*C*) is an active instance of looking for information that encompasses both an overt action (*A*) and a retrieval (*R*). Selecting or setting a value (*S*) and producing a verbal or written instruction (I_P) are both special instances of an action (*A*). Waiting (*W*) in GOMS-HRA is an overriding category that is used to indicate delays in tasking or periods of inactivity due to monitoring activities. Waiting does not inherently consist of a cognitive function, but it has implications across all GOMS-HRA operators.

The TLPs can be mapped to the IDHEAS macrocognitive functions as depicted in Table 4. Several of the TLPs span multiple macrocognitive functions but demonstrate a good match between concepts.

Table 5. Definition of key terms in GOMS-HRA.

Term	Abbreviation	Definition
Task Level Primitive	TLP	A basic human operation occurring at the subtask level. Multiple operations are typically required to achieve specific actions and goals.
Procedure Level Primitive	PLP	A human activity occurring at the procedure step level. Often, multiple task level primitives will be required to achieve a procedure level primitive activity.
Task Level Error	TLE	A nominal human error associated with a task level primitive. Each task level primitive is associated with multiple possible task level errors.

3 TASK LEVEL ERRORS

While it is helpful to automate many of the analytic processes in dynamic HRA as described earlier in this paper and in Rasmussen et al. (2017), such a model falls short on a key area: anticipating the types of errors that will likely occur for each TLP. The HUNTER framework outlined demonstrates a way to extract TLPs from procedure steps and a method to modify their influence using auto-calculated PSFs. Each TLP has particular error proclivities, which might be described as deviation paths from the normal path (U.S. Nuclear Regulatory Commission, 2000). Based on the proximate causes identified in the IDHEAS framework (see Table 3), here we map particular errors to the TLPs. These are called *task level errors* (TLEs). To avoid possible terminological confusion due to unique terms introduced through GOMS-HRA, key terms are summarized in Table 5.

A mapping of TLPs to TLEs is found in Table 6. As noted, the TLEs are derived from the proximate causes in Whaley et al. (2016). However, the mapping is not one-to-one. As depicted in Figure 1, some TLPs span multiple macrocognitive functions. Checking (*C*), for example, includes both an active operation of looking for information and the subsequent information input when the information is found. GOMS-HRA does not explicitly model teamwork, but much of the function of teamwork is covered in the Information Production (I_P) and Information Received (I_R) operations, which also cover both written and spoken communications.

The TLEs do not distinguish between errors of omission and errors of commission. An error of commission occurs when a person performs an unintended action. For example, an operator

Table 6. Task level errors in GOMS-HRA.

TLP	Task level errors
A	TLE-A1: Failure to execute desired action
	TLE-A2: Execute desired action incorrectly
C	TLE-C1: Wrong information checked
	TLE-C2: Information missed
	TLE-C3: Information misinterpreted
	TLE-C4: Failure to check information
R	TLE-R1: Information not attended to
	TLE-R2: Information not perceived
	TLE-R3: Information misinterpreted
I_P	TLE-IP1: Failure to produce desired communication
	TLE-IP2: Failure to produce correct communication
I_R	TLE-IR1: Communication not attended to
	TLE-IR2: Communication not perceived
	TLE-IR3: Communication misinterpreted
S	TLE-S1: Failure to select
	TLE-S2: Selection make incorrectly
D	TLE-D1: Incorrect goals or priorities
	TLE-D2: Incorrect use of information
	TLE-D3: Incorrect mental model
W	TLE-W1: Incorrect inaction
	TLE-W2: Waiting too long
	TLE-W3: Waiting too short

might accidentally activate a pump. In a plant, such actions can be particularly troublesome, because they may shift the plant beyond its standard operating range and may confound the normal procedural sequence by triggering anomalies beyond hardware failures. As noted in Whaley et al. (2016), errors of commission manifest at the action phase. The thought by an operator to activate a pump (perhaps due to an incorrect situation assessment) is caused by faulty decision making, but it will have no effect until that decision is put into action. As such, the TLEs that are mapped to Action—namely *A*, I_P, *C*, and *S*—include provision for errors of commission. One critique against the macrocognitive functions like those found in IDHEAS is that they focus primarily on cognition to the exclusion of behavioral or activity functions. The GOMS-HRA TLPs attempt to redress some of this shortcoming, which is also reflected in an expanded series of behavior operations as depicted in Figure 1.

4 CURRENT AND FUTURE APPLICATION OF TASK LEVEL ERRORS

The task level errors in GOMS-HRA provide two important additions to HRA: (1) The human error probability will vary depending on the type of error. Although the same overt failure may manifest from different causes, it is not the same error and should not be treated as a single probability value. This paper introduces a crosswalk of task level primitives to task level errors that can provide a more precise measure of human error and accompanying probabilities. (2) The task level errors bound the types of decision errors that can occur. This part of GOMS-HRA benefits decision trees, where branch points in operator decisions can have markedly different outcomes on event progression. Task level errors related to decisions can guide the likelihood of particular decision paths. Work still remains to specify such decision making and branching in HUNTER.

TLEs present an opportunity to model different errors that may occur for each subtask that is modeled in GOMS-HRA. Each TLE is an opportunity for error. As such, a human failure event is not the occurrence of a single error probability but rather the composite of multiple error types across multiple subtasks. The aggregation of these subtasks and co-likely error types presents a challenge for HRA aggregation. One way to link subtasks is through dependence. Dynamic dependence is far more complicated than the simple dependence used in static HRA methods, and the approach is not yet mature (Boring, 2015). Likewise, calculating dynamic HEPs can be orders of magnitude more complex than their static HRA counterparts. To date, HUNTER has not resolved the subtask-by-error type aggregation issue. There remains work to be done to determine suitable equations and then to calibrate them to HEPs for HFEs that have been generated by human analysts. In bringing subtask aggregation into HUNTER, there is the promise for greater consistency in the level of human task decomposition in HRA. Previous research (Poucet, 1989) has shown that not controlling for the level of decomposition results in spurious estimates in HRA. GOMS-HRA, as an implementation of HUNTER, aims to map the layers of decomposition to the appropriate HEP, enabling true dynamic autocalculation of human error.

A computational cognitive modeling approach to human performance assessment in nuclear power plants

Y. Zhao & C. Smidts
Nuclear Engineering Program, Department of Mechanical and Aerospace Engineering, The Ohio State University, Columbus, USA

ABSTRACT: A computational modeling approach to human performance assessment in nuclear power plants is proposed. The approach takes into consideration three main processes involved in a human's cognitive process: information perception, reasoning and response. Both the saliency and activation levels of a sensor signal in the control room are used to determine whether the signal can be actually perceived by the operator. The corresponding nodes in the operator's knowledge base are activated by the perceived signals and the activation is propagated in the knowledge base to reach diagnoses and develop responses. Uncertainties in these processes are dealt with using sampling methods. The interplay between an operator's stress and fatigue levels and the cognitive process are considered. A case study derived from the Three Mile Island accident is conducted to demonstrate the proposed approach.

1 INTRODUCTION

In complex technological systems where operator intervention is needed, such as nuclear power plants, chemical plants, and air traffic control centers, operator performance plays a central role in maintaining the normal operation of these systems and in mitigating consequences in case of incidents. However, high operator performance is challenged by a number of factors, for instance the increasing complexity of modern technological systems and the stricter requirement for the operator's knowledge in the systems. As a result, human performance assessment becomes necessary and has drawn increasing attention since the 1970s. The assessment not only serves as an integral part of the overall risk assessment of the systems (e.g. probabilistic risk assessment for nuclear power plants), but also provides insights into the ways of improving human performance (e.g. optimization of the human-machine interface).

To assess human performance, conventional methods, for instance the Technique for Human Error Rate Prediction (THERP) (Swain and Guttmann, 1983) and the Standardized Plant Analysis Risk-Human Reliability Analysis (SPAR-H) (Gertman et al., 2005), use performance shaping factors (PSFs), for instance stress and experience, to represent the context that influences human performance and to adjust nominal human error probabilities. The number of PSFs varies between different methods, ranging from just one single factor (e.g. time available) up to 50 or more in some current methods (Boring, 2010). In these methods, expert judgment is extensively used to assign the levels of PSFs and to determine the relationships between PSFs and human error probabilities. These lead to variations in the results of different methods and even of the same method but conducted by different individuals. Besides, these methods deal with human performance assessment at the macroscopic level, which means that they cannot provide the users detailed information about how an operator commits an error. To address this limitation, novel methods based on a representation of human cognition were introduced (Chang and Mosleh, 2007a; Li, 2013; Smidts et al., 1997; Zhao and Smidts, 2017). These methods take explicitly human cognitive processes into consideration, for instance information perception, reasoning and decision making. The most prominent advantage of this type of methods is that they are able to provide more detailed interpretation of a human error.

In this paper, we further extend the capability of existing methods based on human cognition for human reliability assessment by proposing a computational cognitive modeling approach to human performance assessment in the context of nuclear power plants. In this approach, three main processes of human cognition, information perception, reasoning and response (Endsley, 1995), are modeled explicitly. The main contributions of our research include: 1) development of an approach to modeling information perception based on the saliency of and the attention paid by the operator

to a piece of information; 2) application of activation propagation in modeling the reasoning and response processes of an operator; 3) development of an approach to modeling the interplay between two significant PSFs, stress and fatigue, and the cognitive process; 4) development of an approach to modeling the uncertainties in the cognitive process based on sampling techniques; 5) integration of the pieces of the cognitive process into a framework. The proposed method exhibits several advantages compared with conventional methods of human performance assessment. In addition to the capability of providing microscopic interpretations of human errors, it is able to model the effect of task dependence on human performance, and to model the uncertainties in the human cognitive process based on simulation. The proposed approach is illustrated by the operator error in identifying the failure in the Pilot-Operated Relief Valve (PORV) in the Three Mile Island accident.

The paper is organized as follows. Section 2 provides a detailed introduction of the approach. In Section 3, the case study is introduced and the results are discussed. The paper is concluded in Section 4.

2 METHODOLOGY

2.1 *Framework*

The framework of the approach is shown in Figure 1. It consists of three main modules: information perception, reasoning and response, and PSFs.

In a nuclear power plant, an operator is faced with a large number of sensor signals in the control room and uses them to infer the dynamics and state of the plant. The first module, that is the module of information perception, is used to determine which signals can be perceived by the operator. The process of information perception is influenced not only by the signals themselves, but also by certain PSFs and the operator's mental state, as shown by the dashed lines in Figure 1.

The signals that are actually perceived then enter the operator's knowledge base and initiate the reasoning process. The knowledge base is represented as a network of nodes representing for instance specific systems or phenomena. The reasoning process is modeled by activating the nodes in the knowledge base corresponding to the perceived signals, as illustrated by the light grey node in Figure 1, and propagating the activation through the knowledge base. At the end of this process, the mental state of the operator is updated, for instance a system failure may be identified as illustrated by the medium grey node in Figure 1.

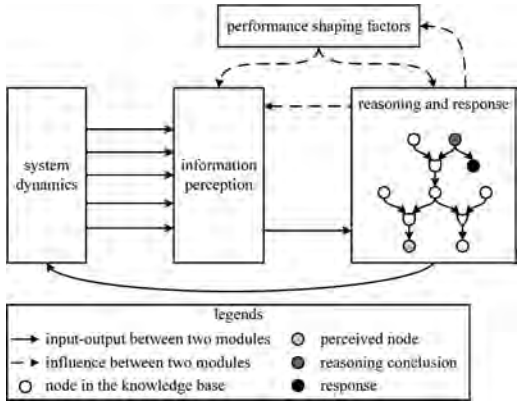

Figure 1. The framework of the approach.

An updated evaluation of the plant state will direct the operator to take corresponding actions, as illustrated by the black node in Figure 1. The developed actions are then executed, which in turn influences the plant's dynamics and state. System dynamics, information perception, reasoning, and response form a cycle, which represents the interaction between the nuclear power plant and the cognitive process of an operator.

It needs to be noted that there are uncertainties in the information perception, reasoning, and response processes as to whether a sensor signal can be perceived and whether a node in the knowledge base can be retrieved. These uncertainties are modeled by simulating the processes with sampling methods.

As shown in Figure 1, certain PSFs (i.e. stress and fatigue in our model) influence the cognitive process and the PSFs themselves are influenced by the reasoning and response processes. The interplay between them is modeled in the proposed approach.

The elements in the framework are introduced in further detail in the following sections.

2.2 *Information perception*

In a nuclear power plant, the data from the sensors plays a central role in the operator's situation awareness. An operator is usually faced with a large amount of information from the sensors (e.g. pressure, temperature, flow, water level). However, there is a limit in a normal human's capacity of perceiving the information around him/her. So only a sub-set of the available information can be perceived by the operator (Endsley et al., 2003). There are also uncertainties in information perception as to which signal or signals can be perceived by the operator (Chang and Mosleh, 2007b). These

two factors lead to the fact that some information important for situation awareness may be ignored by the operator, which may then result in human errors. As a result, information perception is an important element in the cognitive model.

The process of information perception is influenced by several factors. Research in the field of cognitive science shows that the perception of a piece of information depends on two factors: the saliency of the signal and the attention paid by the human to the signal (Corbetta and Shulman, 2002; Rybak et al., 1998; Theeuwes, 2010; Wolfe, 1994). The first factor corresponds to the stimulus-driven process of information perception, and the second factor corresponds to the goal-directed process. This finding is used as the basis of modeling the process of information perception in our research.

To be specific, the saliency of a signal is represented as the average of the contributions from three sources: the signal's variation, whether the signal is an alarm, and the signal's importance. The variation measures the change of a signal with time. The more significant the change, the more likely it is that the signal successfully draws the operator's attention. Whether a signal is an alarm or not indicates whether the signal has exceeded a specified threshold. An alarm is more likely to attract the operator's attention compared with a regular signal. The importance here refers to the accumulated emphasis on a signal through training or practice. For instance, the primary system pressure in a Pressurized Water Reactor (PWR) is usually emphasized more often compared to the position of a non-safety related valve during the training of an operator. As a result, the importance of the first signal is usually higher in the operator's mind and more easily draws the attention of an operator. The attention paid by an operator to a signal is represented by the activation level of the node that corresponds to the signal in the operator's knowledge base. As will be introduced in Section 2.3, the activation levels of the nodes in the operator's knowledge base are updated as the reasoning and response processes are ongoing. A node with a high activation level means that the node relates more to the operator's current cognitive activity and the operator pays more attention to the node. Finally, the overall activation level of a signal can be calculated with Equation 1 below:

$$A = \alpha S + \beta G = \alpha\left(\frac{1}{3}(V + Al + I)\right) + \beta G \tag{1}$$

where A is the overall activation level, S is the saliency, G is the goal related contribution, V is the variation, Al represents whether the signal is an alarm or not, I is the importance, α is the weight for the stimulus-driven contribution, and β is the weight for the goal-directed contribution.

With the overall activation level of a signal, the probability that the signal is perceived is calculated with Equation 2 below (Anderson et al., 2004):

$$p = \frac{1}{1 + e^{-(A-\tau)/s}} \tag{2}$$

where τ is the activation level threshold, and s is the noise in information perception. Both parameters are greater than 0.

From Equation 2, it is easy to see that the higher A is, the higher the probability p is. It is also easy to see that when A is greater than τ, p is greater than 0.5, and in this case the smaller s is, the higher p is, which means that the operator's attention is more focused. In contrast, when A is smaller than τ, p is smaller than 0.5, and in this case the higher s is, the higher p is, which means that the operator's attention is more dispersed. Based on the probability, sampling methods can be used to determine whether the signal can be actually perceived.

2.3 *An operator's knowledge base*

The reasoning and response processes are implemented in the operator's knowledge base. Before introducing these processes, a brief description of the representation of the knowledge base is provided in this section.

In our method, an operator's knowledge base is represented as a network (Zhao et al., 2017; Zhao and Smidts, 2017). In the network, the nodes are used to represent their counterparts in the physical world. They are classified into four categories: system, process, action, and state. System nodes represent systems or components in a nuclear power plant, for instance the reactor coolant piping and the relief valve in the pressurizer in a PWR. Process nodes represent the physical variables or phenomena in a nuclear power plant, for instance the pressure level in the primary system and hydrogen ignition in the containment. Action nodes represent the possible operator actions during the progression of an incident. State nodes here are used to represent the possible states of system and process nodes, for instance "open" and "closed" states for a relief valve and "high" and "normal" states for primary system pressure level.

In the network, the relationships between the nodes are modeled with three types of links: affiliation, AND gate, and OR gate. Affiliation links are used to represent the relationships between state nodes and the corresponding system or process nodes. There are no directions on affiliation links. AND and OR gates are used to represent the

cause-effect relationships between state nodes, and between state nodes and action nodes. The second class of cause-effect relationships is meant to model the fact that operator actions are guided by specific states of systems or process variables and the actions influence the states in turn. For instance, when the operator realizes that the reactor coolant piping is in the "break" state, he/she will take corresponding actions such as "shut down reactor".

In addition to the nodes and links in the network, three other elements are tied to some nodes. Specifically, beliefs, which are greater than 0, are tied to state nodes to represent the operator's belief in each state. Activation levels, which are from 0 to an upper limit A_{upp} are tied to all the nodes to represent the operator's attention on the nodes. Observability is tied to state nodes to indicate whether a state is observable or not to the operator. Observability has two values: 1 if the node is observable, and 0 otherwise.

An example knowledge base is shown in Figure 2.

2.4 *Reasoning and response*

Information perception plays an important role in the operator's situation awareness and response development. However, perception of the right information does not guarantee a successful diagnosis of the situation and an appropriate response.

Errors may be introduced in the reasoning and response processes. The operator's thought may be stuck at one point in either process. This means that the operator cannot identify the failure of a system, or cannot develop the appropriate response even if the operator has identified the failure.

To cover these possible errors, a method of modeling the reasoning and response processes based on activation propagation (Anderson, 1983; Anderson et al., 2004) and updating of belief is proposed. Based on the updated beliefs in the nodes, diagnoses will be reached and responses will be developed. The modeling method is illustrated in Figure 3 with the same example in Figure 2.

In the first step (see s1 in Figure 3), the node in the operator's knowledge base corresponding to the perceived signal is activated, and the activation level of this node is raised to an upper limit A_{upp}. In this example, low pressure in the primary system is observed, and the activated node is marked in light grey in Figure 3. It needs to be noted that only if the perceived information is inconsistent with the operator's belief, further inference is then made. This is modeled in a way as follows. First, for a perceived node, the ratio of the belief in the node to the summation of the beliefs in all the state nodes of the corresponding process node (i.e. "primary system pressure" in this example) is calculated. This ratio is then compared with a threshold ω (e.g. 0.8) to determine whether the perceived information is consistent with the operator's belief or not. If the ratio is greater than ω, the reasoning process is not implemented because the perceived information is normal, at least in the operator's mind. Otherwise, further inference is made, and the belief in the perceived node is raised by a predefined value ΔB.

In the second step (see s2 in Figure 3), the activation of the perceived node is propagated from bottom (i.e. the perceived node) up to the causal state nodes to infer the possible system failures that gave rise to the erroneous situation. In the example in Figure 3, the activation propagates from the "low" state of "primary system pressure" to two causal state nodes, "standby" of "injection system" and "break" of "reactor coolant system" through the AND gate. In this case, activation propagation and belief updating are carried out based on the following procedure. First, Equation 2 is used to calculate the probability of a causal node being retrieved, and sampling methods are applied to determine whether

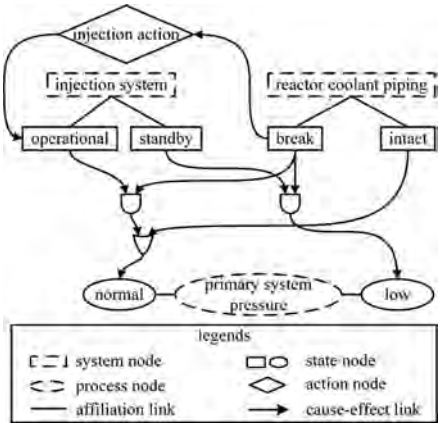

Figure 2. An example knowledge base.

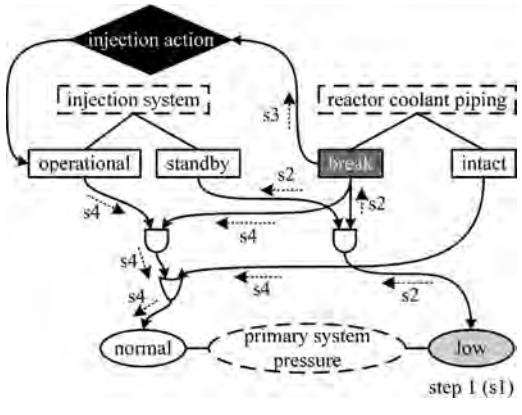

Figure 3. Illustration of the modeling of the reasoning and response processes.

the causal node is actually retrieved. A in Equation 2 now is the activation level of a causal node, for instance "standby" or "break" in this example. Then, for each retrieved causal node, its activation level is raised to the upper limit A_{upp} and its belief level is raised by ΔB. If no node is retrieved, the reasoning process stops at this point, which means that the operator's thinking process is stuck at the perceived node. For the cases of OR gate and multiple gates between the perceived node and its causal nodes, similar procedures are followed. Usually, there are several layers of nodes between the perceived node and system failure nodes rather than direct links as in the example in Figure 3. In this case, activation propagation and belief updating can be carried out step by step from bottom up following the same procedure. The result of this step is also the result of the reasoning process. It outputs the diagnosis of possible system failures (e.g. "break" in medium grey in Figure 3).

In the third step (see s3 in Figure 3), if the ratio of the belief in the failure state of a system is higher than a threshold Th_A, the operator will take corresponding actions, for instance "injection action" in the example in Figure 3. This step is also subject to errors of omission. So Equation 2 and sampling methods are used again to determine whether the operator will develop the response. In this calculation, A in Equation 2 is the activation level of an action node, for instance "injection action" in this example. If the action node is retrieved, its activation level is raised to the upper limit A_{upp}. An action will affect the state of the corresponding system (e.g. "operational" of "injection system"). The activation level of the affected state is then raised to A_{upp} and the belief in this node is raised by ΔB.

Situation awareness and response development have been modeled in the first three steps. In the last step (see s4 in Figure 3), activation propagation is implemented from top (i.e. identified system failures and executed actions) down to process nodes. This represents the fact that the operator will pay more attention to the system response related to the executed actions and the identified system failures, and those signals that represent the system response are more likely to be perceived in the next time step. Specifically, the process starts from the activated state nodes (i.e. "break" and "operational" in this example), and ends at the last state node (e.g. "normal" in this example). It is implemented following slightly different procedures as in the bottom-up process. For the example in Figure 3, as both "operational" and "break" have been activated, their activation is propagated to the OR gate through the AND gate. In addition to propagating the activation to effect node (i.e. "normal"), activation propagation to the other causal nodes of the effect node is also implemented, because all these nodes will draw the operator's attention. Equation 2 and sampling methods are used to determine whether a node can be retrieved or not. For the retrieved nodes, their activation levels are raised to A_{upp}. The change in the process variables of the nuclear power plant is usually delayed for some time after operator actions are taken, so the operator's belief in the states of these process variables are not updated. As a result, belief updating is not implemented in the top-down process.

In addition to activation increase resulting from the propagation from other nodes, the activation levels of the nodes in the knowledge base are also subject to decay (Endsley et al., 2003), which is calculated with Equation 3:

$$A_i(t+\Delta t) = A_i(t+\Delta t)e^{-\lambda \Delta t} \tag{3}$$

where Δt is the time duration between two discrete time steps, and λ is the decay constant.

2.5 *Integration of stress and fatigue into the model*

All the processes of information perception, reasoning and response are influenced by certain PSFs. On the other hand, the PSFs are also influenced by the operator's mental state, which is updated by the three processes. In our research, the interplay between two significant PSFs (i.e. stress and fatigue) and the three processes are modeled.

With respect to the effects of stress and fatigue on human performance, the major effects of the stress level can be summarized as: 1) people under high stress tend to focus on what they are focused on and ignore the other information (Endsley, 1995); 2) people under high stress tend to make premature decisions (Endsley, 1995); and 3) high stress influences human performance through decrements in working memory retrieval (Weerda et al., 2010). These effects are modeled by adjusting the parameters in the model accordingly following Equations 4 through 7 below:

$$\frac{\alpha}{\beta} = \frac{\alpha^*}{\beta^*} \cdot \ stress \tag{4}$$

$$s = s^* \cdot \frac{1}{stress} \tag{5}$$

$$Th_A = Th_A^* \times \frac{1}{stress} \tag{6}$$

$$\lambda = \lambda^* \cdot \ stress \tag{7}$$

where α and β are the weights in Equation 1, s is the noise parameter in Equation 2, Th_A is the threshold for action development, λ is the decay constant in Equation 3, and *stress* is the stress level. The parameters with a superscript of star denote the parameters

before they are adjusted by stress. Equations 4 and 5, 6, and 7 correspond to the three effects respectively.

The major effects of the fatigue level can be summarized as: 1) people with high fatigue are easily distracted by irrelevant subjects (Boksem et al., 2005); and 2) people with high fatigue tend to commit errors more easily because of the decrement of the activation level (Li, 2013). These effects are modeled by adjusting the parameters following Equations 8 through 10 below:

$$\frac{\alpha}{\beta} = \frac{\alpha^*}{\beta^*} \cdot \frac{1}{fatigue} \tag{8}$$

$$s = s^* \cdot fatigue \tag{9}$$

$$\lambda = \lambda^* \cdot fatigue \tag{10}$$

where α, β, s, and λ are the same parameters as in Equations 4, 5, and 7, and *fatigue* is the fatigue level of the operator. Equations 8 and 9, and 10 correspond to the two effects respectively.

As to the effects of the cognitive process on PSFs, the stress level is updated every time step with Equation 11:

$$stress = \frac{1}{N_s} \sum_{i}^{N_s} R_i \tag{11}$$

where N_s is the number of system and process nodes related to negative consequences, for instance "reactor coolant piping" in Figure 3, and R_i is the ratio of the belief in the state node corresponding to negative consequences, for instance "break" in Figure 3, to the summation of the beliefs in all the state nodes of system or process node *i*.

The fatigue level is updated every time step with Equation 12:

$$fatigue = \alpha_1 \left(\frac{1}{N_f N} \sum_{j=1}^{N_f} \sum_{i=1}^{N} A_i\left(t - j\Delta t\right) \right) + \alpha_2 \min\left\{1, \frac{T}{T^*}\right\} \tag{12}$$

where N_f is the number of past time steps from the current time point, N is the number of nodes in the knowledge base, Δt is the time duration between two time steps, T is the time the operator has spent on the accident management, T^* is the threshold for the time period that leads to the exhaustion of an operator, and α_1 and α_2 are weights. This calculation represents the fact that the fatigue level of an operator can be contributed by two sources, one is the attention the operator has paid on the tasks, and another one is the time duration the operator has been involved in the tasks.

3 CASE STUDY

A simple case study is conducted with the proposed computational modeling approach. Results are obtained and discussed.

3.1 *Case introduction*

The case studied is derived from the Three Mile Island accident. To be specific, it refers to the operators' failing to identify the failure in the Pilot-Operated Relief Valve (PORV) at the top of the pressurizer which caused the valve to stick open during the accident and aggregated the situation (Rogovin, 1979). During the accident progression, there were several instrument readings relevant to this failure available to the operator in the control room. Some were misleading but the others provided useful evidence of this failure. Unfortunately, the operator paid too much attention to the misleading readings and ignored the useful readings for over 2 hours. The misleading instrument readings include high water level in the pressurizer which in fact was caused by steam voids and gas in the reactor coolant system, and closed indicator of the PORV which was only circumstantial evidence of the actual state of the PORV. Useful instrument readings include low pressure of the reactor coolant system because of the release of coolant from the stuck-open PORV, and high temperature downstream of the PORV which was also caused by the release of high-temperature coolant from the PORV.

To provide a clear illustration of the essence of the proposed approach, the case study is simplified in the following ways. Firstly, the task in the case study is defined as to identify the failure in the PORV mechanism. This means we are just focused on the information perception and reasoning processes. The actions following this diagnosis are not considered. Secondly, only one time step is considered, and the dynamical environment around the operator which needs to be represented by multiple time steps is not considered. This means that the information perception and reasoning processes are implemented one time. Thirdly, the operator's knowledge base about this situation is simplified as in Figure 4, which only consists of the aforementioned relevant instrument readings and the PORV. Six nodes without any notation are added in Figure 4 to represent the distracting effects of irrelevant readings. It is assumed that perception of these nodes has no contribution to the completion of the task.

In the case study, "primary system pressure", "PORV position", "temperature downstream of PORV", "pressurizer water level", and the six irrelevant nodes are observable. The instrument readings indicate that the states of the relevant nodes are "low", "closed", "high", and "high" respectively. Normally, only when the ratio of the belief in the

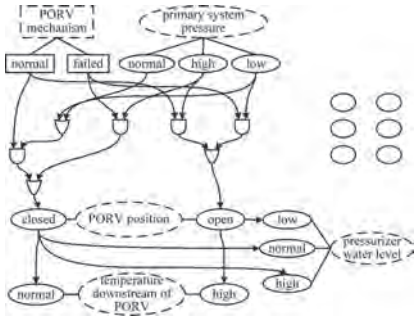

Figure 4. The knowledge base in the PORV case study.

"failed" state to the summation of the beliefs in all the state nodes of "PORV mechanism" is above the action threshold Th_A, the task is seen as success. However, the cognitive process is implemented for only one time step in the case study. This means that the belief in the "failed" state may be increased but may not be increased to be above Th_A. As a result, the success criterion is relaxed to be the activation of the "failed" state. This means that once the "failed" state is reached in the reasoning process, the task is thought to be successful. The values of the parameters are as follows: τ, the initial value of A for each node, and s in Equation 2 are 0.4, 0.5, and 1 respectively. The initial belief in each state is 1 and the default belief ratio ω is 0.8. These values are just used to illustrate the calculation, and do not necessarily reflect the real situation.

3.2 *Results*

The information perception and reasoning processes for the case study are simulated 1000 times. The perceived nodes and activation propagation paths in the knowledge base are recorded at each time. The results are analyzed from the following two aspects.

First, the probability of success is calculated with Equation 13:

$$p_S = \frac{N_S}{N_T} \tag{13}$$

where N_S is the number of successes, and N_T is the number of simulations which is 1000 in the case study. The simulation results show that the probability of success is 0.39.

Second, statistics on the combinations of perceiving useful or useless information and success or failure of the task are obtained. Here perceiving useful information means that at least one of the two useful signals are perceived. Perceiving useless information means that none of the two useful signals are perceived. Useless information refers to the misleading signals and the distracting instrument readings. The probabilities of success condition on perceiving useful information, success condition on perceiving useless information, failure conditioned on perceiving useful information, and failure conditioned on perceiving useless information are 0.91, 0.09, 0.83, and 0.17 respectively. From the result, we can see that perceiving useful information does not guarantee the success of the task, and perceiving useless information does not necessarily lead to the failure of the task. But perceiving useful information does help increase the success probability, as can be seen from the comparison between 0.91 and 0.83. The small increase of the probability of success also suggests that the failure of the task is dominated by the unsuccessful retrieval of information in the reasoning process and by the high complexity of the situation under study.

Two examples, one for success and another for failure, are explained to illustrate the reasoning process. In the example for success, "closed" state of "PORV state", "high" state of "temperature downstream of PORV", and the six irrelevant signals are perceived by the operator. However, except for the "closed" state, the activation propagation from the other signals is stuck at the initial points. The "closed" state leads to the activation of "failed" state of "PORV mechanism" and "normal" state of "pressurizer pressure". In the example for failure, "high" of "pressurizer water level", "low" of "primary system pressure", and two irrelevant signals are perceived. Perception of "high" of "pressurizer water level" leads to the activation of "closed" of "PORV state", then to the activation of "normal" of "primary system pressure" and "normal" of "PORV mechanism". The activation propagation from all the other signals is stuck at the initial points.

3.3 *Discussion*

From the case study, it is easy to see that the proposed computational cognitive modeling approach is able to provide the probability of success or failure in an easy way from the simulation results. In the calculation, no expert opinion is needed. Another more prominent strength of the proposed approach is that the simulation results provide the basis for detailed investigation of an operator's cognitive process in a specific situation from different perspectives, for instance the relation between failure in the task and perceived signals in the case study.

However, significant improvements are still needed to enable the proposed approach for practical applications and to further enhance the capabilities of the approach. First, a better way of representing the knowledge base needs to be developed to cover more complex structures of an operator's knowledge in one field. Second, a systematic method of determining the parameters in the cognitive model through experimental results

or the results in existing research is needed. Third, the proposed approach needs to be validated by comparison with experimental results.

4 CONCLUSIONS

In this paper, a computational cognitive modeling approach to human performance assessment in nuclear power plants is proposed. The three main processes in a human's cognitive process, that is information perception, reasoning and response development, are modeled. The interplay between two significant PSFs (i.e. stress and fatigue) and the cognitive process is considered. Sampling methods are used to simulate the possible outcomes of an operator's cognitive process. The simulation results enable the probability of success or failure of an operator performing a specific task to be calculated in an easy way. In addition, the simulation results provide the basis for detailed investigation of the cognitive process. With the proposed approach, the effect of task dependence on human performance is considered implicitly based on the use of activation levels for the nodes. A case study derived from the Three Mile Island accident is conducted with the proposed approach. Although the case study is simplified and the results are preliminary, it demonstrates the power of the approach. Future research for further improvements of the proposed approach is pointed out.

ABSTRACT: We discuss potential assurance frameworks for autonomous navigation systems in the maritime industry, with emphasis on testing and verification of the system's perception performance and capacities. Ongoing research in this field has revealed profound challenges related to artificial situation awareness and machine perception specific to the marine environment. The lack of a clear and transparent framework and methodologies to assure the safety associated with the usage of such solutions, have been identified as key barriers for the implementation of autonomous navigation solutions at scale. Because the machine perception and situational awareness algorithms are expected to be partly or fully based on machine learning algorithms, including deep learning, whose functional reasoning is challenging or even impossible to understand and predict, the verification of such systems is fundamentally different from a traditional verification process based on physical understanding and theory. We review several methods for testing autonomous navigation systems, proposed and used mainly in the automotive industry, and discuss how these methods can be adapted, combined and applied to form a framework for assurance of autonomy in the maritime industry.

1 INTRODUCTION

Autonomous transport on land, in the air and at sea has been coined the technology trend with the highest potential to disrupt the transport sector in the future. It has the potential for making transport solutions more cost effective, safe and environmentally friendly, but also to disrupt entire business models and value chains associated with the mode of transport. Given the disruptive potential of this technology trend, increasing research efforts are being invested to realize the technological solutions.

1.1 *The autonomy revolution*

Technologies and methods for autonomous systems is a very active area of research both in the industry and in academia. However, the majority of the research being done for autonomous vehicle navigation is focused around the automotive industry. The amount of test data for such vehicles is becoming abundant and is considered an important contributor to the current state of the art in the research field. Major advances in object detection, classification and image analysis have been made in recent years, with extensive use of artificial intelligence related technologies such as feature extraction, artificial neural networks, deep learning models such as Convolutional Neural Networks (CNNs), gradient-based and derivative-based matching approaches (see for example (Hofmann 2013, Rout 2013, MathWorks 2017c)). Research is needed to identify if and how the algorithms, methods and sensors, developed for the automotive industry, can be utilized in the maritime domain.

1.2 *Opportunities in the maritime industry*

Several studies have shown that human error contributes to a majority of marine casualties (Rothblum 2000, Harrald et al. 1998). However, automated systems and autonomy can also introduce new challenges, and existing challenges might be amplified (Lützhöft & Dekker 2002). Nevertheless, we expect that if the interaction between the humans and machines are treated carefully, with thorough testing and verification, autonomy can contribute significantly to increase safety in many maritime operations.

Unmanned ships will enable optimization of energy efficiency due to changes in design

constraints and freeing of space, previously used to accommodate crew. In addition, more hydrodynamic and aerodynamic designs may in turn lead to less fuel consumption and reduced emissions. Furthermore, autonomous ships might be able to compete with road transportation and contribute to reduced emission from road transportation as well as reduced road wear and tear.

If autonomous ships are successfully implemented, it will most probably enable fundamentally new types of ship transportation operations, such as for example single container shipment (Woodgate 2017); extremely slow speed transportation with very low emissions (Tvete 2017); container feeder to replace road transport (Kongsberg 2017); and unmanned patrol ships (Fingas 2017).

Several demonstrators have already proven that it is feasible for a transport solution to be operated by sensors and software either partially or fully based on deep learning algorithms (Huval et al. 2015, Ackerman 2017). Among others, a company Drive.ai, has an ambition to use deep learning fully from sensory input to decision making, while others usually use deep learning in parts of the system, e.g. situational awareness, while relying on traditional control system logic in other parts of the system (Huval et al. 2015, Ackerman 2017, Muoio 2016). Nevertheless, the solutions are yet to be deployed at scale. One of the reasons for the lack of deployments is that the solutions are still not proven to be sufficiently safe.

1.3 *Early rule development as an enabler for innovation*

A key element required to keep the autonomous system safe, is the ability of the system to achieve situational awareness. Situational awareness algorithms are usually partly or fully based on machine learning algorithms whose functional reasoning are challenging or even impossible to understand and predict. Hence, the verification of such a system is fundamentally different from a traditional verification process based on physical understanding and theory. The machine learning algorithms are data driven, and completely dependent on the quality of the training data. Therefore, verification will likely be carried out by a combination of testing, simulations and benchmarking against real and synthetic data sets. Furthermore, adaptive methods, where data are automatically collected and used to retrain the system, will also be considered.

For a manned system, awareness is achieved by the human operator by using his or her senses and perceptive abilities to interpret instrument signals and input from surroundings. An unmanned ship should use a priori information, such as maps, combined with sensor readings to make observations relative to the environment, and use software to perceive the situation based on this input. This digital perception will be used as input to a decision-making algorithm. In turn, this controls the actuators of the vessel which are effectuating the decision made. For the autonomous system to make safe decisions, the situational awareness must be sufficiently accurate for all feasible situations and conditions which the vessel may encounter.

System functional and performance requirements necessary to obtain a required safety level of an automated situational awareness system should be established as early as possible, as this will offer the technology providers a standard to be met by their solutions. If requirements are not set before or early in the technology development phase, developers risk spending significant efforts and money on developing solutions which in the end may not meet the safety standard. However, establishing such a standard is difficult when no solutions exist to evaluate the standard against.

In addition to a standard for required system and component performance, tools are needed for verifying that the technology meets the requirements set in the standard. For a situational awareness system, this will include verifying that the sensors adequately detect objects affecting the safety of the vessel and its surroundings under various conditions, and that the perception algorithm can use this information together with other a priori information to adequately understand the situation.

1.4 *Focus of this study*

In this paper, we discuss rules and regulations related to autonomous navigation systems in a maritime context, with focus on autonomous perception and situational awareness. However, we believe that a framework for approval developed for autonomous applications will also be applicable to other systems that are based on machine learning algorithms and artificial intelligence.

The remainder of the paper is structured as follows. In section 2, we propose and describe a range of recommended practices and tools that can be applied to test and validate the ability, performance and robustness of safety critical systems which decisions are based on data-driven methods. These practices and tools originate partly from traditional statistical analysis and are suggested and applied for testing and assurance of autonomy in the automotive industry. In section 3, we discuss challenges related to machine perception that are unique or particularly pronounced in the maritime domain, and suggest how the recommended practices and tools should be used and possibly adapted to suit the maritime domain. Furthermore, we present a

possible scope for assurance framework, and discuss potential implications of autonomy such as for example operational dependent requirements. We also describe the IMO guidelines for approval of alternatives and equivalents. We conclude in section 4.

2 TOOLS AND RECOMMENDED PRACTICES FOR ASSURANCE

In the following, we propose and describe a different recommended practices and tools that can all be applied to test and validate the ability, performance and robustness of safety critical systems which decisions are based on data-driven methods. See Figure 1 for an overview of the methods.

2.1 *Confusion matrix*

It is not obvious how to measure and evaluate the performance of autonomous navigation systems. If two systems provides divergent predictions or decision, it is difficult to define and quantify which reaction was most correct. In classification problems, the results are often presented in a confusion matrix, where the predicted class is compared with the actual or the true class. With two classes, for example object detection with two objects, it is straight forward to define the confusion matrix, which inhere the number of

- True Positives (TP), hits
- True Negatives (TN), correct rejections
- False Positives (FP), false alarms, Type I errors
- False Negatives (FN), misses, Type II errors

When more classes are needed, defining the criteria for performance evaluation becomes more challenging. For example, how should we quantify the performance of a perception system which correctly detects a vessel, but misclassifies it as a ferry? And how should this be compared to misclassifying it as a kayak? Or what if the system is not even able to recognize it as an object?

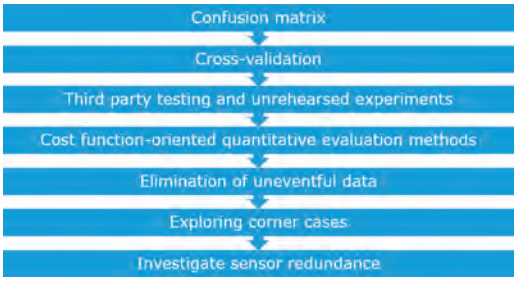

Figure 1. Proposed components in an assurance framework for safety critical systems.

To be able to make the above-mentioned comparison, we are fully dependent on a correctly labelled dataset of the ground truth. An autonomous ship will likely be equipped with multiple sensors, including multiple daylight and IR cameras in various directions, radars with different settings, in addition to Automatic Identification System (AIS) and other satellite data, etc. The labelling process should take all these sources into account when labelling the data. For example, if an object is not visible in the video stream due to thick fog or other difficult weather conditions, but we know the objects position from AIS data or other sources, the object will be labelled in the ground truth data set. All relevant information should be correctly labelled, in all datasets.

Data collection, and especially data annotation or labelling, are surprisingly time consuming and costly tasks for vehicle classification (Schöning et al. 2015, Chen and Ellis 2014). However, various tools and methods for semi-automatic ground truth labelling on video streams designed for the automotive industry are available, such as for example (MathWorks 2017b, MathWorks 2017a, Cuevas et al. 2015, Lopez-Villa et al. 2015, Schöning et al. 2015). Another approach is to crowd source the data annotation like Mighty AI has done in automotive, where they have developed a mobile app in which users may annotate images manually and get paid for it, whereupon Mighty AI makes a business out of selling annotated datasets [https://mty.ai/]. The available solutions should be explored, and if necessary adapted for our use in a maritime context.

2.2 *Cross-validation*

It is well known that when we evaluate predictions from a statistical model on the dataset used to train the model, our accuracy estimates tend to be over-optimistic (Arlot & Celisse 2010). To build robust and accurate models we ideally want to use all data available. The same applies to testing; we want to test our models in all situations, not only on a subset. Cross-validation introduces various methods of repetitively splitting the data $\mathcal{D}$ into two exclusive parts $\mathcal{D}_t$ and; $\mathcal{D}_v$ where one part $\mathcal{D}_t$ is used to train the model, and the other $\mathcal{D}_v$ is reserved for validation.

A range of different splitting techniques can be applied, providing different cross-validation estimates. See for example Arlot & Celisse 2010, Kohavi 1995 for a brief overview of the most common splitting techniques.

One of the most widely used splitting technique is called K-fold cross-validation, which in its

standard form splits the original dataset $\mathcal{D}$ into K subsets (folds), $\mathcal{D}_1$, …, $\mathcal{D}_K$, as described in (Arlot and Celisse 2010, Brandsæter and Vanem 2016). For each $k \in 1,2,\ldots K$ the models are trained on $\mathcal{D}_t = \mathcal{D} \backslash \mathcal{D}_K$, and tested on $\mathcal{D}_k$. To make sure that the results are not strongly dependent on how the folds are selected, we repeatedly run the K-fold cross-validation with new selections. The sets are often chosen to be mutually exclusive with equal size.

2.3 *Extensive testing*

The standard approach for assurance of autonomous navigation in the automotive industry is extensive testing (Pei et al. 2017a, Zhao and Peng 2017, Waymo 2016, Fei-Fei 2010), where large amounts of real world data from ordinary operation is gathered and manually labelled, and data on driver performance, behaviour, environment, driving context and other factors that were associated with critical incidents, near misses and crashes are analysed and used in evaluating the system performance (Zhao and Peng 2017).

Simulated real-world data is also sometimes used to massively increase the amount of data (Madrigal 2017, Zhao and Peng 2017), but usually this is completely unguided, and due to the large input space of real-world scenarios, none of these approaches can hope to cover more than a tiny fraction (if any at all) of all possible corner cases (Pei et al. 2017a). Here, a corner case is defined as an unusual, but far from impossible, scenario. In particular, if each individual parameter, such as temperature, fog, daylight, driving speed, number of other vehicles involved, etc. are well within the normal range for that parameter, but still the combined scenario is unusual. As an example, again from the automotive industry, a Tesla in autopilot recently crashed into a trailer because the autopilot system failed to recognize the trailer as an obstacle due to its white color against a brightly lit sky and the high ride height (Lambert 2016). Such corner cases were not part of Waymos (Googles) or Teslas test set (Pei et al. 2017a) and thus never showed up during testing.

2.4 *Third party testing and unrehearsed experiments*

In 2003 the Defense Advanced Research Projects Agency (DARPA) announced the first Grand Challenge with the goal of developing vehicles capable of autonomously navigating desert trails and roads at high speeds. In Krotkov et al. 2007, the conduct of six evaluation experiments for the DARPA PerceptOR program is described. Key distinctions of the testing methodology include conduct of the experiments by an independent third party, and the use of unrehearsed experiments that provide little advance knowledge of and access to the test courses. The article also presents quantified, objective performance metrics for the systems evaluated. Furthermore, it includes blind experiments that do not allow the system operators to see the test courses until all tests are completed.

The test environment and the test content are described in detail; however, the evaluation approach are not thoroughly discussed (Sun et al. 2011).

2.5 *Cost function-oriented quantitative evaluation methods*

Wei and Dolan 2009 claims that most teams in the 2007 DARPA Urban Challenge preferred to avoid difficult manoeuvres in high-density traffic by stopping and waiting for a clear opening instead of interacting with it and operating the vehicle and human drivers. To encounter this, researchers at Beijing Institute of Technology, propose a design method for a scientific and comprehensive test and evaluation system for autonomous ground vehicles competitions, to better guide and regulate the development of autonomous ground vehicles. The evaluation method proposed by Sun et al. 2014, Sun et al. 2011 aims to evaluate the quality of completion with a cost function-oriented quantitative evaluation method. This evaluation method can presumably evaluate the overall technical performance and individual technical performance of autonomous ground vehicles. A complete test system that includes the test contents, the test environment, and the test methods to meet the demands of testing for autonomous ground vehicles is developed, and a fuzzy evaluation method is combined with an analytic hierarchy process to solve fuzzy and hard-to-quantify problems (Sun et al. 2014).

2.6 *Elimination of uneventful data*

Recently, a new approach to testing autonomous cars was proposed by researchers affiliated with the University of Michigans Mcity connected and automated vehicle center. Zhao and Peng 2017 presents an accelerated evaluation process which aims to eliminate the uneventful driving activity, and filter out only the potentially dangerous driving situations where an automated vehicle needs to respond, creating a faster, less expensive testing program. It is claimed that this approach can reduce the amount of testing needed by a factor of 300 to 100,000.

Four methodologies that form the basis of the accelerated evaluation process are listed (Zhao and Peng 2017):

1. Evaluate how frequently a significant driving event happens on the road, and stripe out the more common, uneventful safe driving situations.
2. Use importance sampling to statistically increase the number of critical driving events in a way that still accurately reflects real-world driving situations.
3. Construct a formula that accurately distils those critical events, tests the formula, and apply it to further reduce the amount of testing required.
4. Analyse interactions between human-driven vehicles and robotic vehicles and optimize the random occurrences of significant driving events in the most complex scenarios.

2.7 *Exploring corner cases in deep learning systems*

In Pei et al. 2017a, Tian et al. 2017, Pei et al. 2017b prepared by researchers at Colombia University, Lehigh University and University of Virginia, a method for automated whitebox testing of deep learning systems is proposed. Deep Learning (DL) has made tremendous progress, achieving or surpassing human-level performance for a diverse set of tasks including image classification (He et al. 2016, Simonyan and Zisserman 2014), which has led to widespread adoption and deployment of DL in security- and safety-critical systems such as self-driving cars (Bojarski et al. 2016). Unfortunately, DL systems, despite their impressive capabilities, often demonstrate unexpected or incorrect behaviours in corner cases for several reasons such as biased training data, overfitting, and underfitting of the models (Pei et al. 2017a).

The proposed method aims to identify erroneous behaviours of a DL system without manual labelling/checking, by jointly maximizing a joint objective function combining a metric called neural coverage, and differential behaviour between multiple tested methods. The objective function is maximized by changing the input variable x, under some physical constraints. For example, an input image can be rotated or scaled differently, brightness and contrast can be changed, and rain and fog can be added to the input image.

With *differential behaviour* we mean that when different deep neural networks (DNNs) are tested, the same input will be classified into different classes by the different DNNs. The aim is to maximize the probability that a randomly selected DNN provides an output that differs from the output of the other DNNs. Suppose we have N different DNNs, then each DNN has its own function model $F_k : x \rightarrow y$ for, $k \in 1 \ldots N$, where x and y are the input and output values respectively. If $F_k[c]$ is the class probability that the output of the k-th neural network c is, and the j-th neural network is randomly chosen, the objective function (which will be maximized) is formulated as

$$obj_1(x) = \sum_{k \neq j} F_k(x)[c] - \lambda_1 \cdot F_j(x)[c] \quad (1)$$

where λ_1 is a parameter to balance the objective terms between the DNNs that maintain the same class outputs as before ($F_{k \neq j}$) and the DNN that produce different class outputs (F_j).

Neural coverage is a measure of how many rules in a DNN are exercised by a set of inputs. The neuron coverage of a set of test inputs is defined as the ratio of the number of unique activated neurons for all test inputs and the total number of neurons in the DNN.

To maximize the neural coverage, Pei et al. 2017a and Tian et al. 2017 propose to iteratively pick inactivated neurons and modify the input such that output of that neuron goes above a predefined threshold t. Hence, for a given neuron, n we maximize the following function

$$obj_2(x) = G_n(x) \text{ such that } G_n(x) > t \quad (2)$$

where G_n is the output value of neural n.

The neural coverage and the differential behaviour is jointly maximized, by slightly changing the input values using gradient ascent. The joint objective function is

$$obj_{joint}(x) = \sum_{k \neq j} F_k(x)[c] - \lambda_1 \cdot F_j(x)[c] + G_n(x) \quad (3)$$

By changing the input variables x to maximize this joint objective function, the paper claims that the method finds thousands of erroneous behaviours in fifteen state-of-the-art DNNs trained on five real-world datasets. Hence, new corner cases are explored and different types of erroneous behaviours are uncovered. In addition, test inputs generated by the proposed method can be used to retrain the corresponding deep learning model to improve classification accuracy, and also identify potentially polluted training data (Pei et al. 2017a).

2.8 *Demonstrate need for sensor redundancy*

Inpired by Pei et al. 2017a, as introduced above, we propose to invoke differential behaviour by repeatedly exclude one information source from the sensor fusion machinery. In addition to revealing differential behaviour, we believe this method will be useful to demonstrate the importance of sensor redundancy. If differential behaviour often occurs when a specific information source is removed

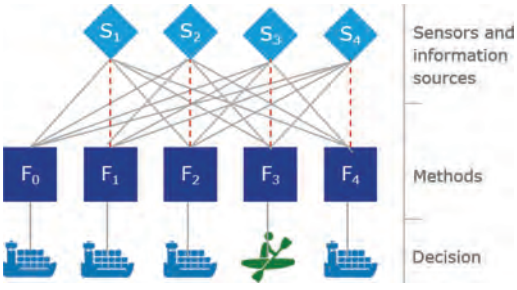

Figure 2. Illustrating how we invoke differential behaviour by repeatedly excluding one information source from the sensor fusion machinery.

from the set of explanatory variables, it can indicate that redundancy of this information is needed to achieve adequate robustness.

To illustrate the idea, we consider a method which fuses four information sources: S_1 a daylight camera; S_2 an IR camera; S_3 a radar; and S_4 AIS (Automatic Identification System). F_0 is the standard method which uses all information sources, while the methods F_k for $k > 0$ cannot use the information from information source S_k. The goal is to change the input variable x in way to invoke differential behaviour as illustrated in Figure 2, where the output of method, F_3 which does not take information source S_k into account, diverges from the other methods.

In the same way as in section 2.7, we let $F_k[c]$ be the class probability that the output of the k-th method is c. Now the k-th method is the method where information source k is excluded as an explanatory variable. In addition, we propose to include method F_0 which includes all variables. Now the objective function (which will be maximized) is formulated as

$$obj_3(x) = \sum_{k \neq j} F_k(x)[c] - \lambda_3 \cdot F_j(x)[c] \quad (4)$$

where j is randomly chosen, and λ_3 is a parameter to balance the objective terms between the method that maintain the same class outputs as before ($F_{k \neq j}$) and the method that produce different class outputs (F_j).

3 ASSURANCE IN THE MARITIME DOMAIN

The assurance of systems which safety is dependent on the accuracy and reliability of data driven models needs to be thoroughly tested. In this chapter, we present challenges related to machine perception that are unique or particularly pronounced in the maritime domain. We describe potential requirements, and discuss how the recommended practices and tools should be used and possibly adapted to form a framework for assurance in the maritime domain.

3.1 *Important technical challenges in the maritime domain*

One of the major differences, relevant for autonomous navigation, between the automotive and the maritime industry is machine perception. Machine perception, also referred to as artificial or digital perception, is the process where information from sensing, maps, satellite data and the vessel condition, are transformed into situation awareness (see Fig. 3).

The requirements of a machine perception system in the maritime industry will most likely concern both what should be *detected*, such as object types, sizes, distances, reflexibilities, etc.; and what should be *classified*, such as ship types, number of ships, seamarks, complexity, etc. The requirements should be evaluated under various external conditions such as weather and daylight.

Several technical challenges, particularly prominent in the maritime domain, remain open as described by for example (Prasad et al. 2016, Prasad et al. 2017):

- *Vessel movements effect on sensors:* For sensors like video cameras which are mounted on-board ships, the unpredictable motion of the ship complicates the object detection.
- *Background subtraction:* The water background is dynamic due to waves. Hence, background learning methods which recognizes background when a pixel stays constant for at least some time, fails. Also, waves and foam are often misinterpreted as foreground objects when using standard methods.
- *Weather and illumination conditions:* The maritime environment is exposed to a variety of different weather and illumination conditions such as fog, rainfall, clouds, bright sunlight, twilight

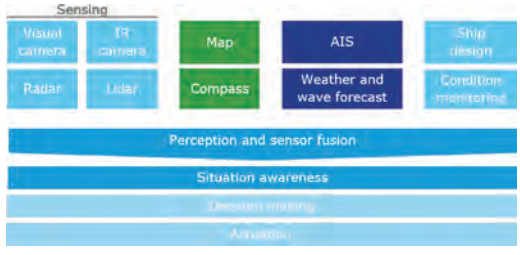

Figure 3. Key components in autonomous navigation in the maritime industry.

and night. The different solar angles pose significant challenges with speckle and glint which makes it difficult to distinguish background and foreground.
- *Insufficient training data from the maritime domain:* Very limited work has been carried out to develop object classification algorithms for objects relevant to the maritime environment. The objects of interest include other ships, leisure boats, kayaks, land marks, buoys, ice bergs, etc.
- *Uneventful sailing:* On ocean going ships especially, a very large fraction of the collected data from a voyage are uneventful, hence a very large portion of the corner cases are left unproven.

3.2 *Operational specific requirements*

Operational specific requirements are not considered in current class rules. We foresee that this might change in the future, especially for ships with autonomous navigation systems, as the operation will be embedded into the technology rather than being the responsibility of the human operator. For example, if the ships perception is limited due to fog, the permitted speed might be lowered, or the ship might be denied access to specific geographical areas, until the weather conditions improve. This decision might also be based on ship type, cargo, manoeuvring capabilities, etc.

3.3 *Triple modular redundancy*

The tools presented in 2.7 and 2.8 above, both search for differential behaviour from multiple algorithms or sensor selections, using a majority organ (or voting circuit). This concept was first described by Von Neumann 1956. Today, the concept is often referred to as *triple modular redundancy* and is perhaps most widely used in space and aeronautics applications (Wu et al. 2017, Yeh 1996), where reliability requirements sometimes are very high. Using the majority vote out of three (or more) methods ensures that a single failure will not cause a system failure. We believe this concept is highly relevant for autonomous navigation, as well as other black box AI algorithms, and believe the use of this should be required, in some form, to ensure sufficient system reliability and robustness.

3.4 *Approval of alternatives and equivalents*

According to the International Maritime Organizations guidelines for the approval of alternatives and equivalents (IMO Maritime Safety Committee 2013), the approval of an alternative and/or equivalent design can be performed by comparing the alternative design to existing designs to demonstrate that the design has an equivalent level of safety. Hence, the approval of autonomous systems used in shipping, including everything from smaller automated tasks to fully autonomously navigated ships, will be based on the equivalence principle: The autonomous functionality must make the operation safer or at least as safe as the conventional operation.

3.5 *Automatic assessment of human perception ability*

To enable the comparison of human and autonomous perception, evaluation metrics and measures should be defined, and performance thresholds should be identified. To achieve this, the human perception in representative real ship operations has to be studied. Research in the field of human errors have shown that a large number of investigated maritime accidents are related to loss of situation awareness (Grech et al. 2002).

It should be noted that the perception ability is not necessarily the ambition. We know that the perception performance can be influenced by many factors such as for example stress, distractions, monotony, boredom, etc. (Horrey et al. 2017, Brodsky and Slor 2013, Schwebel et al. 2012), but our aim is to measure the perception performance in practice.

Simulation tools might be applied to provide more extensive data sets, to complement the data collected from real operation. In addition to increasing the data set, the simulation tool offers the possibilities to create controlled situations, and explore changes in weather, rotated objects, etc. as well as the possibility to explore potentially dangerous situations. Another advantage with the simulated data is that it is pre-labelled, and one will therefore avoid spending time and effort to establish the ground truth on the simulated datasets.

4 CONCLUSIONS

A framework and tentative guidelines for assurance of autonomous systems in the maritime industry are proposed and discussed, with additional focus on the perception and situation awareness functionality. Because vital parts of the autonomous systems, such as the machine perception and situational awareness algorithms, are expected to be partly or fully based on machine learning algorithms, including deep learning, whose functional reasoning is challenging or even impossible to understand and predict, we believe the assurance of such systems are fundamentally different from a traditional assurance process based on physical understanding and theory. Hence, we believe

new guidelines, framework and methodologies are needed.

We propose and describe a range of recommended practices and tools that can be applied to test and validate the ability, performance and robustness of safety critical systems which decisions are based on data-driven methods. We discuss challenges related to machine perception that are unique or particularly pronounced in the maritime domain, and suggest how the recommended practices and tools should be used and possibly adapted to constitute an assurance framework for autonomous navigation in the maritime domain. Furthermore, we discuss potential implications of autonomy such as for example operational dependent requirements. We also discuss the assurance framework for autonomous systems relative to the IMO guidelines for approval of alternatives and equivalents.

ACKNOWLEDGEMENT

We greatly acknowledge the feedback and support from Per Ove Husøy (Kongsberg Digital), Erlend Vågsholm (Kongsberg Maritime) and Jørgen Ernstsen (University College of Southeast Norway).

Subjective assessment of risk among urban work travel cyclists

A.-M. Kummeneje & T. Rundmo
Department of Psychology, Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: The results of the current research are based on two questionnaire studies of risk perception and worry about being involved in an accident when cycling. The data for Study 1 were collected through a questionnaire survey (n = 291) distributed in collaboration with the Norwegian Cyclists' Association. Study 2 was based on survey data collected in a representative sample of the Norwegian public (n = 2000). The results of the first study showed significant associations between risk perception, worry, and risk tolerance on the one hand and cycling frequency during winter on the other hand. Risk perception was not as important for cycling frequency during the other seasons of the year. Study 2 showed that previous accident experience was associated with risk perception and worry.

1 INTRODUCTION

The risk of being involved in an accident is greater among cyclists compared with users of other travel modes (Høye et al., 2012). However, cycling is a more pro-environmental travel mode than motorized travel modes. Hence, Norwegian transport policy and the Norwegian authorities give high priority to increasing the number of cyclists and frequency of trips made by bicycle, especially in urban areas. Therefore, it is important to examine factors that may be associated with the frequency of bicycle use. Risk exposure may be a particular challenge during harsh winter conditions in Norway, and due to the risk factors, priority should be given to examining risk perception among cyclists. Consequently, the aim of the study on which this paper is based was to investigate how urban work travel cyclists perceive risk when cycling, and to investigate the association between perceived risk and the decision to cycle. An additional objective was to investigate whether experiences of accidents are associated with cyclists' perceptions of risk.

2 THEORETICAL FRAMEWORK

2.1 *Risk perception and worry*

In accordance with Breakwell (2007), studies carried out recent years have used assessments of probability and judgments of the severity of consequences as indicators of perceived risk (Moen & Rundmo, 2006, Nordfjaern et al., 2014, Roche-Cerasi et al., 2013, Rundmo & Moen, 2006). Consequently, in the current study perception of risk was measured using the two factors 'assessments of probability' and 'judgments of the severity of consequences' of an accident occurring when cycling. According to Sjöberg, Moen, and Rundmo (2004), risk perception can be defined as people's cognitive assessment of risk on these two dimensions.

Cognitive models have dominated risk perception and decision-making research, but recently affective processes have received increased attention (Breakwell, 2007). The risk-as-feeling approach highlights the role of anticipatory and anticipated emotions for individuals perception of risk (Loewenstein et al., 2001). Anticipatory emotions are immediate visceral reactions to risk, such as worry, fear, anxiety, and dread. Anticipated emotions are those that the individual expects to feel as a consequence of their decision. There are two types of anticipatory emotions: integral emotions and incidental emotions. Integral emotions are caused by the decision problem itself, whereas incidental emotions are caused by other factors, such as mood (Loewenstein & Lerner, 2003). In this paper, we conceive worry as an anticipatory emotion and integral to the decision problem, which implies that worry is defined as a feeling that emerges as a reaction to the individual's cognitive assessment of risk.

Risk perception and worry are primarily of interest because they may be related to people's behavioural choices. According to the risk-as-feeling approach, behaviour is influenced by the interplay between cognitive evaluations of risk and feelings. Further, emotions often produce behavioural responses that differ from the individual's cognitive assessment of the best course of action. According to (Loewenstein et al., 2001), it is apparent that

when such differences occur, behaviour is driven by emotional reactions, not cognitive assessments.

2.2 *Risk tolerance and priority given to safety*

It is not only important to study risk perception but also how risk is tolerated by individuals. Individuals may differ in their thresholds for the level of risk they find acceptable. In his classic study, Starr (1969) aimed to answer the question 'How safe is safe enough?' He measured the level of risk that individuals found acceptable for different activities, and found that the risks involved in activities that were voluntary and perceived as beneficial were tolerated more than the risks involved in other activities. In a more recent study by Fischhoff et al. (1978), respondents were asked to judge the acceptable level of risk associated with different activities or technologies. The researchers found that risk was less tolerated when the activities were associated with dread. Fischhoff et al. (1978) also found that higher risk levels were tolerated in voluntary activities with well-known and immediate consequences.

To date, few studies have measured risk tolerance among cyclists. Parkin et al. (2007) developed a model based on a risk threshold and provided a measure of acceptability for different cycling routes. The model shows how different infrastructure reduces the perceived risk and makes the route acceptable to cyclists. In Parkin et al.'s (2007) study, the model showed that young and old people considered cycling less acceptable than did people in the age group 35–44 years, and that males considered cycling more acceptable than did females.

The terms 'acceptance' and 'tolerance' are often used synonymously. However, Sjöberg (1999) argues that risk tolerance and risk acceptance are two separate concepts. According Sjöberg (1999, p. 131), 'risks are not accepted but tolerated'. One may be aware of the risk and choose to tolerate it, even if one does not accept it. It is more accurate to talk about accepting, for example, cycling as an activity that generates risk, but the risk in itself is not accepted but tolerated. In our study, we investigated risk tolerance.

Several studies have investigated demands for safety priority or risk mitigation related to transport mode use (Nordfjaern & Rundmo, 2010, Rundmo & Moen, 2006, Simsekoglu et al., 2015, Sjöberg, 1999), and some of these studies have included cycling (Nordfjaern & Rundmo, 2010). To date, no studies have investigated how demands for safety priority relate to transport mode use. Nordfjaern and Rundmo (2010) found that in Norway, the demand for risk mitigation and the priorities related to transport safety increased significantly between 2004 and 2008. Demands for risk mitigation can be defined as public demands for decision-makers to reduce specific sources of transport risks (Moen & Rundmo, 2004). In this paper, we define the demand for safety priority as demands from the public directed towards decision-makers to prioritize traffic safety for cyclists. In the following, we examine how both risk tolerance and priority given to safety are associated with cycling.

2.3 *Risk perception and worry among cyclists*

The study of risk perception among cyclists has received little attention to date (Chaurand & Delhomme, 2013). Much of the research in this field has been conducted mainly to aid engineers and planners wanting to design, improve, and prioritize roads and intersections to cater for cyclists. In the majority of these studies, cyclists were asked to rate their overall risk perception of a route shown in video clips or simulations, or described in surveys. In one recent study, mental mapping was used to study cyclists' risk perceptions by drawing their regular route with different colours according to their perception of safety and risk (Manton et al., 2016). Common to the studies of risk perception among cyclists is that the focus is on the perception of either the road infrastructure or the traffic (Lawson et al., 2013). Some researchers have investigated cyclists' risk perception using specific roads (Llorca et al., 2017) or crossings and roundabouts (Moller & Hels, 2008).

Several previous studies have examined risk perception in relation to travel mode use. Moen & Rundmo (2006) and Oltedal & Rundmo (2007) included cycling with other travel modes when investigating perceptions of risk. Both pairs of researchers found that the probability of being involved in an accident was higher when cycling compared with when using other travel modes. However, the severity of the consequences when cycling was judged as small. Another interesting finding was that respondents reported they were more worried about experiencing an accident when cycling than when they used other travel modes.

Further, researchers have found gender differences in perceptions of risk and worry among cyclists. Lawson et al. (2013) studied gender differences in the perception of safety among cyclists, and found that both males and females more often described cycling as less safe than driving, and that older women perceived cycling as less safe than did younger women. Manton et al. (2016) found that females more often perceived their regular cycling routes as dangerous than did males perceive their own routes. Moen & Rundmo (2006) found that, in contrast to women, men scored lower on their perceptions of probability, on expected consequences,

and on worry. They also found that individuals below the age of 25 years regarded the consequences as least serious and were least worried when travelling by private modes of transport, including bicycles, than were individuals aged 25 years or over. The same age group (i.e. individuals under 25 years) perceived the probability of being involved in an accident as highest. Individuals with a university degree perceived the risk as lower than did others and were less worried about being involved in an accident. Other studied predictors of risk perception and worry are age (Hermand et al., 1999, Sjöberg, 1998) and level of education (Sjöberg, 2000).

2.4 *Aims of the study*

The specific aims of the current study were as follows:

1. To examine differences in work travel cyclists' risk perception, worry, risk tolerance, and priority given to safety when cycling in winter and summer conditions
2. To examine whether risk perception, worry, risk tolerance, and priority given to safety were associated with the cycling frequency during winter
3. To compare the role of risk perception, worry, risk tolerance, and priority given to safety, for cycling frequency during all four seasons
4. To examine the association between accident experience, and risk perception and worry.

3 DATA AND METHODS

3.1 *Samples*

The results of the current study are based on two questionnaire studies about risk perception and travel behaviour among Norwegian cyclists. The data collection for both studies was carried out in spring 2017.

3.1.1 *Study 1*

The data for Study 1 were collected through a self-completion questionnaire survey (n = 291) carried out among work travel cyclists in Trondheim Municipality, Norway. The survey was distributed in collaboration with the Norwegian Cyclists' Association (Syklistenes Landsforening). All respondents cycled on a daily basis and were members of an Internet-based group for cyclists. We invited all 2240 members to participate in the study, and the response rate was 13 percent. Respondents who never used their bicycle for travelling to work or university, or during their workday were not defined as work travel cyclists and were excluded from the sample (28 respondents).

The percentages of females and males in the sample were 35 percent and 65 percent respectively. They were all in the age range 20–67 years (mean = 42.63, standard deviation = 11.30). A total of 69 percent of the respondents reported they had more than three years of university education, 19 percent had three years or less of university education, and 12 percent had received their highest level of education at upper secondary school. A total of 91 percent reported their main occupation as employed, and the remaining 9 percent were students. The respondents reported that they used their bicycle to travel to and/or from work (94%), for their work (13%) and/or to and/or from university (10%). A total of 3 percent of the respondents reported that they did not have a driving license.

Figure 1 shows how often the work travel cyclists used their bicycle during the different seasons. The cyclists reported that they cycled less during winter compared with in the other seasons. During winter, 48 percent cycled five or more times per week, compared with 67 percent during autumn, 70 percent during spring, and 76 percent during summer. A total of 8 percent reported that they never cycled during winter. None of the respondents reported that they never cycled during the other seasons.

3.1.2 *Study 2*

Study 2 was based on a telephone questionnaire survey (n = 2000) carried out among a representative

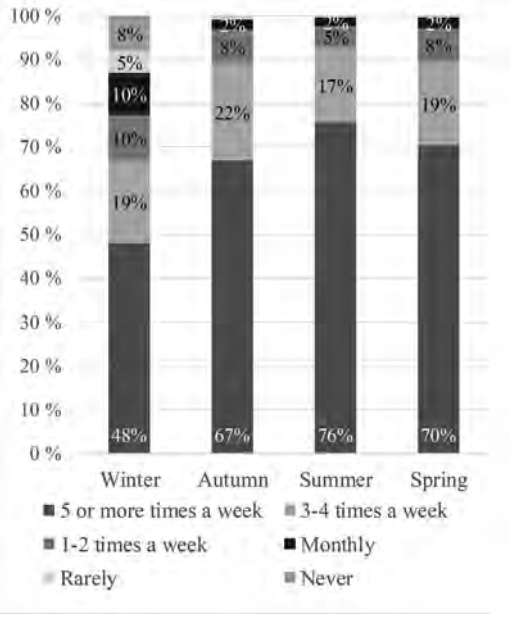

Figure 1. Cycling frequency (%) during winter, spring, summer, and autumn (n = 263).

sample of the Norwegian population in the age range 15–88 years (mean = 45.38, standard deviation = 17.56). The response rate was 27 percent. In the sample, 57 percent were males and 43 percent were females. A total of 9 percent of the respondents had primary or secondary school education as their highest completed education level. A total of 34 percent had upper secondary school as their highest completed education level. A high proportion of the sample (57%) had a higher education level from college or university. A total of 62 percent reported that they were employed or self-employed and 10 percent were students. A total of 10 percent of the responds reported that they did not have a driving license. In the sample, 8 percent (n = 164) had experienced an accident as a cyclist during the last two years. Two-thirds (66%) of the accidents were single accidents (i.e. accidents not involving other road users), and 28 percent of the cyclists involved in an accident needed medical treatment afterwards.

3.2 *Questionnaires and measurement instruments*

In both Study 1 and Study 2, the respondents were asked to evaluate the probability of an adverse event when cycling and the severity of its consequences, and their degree of worry about being in an adverse event when cycling in winter and summer conditions. The questionnaires also contained questions about age, gender, highest level of completed education, employment status, and possession of a driving licence. In addition, the questionnaire used in Study 1 contained questions about risk tolerance, safety priority, and cycling frequency during the four seasons. The survey in Study 2 contained questions about accident experiences as a cyclist during the last two years.

To measure risk perception, the respondents were asked to assess their probability of experiencing an accident or injury, and to judge the severity of the consequences if such an event were to occur. The scale for measuring the probability assessments was a five-point evaluation scale ranging from 'not at all probable' to 'very probable'. For the judgement of severity of the consequences, the scale ranged from 'not at all serious' to 'very serious'. The respondents were further asked to rate how worried they were about being involved in an accident when cycling, and the measurement scale ranged from 'not at all worried' to 'very worried'.

3.2.1 *Study 1*

To measure risk tolerance, the respondents were asked the following question: 'To what extent do you tolerate being exposed to risk when cycling?' The five-point evaluation scale ranged from 'tolerate the risk absolutely' to 'do not tolerate any risk'. To measure priority given to safety, the respondents were asked to assess the following question: 'How important do you think it is that the authorities prioritize measures to improve safety for cyclists?' The five-point scale ranged from 'not at all important' to 'very important'. The respondents were asked how often they cycled each season (winter, spring, summer, and autumn). For this measurement, a six-point evaluation scale was applied: 5 or more times per week, 3–4 times per week, 1–2 times per week, Monthly, Rarely, and Never. This measure has been found appropriate in previous studies of bicycle use in Norway (Kummeneje & Tretvik, 2015, Tretvik, 2015).

3.2.2 *Study 2*

To measure cyclists' experiences of accidents, the respondents were asked whether they had been involved in an accident, including a single accident, as a cyclist during the last two years. If they reported that they had been in an accident, they were further asked if other road users were involved and whether they had needed medical help after the accident.

3.3 *Statistical procedures*

3.3.1 *Study 1*

Paired sample t-tests were used to investigate differences in risk perception (probability and consequences of being in an accident), worry, risk tolerance, and priority given to safety, between cycling in winter and summer conditions. A hierarchical regression analysis was used to predict the amount of cycling done in all seasons.

3.3.2 *Study 2*

MANCOVAs were used to investigate differences in risk perception (probability and consequences of being in an accident) and worry between respondents who had experienced an accident while cycling during the last two years and respondents who did not have the same experience. The results were controlled for gender, age, and education level.

4 RESULTS

4.1 *Risk perception relating to cycling in winter and summer conditions*

The paired sampled t-tests showed significant differences in the respondents' assessment of risk during winter and summer cycling conditions. This was the case for the subjective assessments of the probability of an accident ($t = 5.722$, $p < .001$) and for how worried they were about being involved in an accident ($t = 6.597$, $p < .001$). The respondents' perceived greater risks for cycling in winter

Table 1. Differences in risk perception, worry, risk tolerance, and priority given to safety when cycling in winter and summer conditions (n = 263).

	Winter cycling conditions		Summer cycling conditions		t-value (Sig. 2-tailed)
	Mean	SD	Mean	SD	
Probability	2.94	1.090	2.64	1.014	5.722***
Consequence	3.21	.967	3.24	.944	–.724
Worry	2.60	1.212	2.23	1.015	6.597***
Risk tolerance	2.62	1.083	2.47	1.025	3.320***
Safety priority	4.51	.744	4.56	.622	–1.643

*p < .05, **p < .01, ***p < .001.

conditions compared with cycling in summer conditions. However, it is interesting to note that there were no significant seasonal differences in the respondents' judgements of the severity of the consequences if an accident were to occur. Further, there were significant differences in risk tolerance (t = 3.320, p < .001). With regard to risk tolerance, the larger the mean value was, the less the tolerance for risk was. Table 1 shows that the respondents tolerated less risk when cycling in winter than when cycling in summer conditions. Further, the results revealed that there were no differences in priority given to safety when cycling in winter conditions compared with when cycling in summer conditions (Table 1).

The standard deviations for all variables were relatively high and there were variations in the respondents' perceptions of risk. This was the case for both cycling in summer conditions and cycling in winter conditions.

4.2 *Predictors for cycling frequency during winter*

Table 2 shows the results of a hierarchical multiple regression analysis that were used to predict cycling frequency during the winter season. The independent variables were entered in five blocks: demographics, risk tolerance, priority given to safety, risk perception, and worry. Table 2 shows only the two final steps of the analysis. Demographics were entered as controlling variables in the analysis. Gender and age were found to be significant predictor variables. Female respondents cycled less than male respondents during winter, and the older the cyclists were, the more they cycled during winter. Educational level did not seem to be associated with whether the respondents cycled during winter.

In total, the predictor variables explained an acceptable percentage of variance (adjusted R^2 = .33). The results showed that risk tolerance, when cycling in both winter and summer conditions, were the most important predictors of cycling frequency during the winter. The more the cyclists tolerated exposure to risk when cycling in winter conditions, the more they cycled during the winter. By contrast, the less the cyclists tolerated exposure to risk when cycling in summer conditions, the more they cycled during the winter. The inclusion of priority given to safety improved the model and the explained variance improved significantly, but the variables did not separately significantly influence bicycle use. When risk perception was included in the model as the fourth block of variables, the explained variance improved significantly (Table 2). Both the judgements of probability and the severity of consequences when cycling in winter conditions were found important predictors for cycling frequency during winter. The higher the cyclists perceived the probability of being involved in an accident and the more serious the consequence of an accident was perceived, the less they cycled during winter. The perceived severity of consequences was more strongly correlated with cycling frequency than the probability assessment. Additionally, worry related to cycling in winter conditions was found to be an important predictor of cycling frequency. The more worried

Table 2. Dimensions of cycling frequency during winter, showing only the two final steps of the analysis (n = 263).

	Standardized beta coefficient	
	Model 4	Model 5
Block 1: Demographics

the cyclists were, the less they used their bicycle during the winter.

When worry was included in to the model as the last step in the analysis, the risk perception predictors (probability and severity of consequences) lost prediction power. This may indicate that risk perception has an indirect effect on cycling frequency during winter.

4.3 *Predictors of cycling frequency during all seasons of the year*

Our next step was to predict and compare seasonal differences in cycling. A total of four hierarchical multiple regression analyses were carried out, and the results are summarized in Table 3 and Table 4. The same group of predictors as used previously to predict cycling frequency during the winter were used to predict cycling frequency during all the seasons of the year.

Table 3. Predictors of cycling frequency in winter and summer (n = 263).

*p < .05, **p < .01, ***p < .001.

The model explained the largest amount of the variance in cycling frequency during winter (adjusted $R^2 = .33$). The model was least successful in explaining cycling frequency during summer (adjusted $R^2 = .03$). Therefore, we did not find the model a good fit for predicting cycling frequency during summer.

The model explained an identical amount of variance in cycling frequency during spring (adjusted $R^2 = .11$) and autumn (adjusted $R^2 = .11$). For both seasons, risk tolerance and risk perception were significantly associated with frequency of cycling. In addition, worry was significantly associated with frequency of cycling during spring but not autumn.

To summarize, the results showed that risk perception was significantly associated with cycling frequency during winter. However, perceived risk was not strongly associated with cycling frequency during the other seasons. Additionally, worry was found significant for cycling frequency during winter and spring, but not summer and autumn.

4.4 *The role of accident experience in risk perception and worry*

In Study 2, we conducted a MANCOVA to examine whether the group of individuals that had experienced a bicycle accident during the last two years perceived the risk differently from the other individuals in the sample (Table 5), including both their perceived probability being in an accident and the severity of consequences if an accident should occur. In addition, we wanted to investigate differences between these groups with respect to worry about being involved in an accident. The results were controlled for differences in gender, age, and education level. The results showed differences between the two groups for cycling in summer conditions (Wilks' $\lambda = .990$, $F = 6.792$, $p < .001$) and cycling in winter conditions (Wilks'

Table 5. The role of accident experience in risk perception and worry when cycling in summer conditions (n = 2000).

	Accident experience		No accidents last two years		
	Mean	SD	Mean	SD	F (Sig.)
Probability	2.44	1.175	2.16	1.053	10.238***
Consequence	3.28	1.222	3.27	1.253	.084
Worry	2.22	1.191	1.95	1.081	14.233***

*p < .05, **p < .01, ***p < .001.

$\lambda = .995$, $F = 3.232$, $p < .05$). In the following, we only present the results of investigations of differences in risk perception and worry for cycling in summer condition due to the fact that most cycling accidents happen during summer.

As shown in Table 5, individuals that had experienced an accident as a cyclist perceived their probability of being in an accident as higher than did the other individuals. They also tended to be more worried about being involved in an accident when cycling. There were no differences in the perceived severity of consequences between the two groups.

In addition, we conducted two separate MANCOVAs. One tested whether the experience of an accident that involved other road-users would influence the perception of risk or worry, and the other tested whether the need for medical help after an accident influenced the perception of risk or worry. There were no significant correlations.

5 DISCUSSION

The results showed seasonal differences in work travel cyclists' perceptions of risk, worry, and risk tolerance when cycling. The risk of being involved in an accident was perceived as higher and the cyclists tended to be more worried about such incidents and tolerated less risk when cycling in winter conditions compared with cycling in summer condition. Primarily, the probability of being involved in an accident was perceived as higher when cycling in winter conditions. There were no differences in the perceived severity of consequences. With darkness and icy and snowy roads in Norway in winter, it is natural that cycling in winter may be perceived as a bigger challenge than in summer, and the probability of being involved in an accident in winter was perceived as increased. One reason why the consequences were not perceived as increased might have been that the type of accidents the cyclists imagined they could be involved in did not differ with winter and summer conditions.

We found that, on average, the respondents cycled less during the winter season. Further, the results showed that risk perception, worry, and risk tolerance influenced cycling frequency during the winter season. The assessment of risk was less important for cycling frequency during the other seasons of the year. One explanation for this is that risk in general is perceived as very low when cycling in summer condition and that a cyclist has to experience that a risk is over their tolerance threshold before it will influence their behaviour.

In common with other researchers (Hermand et al., 1999, Lawson et al., 2013, Manton et al., 2016, Moen & Rundmo, 2006, Parkin et al., 2007, Sjöberg, 1998, 2000), we found that demographic variables were associated with risk perception, risk tolerance, and worry. Compared with males, females tended to tolerate risk less, and they were more worried about involvement in an accident and perceived the risk as higher.

The results of our study contribute to an understanding of why work travel cyclists in Norway cycle less during the winter than in other seasons of the year. From a pro-environmental perspective, it is important that people who use bicycles for their daily commutes and work-related travel do not change to motorized modes of travel during the winter season. Campaigns that aim to increase the number of cyclists may be ineffective if they do not take into account that the risk of being involved in an accident is perceived differently during the different seasons of the year.

The results from Study 2 showed that accident experience can influence risk perception and worry when cycling. Primarily, the probability of being in an accident was perceived as higher for who had experienced an accident compared with persons who had not experienced an accident when cycling. The perceived severity of consequences did not differ between individuals who had experienced an accident and those who had not, and in general the consequences were perceived as serious. This may have been due to the fact that the cycling accidents reported in the media are often the most serious ones.

The response rate in Study 1 was relatively low and can be regarded as a limitation of our study. However, low response rates do not necessary constitute a methodological problem. Rather, this is only the case if the sample is overall non-representative of the target population (Krosnick, 1999). We did not have any information about the non-respondents, and we cannot draw any conclusions about whether the respondents and the non-respondents differed significantly. However, the target group of the study was work travel cyclists who cycled on a daily base. We assume that those who cycled often also visited the web page, from where the respondents were recruited, more often than other cyclists.

6 CONCLUSION

Study 1 showed seasonal differences in how work travel cyclists perceived the risk and how worried they were about being involved in an accident as well as how they tolerated being exposed to the risk. As expected, cyclists perceived the risk as higher, were less tolerant of risk, and were more worried about being involved in an accident when cycling in winter conditions compared with cycling in summer conditions. Further, the results showed

that risk perception, worry, and risk tolerance influenced cycling frequency during winter. The poor prediction of the model for cycling frequency during spring, summer, and autumn may have been due to the fact that the majority of the respondents perceived the risk as low during these seasons. Lastly, Study 2 showed that previous experience of an accident was associated with risk perception and worry.

Statoil ASA, Oslo, Norway

ABSTRACT: This paper addresses Operational Barrier Elements (OBE) to strengthen the management of Major Accident Hazards (MAH) in major oil and gas field development project. OBE are defined as safety critical tasks that contribute to prevent and mitigate major accident hazards. 87 OBEs were identified, distributed across four platforms and 15 safety performance standards. The majority of the OBEs are related to gas detection, emergency shut-down, active fire protection, and well integrity. The primary output of the activity is Performance Requirements (PR) for each OBE, and recommendations for strengthening human performance through Performance Influencing Factors (PIF). OBEs were integrated in the field wide safety strategies, and the Operational Readiness team incorporated the OBEs in System descriptions and Operational Procedures (SO). Even though no critical deficiencies in design or barriers were identified, systematic integration of OBEs in engineering and operations will strengthen the fields robustness to withstand major accidents hazards in operations.

1 INTRODUCTION

1.1 *Background*

In recent years there has been a renewed focus on the concept of safety barriers, including safety critical tasks, and its role to prevent and mitigate major accident hazards on the Norwegian Continental Shelf. Partly, this is due to the Macondo accident where human and organizational factors contributed to escalation of the accident (CSB, 2016). In volume 3 of the Macondo well incident investigation report, CSB assert that the safety barrier concept must extend beyond physical safeguard, and that solutions to technical failures cannot prevent future incidents without giving equal attention to failures of less visible, non-physical barriers and support systems (CSB, 2016, pp. 19).

The Norwegian Petroleum Safety Authority (PSA) reinforces these conclusion by describing the principles for barrier management in the petroleum industry (2013; 2017). Here, safety barrier management is defined as the systematic effort to ensure that barriers are in place to provide protection of hazards and accident situations (PSA, 2017).

Traditionally, major accidents risk on offshore petroleum installations is reduced by striving for inherently safe design, automation systems and fail-safe principles. PSA (2017), however, states that the design of safe and robust installations is not sufficient to protect against failures and hazard and that accident will continue to happen. It is postulated that most major accidents are significantly influenced by human actions, both in cause and consequence. Hence, since the safety of petroleum installations are dependent on reliable human performance, safety barrier management must incorporate operational and organizational aspects, in addition to the mere technical ones (PSA 2017).

Barriers and controls mechanisms are often visualized as a bow-tie diagram, with a top event in the center of the model, with the hazards and preventive barrier on the left-hand side, and barrier for mitigation of the event on the right-hand side (Ruijter & Guldenmund, 2014). In Leva, Angel, Plot & Gattuso, (2013) the bow-tie model is applied to assess a scenario where human actions are the main barrier to accidental conditions (overfilling a storage vessel).

The concept of operational barriers in the petroleum industry are addressed in several recent publications. In addition to the PSA, the Norwegian Shipowner Association's (NSA) report on good practices for barrier management for the rig industry (NSA, 2014) provide definitions and framework that are in line with the methodology outlined in this paper. Similarly, Hauge & Øien, (2016) provide practical guidelines for barrier management in the petroleum industry, in accordance to the recommendations in PSA (2013).

In a recent paper on human factors in barrier management, McLeod (2017) describes three generic types of barriers against threats, and their order of importance, or expected strength:

- Engineered controls, which are physical, technical and automated barriers
- Organizational control, including governing systems and procedures, team organization etc.
- Human Controls, which are the individual factors such as training, competence etc.

According to McLeod (2017), human performance is central in maintaining and ensuring the integrity of barriers. Instead of considering human error as a hazard, the focus should be on improving the resilience of barriers, to be able to withstand human errors that degrade the barriers.

1.2 *Safety critical tasks*

Task analysis is the study of what a person is required to do, in terms of actions and mental processes, to achieve a goal (Kirwan & Ainsworth, 1992). For SCTA, Energy Institute (EI) extends this to tasks which contributes to MAHs in positive or negative ways including: initiating events; prevention and detection; control and mitigation, and emergency response. EI list the following steps of SCTA:

1. Identify main MAHs
2. Identify safety critical tasks
3. Understand tasks
4. Represent critical tasks
5. Identify human failures and PIF
6. Determine safety measures

According to OGP (2011), a safety critical task inventory should be established for projects involving major accident hazard potential, e.g. to summarize all human tasks which are identified a safety barrier.

Human performance of safety critical tasks is shaped by a range of factors, which, depending on the operational context, can drive performance both in a negative and positive direction. Systematic management of such PIFs is a key to ensure that Operational Barrier Elements (OBE) are effective.

Different methodologies apply different sets of PIFs. As a basis for establishing a standard framework of PIFs, various methods were reviewed. PIFs generally can be classified into four main categories: According to Boring & Blackman (2007, p. 177), a PIF is an aspect of the human's individual characteristics, environment, organization, or task that specifically decrements or improves human performance, thus respectively increasing or decreasing the "likelihood of human error" (Boring & Blackman, 2007, p. 177).

In the context of operational barriers or safety critical tasks, PIFs are the factors which have a significant effect on barrier element performance. In this context, the definition refers to individual, workplace or other contextual factors which have significant effect on an operator or crews of operator's performance. A task based approach to OBE enables application of Human Reliability Analysis (HRA) to assess the qualitative or quantitative reliability of Safety Critical Tasks. According to Bye et al (2017), HRA can be applied to assess and understand human actions as barriers in major accidents.

Quantification of Human Error Probability can provide valuable input to decision making, i.e. whether to implement design measures such as technical systems to eliminate risk, or whether the risk can be considered acceptable, and operational measures are sufficient. Petro-HRA applies a list eight Performance Shaping Factors (PSF), which are modified for a petroleum context based on SPAR-H (U.S. Nuclear Regulatory Commission, 2005). According to Bye et al. (2017) only the PSFs that have been shown in general psychological literature and in other HRA methods to have a substantial effect on human performance when performing control room tasks are included in Petro-HRA. This includes:

- Task factors: task complexity, time, procedures
- Individual factors: threat stress, experience/ training
- Organizational factors: teamwork, attitudes,
- Environmental factors: physical working environment.

In the framework described in this paper, the PIFs defined in Bye et al. (2017) was selected for assessment of the safety critical tasks. In engineering, the first step of strengthening task performance is through task design, e.g. removing the task entirely by automating a manual task, increasing level of automation or introducing additional technical barrier elements. Other measures to improve human reliability is adapting the physical configuration, conditions and surroundings to human cognition and anthropometrics, e.g. through human centered design (ISO 11064-1).

1.3 *Definitions*

Requirements to operational barriers are outlined in Statoil governing documentation, and chapter 5 of PSA management regulation. Safety barriers shall be effective in all situations, and the role to maintain its intended safety functions must be well-known across the organization PSA, (2017).

This paper applies definitions provided in the Statoil internal report Definitions and guidelines for non-technical barriers (Gould, Sklet & Ludvigsen, 2015), which aimed to standardize the definition and application of operational barrier elements in safety barrier management in Statoil.

In this report**, an operational barrier element** is defined as the safety-critical tasks performed by a person, or team of personnel, which realizes one or several barrier functions.

A technical barrier element is defined as engineered equipment, systems and structures which realize one or several barrier functions.

A barrier function consists of the range of technical systems, structures, personnel and tasks, which are required to fulfill ("realize") the barrier function. These are referred to as barrier elements, and can be defined as technical or operational measures which alone or together realize one or several barrier functions.

Performance Requirements (PRs) shall be established both for technical and operational barrier elements. Performance requirements for operational barrier elements include a description of how the task should be conducted, who is responsible for performing a task (the formal role), and if possible, when (time criterion).

Safety Critical Tasks (SCT) are the physical actions or activities by which human performance contributes positively or negatively to major accident risk, through either:

- Initiation of events;
- Detection and prevention;
- Control and mitigation; or,
- Emergency response

A similar definition is provided by the Energy Institute's report on Safety Critical Task analysis (2011). However, the SCT term is broader and covers a wider range of tasks than just OBEs. Some tasks can be critical because of their indirect influence on barrier performance. This typically refers to inspection, testing and maintenance of technical barrier elements.

This paper aims to capture SCTs that can be defined as OBEs, i.e. tasks that have a direct and real-time role in realizing a barrier function related to preventing or mitigating major accident hazards in an accident sequence are included. The work aimed to strengthen barrier performance by systematically addressing operational elements throughout engineering, to enable barrier management in operations.

OBE includes task required for realization of on-demand barrier functions, where human performance directly contribute to the availability or integrity of a barrier function, as maintaining the primary barrier during well operations, crane operations, and containment during maintenance, etc.

Barrier functions may be gas detection, Emergency Shut Down (ESD), blowdown, etc., where human action may prevent an accident, or where an omission or error of commission may directly contribute to the unavailability or degradation of a barrier function.

In this context, major accidents are accidents leading to multiple fatalities, major environmental harm or loss of an asset. The term "hazard" is a potential source of harm. The term "defined situations of hazard and accident" (DSHA) refers to a selection of hazardous and accidental events that will be used for the dimensioning of the emergency preparedness for the activity.

1.4 *Limitations*

Process disturbances or minor deviations during normal operations are excluded, because they are controlled by inherent safety measures or by control mechanisms that prevent escalation.

Tasks which have an indirect influence on the barrier function are excluded, and for which routine work and operational safeguards are an established part of planned maintenance or safe work process. This may be task such as:

- Routine inspections to check condition
- Maintenance, calibration and testing
- Inhibitions of safety systems as part of planned operations
- Work permits and safe job analysis
- Purely administrative tasks, such as handovers, issuing work orders etc.

The framework does not address barriers that protect against risks related to working environment, personal injury, security, or production regularity. Topics such as strategic management of change, organizational learning, and safety culture are all considered important, are also excluded from the framework described in the paper. This is in line with guidelines stipulate in Gould et al. (2015).

2 CASE STUDY

2.1 *Project description*

The project is one of the five largest oil and gas fields on the NCS. The resources are estimated to be between 2.0–3.0 billion barrels of oil equivalents,

and peak production will reach 660,000 barrels daily. The field will be operated by electrical power generated onshore, reducing offshore emissions of climate gases by 80%–90% compared to installations utilizing gas turbines.

The field development consists of four interconnected topside platforms, including a Living Quarter with more than 500 beds, Drilling Platform with utility module and integrated drilling facilities, Process Platform including 3 stage separation process and gas compression equipment, and a Riser Platform with oil and gas export risers.

The engineering of the different platforms is performed by different engineering teams at separate locations. The field has several safety critical interfaces, such as facility for converting power from shore, gas export pipeline to an onshore plant and oil export pipeline to an onshore oil refinery.

The entire field will be controlled from the Control Centre, including Central Control Room and Emergence Control Centre located at the Living Quarter. The size, complexity and value of the field make high demands on safety and productivity. Production start for Phase One is planned for late 2019.

2.2 *Scope*

This paper describes the effort put into operationalizing the theoretical framework presented above through identifying, analyzing and defining operational barriers in a major oil & gas field development project. The goal of mapping and assessing OBEs was to define the factors that shape human performance, and to strengthen these factors through engineering and operational readiness. This will enable a systematic framework for management of operational safety barriers in operation.

3 METHODOLOGY

3.1 *Mapping and assessment of operational barrier elements*

The methodology for mapping and assessment of OBE is described in a project specific Terms of reference (ToR) document. The purpose of the ToR is to establish guiding principles for the work, and ensure standardization across different platforms and contractors. The method is divided into two main steps, summarized in the section below.

3.2 *Identification and assessment of safety critical tasks*

Data required for identification and assessment of Safety Critical Tasks (SCT) was primarily collected by means of document reviews and workshops with Operations and technical disciplines (Energy Institute, 2011).

First, Safety Critical Tasks were identified by reviewing project information and documentation, and attending workshops (HAZOPs, LOPAs, etc). Experience from other installations and projects was also gathered as input to the SCTA inventory.

A set of meetings and workshops were arranged to collect and analyze the data, task identification and screening. The meetings followed the activities described in the project Terms of Reference, and mostly involved representatives from Statoil Operations and relevant technical disciplines on each platform.

Second, a screening of the SCTA in terms of risk and relevance, and where it could be consisted as critical for realizing a barrier function. Screening criteria consisted of:

- Barrier functions that are depended on the task performance
- The consequence of human failure
- The severity of the MAH
- Task familiarity and complexity

The outcome of the screening was a list of proposed Operational Barrier Elements. The aim of the screening analysis was to reduce the number of tasks such that further work would be limited to the ones significantly contributing to the risk picture. For the tasks identified as highly critical against a set of pre-defined criteria, more detailed task and failure analysis was conducted:

- OBE task analysis; provide task description and assessment of Performance Influencing Factors
- OBE failure analysis; objective is to identify and mitigate risk associated with human failures
- Assessment of Performance Influencing Factors
- Definition of design requirements

Although the definition of major accident refers to safety, environment and asset losses, only OBEs which have a role in managing MAHs with an impact to safety and environment were considered.

A set of criticality levels were used to identify tasks where the barrier function itself is automatic, but where the operator(s) has a back-up role in monitoring and correcting system performance (if necessary).

For example, the task "Manual cancellation of Emergency Depressurization DP in case of gas leak in the flare system/ KO drum" was considered as highly critical. One of the concerns about this task was whether it was applicable to all or just a specific set of scenarios involving gas leaks in the flare system or Knock-Out drum. Discussions focused on whether the Control Room Operator would be able to perform this task safely and reliably, and if there will be enough time available for decision-making and action. To be able to address

these questions in a systematic manner a set of different scenarios was assessed.

3.3 *Definition of performance requirements and performance influencing factors*

This step consisted of definition of performance requirements to each OBE, and providing recommendations about how to improve design and operations to optimize relevant PIFs.

PSA (2017) states that definition of performance requirements is an essential part of establishing effective barrier management. Establishing PRs to OBEs is an integral part of this. Performance Requirements (PRs) are verifiable requirements related to barrier elements to ensure that the intended barrier function is effective (PSA, 2017). For each OBE, the following performance requirements are defined:

1. Coarse description of how the task should be conducted
2. Who is responsible for the task (formal role)
3. When the task need to be conducted
4. If feasible: time available for task performance
5. If feasible: criterion for successful task performance

PRs were established as part of a series of OBE tasks analysis workshops relevant technical disciplines and operations. The agenda of the workshops was structured according to a standard list of Safety Performance Standards (PS), and the OBEs related to these. Participants of the workshops included process technicians (end users), technical safety, process and instrument system responsible and platform management. The information from the OBE analysis was structured according to the following parameters:

- Unique ID
- Reference to relevant safety strategy
- Platform and Areas
- Major Accident Hazard
- Barrier Function
- Performance Standard
- Operational Barrier Element
- Performance Requirement

The main output from this stage included draft Performance Requirement for each OBE, and Design and Operational recommendation, proposed for strengthening the PIFs.

3.4 *Quality assessment and alignment meetings*

Since the OBE framework adapted by the project was new, alignment with key stakeholders in the project was necessary. End-user representatives participated during all phases of the work, however alignment meeting with engineering and operational management was required to ensure mutual understanding of purpose, scope and method, agree upon the quality of the results, and how the results best should be applied by operational readiness.

4 RESULTS

The results section is divided into four sections, including; (1) Operational Barrier Elements and Performance recommendations; (2) inclusion in safety barrier strategies; (3) implementation of recommendations in design; and (4) incorporation of results in Operational Readiness.

4.1 *Operational barrier elements and performance requirements*

87 OBEs were identified for the field development project, and distributed across 15 safety performance standards (see Figure 1 below). Almost half of the OBEs were categorized as generic, indicating that they are applicable to the entire field, not to specific platforms. The drilling platform has highest recorded frequency of OBEs (22), followed by the riser platform (11), process platform (5), and Living Quarter (4) (see Figure 1 below).

Figure 2 illustrates how OBEs are distributed across performance standards. The PSs with

PS	PS 3 – Gas detection
Barrier function	Prevent ignition of H2 gas
OBE	Respond to H2 alarm from battery rooms.
PR	Upon H2 gas detection in battery rooms, the CRO shall electrically isolate the area using the MEI function on the CAP panel. The CRO shall communicate with the Electrical team to ensure the affected room remains unoccupied until the H2 gas has been dispersed via the HVAC and the H2 alarm has been cleared.
Design measures	New HMI symbol H2 gas Priority 1 alarm Alarm text: "Informer over PA Følg instruksen i DFU"
SO	Included in system description for system 84 and 85

highest number of OBEs are Emergency Shutdown (17), Well integrity in drilling (15), Active Fire protection (11), Gas Detection (9), Emergency depressurization (7) and Offshore Cranes (6).

Two examples of how the results are structured are provided below. These data are extracted from the OBE master database.

4.2 *Inclusion of OBE in safety barrier strategies*

During engineering, five separate safety strategies were established, i.e. one for each facility/platform, and one for the entire field. The safety strategies have a standard organization, included common definitions of barrier terminology. A purpose of the safety strategies is to outline the role of safety barriers to be implemented to manage the risks that have been identified for the project. The strategy is used by Operations to understand how risks of major accidents are managed on the field and for each specific area. OBEs and associated Performance Requirements are written into the project safety strategies, established during engineering. The OBEs are related to the relevant safety barrier functions and technical barrier elements.

4.3 *Implementation of recommendation in design*

To ensure traceability and inclusion in design, the main recommendation was included in action follow-up system to be formally handled as part of engineering quality system.

A total of 81 design measures were implemented. It should be noted that these measures are in addition to the Human Factors Engineering process performed in the project (ISO 11064). Most of the findings were related to enabling situation awareness by means of alarm priority and alarm descriptions, operator station HMI and Large Screen Display design. In total, 45 measures were included on HMI (large screen and operators displays), and 38 measures were implemented in the configuration alarm system (alarm priority, alarm text or operator guidance, etc.). This included input to HMI for platform crane cabin and drillers cabin.

The PS that have the highest number of measures are ESD, (23) active fire protection (15), and gas detection (13), see Figure 4 below.

4.4 *Operational readiness*

An essential goal for mapping and assessing of OBE was that the results should be adopted by

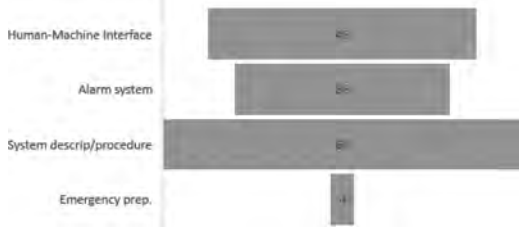

Figure 3. Record of recommendations implemented in design and operational readiness.

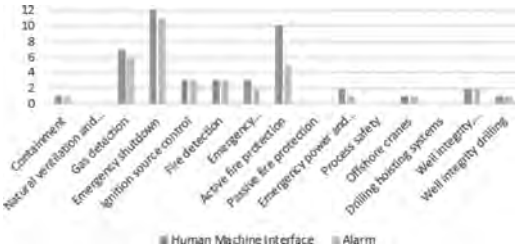

Figure 4. Record of recommendations implemented in HMI and alarm system per performance standard.

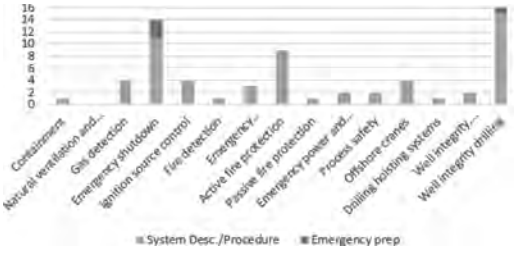

Figure 5. Record of reccomendations implemented in system descriptions & procedures, and emergency preparedness plan.

operational readiness for use in operations. The outcome of mapping and assessment of OBE included a set of recommendations for improvement of human performance through operational readiness.

When the results were finalized, the information was documented in a master OBE database, with additional parameters:

- Reference to existing work process or procedure for a generic OBE
- Actions
- Status of action, i.e. implemented in SO, design etc.

The master database is shared by engineering and operations. The results from the master list is maintained by engineering, and implemented in operational documentation by Operational Readiness.

These are measures such as inclusion of OBE in system description and operational procedures, referred to as SO documents. These documents are organized according to system number, so the results were converted from PSs to systems.

In total, 64 measures were implemented in System Descriptions and Operational Procedures (SO).

The results in the master database was reviewed as part of developing the Emergency Preparedness Plan. Four elements from the database were used as direct input to these plans. One of the purposes of the SO documentation is to provide as a basis for operator training, which is the next step of the project.

5 CONCLUSION

This paper described the systematic integration of operational barrier elements in design and barrier management to strengthening an oil and gas field's robustness to withstand major accidents hazards. The results show how the barrier framework was successfully applied in an engineering context. The results presented indicate how the project captured the criticality of the human role in preventing and mitigating major accident hazards, and ensuring efficient detection, initiate or control effective emergency shutdown, and realize sufficient active fire-fighting means. Also, the human role as a continuous operational barrier in ensuring sufficient well integrity in drilling, and safe operations of offshore cranes is assessed and described.

An essential part of a control room operator role is to monitor and control that safety and automatic systems perform on demand, and act accordingly if these systems fail. It was decided to include the most critical of these control tasks, because they provide valuable input to system design, procedures and other PIFs. Also, it gives an improved understanding of the interaction between technical and operational barrier elements across different accident scenarios.

By limiting OBE to mere cases where the barrier function is entirely dependent on a direct, physical human action, we would not capture the factual human role in protecting and mitigating against MAH, and the dependency between technical and operational barrier elements during accident.

Applying this framework early in detailed engineering allowed for providing input to design. Throughout engineering, adjustments have been made to HMI, alarm system, but also the physical design of the facility to either remove/reduce human intervention or to optimize human reliability. Furthermore, applying the framework in engineering allowed a systematic focus on safety critical tasks in developing procedures, emergency preparedness plans and training. Inclusion of OBE in safety strategies help to improve risk awareness in operations, as OBE and PRs shall be known by the management and the roles responsible for realizing the OBEs.

A central concept in human factors engineering is the use of iterative design cycles. Likewise, it is beneficial to allow for several iterations when working with operational barriers. For example, the project would have benefited from starting earlier than detailed design (e.g. Front-End Engineering and Design), however at a cost of available details to work with. The OBE work for this

project started in Detailed Design and applied several iterations to come to sufficient maturity before starting developing procedures and training.

Currently, the project has focused on identifying and defining OBE and their corresponding PR, facilitating operator reliability through design adjustments, procedures and training. The next steps in the barrier framework are to set up assurance and verification activities to ensure barrier functions remain intact under daily operations and to ensure that the performance of the barriers is working as intended (NSA, 2014).

The framework described in this paper demonstrated the benefits of including assessment of safety critical tasks and PIFs in an engineering context. Second, the performance requirements for OBEs have provided operational readiness with risk-informed input to development of system descriptions, procedures and training program of the operational phase. Third, the framework provides a better understanding of the mutual dependency between operational barrier elements and technical barrier elements in realizing barrier functions, thus contribute to strengthen the field's safety barrier management.

ACKNOWLEDGEMENTS

We would like to acknowledge the contributions made by Sondre Øie and Barnaby Annan for their technical knowledge and developing the project specific methodology.

Naturalistic decision making in process control: The guidance-expertise model and the model of resilience in situation

S. Massaiu
Institute for Energy Technology, Halden, Norway

ABSTRACT: The defining elements of naturalistic decision-making, such as proficient decision makers, ill-defined goals, uncertainty, high stakes, tools, and teamwork, are clearly present in process control. However, the domain is still heavily anchored in normative approaches for design, analysis and evaluation of human-technology systems that make unrealistic assumptions about the operators. The paper presents two naturalistic decision making models for process control developed in the nuclear power production sector and based on extensive observations of control room emergency operation in high-fidelity, human-in-the-loop simulators: the Guidance-Expertise Model (GEM) and the Model of Resilience in Situation (MRS). Unlike better-known naturalistic decision-making models, the GEM and MRS models recognize the central role that operating procedures and other organizational prescriptions play in process control decision making, elaborating on aspects that so far have received little attention in the naturalistic decision making community.

1 INTRODUCTION

1.1 *Process control and naturalistic decision making*

Control centers operators in process industries supervise systems that are extensively automated and intervene in case of malfunctions. Control centers are technological environments in which the operators' interactions with the system are mediated by human-machine interfaces and supported by decision aids ranging from pen and paper to intelligent expert-systems. The single most important decision support aid used by control centers operators is represented by the operating procedures. In the nuclear energy sector, for instance, when an emergency arises the control room operators respond by immediately opening the emergency operating procedures and implementing these until the reactor is brought to a safe state. In this environment understanding decision-making requires understanding how the operators interact with the procedures. The second distinguishing aspect of decision-making in process control industries is the collective nature of the decisions. Most of the times the decisions are made by groups, often called operating crews. Even when single operators are the decision makers, the high level of proceduralization of their work implies some sort of deferred relation with other actors like procedure designers, trainers, or management, who sets expectations on the decisions and behavior of the front-line operators. The most critical decisions in process control centers occur during incidents and accents. In such conditions the decision landscape typically include elements of time pressure, stress, ill-defined or conflicting goals, uncertainty about conditions, and high stakes. In other words, process control is a good illustration of all defining elements of naturalistic decision-making (Lipshitz, Klein, Orasanu, & Salas, 2001). At the same time the central role of operating procedures (and other organizational prescriptions) for process control is an aspect that sets it apart from other, more studied, naturalistic settings and makes widely-known naturalistic decision making models less readily applicable to the sector.

1.2 *The prevalence of normative approaches in process control*

Although process control decision-making is clearly a naturalistic setting, normative approaches still dominate system analysis, evaluation and design in the sector. This is likely a legacy from when these industries viewed their technical core areas as sufficient for designing productive and safe systems. The nuclear industry, for example, did not pay attention to human and organizational factors before the Three Mile Island and Chernobyl accidents, assuming that reactor physics, thermodynamics and other technical factors were solely responsible for designing safe plants (Moray & Huey, 1988). In normative approaches the operators are assigned the role of executors of procedures. As the procedures incorporate the rational

benchmark for how to behave in different situations, they define what the operators are required to do in terms of actions, and even cognitive processes, in order to achieve the system's goals. The situations for which the procedures are made are seen as predictable conditions in which there are limited ways of performing the tasks correctly. Although these assumptions may have been appropriate for workers of the first industrial revolution, they are inadequate for automated and computerized production processes (Vicente, 1999). These are characterized by external disturbances (unanticipated faults, automation failures) and other forms of uncertainty (degraded indicators) for which the procedures do not apply and in which the operators are required to adapt to moment-by-moment changes in conditions by generating appropriate responses based on their conceptual understanding of the work domain. In such cases there are no standards of correct performance and no predefined correct decisions, if not after the fact. Research from anthropology, activity theory and naturalistic decision making has show that "workers' actions frequently do not—and indeed, should not—always follow these normative prescriptions" (id., p. 62). From the point of view of this paper the main problem of relying on normative approaches to decision making in process control is that the assumptions they make on the operators are not realistic and therefore of limited use for the design, analysis and evaluation of systems in which human and organizational factors play a critical role.

2 NATURALISTIC MODELS OF PROCESS CONTROL DECISION-MAKING

This section describes two naturalistic decision making models for process control work. They are both based on extensive observations of nuclear power plant control room emergency operation in high-fidelity, human-in-the-loop simulators. This section provides a description of the models' theoretical foils, concepts, purposes and applications. Their limitations will be discussed also taking into account their level of maturity and intended use.

2.1 *The guidance-expertise model of procedure following*

The Guidance-Expertise Model of Procedure Following (GEM) is a methodology to describe and predict nuclear power plant operating crews' behavior in emergency operation (Massaiu, Hildebrandt, & Bone, 2011; Massaiu & Bones, 2011). The model, based on the framework of cognitive system engineering (Rasmussen, Pejtersen-Mark, & Goodstein, 1994) assumes

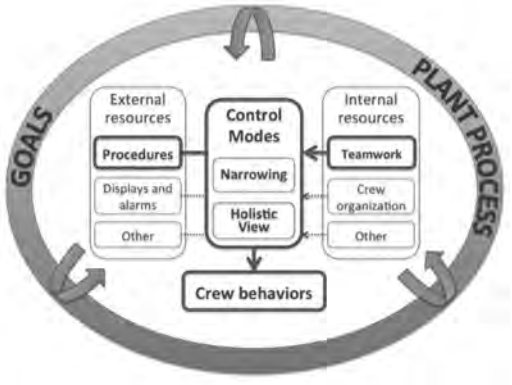

Figure 1. Conceptual diagram for the Guidance-Expertise Model of procedure following (GEM).

that macrocognitive processes, or control modes, determine decisions in proceduralized operational environments (Figure 1). In cognitive system engineering control is defined as the way the next action at any given point in time is chosen. Cognitive control refers to the organization of cognitive functions (e.g. monitoring, evaluating) and processes (e.g. heuristics, externalization of memory storage) in a situation (Hollnagel, 1998). Control modes in the language of activity theory are different orientations towards the object of activity that result in different ways of acting (Kaptelinin & Nardi, 2006). Basically, the control modes are different ways of thinking in a situation that determine behavior.

The GEM model borrows the language of 'situated course-of-action' theory (Theureau, Jeffroy, & Vermersch, 2000) and defines three control modes: Narrowing, Holistic View and Persisting Narrowing. During narrowing the operator's horizon is limited by what is referenced by the procedures. When the operators read the procedure in this mode their attention is focused, the situations are classified by their structural-mechanistic features, and are mapped into pre-planned methods of action. During narrowing, information is not actively searched for except for what is required by the procedure. The pre-planned methods for actions are incorporated in the emergency procedures as well as previously trained. Narrowing in a broader sense is the cognitive control mode in which the operators let the procedures guide them and do not try to figure out ad-hoc plans for dealing with the situation.

Holistic view occurs when the operators interpret the procedure steps relative to the situation dynamics, which include the activities of automated systems and of other people. As such it is analogous to the concepts of situation awareness and sense-making. In holistic view information is actively searched

for in the control panels and through communication with other crewmembers to create an interpretation of the situation in a functional way, by considering the process as an integral whole. Holistic view takes into account larger time windows: the present is explained as the effect of previous events (diagnosis), the future evolution is represented to evaluate if the planned course of action is appropriate (Lipshitz et al., 2001). Holistic view includes metacognition (thinking about thinking) which will manifest itself in activities such as reconsidering the course of actions, determining whether to act outside the procedure while following them, redirecting procedure paths, detecting strains in teamwork and making adjustments.

Switching from one control mode to the other can be challenging in several ways, as the two modes require different cognitive effort and different configurations of cognitive functions, including how much is memorized and consciously represented. Changing from holistic view to narrowing implies difficulties in establishing the necessary local focus and attention as well as the right procedures progression pace. It can also challenge the capacity to re-construct an uncompleted course of action from the exact point it was left. Low-level errors, like slips and lapses, might occur as a result. Yet, most performance difficulties occur when the required control mode is holistic view but the crew struggle in establishing it, thereby continuing in narrowing mode. A typical example is when the crew starts engaging in problem solving behavior (e.g., discussion of transfer points, evaluation of novel events) but ends up reverting to literal procedural adherence. In such cases sustained periods of narrowing impede the achievement of a holistic view (i.e., a level of situation awareness adequate to develop an autonomous plan of action). This state is termed '*persistent narrowing*' and is considered a third control mode. The longer the narrowing continues, the higher the risk of losing global situation understanding. For self-paced processes, like emergency operation in nuclear power plants, the more the crew lags behind the process the more it will be pushed into a reactive mode and the more difficult it will be to achieve holistic view. Persistent narrowing ends when the crew is able to constructively generate a solution strategy, even if this is not an effective one.

In order to make predictions regarding crew behavior in emergency situations, the GEM model relates the control modes to aspects of the situation on one side and to aspects of crew expertise on the other. Regularities among situations, control modes and expertise for specific operational settings are derived from empirical human-in-the-loop simulations. The model outcome behaviors are task-independent behaviors that nuclear power plant operating crews exhibit in emergencies (Table 1).

Table 1. The 16 outcome behaviors included in the GEM model are task-independent behaviors that nuclear power plant operating crews exhibit in emergencies.

#	Outcome behaviour
1	Slow progression by meticulous procedure following
2	Slow reaction to *recently discovered* information
3	No reaction to *important* information received
4	No/slow action to unexpected event
5	Literal step following rather than purpose
6	Incorrect procedural transition
7	Cue explained away
8	Notes/warning/foldout pages ignored
9	No priority between concurrent goals
10	Priority given to minor goal/most recent deviation
11	Autonomous decision avoided
12	Successful step execution
13	Incomplete step execution
14	Inference to previous condition not made
15	Sub-step skipped
16	Stuck in procedure step

According to the model, two formal features of the emergency procedures are the most important environmental aspects to consider. Procedural features are identified as being either 'loose' or 'detailed', with the understanding that there is variance of the degree. Broadly speaking, when the procedures provide meticulous step-by-step direction they are pronounced to be "detailed", otherwise as "loose" (e.g., evaluation of trends, adjustment and control actions, navigational decisions).

Empirically observed regularities between procedural features and control modes should help predicting the crews' procedure progression in accidental conditions. According to the model the procedures-behavior pairings are in fact determined by the control modes, which in turn are determined by the crew expertise. In GEM expertise is measured by teamwork indicators through a classification scheme based on both generic and nuclear-specific process control teamwork literature (Braarud & Johansson, 2010; Klein, 1999; Norros, 2004; Salas et al., 2005; O'Connor et al., 2008). The model considers 8 teamwork dimensions: monitoring progress, communicating intents, communicating interpretations, looking for same cues, reconciling viewpoints, adapting, backing-up, team monitoring & flexibility.

The GEM model has thus three elements: (1) structural features of the procedures, (2) control modes, and (3) the crew expertise.

2.1.1 *Application of the GEM model*

The GEM methodology was tested by Massaiu and Bones (2011) in a retrospective analysis of

74 critical decisions by four Nuclear Power Plant (NPP) operating crews' in simulated Steam Generator Tube Rupture (SGTR) events (Massaiu & Bones, 2011). The four crews that exhibited most operational difficulties (the models' outcome behaviors) were selected to test whether the model could describe the observed performances and help estimating the likelihood of the outcome behaviors given observable aspects of the context of action (i.e., the procedural features) and the crew cognitive control modes.

The analysis showed different patterns of outcome behaviors, control modes and procedural conditions as well as different patterns between the crew expertise (as measured by indicators of teamwork proficiency) and observed control modes. For instance, almost all the times a crew transitioned to a wrong procedure (outcome behavior 6 in Table 1) it was with 'loose' procedural guidance and in 'persistent narrowing' control mode. Different teamwork characteristics were associated with the three control modes. The preliminary results showed that nearly all instances of positive teamwork were observed under the 'holistic view' control mode, and that all negative teamwork dimensions were observed when the crews exhibited 'persistent narrowing'. No positive teamwork indictors and some negative indicators were observed when the crews were in 'narrowing' mode (and to a lesser degree than when in 'persistent narrowing').

2.1.2 *Evaluation of the GEM methodology*

The GEM model can be used as classification system for analysis of observed team decision-making and behavior. Its main benefit is the possibility of evaluating the likelihood of outcome behaviors given observable features of the environment and to measured team expertise. The intended use of the methodology is for cognitive simulation and predictive task analysis. However the methodology has been tested on a small data set only and a number of challenges remain to be solved. These are the main ones:

1. The set of outcome behavior is not a complete and not-overlapping set.
2. Further aspects of the guidance system should be included (e.g., the crew operating policies and training).
3. The model is currently limited to two environmental features: the procedural features and the crew expertise (which determines the control mode). Although these are recognized as the most important factors for crew performance in emergency, the inclusion of other structural features of task and environment in the model is likely necessary for improving its predictive accuracy.

2.1.3 *The model of resilience in situation*

The Model of Resilience in Situation underlies the human reliability method MERMOS (Pierre Le Bot, Cara, & Bieder, 1999). Its primary application has been in the context of predictive risk analysis, but it has proved a valid tool for retrospective accident analysis in the nuclear (Le Bot, 2004) and medical (Le Bot, 2008) fields. Recently it has been proposed as a way to analyze human and organizational factors in a High Reliability Organizations perspective for supporting design of risk-critical systems (Le Bot & Pesme, 2014).

The MRS explains how operating teams in emergency organizations make decisions during the course of an accident. The model is based on Jean-Daniel Reynaud's theory of social regulation (Reynaud, 1989), a sociological theory that understands social relations (particularly in the working environment) as social regulations, that is, the social production of formal and informal rules governing the behavior of groups.

In the MRS the object of analysis is the Emergency Operating System (EOS), the ensemble of control room operating crew, the human-machine interface, and the operating procedures. The MRS is about team decision-making mediated by technology and procedures and thus consistent with Edward Hutchins' distributed cognition paradigm (Hutchins, 1995; Hutchins & Klausen, 1998) in assuming that cognitive resources are not only in the operators' heads but also in the procedures and the interface.

The MRS can be seen as constituted by three interrelated building blocks: (1) a description of the dynamics of emergency operation (Figure 2); (2) the functions that the EOS fulfills during emergency (Figure 3), and (3) the stable characteristics, or features, of the emergency operating system (see Table 3 for an example) (Massaiu & Braarud, 2013).

The dynamics of emergency operation are described by cycles of stability, ruptures, and new stability phases (Figure 2). During a stable

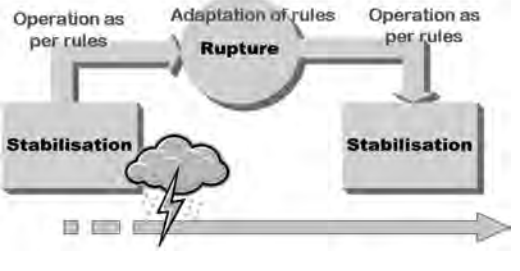

Figure 2. The dynamics of emergency operation according to the model of resilience in situation.

Figure 3. The Model of Resilience in Situation (MRS) identifies five functions of the Emergency Operating System (EOS): 'Execution' and 'Control' ensure the system's robustness, 'Verification' and 'Reconfiguration' the system's adaptation, while 'Information selection and sharing' is a cross-cutting function enabling the other functions.

Table 2. The MRS model specifies 'sub-functions' and 'details' for the main functions of the model depicted in Figure 3. Here are the sub-functions and details for 'Control' (of rule execution).

Sub-function	Detail
Understand goals and priorities	Understand timing of tasks (when to do, when to get info, time lags, urgency)
Allocate resources (cognitive, material, human)	Distribute tasks/Position operators in CR
	Understand task allocation
Continuous monitoring of expected plant responses	
Small deviations detections and adjustments	Keep focus on task and process
Recovery (of individual errors)	Team monitoring, communicate significant actions
	Consult and peer check before performing significant actions (feed forward control to avoid need for recovery)
Concentrate on current plan	Avoid distractions: Do not respond to all incoming information/requests
	Attention on procedure following, read notes, read foldout, referenced parameters
Resist external demands (for resources)	Keep focus on priorities
Reach plan goals	Ensure goals achieved
	Completing pending procedures/steps
Manage dynamics (e.g. Concurrent goals)	Manage multiple/parallel tasks (procedures)
	Manage interruptions and deferred tasks (including continuous EOPs' steps and conditions)

Table 3. The emergency operating system 'Features' are the structural elements that determine the systems' capacity to perform its functions (Figure 3). Here the EOS sub-features and indicators for the category 'Procedures'.

Sub-feature	Indicators
Monitoring/ re-evaluation loops	Re-evaluate procedure appropriateness
	Re-evaluate procedure optimality
	Continuously/periodically re-evaluate priorities
Writable/ bookmarks	To aid memory
Redundant information sources	Look for extra information to validate itself
	Look for extra information to assess reliability of cues
Overview/status trees	Counter fixation on current plan
	Takes into account simultaneous influences
	Easy to look ahead/browse

operating phase, called the stabilization phase, the system follows the effective rules that it has set itself, typically the operating procedures, allowing the attainment of its objectives and avoiding the continual demands made by the dense flow of information (for instance, several hundred alarms in a nuclear power plant control room). However, this organizational inertia, protecting the actors from unexpected demands, must be counterbalanced by permanent redundant verification (or monitoring), i.e., constantly checking that the rules applied are appropriate to the situation (for example, that the procedure in effect is adequate). A rupture occurs when the active rules become inappropriate and the operating system has to be reconfigured so that it has new effective rules. This can happen for two reasons: (1) the objectives may have been reached in compliance with the applied rules; or (2) the rules are not longer adequate due to (2a) errors in rule implementation necessitating a reconfiguration (re-planning) that is more than mere error recovery, or (2b) when the team recognizes that conditions existed or have newly arisen for which the rules in effect are not adequate. In these cases, the verification of the of rule's inadequacy should trigger a "rupture" of the operation so that the system reconfigures itself with new effective rules. (Figure 2).

It should be noted that during emergencies at nuclear power plants the rupture phases may last minutes while the stability phases may last hours.

The second building block of the MRS model is the description of the functions of the operating system (Figure 3).

There are two main functions that define the resilience of the EOS: "Robustness" and

"Adaptation". Adaptation is accomplished by the functions described above of verification (i.e., verifying that the plans are good for the situation) and reconfiguration (the capacity to timely produce plans that fit changed conditions). Robustness is defined by Execution and Control. Execution is defined as "acting on the process given the effective operating rules". It includes object discrimination (selecting the right control out of similar ones and the right mode in multi-mode displays) and situation discrimination (acting differently in different plant operating modes). "Control" consists in a permanent monitoring of the consistency of actions and effective operating rules (are the rules well applied?). Control is about the execution of the rule in effect, is the function that ensures that the rule is being implemented as intended. Effective control requires continuous monitoring of process and staff, detection of deviations, rapid adjustments, and management of concurrent demands and interruptions.

In order to perform these functions the system has also to select and share information from the environment. Information Selection is then defined as a "common function" needed by Control, Verification and Reconfiguration. Teamwork is treated as a set of processes (e.g., cooperation, team situation understanding) used in performing EOS functions. Therefore, teamwork functions are not represented as independent functions but are 'built-in' in the other functions.

The third building block of the MRS model is constituted by the "emergency operating system features", i.e., stable characteristics of the system that allow it to perform its functions. Features are identified for the personnel (e.g., staffing, training, safety culture), the human-system interface (e.g., displays, alarm logs) and the procedures (e.g., symptom based) elements of the system. The EOS features determine the systems' capacity to perform its functions. Different configurations of personnel, HSI, and procedures will produce different capabilities with regard to the various EOS functions. For instance, an operating crew with authoritarian line of command will likely facilitate execution and control functions, but might counter effective reconfiguration. The MRS model organizes the features under the following categories: Team, Prescriptions, Formal communications, Human-Machine Interface (HMI), Training, and Procedures (see for instance the features for Procedures in Table 3 below). These six categories include sub-features, that is, specific indicators that evaluate their contribution to the fulfillment of the EOS functions. For example, the HMI feature includes the "Control Room Layout" sub-feature to evaluate whether the HMI provides "visibility of other operators" and "visibility of others' actions" (i.e. "does the control room layout allow the operators to see each other and their actions?"). Another example is the Team feature's sub-feature "Supervisory function", that evaluates among others the system capability of "Monitoring others actions" and "Searching redundant information" (i.e. "does the supervisor monitor operators actions and search for redundant information?").

The MRS model specifies the influences of the EOS features on the EOS functions. The result is a complete matrix of influences from the features' indicators to the sub-functions' details.

2.1.4 *Evaluation of the MRS methodology*

The Model of Resilience in Situation is the theoretical backbone of the human reliability method MERMOS, and in this form it has been applied in the French nuclear industry for more than a decade. The decision-making model presented in this paper has received a more limited application and testing, but it nonetheless has proved capable of capturing the essentials aspects of the decision-making processes followed by nuclear control room crews responding to simulated accidents in full scope simulators. These were detailed, minute-by-minute analyses of teams of professional operators performing in realistic conditions. Compared to other naturalistic decision-making models the MRS model treats decision processes that span over relatively long time windows and include several decision points, as it is necessary for dealing with emergency operation in nuclear power plants. A second innovative aspect, also strongly dependent on the model's domain of origin, is the importance reserved to the technology and the organizational environment in which the decision makers operate. These are furthermore teams rather than individuals so that teamwork aspects become central. Finally, the model lends itself to predictive applications (trough the MERMOS human reliability method), retrospective accident analysis, for verification and validation purposes (by providing an overall framework that can be used as basis for performance-based evaluation of human-machine systems), and as an observation protocol for on-line recording and classification.

The main limitation of the MRS model is that, beside the applications for human reliability which is at an industrial stage, the methodology needs further refinement and testing (Massaiu & Braarud, 2012).

3 CONCLUSION

Normative approaches are still the preferred option for analysis, design and evaluation of human-technology systems in process control industries.

This is partly due to the field strong technical tradition, one that assumes that the core technical disciplines are sufficient for achieving safe and productive systems, but also to field specificities (like the prominence of operating procedures) that make well-known naturalistic decision making approaches less readily applicable.

This paper has presented two decision-making models specifically developed in process control settings. The models are informed by extensive empirical observations and have been tested and implemented at varying degrees for different applications. The two models contribute to the naturalistic decision making discipline at large by tackling the not so well-studied aspect of team decision making *with* operating procedures.

ABSTRACT: Recent accidents and near-accidents, such as the capsizing of the anchor handling vessel Bourbon Dolphin in 2007 and the unintended list of the drilling rig Scarabeo 8 in 2012, underline the need for addressing sensemaking in safety-critical situations within the maritime domain. This paper is a literature review to answer the research question: *What are the characteristics of sensemaking and resilience in safety-critical situations?* The aim was to establish more knowledge on sensemaking in safety-critical situations and the relationship between sensemaking and resilience. The majority of authors provide definitions based on Weick's work on sensemaking, describing sensemaking as a social process, involving the extracting of cues and enactment to create meaning to events retrospectively. Few authors provide descriptions that characterise sensemaking in safety-critical situations. There is a lack of literature regarding sensemaking in safety-critical situations in the maritime domain that addresses the issues of training and human-machine interactions.

1 INTRODUCTION AND OBJECTIVE

1.1 *Background*

This literature review is part of a research project (SMACS) that addresses the issue of sensemaking in safety-critical situations within the maritime domain. The aim of sensemaking processes in an organisation is to provide meaning to an event or situation in a given context. In such situations, sensemaking can be a source of resilience, in that it enables a person or a crew to "bounce back" when put under stress. Hence, the review not only focuses on sensemaking in safety-critical situations, but also on how the literature describe the relationship between sensemaking and resilience. This paper describes the search strategy and presents the results from the literature review.

1.2 *Purpose and research question*

The purpose of the review was to answer the research question: *What are the characteristics of sensemaking and resilience in safety-critical situations?* This was done by establishing a knowledge base on sensemaking in safety-critical situations, and by exploring the relationship between sensemaking and resilience. In addition, we wanted to examine whether this literature addresses sensemaking in relation to training or Human-Machine Interaction (HMI). This review is not specific to the maritime domain, but it was of interest to be able to later narrow it down to maritime operations.

1.3 *Concepts and definitions*

Sensemaking and *resilience* are two central concepts in this study, both of which have been approached within different theoretical frameworks. In the following, we provide definitions and explanations for these terms, as well as for our use of the term *safety-critical*.

1.3.1 *Sensemaking*

Sensemaking has been of interest in the on-going research project, since the concept supports the idea that human actors in safety-critical operations and their actions are dependent on the whole socio-technical systems consisting of organisational, technological and human factors.

The concept of *sensemaking* started to emerge in organisational literature in the late 1960s (Maitlis &

Christianson, 2014), but was made prominent by Karl E. Weick in 1995 with his seminal book *Sensemaking in Organizations*. In this work, Weick summarised the sensemaking research up to that point and presented seven key properties of sensemaking; 1) grounded in identity construction, 2) retrospective, 3) enactive, 4) social, 5) ongoing, 6) focused on and by extracted cues, and 7) driven by plausibility rather than accuracy. Sensemaking has since been the subject of considerable research and there is an extensive variation in how the term is defined in the organisational literature (Maitlis & Christianson, 2014).

Weick et al. (2005) describe sensemaking as "a sequence in which people concerned with identity in the social context of other actors engage ongoing circumstances from which they extract cues and make plausible sense retrospectively, while enacting more or less order into those ongoing circumstances" (p. 409). Maitlis & Christianson (2014) developed a definition of sensemaking rooted in recurrent themes found in their literature review: "A process, prompted by violated expectations, that involves attending to and bracketing cues in the environment, creating intersubjective meaning through cycles of interpretation and action, and thereby enacting a more ordered environment from which further cues can be drawn" (p. 67). There are several factors that can influence sensemaking. Sandberg & Tsoukas (2015) found from their literature review that context, language, identity, cognitive frameworks, emotion, politics and technology constitute the main factors.

Sensemaking is thus a *process* triggered by ambiguous events that interrupt an ongoing activity and make individuals question what is going on. Individuals will extract cues from the environment that are interpreted and they act on those interpretations and revise them through the consequences of their actions. This is an ongoing cycle and according to Weick (1995) sensemaking never starts or stops as people are always in the middle of things. The events that trigger sensemaking can range from unplanned to planned events and from minor to major events (Sandberg & Tsoukas, 2015).

Sensemaking has been described as an individual cognitive process that has to do with interpretation and development of mental models (Elsbach et al., 2005). However, Weick (1995) described sensemaking as a social process where people actively shape each other's meanings, and argued that even individual sensemaking is influenced by the actual, imagined or implied presence of others.

The concept has traditionally been seen as a retrospective activity that occurs as people look back on action that has already taken place (Maitlis & Christianson, 2014). Weick (1995) argued that people can know what they are doing only after they have done it. The notion of prospective sensemaking (i.e. consideration of impact of actions) has long been a part of the literature (Gioia et al., 1994). In recent years prospective or future-oriented sensemaking has gained more attention (e.g. Gephart et al., 2010; Rosness, Evjemo, Haavik & Wærø, 2016).

1.3.2 *Resilience*

The commonly used definition of safety has been "freedom from unacceptable risk". In resilience engineering safety is defined as the ability to succeed under varying conditions (Hollnagel et al., 2011). Resilience Engineering is concerned with understanding the normal functioning of socio-technical systems and how they perform under varying conditions. Thus, performance variability is not a threat that should be avoided by the use of constraining means; in complex socio-technical systems variability is considered normal and necessary. In this view it is equally important to study things that go right as things that go wrong, with the aim to reinforce the variability that leads to positive outcomes (Hollnagel et al., 2011). Ibid define *resilience* as "the intrinsic ability of a system to adjust its functioning prior to, during, or following changes and disturbances, so that it can sustain required operations under both expected and unexpected conditions" (p. 275).

According to Hollnagel et al. (2011), there are four corner-stones that characterise resilient systems: 1) the ability to respond to events, 2) to monitor ongoing developments, 3) to anticipate future threats and opportunities, and 4) to learn from past failures and successes alike.

1.3.3 *Safety-critical*

In this paper, we use the term *safety-critical situation* or *safety-critical operation* to denote situations or operations that, if they go wrong, have a large potential for causing harm to people, property or environment.

2 METHODOLOGY

A literature search was conducted to establish a knowledge base on sensemaking in safety-critical situations, as well as the relationship between sensemaking and resilience. Literature was obtained through Boolean searches of the following interdisciplinary databases: Scopus, Web of Science, Google Scholar and Oria. Based on the objective of the study, the keywords *sensemaking*, *resilience* and *safety-critical* were selected as the most relevant. In addition, some of the searches in the abstract databases, Scopus and Web of Science, included the keyword *maritime*. To capture variations in these keywords, more specific search terms were used as shown in Table 1. Different combinations of the terms in Table 1 were used due to different search approaches in the various databases.

Table 1. Search terms.

Keyword	Search terms
Sensemaking	sensemaking; sense-making; sense making
Resilience	resilience; resiliency; resilient
Safety-critical	safety-critical; safety-critical situation(s); safety-critical operation(s); safety critical; safety critical situation(s); safety critical operation(s); high-risk; high-risk situation(s); high-risk operations(s); high risk; high risk situation(s); high risk operation(s); hazardous; hazardous situation(s); hazardous operation(s)
Maritime	maritime; at sea; boat; vessel; offshore

Broad search terms (e.g. "high-risk") were used when searching the abstract databases, Scopus and Web of Science, whereas searches in Google Scholar and Oria were conducted using more specific terms (e.g. "high-risk situation").

To avoid an excessive amount of search results, general searches in Google Scholar covered all three keywords of sensemaking, resilience and safety-critical. When searching the abstract databases, and when using the "all in title" function in Google Scholar, search terms related to two of the three keywords were used. To be included, the documents either had to address sensemaking in the context of safety-critical situations or operations, or discuss a relationship between sensemaking and resilience. For this reason, documents discussing sensemaking in other contexts were

excluded. So were documents that primarily discuss resilience and that do not relate to the notion of sensemaking. We did not include books in this literature review, and a few papers were excluded as we requested, but did not receive, the full-text.

Going through the identified documents, we found some key references that we included in this review as background (i.e. not included in Table 2).

3 FINDINGS FROM THE LITERATURE REVIEW

The literature search resulted in 33 documents that were included in the review. See Table 2 for the complete, chronologically listed, literature overview. As can be seen from the table, the reviewed literature includes 25 articles published in peer-reviewed scientific journals, four papers presented at international conferences, workshops or symposiums, three theses and one working paper.

No inclusion criteria were applied regarding publication year. The results clearly indicate that the use of the term sensemaking in the context of safety-critical situations, or in relation to the term resilience, is relatively recent. Except from the papers by Weick (1993), Gephart (1997) and Beunza & Stark (2004), the rest of the included literature was published in the ten-year period from 2009 to 2018.

In addition to the 33 publications in Table 2, we have also included often cited key research, among others Weick (1995) and Endsley et al. (2003).

The following chapters describe how this literature use the term sensemaking; how it characterises sensemaking in the context of safety-critical situations; and how it describes the relationship between sensemaking and resilience. In addition, we describe the few issues we have found of sensemaking in relation to training, human-machine interface, the maritime domain and design/development.

3.1 *The use of the term 'sensemaking'*

As outlined in chapter 1.3.1, the concept of sensemaking does not have one single definition. Weick (1995) stated that "(…) people can make sense of everything. This makes life easy for people who study sensemaking in the sense that their phenomenon is everywhere" (p. 49). For this reason, we started the review by taking a closer look at how the various authors of the included literature use the term.

In 1993, Weick reanalysed the Mann Gulch fire disaster in Montana in which 13 firefighters died. Here he provided analyses of sensemaking as a generic phenomenon, explaining that "the basic idea of sensemaking is that reality is an ongoing accomplishment that emerges from efforts to create order and make retrospective sense of what occurs" (p. 635). He further uses the example of Mann Gulch to argue that sensemaking is about contextual rationality and that it is "built out of vague questions, muddy answers and negotiated agreements that attempt to reduce confusion" (Weick, 1993, p. 636).

As described by Maitlis & Christianson (2014), the term sensemaking is often used without any associated definition from the literature, and when definitions are provided there are a variety of meanings asserted to it. Correspondingly, in our study we found that several authors include sensemaking as a general notion and do not provide any associated definition (e.g. Favarò & Saleh, 2018; Saleh et al., 2014; Sanne, 2012). Some provide references to the work of others, but without reproducing the actual definition (e.g. Grøtan & van der Vorm, 2015; Jahn, 2016).

However, most of the papers in this review provide definitions or references based on Weick's work on sensemaking, describing sensemaking as a social process, involving the extracting of cues and enactment to create meaning to events. These include, among others, the work of Baran & Scott (2010), Danielsson (2016), Hayes (2012) and Tekeda, Jones & Helms (2017).

Some describe sensemaking as a more cognitive process and refer to Klein's macro-cognitive/data-frame model (Hoffman & Hancock, 2017; Siegel & Schraagen, 2017), whereas others refer to the work of both Weick & Klein (e.g. Landman et al., 2017; Norros et al., 2014; Rankin et al. 2014).

Some authors describe sensemaking as a process building and supporting situational awareness (Lundberg et al., 2012; van den Heuvel et al., 2014). Situational awareness being a tactical (short term issue) while sensemaking is a broader strategic concept (long range issue) creating and supporting understanding. In his paper on sensework, Haavik (2014) uses the definitions of Weick to explain how sensemaking is a theoretical, generic framework that addresses mental processes and aspects of work. Alternatively, a few papers focus on the Cynefin sensemaking framework described in the work by Kurtz & Snowden (2003) (Dahlberg, 2015; Grøtan & Størseth, 2012).

The concept of sensemaking has traditionally, and in accordance with the work of Karl E. Weick, been described as retrospective in the sense that we make sense of our actions and experience after they have occurred. Most of the literature in this review uses the notion of sensemaking accordingly, often referring to Weick when doing so (e.g. Baran & Scott, 2010; Rantatalo, 2013; Teo et al., 2017).

However, a few of the authors use the term in a more future-oriented sense. As an example, Barton et al. (2015) introduce the term of proactive leader sensemaking, arguing that leaders in particular play a critical role in creating and maintaining a context for actively managing uncertain contexts.

3.2 *Characteristics of sensemaking in the context of safety-critical situations*

There are several factors that can influence sensemaking; context, language, identity, cognitive frameworks, emotion, politics and technology (Sandberg & Tsoukas, 2015). Thus, in the context of a safety-critical situation there might be characteristics of sensemaking other than or more prominent than the characteristics of everyday sensemaking. For instance, it might be expected that strong negative emotions like stress and fear would be influential on sensemaking in such circumstances. However, the literature found in this review did not discuss these characteristics explicitly.

In his analysis of the Mann Gulch fire disaster Weick (1993) describes the disaster "was produced by the interrelated collapse of sensemaking and structure". The smokejumpers expected to find a fire that they would have control over within the next morning. This positive illusion prohibited them from making sense of the cues in their environment contradicting this expectation. Weick describes unclear roles, identity issues and in the end the intense emotion of panic that led to the disintegration of the group and to the primitive tendency to flight. Unfortunately, this response was too simple to match the complexity of the fire and 13 men lost their lives.

After completing a field study of 80 interviews, Busby & Collins (2014) categorised the many ways of acting through which informants made sense of the risk control task. The authors provide explanations to each of their 32 categories, but elaborate on the five more commonly used. These are 1) being circumscribed (constrained, realistic, moderate), 2) being engaged (closely involved, concerned), 3) being resolute (rapid, and consistent in acting) 4) being socialised (social outcomes and systems of social obligation), and 5) being solicitous (seeks opinion and external references). The authors use their qualitative findings to suggest that the sensemaking of organisational members is simultaneously optimistic and pessimistic about the capacities of social organisation to manage risk. This balance is, however, not of individual sensemaking and is not a deliberate choice.

Lundberg et al. (2012) explored a model for describing and studying resilience in management of safety-critical/irregular events. The model was based on changes in the ongoing process, the actors sensemaking and control functions and the technology used for sensemaking and control. The model helped to identify resilience building processes and sources of resilience emergency responses.

Several other authors describe the characteristics of sensemaking by describing it in terms of how it relates to the concept of resilience. This is the topic of the following chapter.

3.3 *The link between sensemaking and resilience*

As described in the introduction, one goal was to establish a knowledge base on the relationship between the two concepts of sensemaking and resilience.

In his reanalyses of the Mann Gulch fire disaster, Weick (1993) states that the disaster was produced by the interrelated collapse of sensemaking and structure. Weick mentioned the importance of nonstop talk as a critical source of coordination in complex systems. He proposes four potential sources of resilience that "make groups less vulnerable to disruptions of sensemaking" (p. 628). These include improvisation and bricolage, virtual role systems, the attitude of wisdom, and norms of respectful interaction. Thus, from this perspective, resilience is core to maintaining sensemaking in critical situations.

Other authors argue that sensemaking is an important source to achieving resilience. Through their review of disaster management literature, along with illustrative examples from global disasters, Takeda et al. (2017) highlight the importance of resilience in disaster management. They argue that heedful interrelating and sensemaking are two of the central tenets of resilience research and that a greater attention to resilience in the disaster management process could be achieved through a focus on the development of sensemaking and heedful interrelating. Takeda et al. (2017) conclude that future research is needed to further understand resilience and sensemaking.

Rankin (2013) draws lines between Hollnagel's four central abilities to characterise a resilient system and the sensemaking capabilities of seeking information, ascribing meaning and action as described by Grøtan et al. (2008). In a paper from the same year, Rankin and her co-workers present a framework for analysing adaptations in high-risk work (Rankin et al., 2014). Here they explain how *sensemaking variety* "includes the ability to process information and revise it as the world changes, given contextual constraints and the experience and knowledge of the individuals involved" (p. 84). Thus, sensemaking is important for adaptive behaviour, which in turn is a prerequisite for resilience. They focus on the importance of

observing sharp-end adaptations as critical to identify system brittleness and resilience.

Others suggest that sensemaking plays an important role in accomplishing tasks that facilitates organisational resilience, especially when the sensemaking is carried out by leaders (Teo et al., 2017). According to Hunte et al. (2015), "shared (social) sensemaking creates and nourishes common awareness and understanding of the 'operating point', and in so doing facilitates coordination and safer performance. This is an essential condition for the emergence of safety and resilience" (p. 1). Similarly, van der Beek & Schraagen (2015) list sensemaking, or situation assessment, as one of several team resilience abilities. However, they do not provide a thorough discussion on sensemaking as such.

The sensemaking perspective is also used in the literature as a means to analyse or explain resilience. According to Bergström (2012) "the development of a theoretical framework for analysing organisational resilience in escalating situations needs to relate to the explanatory potential of sensemaking theory" (p. 8). To enhance a dynamic understanding of resilience, Hutter & Kuhlicke (2013) analyse its elusive character from a sensemaking perspective. In their paper, resilience is understood as a "content of sensemaking processes in the context of a crisis" (p. 294). The authors state that the work of Weick in 'sensemaking in organisations' on the one hand and 'resilience' on the other is only loosely coupled, and they connect the two a bit more explicitly for planning research about resilience. To understand how groups, organisations and networks make sense of resilience in the context of a crisis, one should consider the four processes of committing to resilience, expecting resilience, arguing about resilience and manipulating with resilience. These are referred to as sensemaking processes in planning research and practice (Hutter & Kuhlicke, 2013).

In their paper, Lundberg et al. (2012) study resilience in the context of sensemaking and control in emergency management of irregular emergencies, and proposes an emergency management analysis model. The model unifies and complements existing models by explicitly modelling resilience factors and the actors 'sensemaking and control functions and technologies' variety. Other authors using sensemaking theory to describe aspects of resilience, is Siegel & Schraagen (2017). In their article on team reflection, they make an attempt to use reflection and the data-frame theory of sensemaking to show the relationship between knowledge and resilience.

Finally, Hoffman & Hancock (2017) aim to promote a discussion on how to measure resilience. They explain how sensemaking provide information to the work system about whether and when the system needs to change its understanding of problem situations, and further argue that this means that "adaptive and resilient sensemaking requires mechanisms for recognizing anomalies and situations that mandate change" (p. 571).

3.4 *Sensemaking as a basis for change, innovation, creativity and design*

The literature has indicated how sensemaking supports innovation, design and creativity. Sensemaking has often been limited to an organisational context, seldom discussing issues such as system design. Saleh et al. (2014), point out that safety science seems to have drifted from the engineering and design side of system safety towards organisational and social sciences or refinement of probabilistic models. To improve safety and resilience in safety-critical operations, we must have a broad based approach involving the sociotechnical system, and also how cues and prospective sensemaking can be enabled from the design phase on.

It is also mentioned that sensemaking is a key process for learning in organisations, teams and individuals (Maitlis & Christianson, 2014) – one challenge is to use new information rather than engage in sensemaking based on prior beliefs. Sensemaking is also concerned with new meanings that can underpin new ways of organizing, understanding and design. When sensemaking of organisational members are impacted, the participants are motivated to change their own roles and practices. This has especially been supported by looking at interpretations and actions through the process of action research, Greenwood & Levin (2006).

3.5 *Topics partly covered in the literature review*

Accident reports have shown that insufficient training and poor HMI may impair sensemaking processes and thus lead to incidents and accidents. After the incident at Scarabeo 8 the investigation report attributed the incident to insufficient training of control room personnel and weaknesses in the control room's human-machine interface (Ptil, 2012). As discussed by Endsley et al. (2003) human-machine-interface is a key factor shaping operator performance, via concepts like sensemaking and situation awareness. We thus expected some of this literature to addresses sensemaking in relation to training or HMI. However, we did not find much relevant literature through our review. In the following, we have summarised our findings related to training, HMI and sensemaking in safety-critical situations within the maritime domain.

Not many of the reviewed documents look at ways of training to improve sensemaking. However, Takeda et al. (2017) focus on building capacity for individual actors to interrelate in a heedful manner. In Saleh et al. (2014) it is mentioned that the ability to diagnose hazardous states provides one way to improve operators' sensemaking and situational awareness after an adverse event. It is synergetic with organisational factors in support of accident prevention, particular safety training, that can be shaped by including off-nominal conditions. Rantatalo (2013) describes how observations that were carried out were targeted joint police management training in the setting of full-scale simulated scenario, arguing that "from sensemaking and organisational reliability perspectives, high-strain situations like that described above offer a possibility to observe interaction patterns during incident management in a realistic setting" (p. 55). One of the conclusions drawn in the paper by Landman et al. (2017) about dealing with unexpected events on the flight deck, is that interventions should focus on "increasing pilot reframing skills (e.g. through the use of unpredictability in training scenarios)" (p. 1161). The authors propose a conceptual model for explaining pilot performance in surprising and startling situations; a model that can be used to design experiments and training simulations. However, several of the reviewed papers discuss training that is aimed at enhancing resilience (Bergström, 2012; Grøtan & van der Vorm, 2015; van der Beek & Schraagen, 2015).

Siegel & Schraagen (2017), describe processes and HMI tools to make boundaries explicit in railway operations. In the maritime sector the ability to handle demanding operations safely is increasingly dependent on ICT-based control systems, e.g. dynamic positioning and ballasting. Hence, the impact of HMI on sensemaking is an important topic for our project. However, few of the documents covered by this literature review address this issue. Relevant, but brief, discussions on such interaction are made in the papers by Dahlberg (2015), Landman et al. (2017) and Sanne (2012).

Furthermore, almost none of the identified publications on sensemaking in safety-critical situations are related to maritime operations. A couple of the papers discuss sensemaking in the context of offshore oil and gas production (Busby & Collins, 2014; Hayes, 2012). The doctoral thesis by Bergström (2012) is the only publication in our review that is related to navigation and shipping, although not specifically concerning sensemaking.

3.6 *Limitation of the review*

Our findings should be considered in light of the limitation in the search terms. In addition to the search terms related to the keyword *safety-critical*, we could have included *surprising*, *emergency*, etc. Also, we could have obtained interesting findings had the review included papers on *situational awareness*. However, we chose to keep this review focused on the terms of specific interest for our project.

4 DISCUSSION AND CONCLUSIONS

The current literature review aimed at describing how the selected literature use the term sensemaking; how it characterises sensemaking in the context of safety-critical situations; and how it describes the relationship between sensemaking and resilience.

We found that several authors use the term sensemaking without providing a definition, and those who do refer to Weick's work describing sensemaking as a social process, involving extracting cues and enactment to create meaning to events retrospectively.

Sensemaking and resilience were found to be described as related in the reviewed literature. Sensemaking creates the context for being resilient; at the same time sources of resilience, such as redundancy (i.e. redundant clues), help to make sense of the situation. Lundberg et al. (2012) have suggested a model for resilient sensemaking, exploring changes in the ongoing process, the actors sensemaking and control functions and the technology used for sensemaking and control. However, little is written on the issue of sensemaking in safety-critical situations that also concern aspects of training, human-machine interaction or the maritime domain; thus, we a see a need to increase our knowledge in these areas by observation studies and targeted literature reviews.

Sensemaking is seen as a long term strategic process, creating understanding. There has been a discussion whether sensemaking is something that happens inside the individuals' heads or if it is a social construct. In our further work, we would like to explore sensemaking as a social construct, impacted by organisations, technology and human factors. Also, sensemaking has been described as both a retrospective and a prospective process. We would like to build on the research of prospective sensemaking to understand how to build resilience through future actions.

Sensemaking is accomplished through perceiving cues, creating meaning/learning (trough interpretations and actions) as discussed in Maitlis & Christianson (2014), thus it is dependent on responsibilities, procedures, training and technology (such as human machine interactions). However, unexpected or safety-critical situations

do not necessarily trigger sensemaking; it happens when there is a discrepancy from what one expects. The expectations are influenced by the amount of experience, training and the degree of questioning attitude, i.e. in line with existing group norms or organisational culture.

Discrepancies must also be supported by design, i.e. having redundant systems that can reveal discrepancies, and by training to ensure a questioning attitude. This is in line with sensemaking in HRO – High Reliability Organisations, where practices such as "preoccupation with failure", "reluctance to simplify" and "sensitivity to operations" support the explorations of cues and interpretations (Weick & Sutcliffe, 2011).

Further work in the project will focus on how to strengthen the loop of perceiving cues, creating interpretations, assert meaning to events taking actions. Further, how to improve the design of interfaces between automation (i.e. HMI and procedures) and how to train to facilitate sensemaking and resilience. Through this work, we aim to contribute to improve the ability to handle safety-critical situations in demanding maritime operations.

Task complexity, and operators' capabilities as predictor of human error: Modeling framework and an example of application

M.C. Leva, A. Caimo & R. Duane
Dublin Institute of Technology, Ireland

M. Demichela & L. Comberti
Politecnico di Torino, Italy

ABSTRACT: This paper presents the initial framework adopted to assess human error in assembly tasks at a large manufacturing company in Ireland. The model to characterize and predict human error presented in this paper is linked conceptually to the model introduced by Rasch (1980), where the probability of a specified outcome is modelled as a logistic function of the difference between the person capacity and item difficulty. The model needs to be modified to take into account an outcome that is not dichotomous and feed into the interaction between two macro factors: (a) Task complexity: that summarises all factors contributing to physical and mental workload requirements for execution of a given operative task & (b) Human capability: that considered the skills, training and experience of the people facing the tasks, representing a synthesis of their physical and cognitive abilities to verify whether or not they are matching the task requirements. Task complexity can be evaluated as a mathematical construct considering the compound effects of Mental Workload Demands and Physical Workload Demands associated to an operator task. Similarly, operator capability can be estimated on the basis of the operators' set of cognitive capabilities and physical conditions. A linear regression model was used to fit a dataset collected in R. The estimation of task complexity and operator skills was used to estimate human performance in a Poisson regression model. The preliminary results suggest that both elements are significant in predicting error occurrence.

1 INTRODUCTION

1.1 *Scope of work and background*

This paper presents the initial framework adopted to assess human error in assembly tasks at a large manufacturing company in Ireland [1].

The aim of this study was to carry out an observational, empirical study on the existing human errors in the dispatching department, find a way to model the issue and if possible propose approaches to reduce and eliminate errors and variations in the end product. The company dispatches technology goods to national and international customers and the focus of the project was the assembly of goods for dispatch. Operators prepare the goods at workstations along conveyor lines, however at these conveyors inefficiencies and inaccuracies relating to human performance were identified. Two primary workstations were selected for inclusion in the dispatching unit based on their recorded error rates. Conditions vary and fluctuate at workstations, which may increase the probability of making mistakes, including the complexity and number of the activities, environmental conditions and the quality of the product. An understanding of both the human nature (characteristics, feelings, and behavioural traits) and the impact of the features of the workstation on human nature (typology of activities, working load, anxiety induced, environmental factors etc.) was required to holistically determine the performance shaping factors for the workstations under examination. The focus is on the role of operator's capability to complete tasks and the means to reduce human errors whilst retraining product quality. Changes were proposed for the assembly lines at the dispatching stations, including changes in the procedures and training to employ an understanding of human performance and improvements to safety, with an overall beneficial impact on both productivity and quality.

The researcher conducted a task analysis of the critical activities completed by operators when packing out the variety of product units at two primary workstations. Questionnaires were prepared examining the skills requirements, skills rating of operators, mental workload requirements, physical workload requirements, perceived task complexity and motivation. Finally, the implementation of an applied model Task Execution Reliability Model (TERM) was used to identify the main fac-

tors affecting human performance for this settings. Three methods were used to inform the research:

1. Firstly, an examination of performance shaping factors in the literature to inform a set of specific questionnaires.
2. Secondly, the collection and analysis of the data from the questionnaires completed by operators, technicians, supervisors, group leaders and process engineers in the manufacturing facility familiar with the work undertaken at the workstations under examination.
3. Thirdly, focus group sessions were run discussing possible participatory redesign for process and procedures at the workstations
4. Finally the data from the questionnaire was also used to predict task complexity and error occurrences using two different types of regression models.

2 MODELLING HUMAN ERROR

2.1 *Human error in manufacturing*

Human nature can be shaped and driven by factors including individual characteristics, personal issues, physical and psychological conditions (Tooby & Cosmides, 1990). These factors interact with each other and may determine the output and productivity of the performance of the individual. Human performance is unavoidably susceptible to human error, as humans are not infallible and the occurrence of errors must be expected (Karl & Karl, 2012). Humans are often capable of recognising errors and rectifying such errors before any serious or critical consequences occur (Sheridan, 2008). With this in mind, human performance can be accepted and understood as the definitive product of the balance between task complexity and capability (Morgeson et al, 2010).

When the capabilities and limitations of humans are understood, incorporated and acknowledged, Harris (2006) argues that benefits can include increased efficiency and improved safety performance. Individual employee's competencies may be challenged by fatigue, stressors and unpredictability, whilst competencies may benefit from skills, training and a clear comprehension of the task (Miller and & Parasuraman, 2007, Jo et al, 2012, Kostina et al, 2012). The capabilities of the operator and the physical skills required for the task must be taken into consideration when reviewing tasks and the errors associated with them (Harris, 2006). A balance between workload, both physical and mental, ought to be reached to reduce human errors among competent operators (Miller and & Parasuraman, 2007).

2.2 *The TERM model: Task execution reliability model*

The model used is linked conceptually to the model introduced by Rasch (1980) to analyse correct or incorrect execution of a task as a function of the trade-off between (a) the respondent's abilities, attitudes or personality traits and (b) the item difficulty. In the Rasch model, the probability of a specified outcome (e.g. right/wrong results) is modelled as a logistic function of the difference between the person and item difficulty parameter.

The mathematical form of the model is provided in equation (1).

$$\Pr\left(X_{ni}=1\right)=e^{\beta_n-\delta_i}\Big/1+e^{\beta_n-\delta_i} \quad (1)$$

Let X_{ni} be a dichotomous random variable with binary values where, for example, $X_{ni} = 1$ denotes a correct response and an $X_{ni} = 0$ an incorrect response to a given assessment item. In the Rasch model for dichotomous data, the probability of the outcome is given by:
where β_n the ability of person n and δ_i the difficulty of item i.

The model needs to be radically enhanced to take into account an assessment of performance that is not dichotomous and feed into the interaction between two macro factors:

- Task Complexity (TC): summarising all factors contributing to physical and mental workload requirements for execution of a given operative task.
- Human Capability (HC): summarising the skills, training and experience of the people facing the tasks, representing a synthesis of their physical and cognitive abilities to verify whether or not they match the task requirements.

Task complexity can be evaluated as a mathematical construct considering also the compound effects of two main factors: "Mental Workload Demands" (MW) and, where relevant, "Physical Workload Demands" (PW), both associated to an operator task. Recent sensorised EEG experimental studies have shown that the simultaneous executions of tasks, whether physical or cognitive, tends to increase cognitive demands for the human brain (Mijović, 2017).

Similarly then, operator capability should be estimated on the basis of the operators' set of cognitive capabilities and physical conditions. A regression model was used to fit a dataset collected in R. The model and the preliminary results are discussed in chapter 3 of the present paper.

3 THE CASE STUDY: SUMMARY OF THE DATA COLLECTED AND THE TERM MODEL AS APPLIED

3.1 *The case study and the data collection plan*
